There is at least another mode of covertness. In this mode, signs of the intervention are noticed by the human operator (therefore, the intervention is not completely hidden and escaping attention), however, the true meaning/significance of the intervention is disguised or distorted or hidden in such a way that they do not easily result in suspicion of

outside influence. This mode of covertness suggests new ways of implementing covertness.

Consider the following scenario: It is 12am and that John, an analyst, is working on a sensitive document on his computer and you have delivered a virus to his computer in order to take a peek. Ideally, you would like your operation is completely invisible to John, but unfortunately, one inevitable side effect of your virus is that John’s computer becomes slow, which *John eventually notices and starts to become suspicious*. Then John receives an alerting pop-out message informing him that the antivirus software on his computer has started scanning as scheduled and that so far no virus has been found. John now understands why his computer becomes slow, is relieved, and continues to work on his document, without realizing your peeking eyes.

Though hypothetical, this example highlights an important aspect of covertness, which has to do with an understanding of how a human operator reasons and explains unexpected observations and if and when the operator becomes suspicious given data. In the example, John becomes suspicious when he notices that his computer slows down, an often-inevitable indicator of attacks. But his suspicion fades away after the pop-out message, which is also delivered by the attacker with the goal to provide a better explanation for the slow-down so as to reduce John’s suspicion.

Instead of directly exploiting the low-level attentional function, this mode of covertness depends upon exploiting a higher-level human inference system called abduction. We argue that this mode of covertness is more general, more realistic and potentially more powerful.

## Abduction-based Covertness

Abduction was introduced by American philosopher Charles S. Peirce (1839-1914) as a form of human inference that is different from deduction and induction. According to Peirce, in abduction one infers causes from effects or explanations from observations (See Fann, 1970 for a general introduction to Peirce’s theory of abduction). The general form of abduction is shown below,

*A fact C is observed,*

*H can explain C;*

*Hence, H may be true.*

Here is a specific example of abductive inference, in the context of the hypothetical scenario above,

*The computer suddenly slows down,  
A malicious attack explains the slowdown;  
Hence, a malicious attack may be occurring.*

And here is another example,

*The computer suddenly slows down,  
Antivirus scanning explains the slowdown;  
Hence, nothing is wrong and just be patient.*

Charniak and McDermott (1985) characterize abduction as *modus ponens* turned backward (see also Brachman & Levesque, 2004). It is clear in abduction the conclusion does not necessarily follow the premises – in the above examples two different explanations are inferred to explain a same observation. However, according to Peirce, abduction is important in that it "is the only logical operation which introduces any new ideas; for induction does nothing but determine a value [to classify], and deduction merely evolves the necessary consequences of a pure hypothesis" (Peirce, 1931, v. 5, p. 171). Though inconclusive, the explanation inferred by abduction "is adopted for some reason, good or bad, and that reason, in being regarded as such, is regarded as lending the hypothesis some plausibility" (Peirce, 1931, v. 2, p. 511).

Modern researchers often regard abduction as a complex process of finding a best explanation for a set of observations (Josephson & Josephson, 1994; Paul, 1993; Thagard, 1992). Since "explaining" is such an inevitable aspect of human everyday activities, abductive reasoning is almost ubiquitous, ranging from hearing the thunder ("It's going to rain?"), seeing a falling maple leaf ("Autumn has come?"), to medical diagnosis (from symptoms to diseases) and scientific discovery (from data to knowledge and theories). In battlefields, commanders have to infer the enemy's motivations based on observations and intelligence and then take proper actions. In cyberspace security, operators have to infer if an attack has occurred given observations.

How do people do abduction? The Theory of Explanatory Coherence (TEC) is an influential theory of human abduction (Thagard, 1989, 1992). According to TEC, abduction is a parallel constraint satisfaction process in that all propositions, including explanations, evidence, and explanatory relations, form a network that constantly seeks harmony. An explanation should be accepted if it is coherent with all other propositions in the network, rejected if it is incoherent, and the best explanation for available observations is the one that enjoys the most explanatory coherence in the network. TEC proposes seven principles that establish explanatory relations among propositions and regulate the global coherence of an explanatory system: (1) *symmetry*: If  $P$  and  $Q$  cohere, then  $Q$  and  $P$  cohere; If  $P$  and  $Q$  incohere, then  $Q$  and  $P$  incohere. (2) *explanation*: If  $P_1...P_m$  explain  $Q$ , then  $P_1...P_m$  cohere with each other and with  $Q$  cohere, and the degree of coherence is inversely proportional to the number of propositions  $P_1...P_m$ . (3) *Analogy*: If  $P_1$  explains  $Q_1$ ,  $P_2$  explains  $Q_2$ ,  $P_1$  is analogous to  $P_2$ , and  $Q_1$  is analogous to  $Q_2$ , then  $P_1$  and  $P_2$  cohere, and  $Q_1$  and  $Q_2$  cohere. (4) *data priority*: Observations have a

degree of acceptability of their own. (5) *Contradiction*: If  $P$  contradicts  $Q$ , then  $P$  and  $Q$  incohere. (6) *competition*: If  $P$  and  $Q$  both explain a proposition, and if  $P$  and  $Q$  are not explanatorily connected, then  $P$  and  $Q$  incohere. (7) *acceptability*: The acceptability of a proposition  $P$  depends on its coherence with all the propositions in the system.

TEC has been computationally implemented in a connectionist system called Echo (Thagard, 1992). In Echo, propositions (both data and hypotheses) are represented by nodes. Coherence relations are represented by excitatory links and incoherence relations are represented by inhibitory links. Node activation represents the node's degree of coherence with all propositions in the network. The system updates itself based on parallel constraint satisfaction (Thagard, 1992). During this process, propositions that are incoherent die out and propositions that are coherent are strengthened. In the end, the most activated propositions represent the most plausible and coherent explanations. Echo has been extended to UEcho to incorporate more sophisticated handling of uncertainty (Wang, Johnson, & Zhang, 1998; Wang, Johnson, & Zhang, 2006).

TEC and UEcho capture several critical constraints in abduction, including explanatory breadth (the model prefers a hypothesis that explains more); simplicity (the model prefers a simpler hypothesis); being explained (the model prefers a hypothesis which itself is explained); data reliability (the credibility of an observation also depends on its coherence in the system); and analogy (analogous hypotheses are coherent). More important, however, they shed interesting new insights on human suspicion and implementing covertness. In this context, suspicion can be viewed as the degree of acceptance of an explanation such as "a malicious attack is occurring", and implementing covertness is not much more than to make the degree of acceptance of this explanation as low as possible.

Based on this reasoning, we hypothesize that effective covert interventions can be delivered in such a way that suspicion-bearing explanations (e.g., "a malicious attack is occurring") cannot become the best (winning) explanation given data. TEC has already offered several straightforward ways to do just this. For example, one way is to "explain away", which says that when delivering an intervention, deliver an explanation for that intervention as well so that the true meaning of observations can be shielded. This is exactly what happens in our previous hypothetical example. an attack is delivered, which caused John's computer to be slower. In anticipating this, a secondary message is delivered to John to "explain" to him that why his computer became slower. This new explanation "explained away" the John's observation and therefore reduced his suspicion – that is, the acceptance of "an attack is occurring" became low. Another example of abduction-based covertness derives directly from the data reliability principle – we can discredit those "suspicion-inducing" observations by introducing conflicting data ("unreliable data"). "Are you sure that your computer becomes slower?" By inducing new

data to promote John to cast his doubt, the suspicion level of “an attack is occurring” is reduced.

To a certain extent the attention-based covertness (i.e., delivering interventions that are invisible to the human attention) is a special case of this new abduction-based covertness. Since abduction starts with observations (that is, the data to be explained, e.g., “the fact C is observed”), completely invisible interventions suggest that suspicion-generating abduction will not even be starting in the first place. However, abduction-based covertness is more general in the sense that in case some suspicion-inducing observations become available, covertness can still be achieved if proper measures are taken so that the suspicion-bearing explanation will not become the most plausible one.

### Stealth and Disruption with IMPs

As a preliminary step toward evaluating the effectiveness of abduction-based covertness, we conducted a study to examine how a human operator digests unexpected interventions and adjusts his level of suspicion. The study utilized a so-called Interface Manipulation Protocol (IMP). The toolbox of IMP contained dozens of possible intervention types that could be delivered to the adversary computers to cause disruption with, for example, keyboard and mouse operations. We were interested in finding out the optimal chain of IMP delivery scheme (e.g., when to deliver what IMP for how long?) that causes maximal disruption with minimal suspicion.

### Method

#### Participants

Nine college students and graduate students in the Houston medical center area were paid to participate in the experiment.

#### Procedure

The experiment was programmed in E-Prime and conducted on a computer with a 20 inch LCD monitor. Subjects were instructed to type in sequences of random numbers as prompted (Figure 1). Table 1 shows three independent variables manipulated in the study, including the type of IMPs and the type of delivery themes.

Target  
Sequence: 2 5 9 8 ... 4 6  
Responses: 2 5 7 8 ...

Figure 1. Subjects were required to reproduce the target sequence. Errors were prompted in red color and need to be corrected with extra keystrokes. Errors could include “IMP errors” (produced deliberately by IMPs) and “genuine errors” (subjects’ own typos). In this example, the subject had mistyped the target character number “9” with number “7”, and subsequently typed number “8” before realizing the error.

At the beginning of each trial, subjects were first prompted with a sequence of 20 characters of random numbers, shown at the top of the computer screen. Then, they were to copy the entire sequence in exactly the same order, and their responses were shown one by one for each keystroke, in a separate line below the target sequence. If an error occurred, either by subjects’ own error (“genuine errors”) or by deliberate IMP interventions, the mismatched character would be shown in red. Subjects were instructed to immediately erase the error by using the backspace key. If subjects have skipped the error for several keystrokes, they had to erase all subsequently typed characters (including the correct ones). That is, correcting an error had to be done in a backward sequential order (similar to the situation of typing documents without the ability of adjusting the cursor position by mouse).

Table 1. Independent variables manipulated

<b>3 types of IMPs</b> <ul style="list-style-type: none"> <li>Non-responsive key (IMP1): when a key is pressed, nothing shows up, so the subject has to retype to correct;</li> <li>repetitive key (IMP2): when a key is pressed, the same character will show up twice. For example, typing “3” would result in “33” shown on the screen, so that the subject has to erase the extra character;</li> <li>altered key (IMP3): when a key is pressed, a randomly selected different character is shown (e.g., typing “3” and “4” shows up), so the subject has to erase the wrong character and retype.</li> </ul>
<b>4 types of delivery themes</b> <ul style="list-style-type: none"> <li>Pure: only one type of IMPs is delivered.</li> <li>Mixed: multiple types of IMPs are delivered.</li> <li>Clumped: IMPs are delivered consecutively.</li> <li>Dispersed: IMPs are delivered sparsely.</li> </ul>
<b>4 experimental conditions (combination of themes)</b> <ul style="list-style-type: none"> <li>PC: Pure-Clumped.</li> <li>PD: Pure-Dispersed.</li> <li>MC: Mixed-Clumped</li> <li>MD: Mixed-Dispersed</li> </ul>
<b>4 levels of IMP delivery rates</b> 10%, 20%, 30%, 40% of the target characters are affected by IMPs).

Three types of IMP interventions were silently delivered by hijacking the subject’s keyboard (see Table 1 and Figure 2). Each delivery of IMP intervention was designed to affect only one keystroke. For instance, by IMP1 (non-responsive key, Figure 2A), when the subjects typed any key on the keyboard (not necessarily matching the target character), the program would silently remove the keystroke such that no response character would be shown below the target character. Then, the IMP intervention would be temporarily

“disarmed” for this particular target character. Only when subjects pressed the same key for second time, the character would show up in the response line.

Four delivery themes were designed based on the mixture of IMP types and the temporal intervals between each IMP intervention (Table 1). In the “Pure” theme, only one IMP type was implemented for the target sequence. In the “Mixed” theme, all three types of IMPs were implemented. In the “Clumped” theme, IMPs were clustered together such that one IMP intervention could be immediately followed by another. In the “Dispersed” theme, IMPs were evenly distributed among the 20 target characters.

The delivery themes were grouped into 4 experimental conditions with each condition containing one particular combination of the mixture and temporal distribution (Table 1). For example, in the “PC” condition, only one type of IMP was delivered but in a clustered fashion. We also implemented 4 levels of IMP delivery rates, which were evenly distributed in each of the delivery themes.

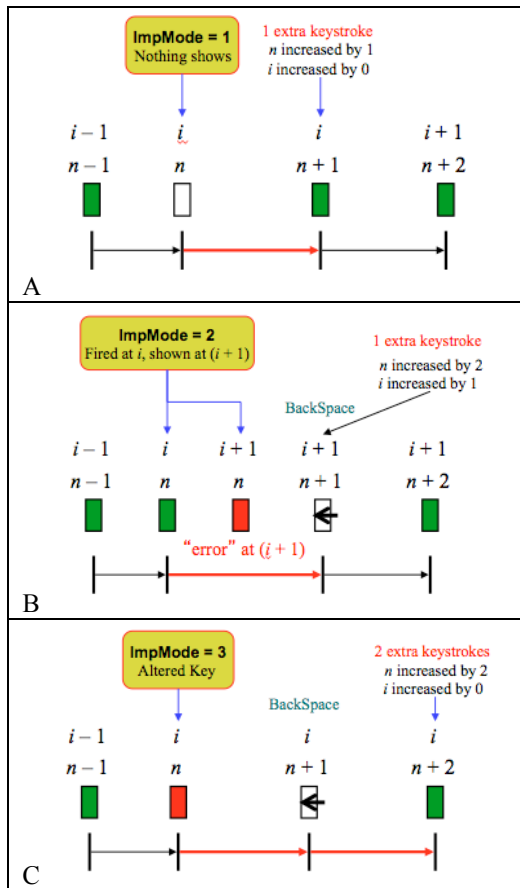

Figure 2. How types of IMPs (A: IMP1; B: IMP2; C: IMP3) affect dependent measures.  $i$  = position in the target sequence;  $n$  = number of keystrokes.

After practice trials, each subject completed 4 blocks of trials, with each block corresponding to one of the experimental conditions. The order of the conditions was randomized between subjects. Each block consisted of 20 trials, and each trial consisted of 2 target sequences. At the

end of each block, subjects were asked to evaluate the “reliability” of the input device on an 1-to-7 scale with “1” for the most “unreliable” and “7” for the most “reliable”. Subjects took a brief break before moving to the next block of trials.

There were two major dependent measures. Stealth (covertiness) was measured by the subjective evaluations of the reliability of the input device. Higher evaluation scores indicated higher tolerance of IMPs and therefore less suspicion. Disruption was measured by the number of extra keystrokes (“ExtraKS”) required to complete the sequence (excluding the extra keystrokes directly caused by IMPs). Higher scores of ExtraKS indicated more severe disruptions to the performance. The relation between IMPs and dependent measures is depicted in Figure 2.

## Results

One main result of the study is shown in Figure 3, which depicts the effect of delivery themes on stealth and disruption. Statistics show that in terms of stealth the mixed-clumped delivery (IMPs with mixed types are delivered continuously) is the best (mean evaluation scores = **4.36**, 3.94, 3.76, 4.01, with standard errors = 0.22, 0.31, 0.19, 0.25, for MC, MD, PC and PD, respectively). And in terms of disruption the pure-dispersed delivery (IMPs with the same type are delivered sparsely) is the best (mean disruption scores = 2.06, 3.08, 2.62, **3.50**, with standard errors = 0.59, 0.58, 0.47, 0.73, for MC, MD, PC and PD, respectively). Further analysis shows that if we combine the two dependent measures, the pure-dispersed delivery has the highest effectiveness score, as shown in Figure 4 (mean effectiveness scores = 0.43, 0.51, 0.49, **0.56**, with standard errors = 0.03, 0.02, 0.03, 0.02, for MC, MD, PC and PD, respectively). Overall, it seems that the pure-dispersed delivery is the most effective IMP delivery theme if the tradeoff between stealth and disruption is considered.

Figure 3. The effect of delivery themes (Base: no IMP was delivered; MC: IMPs were delivered in mixed-clumped fashion; MD: mixed-dispersed; PC: pure-clumped; PD: pure-dispersed).

Figure 4. Effectiveness by themes. The effectiveness index is computed by adding the normalized stealth and disruption measures.

The effect of IMP types is shown in Figure 5. In terms of stealth, statistics show that  $IMP1 > IMP2$  (mean evaluation scores = 4.34, 3.70, with standard errors = 0.21, 0.23, for  $IMP1$  and  $IMP2$ , respectively,  $p < 0.05$ ) and  $IMP1 > IMP3$  (mean evaluation scores = 4.34, 3.62, with standard errors = 0.21, 0.31, for  $IMP1$  and  $IMP3$ , respectively,  $p < 0.05$ ). In terms of disruption, no significant difference is found (mean disruption scores = 2.63, 3.21, 3.34, with standard errors = 0.44, 0.68, 0.71, for  $IMP1$ ,  $IMP2$  and  $IMP3$ , respectively).

Figure 5. Effect of IMP types on stealth and disruption.

The effect of IMP delivery rate is shown in Figure 6. It is clear that with the rate increase the evaluation scores decrease (mean evaluation scores = 6.64, 5.12, 4.28, 3.58, 3.10, with standard errors = 0.17, 0.15, 0.23, 0.25, 0.28, for 0, 10%, 20%, 30% and 40%, respectively) and the disruption scores increases (mean disruption scores = 0.87, 1.77, 2.75, 2.97, 3.76, with standard errors = 0.25, 0.37, 0.50, 0.81, 0.59, for 0, 10%, 20%, 30% and 40%, respectively). A nonlinear regression supports the notion that rate increases led to more disruption and less stealth.

Figure 6. Effect of IMP delivery rates on stealth and disruption, with polynomial fitting curves.

## Summary and Discussion

In this article we explore ways of covertly delivering interventions into the adversary decision cycles so as to effectively shape adversary decision-making and performance without inducing much suspicion. The focus here is not on the delivery technology, which we assume can be achieved, but on the covertness. That is, how can we deliver interventions that do not induce significant suspicion and effectively shape operators' behavior?

Attention is often the first cognitive faculty explored in the attempt to understand covert interventions. On the one hand, there are hardly better ways to implement covertness than designing interventions that are invisible even to the adversary operator's attentional system. In this case, the interventions are completely hidden and therefore can potentially cause most and long-term damage. On the other hand, a large body of evidence in the field of psychology has shown that attention is a fragile function that is subject to exploitation and manipulation. A recent theoretical breakthrough of attention research is the notion that there exist different types of attention, each of which is subserved by different brain regions and is sensitive to different variables (Fan, McCandliss, Sommer, Raz, & Posner, 2002; Posner, 2004). Equipped with the taxonomy, it has been suggested that each type of attention could be subject to different exploitations for the purpose of covertness. Studies have been conducted to systematically examine the effect of parameter changes on inducing covertness and affecting performance (Sun, Wang, Zhang, & Smith, 2008; Wang & Fan, 2007; Wang, Liu, & Fan, 2012).

Recognizing the limitation of attention-based covertness in real world situations, in this article we propose to a more general approach to covertness. That is, instead of delivering completely hidden interventions, it is possible to deliver interventions that may be noticeable but whose true meanings are hidden or distorted. Consequentially the similar effect of covertness can be achieved. This approach, based on insights from human abductive reasoning rather than straightforward attentional manipulations, is easier to implement and potentially more powerful. However, the success of the approach would require a better understanding of adversary decision processes and more sophisticated delivery strategies. The study reported in this

article is a step towards developing and evaluating guidelines and schemes for such deliveries.

In the experiment we manipulated the type of interventions and the delivery themes. In particular, we distinguished pure vs mixed and clumped vs dispersed deliveries. We evaluated the effect of these manipulations on suspicion and performance. Our results support the general notion of abduction-based covertness. We show that covertness can be achieved even when interventions are detected as long as they are not properly explained. Our results demonstrate that different intervention types have different effectiveness. And more important, we show that pure-dispersed delivery scheme is more effective than the other delivery schemes, suggesting that when delivering interventions, to achieve effective stealth and disruption, try to keep the interventions dispersed and do not mix different types of interventions.

In sum, we demonstrate that abduction is a sound and insightful framework for understanding human reasoning in general and human suspicion in particular. Techniques such as “explaining away” and “data reliability” are powerful in manipulating suspicion and implementing covertness. Additional work is clearly needed for a deeper theoretical understanding of the underlying cognitive process and more comprehensive guidelines for covert intervention delivery in real-world situations.

## Abstract

Acquiring the correct meanings of number words (e.g., *seven*, *forty-two*) is challenging, as such words fail to describe salient properties of individuals or objects in their environment, referring rather to properties of *sets* of such objects or individuals. Understanding how children succeed in this task requires a precise understanding not only of the kinds of data children have available to them, but also of the character of the biases and expectations that they bring to the learning task. Previous research has revealed a critical role for language itself in how children acquire number word meanings, however attempts to pinpoint precisely the strong linguistic cues has proved challenging. We propose a novel “syntactic bootstrapping” hypothesis in which categorizing a novel word as a determiner leads to quantity-based interpretations. The results of a word learning task with 4 year olds indicates that this hypothesis is on the right track.

**Keywords:** Number, quantity, language acquisition, learning, determiners, adjectives, quantifiers, syntax.

## Words for quantities

While it is uncontroversial that young children necessarily make use linguistic and extralinguistic information when they set about learning the meaning of novel words, the idea that some pairing of “situation and sound” is *sufficient* has been repeatedly questioned (e.g., Landau & Gleitman 1985, Waxman & Lidz 2006). An especially difficult problem for any view that posits a simple mapping from a portion of experience to the meaning of a novel word has been the acquisition of number words (e.g., *five*, *sixty-seven*). This is particularly challenging as numbers refer to properties of *sets* of objects rather than to properties of any object in particular (Frege 1893; Bloom & Wynn, 1997). Understanding how number words are learned must be informed not only by a precise understanding of the kinds of data children have available to them, but also of the character of the biases and expectations they bring to the learning task.

In this paper, we consider the question of how children decide that a novel word describes numerosity and not some other salient property. To take a simplified example of the problem, consider the novel word *gleeb* in (1).

- (1) The *gleeb* cows are by the barn.

The novel word *gleeb* appearing in an adjectival position may describe any number of properties relevant to the cows, for

instance their color (e.g., they may be *blue*), texture (e.g., especially *soft*), size (e.g., for cows, quite *big*), or even their number (e.g., approximately *many*, or exactly *seven*). Under what circumstances would a child prefer to assume that number is the intended property? Finding such circumstances would aid researchers in finding the unique biases and expectations children must bring to the task in order to accurately acquire number words.

Research on the acquisition of exact number words suggests that language itself must provide critical support for the child to map new words onto such abstract meanings. Wynn (1992; see also Condry & Spelke 2008) found that children at 2;6, who do not yet understand the relationship between the words in the count list and exact cardinalities, nevertheless understand that the number words describe numerosities. This result is striking, as it takes children another full year to gain the knowledge that which exact quantities are intended (Wynn 1992, Carey 2009). Bloom and Wynn (1997) examined the distribution of the numerals in the CHILDES database of child-directed speech to determine what syntactic cues might prompt quantity-based interpretations. They proposed that the appearance of an item in the partitive frame (e.g., as *X in X of the cows*) was a strong cue to number word meaning. The plausibility of such a view is bolstered by the linguistics literature: partitivity has been said to signal to the semantic role of quantification (Jackendoff 1977).

This proposal was recently investigated by Syrett, Musolino and Gelman (2012). Conducting their own corpus study, they pointed out that a great variety of non-quantity-referring expressions occur in the partitive frame (2), so perhaps we should not expect it to be a strong cue to numerical meanings.

- (2) a. **Amount:** *all, two, seven, most, some*  
b. **Segment:** *back, front, edge, side, top*  
c. **Measure:** *mile, hour, pound, bucket*

Regardless, if the partitive were a strong cue, then a novel word embedded in the partitive should lead children to pick a quantity-based interpretation even when the environment supports both this and an alternative interpretation. That is, in a novel word learning task, the novel word *pim* appearing with

the partitive (as in *pim of the trains*) should be analyzed as referring to the quantity TWO but not the quality RED<sup>1</sup> when both interpretations were supported. Syrett et al found that the partitive predicted quantity-based judgments only in restricted cases,<sup>2</sup> casting doubt on the robustness of a “syntactic bootstrapping” account based on the partitive as a strong cue.

The puzzle raised by Wynn’s (1992) original finding remains. Indeed, it appears to raise the question whether it may be necessary to understand how children decide that novel words describe quantities *at all* before we can understand how they learn the meanings of words for *exact* numerosity (see also Barner, Chow & Yang 2009 for discussion). The numerals pattern with a larger class of expressions in natural language called *quantifiers* (i.e., the Amount terms in (2)), which share a similar syntactic distribution. If a child could figure out (as Bloom & Wynn suggested) that a certain bit of syntax corresponded in a stable fashion with the semantics of quantity, they might have a foothold on deciding a novel word referred to numerosity. To get a sense of the problem, consider the sentences in (3a) and (3b) with the novel word *gleebest* against the image in Figure 1.

- (3) a. The gleebest cows are by the barn.
- b. Gleebest of the cows are by the barn.

For adults, *gleebest* in (3a) could in principle describe something about the numerosity or some other property of the cows by the barn in contrast to those in the field. Indeed, the meaning one perceives is similar to that conveyed either by the familiar *most* or e.g. *spottiest*. However, if adults were exposed to the novel word in the syntactic context given in (3b), they would *never* suppose it to designate something about the spottiness of the cows by the barn, only their numerosity.

Adults, however, have had a lifetime of language experience. Under what conditions would a child still in the process of mastering their native tongue hypothesize that *gleebest* means MOST as opposed to SPOTTIEST? Would their pattern of preferences be the same if presented with either of the sentences in (3a) or (3b)?

While the evidence for the partitive frame (*...of the cows*) as a strong cue to quantity-based meanings is mixed, we think pairs of sentences like the above suggest that a stronger cue might be whether something occurs to the left of *X*. Of the classes of counterexamples provided by Syrett et al given in (2), we may note that only amount terms can appear without a determiner (*a* or *the*) on the left:

- (4) a. Two/most of the cows lowed.
- b. \* Back/side of the fridge is blue.
- c. \* Mile/hour of the race was hard.

<sup>1</sup>We follow custom in using italics for linguistic expressions and small caps as shorthand for their meanings.

<sup>2</sup>Only when it was used at test; when the partitive was used during training but not at test, children were at chance at picking the quantity interpretation.

Figure 1: **The gleebest cows** are by the barn.

Such data illustrate an important linguistic generalization. Amount terms, or *quantifiers*, can occur in a privileged syntactic position (e.g., Barwise & Cooper 1981): that of determiners, instantiating the category D. Unlike the partitive frame, Ds have a stable syntax-semantics mapping: their interpretation only references quantities, never qualities, of individuals (van Benthem 1989, Gajewski 2002).<sup>3</sup> Observing this pattern leads us to a novel hypothesis: if a child categorizes a novel word as D, she will understand that word to have a quantity- rather than quality-based meaning.

A test of this would be to make both numerosity and spottiness salient, and test children’s preferences for interpreting a novel word across syntactic contexts. To construct such a test, we turn to superlatives. As we will see, superlatives (the result of combining a word like *heavy* with the morpheme *-est*) allow for a direct comparison of the hypothesis that syntactic category, and not partitivity, is a strong cue to positing quantity-based meanings.

Combining a word with a quality-based meaning like *heavy* with the morpheme *-est* allows the formation of expressions like *the heaviest animals*, with a meaning like THE ANIMALS THAT ARE HEAVIER THAN ANY OTHERS. Similarly, combining *many* with *-est*<sup>4</sup> gives *the most animals*, with a meaning like THE ANIMALS THAT ARE MORE NUMEROUS THAN ANY OTHERS. Importantly for our purposes, both of these types of superlatives surface in the position of an adjective (5a) (where *the* instantiates the syntactic category D), but only the quantity-based superlative *most* can appear bare on its left, instantiating D (contrast (5b) with (5c):

- (5) a. The heaviest/most animals are happy.
- b. Most of the animals are happy.
- c. \* Heaviest of the animals are happy.

<sup>3</sup>As a simple rule to determine which word in a string is D, take *X* in *X of the cows* to be D unless *the* precedes *X*. Since *the* cannot appear without an element to its right before *of* (cp. \**the of the cows*), it instantiates D whenever it is present. In *the most cows*, *the* instantiates D, but *most* instantiates D in *most of the cows*.

<sup>4</sup>It is widely assumed that *most* is the superlative of *many*, following Bresnan 1973; cf. Bobaljik 2007 who argues *most* is *more+est*.

Figure 2: Ambiguous training cards.

This restriction can’t be conceptual: where we understand the sentence in (5b) to mean MORE THAN HALF OF THE ANIMALS BY NUMBER ARE HAPPY, by analogy we might have expected (5c) to mean MORE THAN HALF OF THE ANIMALS BY WEIGHT ARE HAPPY. To see what this would mean, consider a situation in which the only animals are a cow *C*, a lamb *L*, and a rabbit *R*. It is clear that (5b) is true if any two of the animals are happy. But (5c) requires more information: if *C* weighs 700kg, *L* weighs 35kg, and *R* weighs 8kg, we would know (5c) is true **only if *C* is happy**. Individuals and their particular properties matter for quality-based superlatives, where only set cardinality matters for *most*. While it is clear that no conceptual necessity rules out a determiner-like meaning for a quality-based adjective, why it is excluded remains a mystery.<sup>5</sup>

Lastly, regardless of whether they have quantity- or quality-based meanings, superlatives can appear in the partitive frame:

- (6) a. \* The spottiest of the cows were by the barn.
- b. \* The many of the cows were by the barn.
- c. The spottiest of the cows were by the barn.
- d. The most of the cows were by the barn.

In the next section, we put our hypothesis that syntactic category cues category meanings to the test in a novel word learning task. At the same time, we contrast this hypothesis with that suggesting partitivity as a strong cue.

### Testing superlatives

In the previous section, we hypothesized that representing a novel word as an instance of the category D was a strong cue to the learner that the word should be assigned a quantity-based meaning. An alternative was presented that suggested presence of the partitive frame alone was a strong cue. We test

<sup>5</sup>This is especially surprising, given recent proposals in the formal semantics literature that nothing much *semantically* distinguishes *most* from *spottiest* (Hackl 2009). Yet, it is difficult to see how appeal to numerosity would be possible in formulating a *syntactic* constraint to make sense of facts like (5b)-(5c).

these ideas by examining children’s preferences when embedding *gleebest* in a variety of syntactic contexts, using a variant of the Picky Puppet task (Waxman & Gelman 1986).

### Method

In this task, the experimenter first explains that the game is to sort cards according to whether a puppet likes them or not. The puppet is described as picky, but friendly enough to share the reasons for why he likes what he does. The experimenter explains the puppet’s criterion by showing preferred and dispreferred cards along with the sentence: “The puppet said he likes the cards where **target sentence**, but he doesn’t like the ones where it’s not true that **target sentence**”. The target sentence always contained the novel word *gleebest* (see Table 1). The experimenter explains that she doesn’t know what *gleebest* means, but was hoping the child could help her figure it out. In the Training phase, the child is shown 6 training cards (Figure 2), the ones the puppet had “already told” the experimenter it liked or didn’t like.

Table 1: **Target sentences:** “*The puppet likes the cards where DP are by the barn.*”

cond	DP	<i>the</i>	partitive
ADJ	<i>the gleebest cows</i>	✓	×
CON	<i>the gleebest of the cows</i>	✓	✓
DET	<i>gleebest of the cows</i>	×	✓

While the training cards are perfectly ambiguous (the group by the barn is both the most numerous and the most spotty), the test cards are perfectly *unambiguous*.<sup>6</sup> The same cards (in counterbalanced order) were presented to each participant. The form of the target sentence was our between-subjects factor, with *gleebest* appearing in adjectival (ADJ), confounded (CON), and determiner (DET) positions, so our conditions feature different combinations of presence/absence of *the* and the partitive, as schematized in Table 1.

<sup>6</sup>For our test cards, the ratio of the numerosities of the cows was inversely proportional to the ratio of the spots of the cows.

Figure 3: Unambiguous test cards.

At the beginning of the Test phase, the experimenter handed each test card to the child with the question “Do you think he likes this one?”. The child was to place each card below a green circle with a checkmark on it if the puppet likes it, and below a red circle with a black X if he doesn’t like it. At the end of the experiment, the child was probed as to what s/he thought *gleebest* meant, and responses were recorded.

We hypothesized that categorizing a novel word as D restricts a child’s hypothesis about the word’s meaning to a quantity-based interpretation. Another proposal was that the presence of the partitive frame itself was a strong cue to such interpretations. Thus the relevant hypotheses are schematized in Table 2 according to whether they predict a greater-than-chance quantity-based response (indicated by +).

Table 2: Predicted neutral (–) versus increased quantity-based responses (+).

Hypothesis	ADJ	CON	DET
Category as strong cue	–	–	+
Partitive as a strong cue	–	+	+
No bootstrapping	–	–	–

36 children participated (range 4;0-5;2, mean 4;7), recruited from families in the University of Maryland area. Each child was given a small gift for participating. Four additional children were tested and subsequently excluded—2 due to experimenter error, 1 due to presenting with a strong “yes” bias (i.e., the participant indicated the puppet “liked” 11/12 of the test cards), and 1 due to a strong “no”-bias (i.e., they said the puppet “didn’t like” 12/12 of the test cards). We measured the percentage of cards sorted consistent with a quantity-based interpretation.

## Results

Across our three conditions, responses were significantly different from chance (sign tests: ADJ  $p < 0.0001$ , CON  $p < 0.05$ , DET  $p < 0.0001$ ). These differences were in different directions, however. Children sorted cards consistent with a quantity-based interpretation in DET 72% of the time, compared to 29% in ADJ and 40% in CON. In addition, DET was significantly different from both ADJ (t-test,  $p < 0.0001$ ) and CON (t-test,  $p < 0.0001$ ). These results are presented graphically in Figure 4.

It is noteworthy that these results are not simply an averaging effect: 8 out of 12 of the children in DET sorted at least 9 out of 12 test cards consistent with a quantity-based interpretation, while only 2 out of 12 children did so in ADJ and 3 out of 12 in AMB.

Figure 4: Percent quantity responses by condition.

As there were no differences between our conditions except for the syntactic context in which *gleebest* occurred, these results support the idea that syntax cues children into quantity-based meanings, with syntactic category playing a strong role. Partitivity, on the other hand, is a fairly weak cue: while there was a slight effect (CON had slightly higher quantity-based responses than ADJ,  $p < 0.05$ ), in neither of these conditions did children sort cards consistent with a quantity-based interpretation, in fact both conditions displayed *lower* than chance sorting of cards consistent with that interpretation. A table summarizing the predicted versus actual results is given in Table 3.

Table 3: **Predicted neutral (+) versus increased quantity response (+): prediction met (✓) versus not (×).**

Hypothesis	ADJ	CON	DET
Category as strong cue	– ✓	– ✓	+ ✓
Partitive as strong cue	– ✓	+ ×	+ ✓
No bootstrapping	– ✓	– ✓	– ×

Of the three hypotheses sketched, only syntactic category as a strong cue captures the results we found.

## Discussion

Our results show that a syntactic bootstrapping hypothesis for acquiring novel superlatives is supported. An additional hypothesis, that the presence of the partitive frame is a strong cue to quantity-meanings, was not supported. These results are important for a number of reasons. As observed in the introduction, choosing number as the relevant property from a set of available properties is potentially challenging for children. Our results highlight the role of the child's syntactic representations in narrowing her hypotheses about what matters when she tries to determine the meaning of a novel word, in particular the role of the syntactic category D as a strong cue to quantity-based meanings.

A different but related question that this work raises is the strength of the bias towards quality-based meanings in ADJ and CON. Given that children had no problem deciding that *gleebest* referred to numerosity in DET, we cannot assume some inability to reason about number. One might speculate that the bias is due to the child's distribution of known adjective (or superlative) meanings: since many more words in this category refer to object properties than set properties, the prior distribution of meanings biases her towards the former, absent syntactic cues to the contrary. Future work with younger children could examine the degree to which this bias emerges as a function of the size of their lexicons. The line of thought just outlined predicts that the youngest children would show less of a bias in this direction.

## Acknowledgments

This work was made possible by generous support from a Social Sciences and Humanities Research Council of Canada

doctoral award (#752-2010-0499) to Alexis Wellwood. The authors would especially like to thank Tim Hunter, Research Assistants Leah Whitehill and Jessica Lee, the University of Maryland's infant and preschool labs, the Center for Young Children, and the audience at the Linguistic Society of America's 2012 annual meeting.

# Expertise and the Wisdom of Crowds: Whose Judgments to Trust and When

Matthew B. Welsh (matthew.welsh@adelaide.edu.au)

University of Adelaide, North Tce  
Adelaide, SA 5005, Australia

## Abstract

The Wisdom of Crowds describes the fact that aggregating a group's estimate regarding unknown values is often a better strategy than selecting even an expert's opinion. The efficacy of this strategy, however, depends on biases being non-systematic and everyone being able to make a meaningful assessment. In situations where these conditions do not hold, expertise seems more likely to produce the best outcome. Amateurs and professional judgments are examined in a subjective domain – reviews of shows from an Arts festival – asking which group provides better information to the potential theatre-goer. In conclusion, while following the crowd produces good results, where a smaller number of reviews are available, taking expertise into account improves their usefulness and discrimination between shows.

**Keywords:** Expertise, Wisdom of Crowds, subjective judgment.

## Introduction

When making decisions between diverse options, we often do not have sufficient time or resources to conduct the sorts of thorough analyses recommended by decision analysts (see, e.g., Newendorp & Schuyler, 2000). Instead, we rely on simple rules to greatly reduce the complexity of our decision making while maintaining as much quality as possible (Gigerenzer & Todd, 1999). Perhaps the simplest such rule is: if someone recommends option A, then I will select option A.

This approach, of course, requires that you have some idea of whether or not you should trust the opinion of the person offering it, which is easy when it is a person you know but more difficult when you are forced to rely on the opinions of strangers – as is often the case.

As an example, consider a person's decisions regarding what to spend his/her entertainment budget on. While they could wait and hope that their friends will go to see all of the various shows that they were interested in, more often, they will have to rely on reviews from either professional reviewers or sites such as "Rotten Tomatoes" that aggregate amateur review data. In either case, the criteria on which the reviewers have provided their rating is generally unknown to the people using the information.

The question, then, is how to make the best use of the available information – from both professional and amateur reviewers – in order to make informed decisions about the quality of entertainment on offer.

## The Wisdom of Crowds

The wisdom of crowds describes a well-known effect first discussed by Galton (1907) and more recently repopularized

by Surowiecki (2004). The observation is simply that, when making decisions under uncertainty, the median or mean estimate of a crowd is often a better predictor than the estimate of a randomly chosen individual – even an expert.

This initially surprising observation results simply from the underlying mathematics of the problem. If any biases or errors in people's estimates are independent, then they will tend to be in random directions and thus, when averaged, will be removed. This has allowed researchers to demonstrate that even having the same individual make an estimate twice and averaging those values can produce better estimates – so long as some degree of independence can be established between the two estimates (Herzog & Hertwig, 2009; Vul & Pashler, 2008).

For the wisdom of crowds to work, therefore, one needs to be considering a domain in which biases in people's judgments are not systematically related to those of other people. If this condition is met, then one expects that averaging the judgments of a group regarding the quality of a particular show would provide a better estimate of how much you will enjoy it than relying on the advice of any single reviewer.

## Expertise

By comparison with the wisdom of crowds, expertise is a harder creature to pin down. While we all have an implicit understanding of what expertise is, actually defining it proves surprisingly difficult (see, e.g., Shanteau, 2002; Weiss, 2003) and people commonly confuse it with simple length of experience (Malhotra, Lee, & Khurana, 2005).

Despite this, given that we know there is such a thing as expertise and that people are employed on the basis of this to provide expert advice, it would seem reasonable for us to expect that this advice will be valuable – more valuable, at least, than a non-expert's judgment.

## Decision Criteria

An important question, which should be asked before continuing, relates to the decision criteria being used. This is important as, when we ask a question, we can only receive meaningful responses if the person understands and answers the question we have asked. In the case of reviews of entertainment, then, what is the question that is being asked?

The difficulty here is that expert and non-expert reviewers may be answering different questions. Experts might be answering the question – how much artistic merit does the show have? Non-experts, by comparison, may be answering the simpler question – how much did you enjoy the show. In both cases, the judgment is subjective and dependent on the

reviewers personal tastes but, in the first, it is also being judged against taught norms of quality.

A secondary concern is the fact that most reviews are undertaken on an absolute scale, whereas people are far more comfortable and more accurate making relative judgments (see, e.g., Stewart, Brown, & Chater, 2005; Stroop, 1932). Given this, we need to be cautious in interpreting what a reviewer may mean by any given review.

## This Study

In this study, reviews of entertainment will be analyzed in order to determine how a person could best use the available information to select a show to attend. It thus overlaps significant with problems such as the Netflix Prize (Bennett & Lanning, 2007) but is approached from a psychological rather than machine learning stance – that is, incorporating concepts such as expertise and considerations of *why* we have the data we do and how this should affect its use (for further discussions of this, second, point, see, Welsh & Navarro, 2011; Welsh, Navarro, & Begg, 2011).

## Method

The data sets selected for analysis consisted of reviews of acts performing at the 2011 Adelaide Fringe Festival – a large, “unjuried” Arts Festival held annually in Adelaide, Australia. Being an unjuried festival, any act is free to register to perform without being selected by the festival’s governing body. As such, the quality of performances is (presumably) more variable than would be observed in a juried festival where acts must convince the festival’s jury of their quality before registering.

Given this, selecting a quality show to attend from the hundreds (750 in 2011) on offer becomes a difficult task in the absence of reliable indicators of quality. To this end, two databases of reviews were acquired: first, the Adelaide Fringe’s summary of published, professional reviews from newspapers and news websites – labeled simply “Fringe” hereafter; and, second, the database from BankSA’s “Talkfringe” website which allows anyone to register and post reviews of any Fringe shows that they have seen.

All of the Talkfringe reviews use the same 1 to 5 ‘Star’ rating system (with half stars). The professional reviews, however, were in a variety of formats. To maintain comparability, therefore, only professional reviews that used a 5-star rating system were included in the analyses.

## Data Characterization

The Fringe database records 365 reviews in the required 5-star format, made by 54 reviewers – an average of 6.8 reviews per reviewer. By contrast, the Talkfringe database contains 1436 reviews made by 731 reviewers. Figure 1 displays this information as a histogram of reviews per reviewer for the Amateurs (Talkfringe) and Professionals (Fringe) separately. Between the two databases, reviews were obtained for a total of 420 shows, with each being reviewed an average of 4.3 times.

Looking at Figure 1, one sees that both subplots seem to display similarly shaped distributions – a decay function of some type. The figure is, however, somewhat misleading as the y-axis of the Amateur subplot is displayed as if the highest count was 100 when, in fact, it was 529 (as indicated by the high value on the y-axis).

Figure 1. Histogram of number of reviews per reviewer by reviewer group. Note: Amateur y-axis is non-linear at top.

That is, while only a modest proportion (12/54) of the professionals reviewed only a single show, the majority of amateurs (529/735) did so.

## Results

### Indirect Comparisons

As an initial approach to the question of whose reviews should be trusted, the distributions of star-ratings within each database were compared. Figure 2 shows the histograms of this data.

Figure 2. Histogram of Star ratings by reviewer group.

Looking at Figure 2, one sees that the two distributions differ significantly from one another, as confirmed by an independent samples t-test,  $t(1799) = 13.9$ ,  $p < .001$ , Cohen’s  $d = 0.81$ . The Amateurs display something close to an exponential distribution of star-ratings, with a median and mode at 5 and a mean of 4.33, while the professionals display something closer to a Gaussian, with a mean and median around 3.5 and a mode at 4. This raises questions about the discriminability of Amateur reviews – that is, whether seeing a 5 star review from an amateur allows you to conclude anything meaningful about that show.

There are, however, alternate possible explanations for this pattern of responses. The first is that amateurs tend to be less discriminating in their tastes than the professional

and, thus, enjoy shows more. The second, however, is a selection effect – while professionals are told which shows to attend and write reviews of all of the shows that they attend, amateurs choose shows that they think they will like and are less likely to write a review unless motivated by particularly enjoying or disliking the show. Given that more popular shows attract greater audiences, and assuming a positive relationship between quality and popularity, this will tend to result in large numbers of high-star reviews for popular shows and relatively few reviews of any sort for less popular shows.

Based on this reasoning, one could assume that any show that has multiple, high-star reviews from amateur reviewers is likely to have been a popular show.

## Direct Comparisons

The above discussion considers only the distributions of star ratings, rather than those instances where we have reviews of the same show made by both amateur and professional reviewers. An examination of the two databases revealed that, of the 420 shows, 191 of these were ‘shared’; that is, had been reviewed by at least one member of each reviewer group.

Looking only at these ‘shared’ shows, the difference between the professional and amateur groups (3.59 versus 4.33) is almost exactly the same as for the full dataset (3.55 versus 4.33) and remains significant by a paired samples t-test,  $t(1231) = 11.2$ ,  $p < .001$ , Cohen’s  $d = 0.79$ .

Figure 3. Scatterplot of mean amateur versus mean professional review for all 191 ‘shared’ shows. NB – some jitter has been added to the points to reduce overlap and facilitate display.

Despite the removal of over 200 shows that lacked a rating from each group, a consideration of only the overlapping shows still contains the majority of the review data as these 191 shows attracted 1233 of the total 1801

reviews and a comparison of the distribution of star ratings within this group with that for the complete datasets shown in Figure 2 revealed no noticeable differences. Figure 3 plots the mean reviews provided by each group for each show against that calculated from the other group.

Looking at Figure 3, one can see that the relationship between the amateur and professional reviews is positive, but not particularly strong – confirmed by a correlation  $r(190) = 0.32$ ,  $p < .001$ , indicating significant disagreement between the two groups on the quality of shows.

A closer examination of the figure reveals that a partial explanation for the poor correlation may be restricted range – with relatively few datapoints in the lower left quadrant. Again, this is likely to reflect selection biases, with all type of reviewers more likely to attend and review popular shows – which, in turn, are likely to be of higher quality.

## Quality by Popularity

Given the data above, what can we say about how a person should go about selecting a show to see? As noted above, there is an assumption that higher quality shows are more likely to become more popular and that the number of reviews can be used as a proxy for popularity. This means that we can compare the star-ratings for shows of differing popularity to see how these variables interact. Figure 4, below, plots show star-ratings against number of reviews for all 420 shows contained in both databases.

Figure 4. Scatterplots of number of reviews (show popularity) versus mean rating (show quality) for Amateur and Professional reviewers. NB – some jitter has been added on the y-axis to facilitate display.

Looking at Figure 4, one sees that the mean ratings of shows that received low numbers of reviews vary quite significantly – indeed for shows with only one or two reviews, the mean ratings are fairly uniformly distributed across the 1-to-5 range.

For shows with higher numbers of reviews, however, one sees a striking pattern emerge – as the number of reviews increases, so does the *minimum* mean rating that that show

received. Comparing the bottom two subplots, one sees that this pattern emerges early in both the amateur and professional reviews; no show with 3 or more reviews averages less than a 2-star rating.

Looking across the top subplot of Figure 4, one can see this predictive power continues for higher numbers of reviews: no show with 6 or more reviews was rated lower than 3 star (on average); no show with 14 or more reviews was rated lower than 4 star (on average); and the 7 shows that were reviewed by 25 or more people all averaged at least 4.5 star reviews.

This would seem to confirm the prediction that popularity and quality are, in fact, linked and suggest that an appropriate strategy for selecting a quality show would be to select one that many people have reviewed – even without reading those reviews.

### Expert vs Non-Expert Reviews

A final question to be addressed is that of expertise. While we have, above, divided reviewers according to whether they are Professional or Amateurs – and assume that this reflects some difference in expertise (in reviewing shows) – the data afford us some scope to test this assumption.

Looking once more at Figure 4, for example, one can see a suggestive pattern in the comparison between the Amateur and Professional results – where the speed at which the predictive multiple reviews increases seems greater for the Professional. That is, having had multiple Professional reviewers attend a show may be a better indicator of quality than having had the same number of Amateurs review it.

A more important question, however, is whether we can establish that expert reviews are *better* than non-expert reviews. The difficulty, of course, is in determining how we measure the quality of a review – after the fact and in the absence of any objective standard. A simple wisdom of crowds approach would suggest that we use the median or mean review from all reviewers as the standard but this runs into the problem of non-discriminability in the amateur data where too many shows will all be rated 5-star.

There are, however, at least two methods of using the current data to shed light on the relative usefulness of professional and amateur reviews in selecting a good show.

### Measuring the Expertise of Amateur Reviewers

The first of these involves a comparison of the differences within the two groups. For example, it seems a reasonable assumption that those Amateurs who review more shows become more expert in doing so. The same relationship, of course, is less likely to hold in the Professional reviewers as the assumption is that these people have significant previous experience that is not available to us through the data set; and which is likely to outweigh any effect of the relatively few reviews they made during this event. Given the above, it seems necessary to restrict this discussion to differences within the Amateur group.

What then are the differences between the more and less ‘expert’ amateurs – that is, between those who posted many

rather than few reviews. Figure 5 thus plots number of reviews per amateur reviewer against star ratings.

Figure 5. Scatterplot comparing number of reviews to mean star rating (amateurs only). ‘Jitter’ has been added to the data along the y-axis to prevent datapoints overlapping. The red line shows the overall mean for each group of reviewers.

Looking at Figure 5, one sees a trend as the number of reviews that a person has posted increases; specifically, as the number of reviews increases, the average review tends to decrease,  $r(729) = -0.20, p < .001$ .

This could be explained by a drop-off in the quality of shows – if everyone were seeing the same shows and there were only a small number of genuinely 5-star shows, for example. Given the number of shows involved, however, and how many of these received 5 star ratings from someone, this seems an unlikely explanation. Instead, it seems more likely that we have support for the idea that increased experience in reviewing (and, therefore, seeing more shows) changes the ratings that one is likely to give.

Suggestively, the most prolific reviewers in Figure 5 give average ratings that are more typical of Professional reviewers than the other Amateurs. That is, their mean ratings tend to be between 3 and 4 rather than 4 and 5.

The question remains, however, as to whether this reflects *better* reviews; and the problem is, of course, that as enjoyment of a show is highly subjective, it is possible that what is the *better* (i.e., more predictive) review differs between individuals.

On the basis of these results, for example, one might conclude that the more shows one is inclined to see, then the more similar one's own ratings will be to those of Professional reviewers. If so, then one should weight professional reviews more highly than amateur ones – or, where these are unavailable, downgrade ‘overly-enthusiastic’ amateur reviews.

### Consistency of Different Reviewers

A second consideration in what makes one review *better* than another is their reliability. That is, when two people have seen the same show, are they inclined to give the same rating? A comparison between the Amateurs and

Professionals on such a measure might allow one to have greater or lesser confidence in one group's ratings.

Within the Professional reviewers group, there were 70 shows that had been reviewed by at least 2 reviewers – which yielded a total of 97 pair-wise comparisons (due to some shows being rated by three or four reviewers). Thirty of these had exactly the same rating, with another 40 differing by only half a star. Overall, the average difference between ratings of the same show by professional reviewers was approximately half a star ( $M = 0.56$ ,  $SD = 0.52$ ).

The Amateur group, by comparison, had 228 shows with multiple reviewers, which resulted in 10,401 pair-wise comparisons. This number, however, is dominated by the relatively small number of very popular shows – those on which we see a ceiling effect resulting from the selection bias. The most popular show, for example, has 60 reviews, 58 of which are 5-star – with one 1-star and one 3-star review making up the numbers. This show contributes 1770 unique pair-wise comparisons – over a sixth of the total – and would thus, if included, overwhelm any effects of the inter-rater reliability more generally. To ensure comparability with the Professional results, therefore, only shows that had been reviewed by between 2 and 4 reviewers (the numbers observed in the professional sample) were included in the analyses. This resulted in the removal of 79 shows, leaving 149 and a total of 404 unique pair-wise comparisons.

Of these, 120 had exactly the same rating, 114 differed by half a star and 170 differed by 1 full star or more. The average difference between the amateur reviewers' ratings for these shows was 0.82 stars ( $SD = 0.87$ ), significantly higher than that observed in the Professional reviewers' ratings,  $t(499) = 2.83$   $p = .002$ .

## Discussion

The results paint a complex picture of the relationships between reviewer expertise and the use of aggregation strategies such as the wisdom of crowds for reviews from multiple sources.

Perhaps the single best predictor of show quality (i.e., how much people enjoyed the show) was the total number of reviews that the show had received – reinforcing the assumption that popularity and quality are linked. Note, however, that this is a distinct effect from the wisdom of crowds as the results suggest that we don't need to look at the ratings provided by reviewers at all. Instead, all we need to do is "follow the crowd" and they will lead us to good shows.

In cases without such overwhelming endorsement, however, we are forced to rely on the numerical ratings provided by the expert and amateur reviewers and can run into difficulties in determining what to do.

The first problem we observed in the data was the strong selection bias in the amateur data; because people tend only to pay to see shows that they expect to like, the distribution of star ratings gets shifted to the right – with more 5-star reviews. Added to this is the voluntary nature of amateur

reviews, which results in people only writing a review if they are motivated to do so – which, we suggest is most likely when they particularly like or dislike a show. This effect will, therefore, tend to push results even further towards the extremes and, given the effect described above, this will tend to push more people into the very high part of the rating range.

Thus we have a large number of reviews that are relatively uninformative – reflecting the fact that a person predisposed to like a particular show really liked it. A result of this is the lack of discrimination in the amateur data where, because so many reviews give 5-star ratings, it simply doesn't help us to make a decision regarding which of these shows we should attend and short-circuits attempts to use the wisdom of crowds based on median values – as we would end up comparing 5-stars with 5-stars.

A second (but related) concern is that the majority of amateur reviewers (529 of 731) wrote only a single review. Given what we know about people's inability to directly assess values, the use of relative preferences (e.g., converting the ratings to rankings) is a sound method for improving our understanding of what people's expressed preferences actually mean. With only one review per reviewer, however, we cannot meaningfully assess relative preferences.

By comparison, a professional reviewer, while exercising some choice over which shows to see will also have some dictated by their employers and will be asked to write a review of all of the shows that they see. They are, from our data, far more likely to see multiple shows, and have a less-skewed distribution of ratings. They were also, in the subset of shows with a relatively few reviewers, more often in agreement with one another than were the amateurs.

This means that, in relying on professional reviews, one is better able to discriminate between their preferences for those shows that they have seen and also can be more assured that their review is reliable – that is, that another professional reviewer would have a similar opinion.

An addendum to this is that the data support the idea that the difference between amateurs and professional is related to experience/expertise. Amateurs who reviewed larger numbers of shows gave ratings that were more like the professionals. This could suggest that people are, in fact, rating shows on a relative scale but that the single-review amateurs have fewer shows to compare with and thus the chance of the show being amongst the best they have seen is relatively greater. The professionals and high-rate amateurs, by comparison, have a great many shows to compare the current show to and thus the likelihood of it being judged exceptional (5-star) is relatively less.

## Caveats

In so subjective a domain, there are, of course, a number of caveats to consider in conjunction with the arguments made above. A primary one, of course, is that we have not made any attempt to look at the types of shows that different people have attended and rated. If we expect that different

people have different tastes in entertainment, then we could conduct a far more fine-toothed analysis of preferences.

This importance of this for the current findings, however, is that one might expect a difference in preferences between professional and amateur reviewers. For example, while purely speculative, it would seem entirely feasible that professional reviewers prefer more serious art whereas the amateurs prefer lighter, comedic events.

If this is the case, then one would have to take into account such between group differences when determining whose reviews should be taken into account when making a decision. That is, knowing that professionals reliably tend to rate a show highly may be of no help at all if it is a type of show that you do not enjoy.

A second caveat is that there has not, as yet, been any attempt to weight or rank the data, which would, as described earlier, be expected to improve the predictive power of ratings – from those reviewers who reviewed multiple shows at least. An appropriate application of such tools, however, requires a fundamental grasp on the nature of the data; a grasp that has been greatly strengthened by the exploratory approach taken here.

### Future Research

Given the findings and the caveats noted above, a number of directions for continuing the research suggest themselves. The first is to examine the data in finer detail, dividing shows according to type - to see whether specific reviewers can be identified as having preferences between these.

Data beyond the ratings could also be accessed – for example, using ticket sales to directly measure the popularity of a show rather than simply assuming that number of reviews is a reflection of popularity.

This additional information, used in conjunction with ranking and weighting algorithms, could then be used to generate predictive models for individuals based on the shows that they have seen and how much they enjoyed them and using one half of the data to predict the other – in a similar fashion to the Netflix recommendation algorithms developed as part of the Netflix Prize competition (Bennett & Lanning, 2007).

Finally, experimental work designed to directly measure selection biases in reviews could be conducted, building on the work herein. Similarly, such work could potentially distinguish between alternative judgment strategies – for example, if experts are attempting to provide ‘absolute’ quality judgments whereas amateurs are just indicated whether they like a show or not.

### Conclusions

Within a domain such as entertainment reviews, good decisions can be made by following the crowd – if not always using the wisdom of crowds, per se. Where choices need to be made between shows, however, amateur reviewers ratings tend to cluster too closely around the maximum rating – as a result of selection bias in both show choice and the decision to write a review.

In these cases, therefore, following the advice of more expert reviewers (i.e., professionals and experienced amateurs) seems more likely to provide discrimination as they display less selection bias in their shows seen, meaning that they tend to write reviews of a variety of shows and have clearly discriminable preferences between these.

### Acknowledgments

Thanks to ExxonMobil and Santos for their support of the CIBP group in the Australian School of Petroleum; to Michelle Read from the Adelaide Fringe Festival and Simon Evans at BankSA for their assistance in accessing the review databases; and to Dan Navarro, Anna Ma-Wyatt, Steve Begg and three reviewers for their comments.

# Complex First? On the Priority of Nouns in Language Acquisition and Evolution

Markus Werning (markus.werning@rub.de)

Department of Philosophy II, Ruhr University Bochum  
44780 Bochum, Germany

## Abstract

The paper points to an apparent paradox in the science of language. It regards the semantics of nouns and consists of a set of together incompatible, but individually well confirmed propositions about the evolution and development of language, the semantics of word classes and the cortical realization of word meaning. Theoretical and empirical considerations support the view that the concepts expressed by concrete nouns are more complex and their neural realizations more widely distributed in cortex than those expressed by other word classes. For a cortically implemented syntax-semantics interface, the more widely distributed a concept's neural realization is, the more effort it takes to establish a link between the concept and its expression. If one assumes the principle that in ontogeny and phylogeny capabilities demanding more effort develop, respectively, evolve later than those demanding less effort, the empirical observation seems paradoxical that the meanings of concrete nouns, in ontogeny and phylogeny, are acquired earlier than those of other word classes.

**Keywords:** evolution of language, language acquisition, compositionality, modularity, complexity, frames, situated conceptualization

## Introduction

When one conjoins relatively well supported views on language acquisition and typology with frequently held views on the neural realization of meaning and some general principles of evolution and development, one seems to arrive at what I shall call the Complex-First Paradox. At its core is the question why concepts of substances, typically expressed by concrete nouns, seem to lexicalize ontogenetically and phylogenetically so early, even though they are apparently semantically far more complex than concepts that lexicalize later. The paradox consists of five propositions each of which seems plausible in its own right and is supported by empirical or theoretical reasons. The set of propositions – as is the nature of paradoxes – is apparently inconsistent, though, and thus points to an explanatory deficit in linguistic theory (Werning, 2008, 2010):

- (P1) The meanings of concrete nouns, in ontogeny and (probably) phylogeny, are acquired earlier than those of many – eventually even all – other word classes.
- (P2) The meanings of concrete nouns are substance concepts.
- (P3) Substance concepts are semantically more complex and their neural realizations more widely distributed in cortex than those expressed by the other word classes in question.

- (P4) For a cortically implemented syntax-semantics interface, the more widely distributed a concept's neural realization is, the more effort it takes to establish a link between the concept and some lexical expression thereof.
- (P5) In ontogeny and phylogeny, capabilities demanding more effort, all other things being equal, develop and, respectively, evolve later than those demanding less effort.

The paradox should be obvious now: Assume that the meanings of concrete nouns like *daddy*, *milk*, and *cat* are indeed semantically more complex or, to use another word, thicker than the meanings of other word classes, e.g., adjectives like *blue*, *big*, and *bold*. If one accepts that meanings are mental concepts, the view is illustrated as follows: The substance concept [milk] has not only perceptual components of various modalities like [white], [fluid], and [sweet], but also components that relate to affordances like [to drink]. The attributive concept [blue], in contrast, seems to be relatively thin: it does not decompose into distinct conceptual parts and seems to pertain to the visual domain only. Assume, furthermore, that conceptual complexity correlates with a wider distribution of the conceptual parts, respectively, their neural realizations in the cortex. One then expects the neural correlate of [milk] to pertain to visual, tactile, gustatory, and action-related regions. In contrast, the correlate of [blue] seems to be bound to the visual cortex. Following another of the assumptions, a word-to-meaning assignment ought to be more easily tractable for a cortically realized syntax-semantics interface if the neural correlate of the meaning is relatively local, rather than widely distributed. Consequently, the link between the adjective *blue* and the attributive concept [blue] should require less effort than the link between *milk* and [milk].

Take it as a quite general principle of evolution now that with regard to one and the same domain incrementally more complex capabilities *ceteris paribus* evolve later than simpler ones. There had to be feathers first, only then some reptile species could evolve wings. Vision could succeed in evolution only after light-detection had evolved. It seems to be a simple truth that lies behind it: *Natura non facit saltus*. There is an outright analogy in development: A child must have acquired the capability to hold a stick before it will be able to use a hammer. Children have to acquire simple closed syllables (CVC, e.g., *come*) before they are able to pronounce syllables with complex codas (CVCC, e.g., *cast*).

Given those assumptions, how can it be that the meaning of the noun *milk* ontogenetically and phylogenetically still is

acquired earlier than that of the adjective *blue*? Since the concept [milk] is semantically more complex than [blue], its neural correlate should be more widely distributed, the link between the concept and its expression should imply more effort, and thus ought to be established later in ontogeny and phylogeny. Rather than the empirical claim made by the first proposition, we should on the basis of the other four assumptions expect that the meanings of concrete nouns, in ontogeny and phylogeny, be acquired later than those of other word classes. In the paper I would like to press the paradox a little further by putting forward arguments for each of the five propositions and rejecting objections against them. Even though my résumé will be rather pessimistic, I will conclude with some more speculative remarks on a potential solution. The paper is primarily intended as an exposition of the paradox, rather than as its solution. Due to limited space and time I defer to Werning (2008, 2010) for a more elaborate discussion of each of the five propositions.

## Words and Concepts

The primary role for concepts is the integration of perception and action control. In order to survive in a world with a multitude of things, subjects must subsume them under concepts. Categorization allows the subject to recognize objects and events in the world as well as states of the body, to generate generalizations, and to preserve this information over time. Only thus goal directed interaction between one's body and the world is possible to the degree we observe it in many species.

With regard to humans, concepts are assigned a twofold explanatory role: (i) as content providers and (ii) as meaning providers. In their first role concepts provide contents to intentional states. In their second role concepts are identified with the meanings of linguistic expressions. Concepts are apt to fulfill the two roles because they are individuated as internal states of the system that essentially bear a causal-informational relation of co-variation to external contents (Fodor, 1992). This way, concepts may explain why intentional states are about things and why the meanings of expressions in a given context determine which things are referred to.

Intentional states include such diverse modes as perception, belief, desire, memory, expectation, imagination, emotion, and the will. Concepts provide the satisfaction conditions of intentional states, enter into inferential relations, and play a role in the causation of action. The twofold role of concepts suggests a view that intimately links meaning to intentionality. A unified approach of meaning and intentional content holds that the meaning of the sentence *There is milk in the bottle*, the perception of milk being white, the belief that milk is nutritious, and the desire to drink a glass of milk have one thing in common: they involve the concept [milk]. This at least follows if one assumes (i) the compositionality of linguistic meaning, and (ii) the compositionality of intentional content. The compositionality of meaning is the

principle that the meaning of a complex expression is in a syntax-dependent way determined by the meanings of its parts. It explains how the concept [milk] contributes to the meaning of the sentence *There is milk in the bottle*. The compositionality of content says that the content of a complex intentional state is in a structure-dependent way determined by the contents of its parts. It explains how the content of the concept [milk] determines the contents of the perceptual, doxastic, and volitional states just mentioned (for a discussion of the reasons for compositionality see Werning, 2005; Werning et al. eds., 2012).

In our context, the most important distinction in the domain of concepts is that between attributive concepts and substance concepts. Attributive concepts represent features of objects that are volatile in the sense that one and the same object can fall under different attributive concepts at different times: An object may, e.g., change its color, size, or speed, but still continues to exist. [blue] thus is a paradigmatic attributive concept.

Substance concepts, in contrast, are governed by the identity conditions of objects: A mug ceases to exist when it no longer falls under the substance concept [mug], say, because it has been shattered. Substance concepts serve to re-identify things over time in spite of their contingent changes of attributes and so allow us to gather, store and update information in a systematic and enduring way (Millikan, 1998). They are typically expressed by concrete nouns. Attributive concepts, in contrast, are typically expressed by adjectives or abstract nouns.

## Nouns and Adjectives

The paradox arises from the fact that substance concepts are ontogenetically and probably phylogenetically earlier lexicalized than attributive concepts. The great mass of children's earliest words are concrete nouns. During the so-called naming explosion, when children around 18 months of age first systematically organize their concepts by means of a lexicon, they preponderantly pair substance concepts with concrete nouns, whereas the assignment of adjectives and abstract nouns to the attributive concepts they express comes much later (Ingram, 1989). Some languages even don't have adjectives or just a closed set of them (Dixon, 1999), while the class of concrete nouns is arguably universal and always open. One may thus also argue that nouns in phylogeny are prior to adjectives. With respect to the typology of the earliest words, Barrett (1995) in a handbook article provides the following overview:

- 0th-100th word: high proportion of common nouns.
- 200th-...: proportion of common nouns decreases.
- 50th-100th word: proportion of verbs begins to increase.
- 400th-500th word: verb proportion continues to increase and finally begins to level out.
- 50th-100th word: proportion of adjectives begins to increase.

100th-500th word: proportion of adjectives continues to increase.

Even authors like Bloom (2000) who are more critical of the notion of a naming explosion concede that in the earliest phase of language development there is an “object bias”: A new word by default is interpreted as a name of an object (i.e., as a concrete noun). It needs some counterevidence for the child to realize that a word (an adjective or verb) expresses a property or an action, instead.

If the data are interpreted correctly, we can make the following inference: Since concrete nouns express substance concepts and prototypical adjectives express attributive concepts, and since concrete nouns are earlier acquired by the child than adjectives, it logically follows that substance concepts are ontogenetically earlier lexicalized than attributive concepts.

With respect to the claim on phylogeny, the evidence is more indirect and less compelling – hence the qualification “probably”. It is an undeniable fact that in all languages, in which the types of nouns and adjectives exist, there are more concrete nouns than adjectives (Dixon, 1999). Even in English (Givon, 1970) most adjectives are derived from either nouns or verbs, while there are only very few original adjectives. One can still defend the claim that the noun type is universal (Mithun, 2000). Even in languages like Iroquoian, which is sometimes said to have no nouns, there are at least very noun-like words. The adjective type, in contrast, clearly is not universal. If adjectives were phylogenetically earlier than concrete nouns, we should expect the situation with regard to universality be the other way round. In light of the available evidence, proposition P1 is hence relatively well supported, at least if one identifies the contrasting word class with the class of adjectives.

## The Structure of Meaning

One of the main controversies regarding the processing and neuro-cognitive implementation of meaning is whether the semantics of language is processed in a modular or non-modular way. According to modular approaches, the meanings of words and sentences are processed in an informationally largely encapsulated, autonomous, and amodal way (Clifton & Ferreira, 1987). Candidates for cortical correlates of semantic processes are often supposed to be localized in left temporal and partially frontal regions (Friederici, 2002). Regions typically associated with either perceptual or motor processes in this paradigm are typically not regarded as contributing to semantics.

Modular approaches towards perception, in turn, argue for informationally encapsulated, domain-specific and cognitively impenetrable modules for various perceptual tasks (Barrett & Kurzban, 2006, for review). Modularism with respect to semantics, perception, and perhaps other types of intentional states would thus be hardly compatible with the view that the same mental concept, respectively its neural correlate, is both a meaning provider for linguistic expressions and a content provider for various types of

intentional states. A manifold of concept tokens with the content of milk would thus be required: the concepts [milk]-in-meaning, [milk]-in-perception, [milk]-in-desire, etc. – eventually even [milk]-in-desires-to-drink, [milk]-in-desires-to-cook, etc. It is easy to imagine that such a view would quickly lead to an ontological explosion of concepts, at least, if concepts are supposed to exist in a realist manner.

Much more compatible with a realist attitude towards concepts and the methodological goal of ontological parsimony is the anti-modularist view of situated conceptualization (Barsalou, 2005). Here concepts are regarded as situated, i.e., largely based on sensori-motor schemata. The controversy between semantic modularism and semantic anti-modularism relates to the question whether some lexical concepts – i.e., concepts listed in the lexicon and thus expressed by single words – decompose into conceptual parts. Some authors believe that lexical concepts are altogether not decomposable (Fodor & Lepore, 1992). According to those so-called atomist positions, only concepts that are linguistically expressible by syntactically explicitly combined expressions can be complex. In neuroscience some researchers hold that substantial features like that of being an elephant or even features as specific as that of being Halle Berry are represented by highly specialized single neurons (Quiñero et al., 2005). Lexical atomism is a view semantic modularists can easily live with. For, if meanings are unstructured, it is completely unproblematic to conceive them as localizable elements in an encapsulated module. Proponents of a situated view of meaning, in contrast, will assume that at least some lexical meanings are structured so that parts of the meaning providing concepts may involve various sensori-motor schemata. Semantic anti-modularism seems to exclude lexical atomism.

Our propositions P3 and P4 seem hardly tenable for someone who shares the views of lexical atomism or semantic modularism. Proposition P3 saying that substance concepts expressed by nouns are semantically more complex than concepts expressed by other word classes immediately contradicts lexical atomism, according to which all lexical concepts have the same complexity, viz. zero. Proposition P4 seems to be empty if lexical atomism is true and largely unmotivated if semantic modularism holds. The proposition says that for a cortically implemented syntax-semantics interface, the more widely distributed a concept’s neural realization is, the more effort it takes to establish a link between the concept and its lexical expression. Now, if lexical atomism is true, there simply should not be any concepts with a widely distributed neural realization. For, how could this be the case if all lexical concepts are unstructured? If semantic modularism were to hold, the meanings even of words that are semantically complex – modularism does not entail atomism – would still be locally realized in the postulated semantics module. There would thus be no reason to assume that significantly more effort is needed to assign a word to its meaning, even if the expressed concept is complex.

Since the doctrines of lexical atomism and semantic modularism conflict with P3 and P4, the natural way to defend the two propositions is to argue against lexical atomism and semantic modularism. This is what I will do in the next section. I will outline a view of situated conceptualization which refutes atomism and modularism.

## Situated Conceptualization

In psychology, philosophy and linguistics various theories have been proposed to account for the decomposition of concepts. For the present purpose the choice of frame theory as a starting point seems most fruitful (Barsalou, 1992). Frame theory provides us with a universal account not only for categorization and its link to action-control, but also for the decomposition of concepts. Frames are recursive attribute-value structures. Attributes assign unique values to objects and thus describe functional relations. The values can be structured frames themselves. A frame is defined for a large domain of things and contains a fixed set of attributes (e.g., color, form) each of which allows for a number of different values (red, green, ... ; round, square, ...). The attributes in question are not constrained to perceptual modalities, but may as well involve attributes of motor affordances. Frames can be nested hierarchically and mutual constraints between attributes (e.g., between states of an object and actions directed to it) and between larger frames can be incorporated (see Figure 1).

Figure 1. Hypothetical fragment of the frame for the concept [banana]. The substance concept to be decomposed is marked by a double-circle as the referring node of the frame. The labeled arrows denote attributes, the nodes their values. Nodes are themselves regarded as concepts and thus as conceptual parts of the central concept. Whereas, in English, feature attributes (shown on the right) are frequently lexicalized – their arguments typically enter possessive constructions like *The color of the banana is yellow* or *The banana has the color yellow* – affordance attributes (on the left) are rarely overtly expressed. Based on linguistic and neurobiological evidence, we assume that affordances often relate to body parts and hence use the convention “@ + body part”. Formally, attributes are mappings from domains of some type into domains of some other type. Petersen & Werning (2007) provide an explicit account of frames using a calculus of typed feature hierarchies and incorporating typicality effects.

For many attributes involved in perceptual processing one can anatomically identify cortical correlates. Those areas often exhibit a twofold topological structure and justify the notion of a feature map: (i) a receptor topology (e.g., retinotopy in vision, somatotopy in touch): neighboring regions of neurons code for neighboring regions of the receptive field; and (ii) a feature topology: neighboring regions of neurons code for similar features (See Figure 2). With regard to the monkey, more than 30 cortical areas forming feature maps are experimentally known for vision alone (Felleman & van Essen, 1991). Also affordance attributes seem to have cortical correlates, predominantly in the premotor cortex. The discovery of the so-called mirror neuron system (Rizzolatti, & Craighero, 2004, for review) may provide a basis to integrate affordances into frames.

Figure 2. Cortical realizations of frame attributes. Fragment (ca. 4mm<sup>2</sup>) of the neural feature map for the attribute orientation of cat V1 (adapted from Crair et. al., 1997). The arrows indicate the polar topology of the orientation values represented within each hypercolumn. Hypercolumns are arranged in a retinotopic topology.

The fact that values of different attributes may be instantiated by the same object, but are processed in distinct regions of cortex poses the problem of how this information is integrated in an object-specific way: the binding problem. A prominent and experimentally well supported solution postulates oscillatory neural synchronization as a mechanism of binding: Clusters of neurons that are indicative for different properties sometimes show synchronous oscillatory activity, but only when the properties indicated are instantiated by the same object in the perceptual field; otherwise they are firing asynchronously. Synchronous oscillation, thus, might be regarded to fulfill the task of binding together various property representations to form the representation of an object as having these properties (Singer, 1999). Using oscillatory networks as biologically motivated models, it could be demonstrated how the topological organization of information in the cortex, by mechanisms of synchronization, may yield a logically structured semantics of concepts (Werning, 2005). Oscillation functions play the role of object concepts. Clusters of feature sensitive neurons play the role of attributive concepts. Schnitzler et al. (2006) could experimentally demonstrate the essential role of neural synchronization for action control. This may justify

the extension of the synchrony-based neuro-frame approach from features to affordances.

Provided that a concept is completely decomposable into a fully specified frame and provided that neural maps for each attribute can be identified in the cortex, the degree to which the cortex represents an object as an instance of the concept is rendered by a general pattern of synchronizing neural activity distributed over neural clusters that correspond to the basic values of the frame. This pattern may be called the cortical fingerprint of the concept.

Support for the theory of neuro-frames also comes from a number of neuro-linguistic studies. Based on a review of neurobiological data, Pulvermüller (1999) suggests that neural assemblies that pertain to the sensori-motor cortices and are bound by neural synchronization play an important role in understanding the meanings of words. FMRI studies (Pulvermüller, 2005) regarding the understanding of verbs, e.g., hint to a differential top-down activation of motor and pre-motors areas. We know that the understanding of concrete nouns like *hammer*, for which not only features, but also affordances are salient, results in an activity distributed over the premotor and the visual cortex (Martin et. al. 1996). The hypothesis that words for substance concepts arouse more widely distributed activity than words for attributive concepts is, furthermore, supported by EEG studies (Rappelsberger et al., 2000).

From this and further evidence (reviewed by Martin, 2007, Werning, 2012) we may conclude that the correlates of substance concepts are highly distributed neural states. Substance concepts are thus not expected to be realized by single cells, or locally circumscribed regions of the cortex, but by cell assemblies that may pertain to highly distinct parts of the cortex and involve perception as well as motor areas. In contrast, the neural correlates of attributive concepts would be constrained to local cortical regions. The view that substance concepts decompose into complex frames and that their neural realizations are widely distributed in cortex contradicts the doctrines of atomism and modularism.

### **Evolution and Development of the Syntax-semantics Interface**

Another strategy to avoid the paradox is to limit the scope of the assumption P2 that the meanings of concrete nouns are substance concepts. One might advocate a meaning shift of a certain kind in nouns during development or evolution: Whereas for modern adults concrete nouns express substance concepts with a complex semantics, it might be that the child's usage of the noun *mama* only labels a salient person in his or her daily life or that, for an early human, the noun for water just expressed the affordance of being drinkable. It is indeed very likely that the concepts expressed by nouns change in development and evolution. [birth-giving] is not a conceptual part of [mama] for the two-year old as it is for us. Early humans did not represent water as molecularly complex. However, is it plausible that

nouns of young children and early humans do not at all express substance concepts with some decent, if only different, semantic complexity? How could the word *mama* in the child's language be a label for a particular person if the child were not able to recognize and treat that person as *mama* (in his/her sense)? To recognize and treat *mama* as *mama*, the child mentally represents a number of salient features and affordances. Otherwise we would have to withdraw to a rather unwarranted iconic theory of representation.

In the case of phylogeny, the challenge could also be phrased as follows: Was there a time when [water] was an attributive concept – for a simple affordance or feature? That substance concepts finally reduce to a single attributive concepts is the tenet of essentialism: If essentialism about conceptual representation is true, we represent a substance by an essential feature or affordance which the substance must never change. The problem is that for most everyday substances one can hardly find any cognitively plausible candidates for essences. Being H<sub>2</sub>O is essential for water, but is this how humans cognitively represent water? The alternative is to decompose a substance concept into a structure of feature and affordance concepts, none of which specifies an essential property, but only a typical one. Even though water prototypically is tasteless, there is salty water. Water can change its color, taste, aggregate state, etc., even though some values for each of those attributes are more typical than others. Water is also used in typical ways: for drinking, washing, swimming, but it can also be burned by magnesium torches.

There are, of course, lots of nouns in English that express single attributive concepts: abstract nouns. The large majority of them are morphologically derived or, at least, syntactically marked (compare *water* to *beverage*, *fluidity*, etc.). This indicates that nouns expressing single attributive concepts are evolutionarily rather late. There is thus little evidence that [water] in the early stages of language evolution ever was a semantically simple attributive concept, rather than a semantically complex substance concept as it is today. P2 holds also for the early stages of development and evolution.

The remaining option to attack the paradox seems to be the principle P5 that capabilities demanding more effort, *ceteris paribus*, develop and, respectively, evolve later than those demanding less effort. One might argue that the demand of effort is not the only, maybe not even the most important factor that determines evolutionary priority. One may point out that there is stronger evolutionary pressure to lexicalize concepts as complex as substance concepts than to lexicalize attributive concepts. It arguably is rather economic to lexicalize concepts for often recurring, highly specific entities of great survival value. Telling someone that there are bananas somewhere is not only shorter, but also more exact than telling someone that there are sweet, longish, bowed, bright, yellow things around that one may peel and eat. However, an appeal to greater selection pressure does not suffice to explain evolutionary priority:

To explain why proto-birds evolved wings, one has to appeal to some sort of evolutionary pressure to fly. If flying did not have a selective advantage for proto-birds, wings would not have evolved. Maybe proto-birds had to reach or leave trees quickly to escape predators. However, if proto-birds had not had feathers in the first place (maybe for cooling as some hypothesis goes), wings would not have evolved either. Even if selection pressure were maximal and flying the only way a certain reptile species could have survived, if the species did not have feathers and very wing-like forelimbs, it would have died out rather than evolve wings. In addition to evolutionary pressure any explanation of capabilities must appeal to some step-by-step evolution of mechanisms: from the more primitive to the more complex.

What we still have no answer for is the following question: How could a mechanism evolve that enables certain regions of cortex that are involved in representing a word (phonologically, syntactically, etc.) to address those regions of the sensori-motor cortices that represent the word's meaning, i.e., the concept it expresses. Given that semantically complex words are evolutionary prior such an interface must have had strong distributive capacities from the beginning.

### Abstract

Research on moral judgment has shown that the order in which dilemmas are presented to subjects often has a strong influence on their judgment. However, the psychological mechanisms underlying order effects are still opaque. In this paper we aimed to isolate the features that a scenario must exhibit in order to influence judgment of subsequent scenarios. For this enterprise, we identified several features from a scenario known to cause order effects, and tested which of these features are necessary to influence subsequent scenarios. Although we still do not have a full understanding of what causes order effects, we made significant progress towards this aim. In five experiments we ruled out some promising explanations such as order effects being driven by an emotional activation linked to the first scenario. Instead, we found order effects to depend on whether the scenario being influenced and its preceding scenario share rather subtle structural similarities.

**Keywords:** Order effects; moral judgment; trolley dilemma.

### Introduction

Imagine one group of subjects is presented with two moral dilemmas, A and B, one after the other. For each of these scenarios subjects have to make a judgment concerning which of two different hypothetical actions should be taken by the agent in each case. In both dilemmas, the life of people is at stake. Imagine a second group of subjects is presented with the same task, the only difference being the order in which the two scenarios are presented. From a normative perspective it seems clear that the order of presentation should not influence subjects' judgments. However, a number of studies have shown that the order of presentation actually influences judgments. Moreover, the impact of the order of presentation is often stronger than that of factors that are generally considered to influence moral judgments (e.g., the existence of physical contact with the potential victim in the scenarios; Wiegmann, Okan, & Nagel, 2012). Interestingly, not only lay people are susceptible to order effects but also professional philosophers (Schwitzgebel & Cushman, 2012). In the paper at hand we present five experiments aiming to identify the factors causing order effects. The question guiding the experiments that will be reported is: Which are the features of a scenario known to cause order effects that enable it to influence other scenarios?

Wiegmann et al. (2012) claimed that research on moral judgment pointed to a systematic pattern of order effects that had been previously overlooked: Only judgments of actions that are normally (i.e., if judged in isolation) regarded as morally acceptable are affected by the order of presentation, and this is only the case if the dilemma is immediately preceded by a dilemma in which the proposed action was not considered as morally acceptable. If there is such a constellation, judgments of actions normally regarded as morally acceptable can approach judgments of previous actions (i.e., they can be deemed as less acceptable).

In order to test this claim Wiegmann and colleagues presented two groups of subjects with five trolley dilemmas, one after another (see Table 1). In all cases a train out of control was heading towards three railroad workers. An action was described that could be conducted by an agent in the situation to save the workers. This action varied in each of the five scenarios. The ordering of the scenarios was based on the level of agreement with the proposed action in each case, according to independent judgments provided in an independent pilot study (see Table 1). Level of agreement was measured on a scale of 1 to 6, where 1 was "not at all", and 6 was "absolutely". While in one group the level of agreement with the proposed action steadily increased, it decreased in the other group.

Table 1: Summaries of the actions proposed in the five dilemmas.

Scenario	Proposed action
Push	Push a large person from a bridge to stop the train
Trap	Push a button that will open a trap door that will let a person on top of the bridge fall and stop the train
Redirect	Redirect a train with a person inside that is on a parallel track onto the main track to stop the train
Run Over	Redirect an empty train that is on a parallel track onto the main track to stop the train, running over a person that is on the connecting track
Standard	Press a switch that will redirect the train that is out of control to a parallel track where one person will be run over

Table 2: Mean ratings (standard deviations) of agreement and percentage of subjects disagreeing with the proposed action in the five scenarios when evaluated independently.

Measure	Scenario (each $n=20$ )				
	Push	Trap	Redirect	Run Over	Standard
Mean Rating	1.95	3.4	4.15	4.4	4.45
(SD)	(1.76)	(1.76)	(1.42)	(1.14)	(1.15)
% Disagreement	80	40	30	10	15

Note. % Disagreement is the percentage of subjects who gave a rating  $\leq 3$  on a scale ranging from 1 to 6.

According to the pattern of order effects outlined above, subjects' ratings for actions in the condition where the level of agreement was steadily decreasing (i.e., from Standard to Push; in the following called Least Aversive First, LAF) should not differ from ratings for the same actions when presented separately. The reason is that in such a constellation it is never the case that a judgment of an action normally (i.e., if judged in isolation) regarded as morally acceptable is preceded by an action that is normally regarded as morally unacceptable. In contrast, ratings for the actions in the last three scenarios in the Most Aversive First (MAF) condition (i.e., Redirect, Run Over and Standard) should decrease to the level of agreement of the preceding scenario (i.e., Trap), according to the pattern outlined above. That is, the low rating of Trap is assumed to reduce the level of agreement in Redirect, that in turn is assumed to decrease the rating for Run Over, that eventually decreases Standard's rating. This prediction was confirmed (see Figure 1). Unexpectedly, the ratings of the action in Trap were also affected by the ratings of the action in Push, although Trap is normally judged as unacceptable by a slim majority of subjects.

Figure 1: Mean ratings of agreement (1 stands for “not at all, 6 stands for “absolutely”) with the proposed action in the five scenarios when evaluated sequentially, as a function of the order of presentation. Error bars indicate SEM. MAF = Most Aversive First; LAF = Least Aversive First.

This finding motivated a closer look at the results at the level of individual participants. In particular, the data was explored treating the ratings as a set of binary choices made by each participant (i.e., treating ratings  $\leq 3$  as indication of disagreement and ratings  $\geq 4$  as indication of agreement with the proposed action). The following tendency was observed: A disagreement with an action was virtually always “transferred” to the judgment of the action in the next scenario. That is, an action receiving a positive rating when judged independently received lower ratings when presented as part of a sequence if the preceding action was rated negatively by the same participant. However, positive ratings did not affect the ratings of the next action (by changing them into positive ones) if this action was rated negatively in independent ratings. Reformulating the pattern this way allows order effects to occur not only for actions rated positively when judged independently, but also for actions rated negatively on average. It just has to be the case that the number of participants that disagree with the proposed action in a particular scenario is sufficiently higher than the number of participants that disagree with the action in the subsequent scenario. This excess of “disagreements” can be transferred to the next scenario and cause an order effect. On the flipside, an order effect might also occur when a particular dilemma is preceded by another one where the proposed action is judged positively. Again, it just has to be the case that the number of disagreements in the preceding scenario is sufficiently higher than in the following scenario.

Although the pattern outlined at the individual level fits the data and allows making accurate predictions, the psychological mechanisms underlying order effects are still opaque. The experiments reported below pinpointed some of the features of the Push scenario that could be affecting other scenarios, and tested the effect of each of them individually. Features include differences in an emotional activation associated with Push, the activation of moral principles (e.g., “do not kill”) and the trade-off of lives.

## Experiment 1

In this experiment we aimed to test the hypothesis that the order effect described can be explained in terms of an emotional activation linked to Push, which would affect judgments in subsequent scenarios. As Green and his collaborators have shown, dilemmas like Push are more likely to activate brain regions associated with emotional processing than dilemmas like Standard (Green, Sommerville, Nystrom, Darley, & Cohen, 2001). Thus, in the sequence of scenarios described above (MAF) subjects might first experience a negative emotion when they are presented with Push, and once this negative emotion is in place, it might lead subjects to judge all the actions proposed in the remaining scenarios as morally unacceptable (cf. Haidt, 2001, Prinz, 2007). If the activation of such negative emotion is sufficient to cause order effects, then the presentation of other aversive scenarios that elicit a

similar emotion should also affect the judgment for other less aversive dilemmas (e.g., Standard).

**Participants** 259 subjects were recruited for a compensation of £ 0.50 via an online database located in the U.K..

**Design, Materials, and Procedure** Subjects were randomly assigned to one of four conditions. In two conditions subjects first had to read an aversive story, and then they were asked to judge the proposed action in Standard. The story was different in each of these two conditions. The following two stories were used:

**Incest (Haidt, 2001):**

Julie and Mark are brother and sister. They are traveling together in France on summer vacation from college. One night they are staying alone in a cabin near the beach. They decide that it would be interesting and fun if they tried making love. At the very least it would be a new experience for each of them. Julie was already taking birth control pills, but Mark uses a condom too, just to be safe. They both enjoy making love, but they decide not to do it again. They keep that night as a special secret, which makes them feel even closer to each other.

**Starving Child (actual newspaper article):**

The 41-year-old man and 25-year-old woman, who met through a chat website, reportedly left their infant unattended while they went to internet cafes. They only occasionally dropped by to feed her powdered milk.

According to the Yonhap news agency, South Korean police said the couple had become obsessed with raising a virtual girl called Anima in the popular role-playing game Prius Online. The game, similar to Second Life, allows players to create another existence for themselves in a virtual world, including getting a job, interacting with other users and earning an extra avatar to nurture once they reach a certain level.

In the two remaining conditions subjects had to either judge Standard alone (to obtain a baseline rating), or Standard after having judged Push. Additionally, as the study was conducted online, at the end of the questionnaire subjects completed a simple logical task to identify those who did not pay sufficient attention to the task.

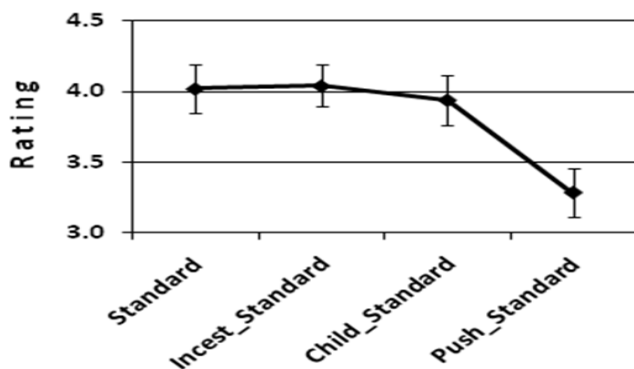

Figure 2: Mean Ratings for Standard as a function of the preceding scenario. Error bars indicate SEM.

**Results** Fifty subjects dropped out because they did not

answer the test question, failed to solve the logical question or went through the whole survey in less than 40 seconds.

The results for the remaining subjects are summarized in Figure 2. The mean rating for Standard when judged independently was 4.02 ( $SD=1.18$ ), while it was lower ( $M=3.28$ ,  $SD=1.39$ ) when it was preceded by Push (Push\_Standard), as predicted. A planned-contrast test confirmed this difference to be significant,  $F_{1,205}=9.68$ ,  $p<0.001$ . In contrast to this, reading and judging Newspaper or Incest did not have any effect on Standard (Standard vs. Incest\_Standard:  $F_{1,205}=0.01$ ,  $p>0.9$ ; Standard vs. Child\_Standard:  $F_{1,205}=0.10$ ,  $p>0.7$ ).

**Discussion** The findings obtained suggest that an emotional activation may not be sufficient to cause the kind of order effect described above. That is, judgments for Standard were not affected by the prior presentation of different scenarios that are likely to have elicited negative emotions. Further evidence for this idea comes from ongoing research conducted in Spain in which participants were presented with selected pictures of unpleasant affective valence and high arousal, before judging Standard. In line with the study described above, preliminary results revealed that the emotional priming did not affect judgments for Standard.

## Experiment 2a and 2b

The two following experiments test the hypothesis that the order effect described is related to differences in the activation of principles associated with each dilemma. In particular, Push could trigger the urge for subjects to justify their judgment, or the principle “Do not kill!”, while Standard may not. If the activation of such principle can account for the carry over effect of judgments when Push is presented first, it is reasonable to expect that forcing the activation of a principle relevant for Standard when this dilemma comes first (e.g., “Save the greater number”) should lead to an order effect in the opposite direction (i.e., people should be more likely to agree with the action proposed in subsequent scenarios).

### Experiment 2a

The rationale for this experiment was as follows: When subjects judge the action proposed in Push as morally unacceptable they articulate, so to say, a prohibition or imposing a ban. Actions which we prohibit are generally accompanied by a justification. For instance, one often has to justify or explain to kids why something is forbidden. In contrast, there are fewer situations where one has to explain why something is allowed. Justifications for allowed actions generally only happen when the actions were expected to be forbidden. In Push, the vast majority of subjects judge the proposed action as forbidden while in Standard they don't. Hence, it could be the case that subjects first judging Push have a stronger urge to justify their judgment. If the justification is “You are not allowed to kill innocent people” (or something similar), judgments for subsequent scenarios could accommodate this justification, explaining why all

proposed actions are regarded as not acceptable. In contrast, subjects starting with Standard might not have an urge to justify their initial judgment, explaining why subsequent judgments are not affected.

**Participants** 36 subjects were recruited from a student subject pool. Participants were compensated with course credits.

**Design, Materials, and Procedure** Subjects were presented with the LAF condition. However, in contrast to the original LAF condition described above, here participants were required to justify their judgment for Standard. Since participants were recruited from the same student pool (mainly psychology students) and this experiment was conducted only a few weeks after the one conducted by Wiegmann and colleagues (2012), the original LAF condition was used as a control condition.

Figure 3: Mean Ratings for the five scenarios as a function of whether subjects had to justify their judgment for Standard. Arrow indicates order of presentation. Error bars indicate SEM.

**Results** One subject failed to answer all questions for unknown reasons. Results for the remaining subjects are summarized in Figure 3. As can be seen, being forced to justify the judgment for Standard did not influence judgments for the actions proposed in the following scenarios. An ANOVA with justification (required vs. not required) as a between-subjects factor and scenario as a within-subjects factor revealed that there was neither a main effect of justification ( $F_{1,58}=0.02, p=.88$ ) nor an interaction between justification and scenario ( $F_{4,232}=0.62, p=.65$ ).

## Experiment 2b

The rationale for this experiment was as follows: When judging Push the principle “Do not kill!” comes easily to mind because the proposed action in this dilemma is a paradigmatic case of killing a person. In contrast, Standard might not trigger such a clear principle. In philosophy, the permissibility to intervene in Standard is often justified by rather subtle principles like the Doctrine of Double Effect or

even more subtle principles (Kamm, 2007). In this experiment we sought to trigger a clear principle (saving the greater number) and test whether it would be carried over to the following scenarios, thereby affecting judgments.

**Participants** 63 subjects were recruited from a student subject pool. Participants were compensated with course credits.

Figure 4: Illustration of the Rescue scenario

**Design, Materials, and Procedure** Two of the three conditions tested were LAF and MAF. The third condition included a new scenario called Rescue that was placed before Standard and was intended to trigger the principle “Save the greater number of lives” (see Figure 4). In this scenario a train is threatening one person and another train is threatening three persons. There is not enough time to throw the switch for both trains so that everyone is saved. We assumed that in such a case virtually everyone would agree to throw the switch that will save three persons rather than only one.

Figure 5: Mean ratings for the 5 (6) scenarios as a function of both the order of presentation and whether the Rescue scenario was present. For example, Push->Standard means subjects started with Push and ended with Standard.

**Results** The results are shown in Figure 5. As expected, a transference in judgments was observed for MAF, but not for LAF ( $F_{4,160}=11.37, p<.001$ ). However, introducing Rescue before Standard did not affect judgments for Standard, as evidenced by the absence of an interaction of condition and scenario between LAF and the new condition starting with Rescue ( $F_{4,160}=0.60, p=.67$ ).

**Discussion** The results of these two experiments can be interpreted in at least two ways. First, it could be the case that the order effect in MAF is neither based on a stronger urge to justify one’s judgment in Push (2a) nor due to Push triggering a clear principle (2b). Alternatively, the order effect in MAF could indeed be driven by a principle

triggered by Push which is carried over. However, the principle triggered by Standard or Rescue may not be, so to say, strong enough to override intuitions in other scenarios. In other words, while a principle like “Do not kill!” may be carried over once it has been triggered, a principle like “Save the greater number!” may not be potent enough to influence moral judgments in following scenarios (cf, e.g., Gert, 2007).

### Experiment 3

In this experiment we took a further step aiming to investigate which features of Push are necessary to cause an order effect. In particular, we examined the impact of the number of lives that are traded-off in Push.

**Participants** 343 subjects, each receiving £ 0.50, were recruited via an online database located in the U.K..

**Design, Materials, and Procedure** Subjects were randomly assigned to one of four conditions. In one condition Standard was judged alone (to obtain a baseline rating), while in a second condition Standard was judged after Push, involving the same number of potential victims as in previous experiments (Standard\_Push\_3). In the third and fourth conditions we manipulated the number of potential victims that would be saved by the intervention in Standard. In one condition nobody would be saved by pushing the person from the bridge (Standard\_Push\_0), while in the other condition a group of one hundred people would be saved (Standard\_Push\_100).

Figure 6: Mean ratings for Standard and its preceding scenario, i.e. Push-0 is the rating for Push if nobody is rescued by killing the one person and Push-0\_Standard is the rating for Standard if preceded by Push-0.

**Results** 96 subjects did not answer the test question, gave the wrong answer to the logical task, or took less than 40 seconds for completing the task.

The results for the remaining subjects are summarized in Figure 6. The baseline rating for Standard was the highest in descriptive terms ( $M=4.4$ ,  $SD=1.26$ ). The next highest rating for Standard was delivered if it was preceded by the version of Push where pushing the man from the bridge would not

save anyone (i.e., Standard\_Push\_0) ( $M=4.26$ ,  $SD=1.46$ ). The difference between Standard in this condition and the baseline rating was not significant,  $F<1$ . In contrast, ratings for Standard were lower in Standard\_Push\_3 and in Standard-Push-100 than for the baseline ( $F_{1,243}=18.14$ ,  $p<0.001$  and  $F_{1,243}=4.57$ ,  $p<0.05$ , respectively).

**Discussion** One might wonder why the rating for Standard is lowered to a lesser extent when it is preceded by Push involving saving 100 people than by Push involving saving three. However, the pattern outlined above can account for this finding. Recall that most of the time only negative ratings were transferred to the next scenario. Since the rating for Push\_100 ( $M=3.61$ ,  $SD=1.50$ ) was already high, it is not surprising that the rating for Standard\_Push\_100 was relatively high too. There were seemingly just not enough negative ratings for Push\_100 to be transferred and lower the rating of Standard\_Push\_100 to the same extent as for Standard\_Push\_3. Interestingly, the results show that Standard is not influenced by a version of Push in which killing the person does not save anyone. Since Push\_0 and Push\_3 only differ with regards to whether there is a trade-off of lives involved, we can infer that a dilemma must contain such trade-off to influence judgments for Standard.

### Experiment 4

The results of experiment 3 suggest that a scenario preceding Standard needs to contain a trade-off of lives in order to influence Standard. In this experiment we aimed to investigate whether Standard could be influenced by a preceding scenario similar to Push with regards to being aversive and containing a trade-off, but with a different cover story. Furthermore, we tested whether just reading (and not judging) Push or similar scenarios would be sufficient to influence Standard.

**Participants** 321 subjects were recruited for a compensation of £ 0.50 via an online database located in the U.K..

**Design, Materials, and Procedure** Subjects were randomly assigned to one of five conditions. As in previous experiments there was one condition to get a baseline for Standard and another where Standard was preceded by Push. In a third condition (Organ) Standard was preceded by a scenario in which a doctor can save three patients by transplanting organs from a healthy person into them.. The last two conditions, (Push\_readonly) and (Organ\_readonly) were identical to Push and Organ, respectively, except that subjects were not given the opportunity to judge the proposed action.

**Results** 43 subjects did not answer the test question, gave the wrong answer to the logical task, or took less than 40 seconds for completing the task.

The results for the remaining subjects are summarized in Figure 7. The baseline rating for Standard was the highest in

descriptive terms ( $M=4.35$ ,  $SD=1.25$ ). Again, the difference between Standard\_Push\_3 ( $M=3.37$ ,  $SD=1.37$ ) and the baseline rating was, as expected, significant ( $F_{1,282}=14.46$ ,  $p<0.001$ ). Interestingly, ratings for Standard when preceded by Organ were also significantly lower than the baseline ( $F_{1,282}=6.13$ ,  $p<0.05$ ). As Figure 7 shows, it did not make a difference whether subjects just read or also judged the action proposed in Push or Organ.

Figure 7: Mean Ratings for Standard as a function of the preceding scenario. Error bars indicate SEM. “ro” stands for “read only”.

**Discussion** The results showed that Standard can be influenced by a scenario with a different cover story than Push, but that also involves a trade-off of lives. This influence is not as strong as the influence of Push but it is still significant. Moreover, whether subjects only read a scenario or also judged it did not affect judgments.

### General Discussion

In this paper we sought to search for an explanation of order effects in moral judgment. The overarching question guiding our experiments was: Which features of the Push scenario are the ones that enable Push to influence other scenarios such as Standard? Although we still do not have a complete explanation, we think we have made some progress towards this aim.

Our findings suggest that the order effect is likely not be caused by negative emotions activated by Push. Presenting subjects with aversive stories which were likely to elicit such emotions did not have any effect on the judgment for Standard (Experiment 1).

Forcing participants to justify their judgment for Standard or saliently triggering the principle “Save as many lives as possible!” did not affect judgments for Standard either (Experiments 2a and 2b). As noted above, these results can be explained in two ways: First, it might be that the order effect is not driven by the activation of a principle for the Push scenario, which is then applied to subsequent scenarios. Second, it might be that the principle “Save lives” affects subsequent judgments only to a lesser extent than the

principle triggered in Push (presumably: “Do not kill!” or “Do not kill in order to save lives!”).

Interestingly, we found a feature of Push that seems necessary to influence a subsequent scenario: The trade-off of lives. A version of Push which did not involve such trade-off had no influence on judgments for Standard. Hence, apart from being judged more negatively than Standard (see Introduction) containing a trade-off of lives seems to be a necessary feature for a scenario to influence subsequent scenarios.

Interestingly, when we presented subjects with a scenario (Organ) similar to Push in that it contained a very aversive action and a trade-off of lives, but that differed with regards to the cover story, the agreement with the action proposed in Standard was also reduced. Future research should examine other similarities between Push and Organ which could be related to their potency to cause order effects.

In summary, our findings suggest that the features that a moral dilemma must exhibit in order to affect judgments in subsequent dilemmas (here, in Standard) are:

1. It must receive significantly more negative ratings than the following dilemma (see Introduction)
2. It must contain a trade-off of lives

Furthermore, if the preceding scenario exhibits these two features the influence on Standard becomes even stronger if the superficial features of the cover story resemble the ones in Standard.

# Explaining increases belief revision in the face of (many) anomalies

## Abstract

How does explaining novel observations influence the extent to which learners revise beliefs in the face of anomalies – observations inconsistent with their beliefs? On one hand, explaining could recruit prior beliefs and *reduce* belief revision if learners “explain away” or discount anomalies. On the other hand, explaining could *promote* belief revision by encouraging learners to modify beliefs to better accommodate anomalies. We explore these possibilities in a statistical judgment task in which participants learned to rank students’ performance across courses by observing sample rankings. We manipulated whether participants were prompted to explain the rankings or to share their thoughts about them during study, and also the proportion of observations that were anomalous with respect to intuitive statistical misconceptions. Explaining promoted greater belief revision when anomalies were common, but had no effect when rare. In contrast, increasing the number of anomalies had no effect on belief revision without prompts to explain.

**Keywords:** explanation, self-explanation, learning, generalization, statistics, misconceptions, anomalies.

## Introduction

Human learning relies on the ability to use novel observations about the world to revise current beliefs. This raises basic questions about how observations impact beliefs, and in particular how different cognitive processes influence the process of belief revision. The current paper examines how *explaining* observations that are anomalous with respect to a learners’ current beliefs influences the nature of belief revision.

Previous research reveals that seeking and generating explanations can play an important role in learning and reasoning across a variety of task and domains, including learning novel categories (Williams & Lombrozo, 2010), inferring causal relationships (Koslowski, 1996), and generalizing the properties of people and objects from known to unknown cases (Rehder, 2009; Sloman, 1994). In addition, generating explanations can drive conceptual development in children (Wellman & Liu, 2006) and has been shown to have important pedagogical benefits in a variety of educational contexts (e.g. Fonseca & Chi, 2011).

Despite widespread appreciation for the impact of explaining on learning and belief revision, current accounts of explanation’s effects pose a challenging puzzle. On the one hand, explaining is frequently hypothesized to encourage learners to accommodate novel observations in

the context of their prior beliefs (Ahn, Brewer & Mooney, 1992; Chi et al, 1994; Lombrozo, 2006; Walker, Williams, Lombrozo & Gopnik, under review; Williams & Lombrozo, 2010). This suggests that explaining could lead learners to draw on a range of belief-preserving strategies in the face of anomalous observations (Chinn & Brewer, 1993; Kuhn, 1962; Koslowski, 1996; Lord, Lepper, & Ross, 1979). Learners who seek explanations could engage in less belief revision (relative to those who do not explain) if they “explain away” anomalies by discounting them as implausible, or reinterpret observations as consistent with or irrelevant to preferred theories.

On the other hand, explaining anomalies could prompt learners to reject their currently-held beliefs and construct new theories that better accommodate the anomalous observations. For example, explaining could ensure that anomalies are not simply ignored, increasing learners’ allocation of attention and processing time to these unanticipated observations (Legare, 2010; Siegler, 2002). In addition, explaining could encourage learners to seek and discover general patterns that go beyond prior beliefs to capture the anomalies being explained (Walker, Williams, Lombrozo & Gopnik, under review; Williams & Lombrozo, 2010).

A third possibility is that explaining has the potential to produce both effects. Whether explaining preserves or revises beliefs could depend on the nature of the evidence provided by the anomalies. For example, relative to other learning strategies, explaining could encourage learners to discount anomalous observations if they are infrequent or there is no alternative theory available to explain them. However, seeking explanations for more extensive inconsistencies could emphasize the limitations of current beliefs and guide learners to alternative theories, thus promoting more radical belief revision.

We investigate these possibilities in the context of a statistical judgment task in which participants learn a system for ranking students’ performance across different courses. Participants learn to rank by observing sample rankings, and they are either prompted to provide explanations for the rankings or to engage in free study as a control condition. Previous research suggests that participants’ prior beliefs will favor rankings on the basis of statistically problematic principles rather than one that is normatively defensible (e.g., Schwartz & Martin, 2003; Belenky & Nokes-Malach, in press). We can therefore manipulate how many of the sample rankings happen to be consistent with the non-

normative principles, and how many are anomalous and only accounted for by the correct principle. This allows us to examine how the process of belief revision is influenced by explaining the novel observations (the sample rankings), by the number of anomalous observations, and by any interaction between these factors.

## Experiment

Participants were instructed to learn how a university ranks their students across different courses by studying five examples of ranked pairs of students. Each example reported which of two students in two different courses was ranked higher, listing each student's (percentage) grade along with each course's mean grade, average deviation (the average absolute deviation), and minimum and maximum grade. We used average deviation as a measure of variability instead of standard deviation to follow past research in avoiding the need for formulas and using a concept more transparent to participants (Schwartz & Martin, 2003; Belenky & Nokes-Malach, in press).

All five examples were ranked according to a *relative-to-deviation* principle: the better student was the one that scored a greater number of average deviations above the mean (see Schwartz & Martin, 2003; Belenky & Nokes-Malach, in press). However, some of the examples were also consistent with three non-normative principles (e.g. the student with higher absolute scores is always ranked higher). These are described further in the *Materials & Procedure* section, below.

To probe how anomalous observations influenced belief revision, we manipulated how many of the five ranked examples were consistent (or anomalous) with respect to the non-normative principles. The relative-to-deviation principle always accounted for all five examples. In the *single anomaly* condition, four of the five example rankings also conformed to the non-normative principles, and there was just one anomaly that was inconsistent with them. In the *multiple anomalies* condition, there were four anomalies and only one of the five rankings was consistent with the non-normative principles.

To examine how explaining interacted with anomalies to impact learning, we also manipulated the extent to which participants engaged in explanation. In the *explain* condition we prompted participants to explain each ranked example. In the *free study* control condition, participants were free to use any study strategy, but were prompted to articulate their thoughts while studying each ranked example. Like explaining, this control condition involved paying attention to the details of the cases and articulating one's thinking in language.

As discussed in the introduction, engaging in explanation and varying the number of anomalies could impact belief revision in several ways. Explaining the anomalies could reduce the revision of prior beliefs and inhibit learning about the relative-to-deviation principle. This effect could be especially potent when there is only a single anomaly to the non-normative principles. On the other hand, explaining

could magnify the effects of anomalies in rejecting belief in the non-normative principles and instead encourage learners to induce and adopt the relative-to-deviation principle.

Finally, the effects of explaining could depend on whether the explained observations include a single anomaly or many. Explaining could have a large impact on belief revision in the context of multiple anomalies, but have no effect or even inhibit belief revision when only a single (and easily discounted) anomaly is present. Alternatively, explaining could boost the impact of a single anomaly that might otherwise be ignored, but have no effect (relative to control) when there are multiple anomalies that make the need for belief revision completely apparent. The design of our experiment allows us to differentiate these possibilities.

## Methods

### Participants

Participants were 275 adults recruited online through the Amazon Mechanical Turk marketplace and reimbursed for their time.<sup>1</sup>

### Materials & Procedure

The materials consisted of five examples of student pairs ranked by the university, ten unranked pre-test pairs, and ten unranked post-test pairs. The experiment involved introduction, pre-test, study, and post-test phases.

**Introduction** Participants were informed that they would observe pairs of students from different classes whose academic performance had been ranked by the university, and that their goal was to learn the ranking system employed. They were given the definition of "average" – the sum of all scores divided by the number of students in a class – and "average deviation" – the sum of all the (absolute) differences between student scores and the average, divided by the number of students.

**Ranked examples for study** During study, five examples of ranked student pairs were presented. A ranked example (see Figure 1a and 1b) stated which student was ranked higher by the university, and reported each student's: (1) name (e.g., Sarah); (2) class (e.g., Sociology); (3) class's mean score (e.g., 79%); (4) class's average deviation (e.g., 8%); (5) class's minimum score (e.g., 67%); and (6) class's maximum score (e.g., 90%).

**Principles for ranking students** Participants could interpret or predict the rank of each student pair using at least four principles. The three *non-normative* principles were incorrect but designed to correspond to intuitive statistical misconceptions.

---

<sup>1</sup> We included a question that assessed whether participants were actually reading instructions (Oppenheimer et al, 2009). The pattern of results was the same if participants who did not pass this test were excluded.

(a) Sarah got 85% in a Sociology class, where the average score was 79%, the average deviation was 8%, the minimum score was 67%, and the maximum score was 90%.

Tom got 69% in a Art History class, where the average score was 65%, the average deviation was 3%, the minimum score was 42%, and the maximum score was 87%.

Sarah was ranked more highly by the university than Tom.

(b) Sarah got 85% in a Sociology class, where the average score was 79%, the average deviation was 3%, the minimum score was 67%, and the maximum score was 90%.

Tom got 69% in a Art History class, where the average score was 65%, the average deviation was 8%, the minimum score was 42%, and the maximum score was 87%.

Tom was ranked more highly by the university than Sarah.

Figure 1: (a) A *consistent* ranked example for which all four principles predicted the same ranking. (b) An *anomalous* ranked example constructed by switching the class average deviations of the consistent example from Figure 1a. The switch means that the correct relative-to-deviation ranking is now the opposite of what is predicted by the raw-score, relative-to-average, and relative-to-range principles. Emphasis is added for illustration and was not provided to participants.

We term the principles (1) *raw-score*: the higher ranking went to the student with the higher score, irrespective of mean, average deviation, and minimum or maximum score; (2) *relative-to-average*: the higher ranking went to the student whose score was the farthest above (or least below) the class's mean score; (3) *relative-to-range*: the higher ranking went to the student whose score was farther from the average *relative to the range* in class scores, where this was calculated as the difference from the mean divided by the range.

The *relative-to-range* principle privileges the score that is farther from the mean as measured in "range-units," capturing some notion of variability (when range is correlated with variability), and could be approximated by looking at a score's distance from the maximum score.

The fourth and more accurate *relative-to-deviation* principle favored whichever score was a greater number of average deviations above the mean. This was calculated as the difference from the mean divided by the average deviation, and is closely related to normative measures such as the standard deviation and z-score, indicating the person's score relative to the distribution of scores in the class.

**Consistent vs. anomalous examples** All five ranked examples conformed to the relative-to-deviation principle. However, a ranked study example could be *consistent* with or *anomalous* with respect to the ranking given by the raw-score, relative-to-average, and relative-to-range principles, all of which always generated identical rankings on study examples (see Figure 1a and 1b). Five consistent examples were constructed so that each could be converted to an anomalous example by switching the average deviation of the two students' classes. This permitted a close match between consistent and anomalous examples on all other dimensions (compare Figure 1b to Figure 1a).

In the *single anomaly* condition there were four consistent examples and one anomalous example. The *multiple anomalies* condition had the opposite ratio: one consistent example and four anomalous examples.

**Pre-test** To provide a baseline measure of belief before study, participants were presented with ten unranked student pairs. They judged which student the university would rank higher, and rated confidence in their judgment on a scale from 1 ("not at all") to 7 ("extremely").

The ten student pairs were designed to identify the principle(s) that participants used to rank students, and thus pitted candidate principles against each other. Specifically, there were two instances of each of the following types of pairs, pitting (1) the relative-to-deviation principle against the three non-normative principles (like anomalous study examples); (2) the raw-score principle against the other three principles; (3) the relative-to-average principle against the other three principles; (4) the relative-to-range principle against the other three principles; and (5) the two principles that were most sensitive to variability, relative-to-range and relative-to-deviation, against the raw-score and relative-to-average principles.

**Study** Each of the five ranked examples was presented onscreen for exactly 90 seconds in a format similar to Figure 1a and 1b. Participants in the *explain* condition were prompted to explain why the higher-ranked student was ranked more highly, typing their explanation into a text box onscreen. Participants in the *free study* control condition were told to type their thoughts during study into an equivalent text box.

**Post-test** To assess belief after study, participants' ranking judgments and confidence ratings were solicited for ten unranked student pairs. All names and grades were changed from the pairs used in pre-test, but five points were added to each grade to generate novel numbers while preserving the way in which the items pitted the principles against each other.<sup>2</sup>

<sup>2</sup> Additional questions were asked at the end of the experiment (e.g. demographics, sufficient time for task, strategy) but are not further discussed here in the interest of space.

## Results

**Overall pre- and post-test accuracy** Learning was assessed by comparing accuracy on the pre-test and post-test items. Correct responses were considered to be those that were consistent with the relative-to-deviation principle. Figure 2 reports an overall measure of accuracy across all pre-test and post-test items as a function of learning task and number of anomalies. Accuracy improved from pre- to post-test: A 2 (task: explain vs. free study)  $\times$  2 (number of anomalies: single vs. multiple)  $\times$  2 (test: pre-test vs. post-test) repeated measures ANOVA found a main effect of test (pre- vs. post-) on overall accuracy,  $F(1, 269) = 4.33, p < 0.05$ .

The ANOVA additionally revealed interactions between test and learning task,  $F(1,269) = 4.95, p < 0.05$ , and between test and number of anomalies,  $F(1,269) = 3.88, p < 0.05$ . These effects were driven by a greater boost in pre- to post-test accuracy for participants in the *explain – multiple anomalies* conditions, which in turn was driven primarily by rankings on anomalous items, as discussed further below.

**Anomalous items: Change in pre- to post-test accuracy** Figure 3 reports accuracy on *anomalous* pre-test and post-test items. These items were analogous to the anomalies at study in pitting the relative-to-deviation principle against all three non-normative principles. Accuracy on these items was critical to testing our hypotheses about the effects of explanation and anomalies on the revision of beliefs to favor the relative-to-deviation principle over the non-normative alternatives. Accuracy on anomalous items improved from pre- to post-test: A 2 (task: explain vs. free study)  $\times$  2 (number of anomalies: single vs. multiple)  $\times$  2 (test: pre-test vs. post-test) ANOVA on accuracy on anomalous items revealed a main effect of pre- vs. post- test,  $F(1, 269) = 63.85, p < 0.05$ .<sup>3</sup>

Subsequent analyses directly examined the pre-test to post-test *change* in accuracy on the anomalous items. Figure 4 reports performance on this measure, calculated as post-test accuracy minus pre-test accuracy.

A 2 (task: explain vs. free study)  $\times$  2 (anomalies: single vs. multiple) ANOVA on the pre- to post-test change in accuracy on anomalous items revealed a significant effect of number of anomalies,  $F(1, 266) = 12.8, p < 0.05$ . This main effect was qualified by an interaction between learning task and number of anomalies,  $F(1, 266) = 7.77, p < 0.05$ . No other effects were significant.

<sup>3</sup> The ANOVA on accuracy for anomalous items revealed a number of additional effects, the relevance of which is more readily communicated in our subsequent analyses on the pre- to post- test *change* in accuracy. These include a two-way interaction between test and number of anomalies,  $F(1,266) = 12.80, p < 0.001$ , a three-way interaction between test, learning task and number of anomalies,  $F(1,266) = 7.77, p < 0.01$ , and main effects of task,  $F(1,266) = 4.80, p < 0.05$ , and number of anomalies,  $F(1,266) = 8.45, p < 0.005$ .

Figure 2: Accuracy on *all* pre-test and post-test items, by learning task and number of anomalies.

Figure 3: Accuracy on *anomalous* pre-test and post-test items, by learning task and number of anomalies.

Figure 4: Change from pre-test to post-test in accuracy on *anomalous* items, by learning task and number of anomalies.

When there were multiple anomalies, participants prompted to explain showed greater learning (relative to free study) about the relative-to-deviation principle,  $t(126) = 2.44, p < 0.05$ . But when only a single anomaly was present, there was no significant effect of explanation,  $t(143) = 1.13, p = 0.26$ .

In sum, although explaining helped participants learn the challenging relative-to-deviation principle over more intuitive alternatives, this benefit only exceeded that observed in the control condition when many anomalies were explained. It could be that the effects of explaining one anomaly were too small to yield a statistically significant effect. But a more intriguing possibility – suggested by the (non-significant) trend for control participants to show greater learning gains than explain participants in the single anomaly condition (see Figure 4) – is that explaining actually hindered belief revision by encouraging participants to discount the single anomalous observation.

It is worth emphasizing that the learning benefits observed in the *explain – many anomalies* condition cannot be attributed simply to the effects of receiving more anomalies. Receiving multiple anomalies (relative to observing a single anomaly) promoted greater learning when participants were prompted to explain,  $t(135) = 2.24$ ,  $p < 0.05$ . However, in the free study control condition, observing a greater number of anomalies did not produce a significant learning benefit,  $t(134) = 0.55$ ,  $p = 0.58$ . Without explaining, the potential learning benefits of anomalous information may not be realized.

## Discussion

In an experiment involving statistical judgments, we found that participants who were prompted to explain observations engaged in greater belief revision than participants who engaged in a control task matched for time, attention, and use of language. Specifically, participants who explained showed a greater increase from pre- to post-test in their use of a normative principle for ranking students' performance across courses (the relative-to-deviation principle). However, this benefit was only observed when the observations that participants explained involved multiple anomalies – observations inconsistent with non-normative principles that were arguably more intuitive and more consistent with prior beliefs. When a single anomaly was presented, participants who explained showed comparable or (nonsignificantly) less learning than those in the control condition.

In the introduction we presented several plausible hypotheses about the effects of explaining anomalies. One possibility was that explaining anomalous observations would lead learners to consult current beliefs in making sense of the unanticipated observation, and therefore be more likely to preserve their current beliefs by somehow explaining away or discounting the anomaly (Chinn & Brewer, 1993). In the present experiment, for example, participants could have invoked a clerical error to explain an unanticipated observation, or generated reasons for a ranking that went beyond the information provided (e.g., perhaps a given course was especially difficult and therefore taken by students who were already high achievers).

If explaining encouraged participants to engage in such belief-preserving strategies independently of the number of anomalous observations, then pre- to post-test performance

should have increased more for participants in the control condition than for those in the explain condition. While there was a trend in this direction when a single anomaly was presented, the findings do not provide clear support for this hypothesis.

Explanation-induced failures to revise belief in light of anomalies could be more likely in contexts where participants hold stronger prior beliefs. In fact, Williams, Lombrozo, and Rehder (2010) report an “explanation impairment effect” along these lines. It should be noted, however, that under some conditions maintaining current beliefs in the face of anomalous observations could be the correct or rational strategy. For example, when observations are erroneous or generated by probabilistic processes it could be preferable for learners to discount anomalous observations on the basis of (more accurate) prior beliefs.

A second hypothesis that we considered at the outset was that explaining anomalous observations would increase belief revision, perhaps by drawing attention to anomalies or forcing participants to identify patterns that would account for the anomalous observations and past observations in a unified way. While we found support for this hypothesis when many anomalies were presented, explaining did not have a measurable advantage when participants only observed a single anomaly.

Our findings are therefore consistent with a third possibility: that the effects of explanation interact with the number of anomalous observations. The *number* of anomalies per se may not be crucial, but rather serve (in the current experiments) as an indication of the strength of the evidence that current beliefs require revision. It could be that explaining *few* anomalous observations has no effect (relative to control), encourages belief-preserving strategies, or has variable effects across participants, while explaining multiple (or more problematic) anomalies more uniformly increases the extent to which participants revise beliefs to achieve consistency with observations.

It's also noteworthy that in the absence of explanation, encountering additional anomalies was insufficient to increase belief revision: In the free study condition, observing multiple anomalies (80% of observations) did not yield any significant learning benefit beyond observing just one. Chinn and Brewer (1993) point out that anomalies do not always lead to changes in belief given the number of belief-preserving strategies available to learners, and our findings are consistent with this observation. Explaining could therefore be especially valuable as a strategy for ensuring that learners benefit from anomalous observations, especially in pedagogical contexts in which anomalies are likely to highlight misconceptions and point to normative alternatives.

In previous work we have proposed a *subsumptive constraints* account of the effects of explanation on learning (Williams & Lombrozo, 2010), and we interpret the current results as broadly consistent with this proposal. According to this account, explaining does not provide a general boost to processing, but rather exerts a selective constraint to

interpret what is being explained as an instance of a broader pattern or generalization. One substantiated prediction of this account is that explaining guides people towards patterns that apply to more observations – that is, those that render fewer observations anomalous (Williams & Lombrozo, 2010). A second is that explaining increases learners' consultation of prior beliefs to privilege patterns that prior beliefs suggest will generalize to other contexts (Walker et al., under review; Williams & Lombrozo, 2010b; Williams & Lombrozo, under review).

In the current experiment, the correct relative-to-deviation principle involved fewer (zero) anomalies, but the alternative principles were more consistent with most people's prior beliefs concerning ranking. Explaining could therefore have favored the relative-to-deviation principle in the multiple anomaly condition because the evidence indicated that current beliefs were problematic. In contrast, participants in the single anomaly condition – depending on the strength of their prior beliefs – could have been inclined to favor current beliefs or to consider revision in the face of weak evidence for an alternative. These observations raise a number of important questions for future research concerning the precise conditions under which explaining anomalies will revise or entrench current beliefs.

## Abstract

According to a widely-held view among various scholars, olfaction is inferior to other human senses. It is also believed by many that languages do not have words for describing smells. Data collected among the Maniq, a small population of nomadic foragers in southern Thailand, challenge the above claims and point to a great linguistic and cultural elaboration of odor. This article presents evidence of the importance of olfaction in indigenous rituals and beliefs, as well as in the lexicon. The results demonstrate the richness and complexity of the domain of smell in Maniq society and thereby challenge the universal paucity of olfactory terms and insignificance of olfaction for humans.

**Keywords:** olfaction; language of perception; smell terms; Maniq; Aslian.

## Introduction

For centuries, great thinkers and scientists have underestimated the sense of smell in humans. Olfaction is often singled out as the least useful perceptual sense, whose role in life is negligible. “Of all the senses it is the one which appears to contribute least to the cognitions of the human mind” (Condillac, 1754/1930, p. xxxi). Darwin (1874) deemed it to be “of extremely slight service” (p. 17), while to Kant (1798/2006) it appeared as “the most dispensable” (p. 50) of the senses. It has also been claimed that olfaction is of “little special value across cultures” (Gardner, 1993, p. 61) and that man “has left the world of smells” (Burton, 1976, p. 109). Neuroscientists have expressed the belief that smell is insignificant for humans and that, in fact, it is “extremely rudimentary” (Grinker, 1934, p. 313), vestigial (Pinker, 1997), or as Stanley-Jones (1957) phrased it, the human rhinencephalon is “untenanted” (p. 594).

Hand in hand with these ideas came the popularization of the belief that olfactory language is impoverished. Dan Sperber (1974/1975), a co-author of the cognitive approach to communication known as Relevance Theory, wrote:

Even though the human sense of smell can distinguish hundreds of thousands of smells and in this regard is comparable to sight or hearing, in none of the world’s languages does there seem to be a classification of smells comparable, for example, to colour classification... There is no semantic field of smells. (pp. 115–116)

According to Henning (1916), “olfactory abstraction is impossible” (p. 66), while Kant (1798/2006) remarks on a

margin of his manuscript: “Smell does not allow itself to be described, but only compared through similarity with another sense” (p. 51).

In spite of the fact that smell is either devalued or ignored in the accounts of many fields of science, there is a growing body of literature which attempts to bring to the fore the importance of smell across cultures (e.g. Classen, Howes, & Synnott, 1994). However, to date there are relatively few studies providing detailed descriptions of olfactory vocabularies in various languages. The current article is intended as a contribution to filling that gap by providing a description of the olfactory lexicon in the language of the Maniq, a group of nomadic hunter-gatherers living in southern Thailand. At the same time, it adds to the knowledge on olfaction of the larger linguistic group of Aslian (belonging to the Austroasiatic family), which is a locus of considerable olfactory elaboration in the cultural and linguistic realm (Burenhult & Majid, 2011). The Maniq data challenges the view that olfaction is of little value to humans as well as the idea that olfactory lexica are necessarily impoverished and lacking in abstract terms. This is important evidence, since the generalizations cited earlier are made primarily on the basis of WEIRD (Western, Educated, Industrialized, Rich, Democratic) communities (Henrich, Heine, & Norenzayan, 2010) and we know that even apparently basic processes such as visual perception may vary across populations (Segall, Campbell, & Herskovits, 1966).

In order to give as comprehensive account as possible of the complex domain of smell in the Maniq language and culture, the topic was explored with the use of multiple methods: ethnographic observation and interview, linguistic elicitation and experimentation. We begin by providing a cultural background to the role of olfaction in the beliefs and practices of the group. We then go on to discuss Maniq smell terminology and, finally, turn to the analysis of speakers’ similarity judgments of Maniq smell terms with the use of multidimensional scaling.

## The Maniq and their Language

Maniq [ma’niʔ] is spoken by 240–300 people living in scattered groups in the Banthad mountain range of southern Thailand (more specifically, in Trang, Satun and Phatthalung provinces). Maniq people belong to the larger ethnographic cluster of Semang with a traditionally mobile lifestyle and hunter-gatherer mode of subsistence. Despite

on-going deforestation and pressure towards sedentism, many Maniq are still nomadic and continue to hunt animals and forage wild plants. Their economy is further supported by income from tourists and small-scale exchange of forest produce. Maniq language belongs to the Northern Aslian branch of Aslian, which forms part of the Austroasiatic family.

### Indigenous Beliefs and Practices

Smell offers a heuristic method of making judgments about odor-emitting sources. Whether to approach something or stay clear of it might depend on the olfactory input one gets from the environment. This function of olfaction is said to be basic for all humans and is believed to be tightly related to the fact that we perceive and categorize smells according to their pleasantness (Yeshurun & Sobel, 2010).

There are numerous examples of odors in the Maniq world which have very clear associations in terms of whether their source is desirable or not. The Maniq make constant use of this information in a variety of contexts – ranging from everyday foraging activities, through indigenous medicine to the ritualized uses of scents. This section explores a number of instances which reflect the relevance of odor in the beliefs and practices of the tribe.

A large number of medicinal herbs collected by the Maniq have intense aromas, the majority of which can be described by the term *lspas* ‘to be fragrant’. Exemplars include: *kasay* ‘*Dianella ensifolia*’, *kupit* ‘turmeric (*Curcuma domestica*)’, *biha* ‘*Triomma malaccensis*’ and *p<sup>h</sup>ley* ‘Cassumunar ginger (*Zingiber montanum*)’ (from Thai *phlai*). The fact that pleasing odors and healing or disease-preventive powers come together in a sizeable group of plants seems to be perceived not as a coincidence, but instead speakers perceive a causal relationship between them. A Maniq woman asked whether a rhizome of the cassumunar ginger she wore in a necklace protected her against illness answered affirmatively adding *ʔeʔ lspas* ‘it is fragrant’. This links to an idea found among the closely-related Aslian groups (e.g. Jahai, Batek), namely that on some occasions odor is believed to be the curing agent of medicine (Burenhult & Majid, 2011; Endicott, 1979).

The beneficial properties of aromatic herbs extend beyond health-protective talismans such as necklaces, headbands and wristbands. A good example of this is the plant called *kasay* ‘*Dianella ensifolia*’, whose roots are ‘burnt in fire during windstorms’ (*tət buwaʔ ʔeʔ hayhəy*) in order to appease the wind (cf. the use of *kasay* and other fragrant plants during thunderstorms among some Aslian groups; Dallos, 2011; Endicott, 1979). At the same time, *kasay* is a multi-purpose medicine which apart from being boiled in water and used to treat stomachache is also burnt in fire in order to produce smoke to be inhaled by the sick.<sup>1</sup>

The Maniq do not offer detailed explanations of how

smoke counters disease or wind, but considering how frequently the term *lspas* is mentioned in such contexts one can be confident that smell plays an important role. A valuable insight into understanding these practices can be gained from the description of a similar act (blowing incense smoke on the body of a sick person) performed by the Batek:

The smoke is supposed to enter the body and cause the disease to flee. This is because the odour of the smoke is good (*bed’ət*) and that of the disease bad (*jebéc*), and they cannot mix. If the smoke goes in, the disease must leave. Alternatively, some say the good-smelling smoke draws the disease out of the body by attracting it, causing it to follow the smoke as it wafts upward from the patient's body. (Endicott, 1979, pp. 107-108)

Another situation in which a good-smelling smoke is used for fighting against a bad force is perhaps one of the most salient and common Maniq rituals of ‘burning animal hair’<sup>2</sup> (*tət sək ʔay*) and ‘bones’ (*ʔiyen*). It is performed on hot days when the sun has a yellow color and when it releases the characteristic smell *hamis*<sup>3</sup>. *Hamis* descends into the forest and spreads around causing illness among the people. Maniq, like other Semang (Benjamin, 1985; Endicott, 1979; Lye, 2004), believe that a cool and shaded environment is healthy and provides protection against disease. Exposed locations without too many trees, on the other hand, are dangerous since the sun heats people’s bodies and turns their eyes red. At such moments, the shelters provide safe refuge from both the heat as well as the malicious *hamis*. Burnt animal hair and bones give off a pleasant smell, *cajes*, which together with the smoke floats up to the sun and neutralizes *hamis*. This belief is a vivid illustration of how much power is attributed to odor in that it can have direct physical effects on the human body and the sun. Yet, people can actively defend themselves by releasing good odors thus forcing out harmful ones and bringing a balance to their immediate environment.

Smells are held as projections of their sources which can directly affect the human body or the environment. As Classen (1993) puts it noting the same phenomenon in a number of cultures across the world, “Involved here is the notion of odor as ‘essence’, containing the intrinsic identity of its source of origin” (p. 99). By this token, according to the Maniq viewpoint, invasive and dangerous odors constitute danger while benevolent ones can be employed as cures and defense mechanisms.

### Language of Olfaction

The cultural importance of olfaction is accompanied by a remarkably complex set of odor distinctions in the language.

<sup>1</sup> The latter practice was used by a man whose condition (immobilizing pain in the legs) was attributed to the ‘soil spirit’ (*tames tieʔ*).

<sup>2</sup> Burning hair (though in this case, it is human hair) is reported to be another thunderstorm-appeasing practice among the Batek, Lanoh and Temiar (Dallos, 2011; Endicott, 1979).

<sup>3</sup> The Batek, too, believe that the sun has an unpleasant odor (*pel’eng*) (Endicott, 1979).

These provide additional support for the claim that the domain of smell is of special value for Maniq society.

## Smell Terminology

In this section, we discuss the main Maniq smell terms. Twelve of these were elicited in a free naming task using “Sniffin’ Sticks” (Hummel, Sekinger, Wolf, Pauli, & Kobal, 1997), where Maniq speakers described different odor stimuli. Due to space limitations, the results of that task will not be reported here. Three additional terms (*paleŋ*, *caŋə*, *caŋes*) were attested during other language elicitation sessions.

In order to move towards understanding the meaning of the smell terms, an exemplar listing task was conducted with the speakers. In this task, consultants were presented with smell terms, one by one, and asked the question “What smells x?”. Participants were free to list as many exemplars as they wished. The task was carried out in Maniq. Table 1 lists the terms together with their exemplar sources elicited from 8 speakers. Numbers in brackets next to each exemplar indicate the number of consultants who gave that response. Six participants contributed responses to the entire (or almost entire) set of smell terms whereas 2 speakers commented on a limited number of terms while another participant was being interviewed. All data is taken into account, though in situations where one of the speakers repeated the response heard from another speaker, it is counted only once. Most plants were identified with the help of Maneenoon (2001). It was not possible to identify some of the plant and animal species – these are given in square brackets.

Maniq smell terms share a number of semantic properties. First, they are dedicated to describing olfactory sensations rather than being general descriptors applicable across sensory domains.<sup>4</sup> Second, they are abstract, meaning that they do not make direct reference to the source of the smell (like e.g. fruity), but rather denote an odor quality. This quality is often a common feature of a range of diverse objects, though examples of terms associated with essentially one referent seem to occur, too (e.g. *hamis*).

Note that some smell terms seem to have clearly identifiable prototypical sources, e.g. *kameh*, *paleŋ*, while others do not have such salient core exemplars, e.g. *mi?* *paŋtu?*, *mi?* *bayɔ̌ɔ̌*. On the whole, unique listings of exemplars are common, which may, to some extent, be an artifact of the listing task, or the small number of participants. It may also be indicative of a certain amount of subjectivity in the understanding of smell terms, but this is not clear at this point.

Another important aspect of odor terminology in Maniq is its presence in everyday conversation. The smell lexicon does not consist of specialist terms known to a limited group of people, nor is it restricted to particular contexts or

Table 1: Maniq smell terms with their corresponding exemplars. Numbers in brackets indicate the number of consultants who listed that exemplar. Unidentified animal and plant species are given in square brackets.

Term	Exemplars
caŋə	tubers ( <i>Dioscorea</i> spp.) (4), food (2), cooked meat (2), rice (1), pork (1)
caŋes	animal hair (2), burnt animal hair (2), burnt animal fat (1), sun (1)
caŋus	soap (3), washing oneself (2), fruit ( <i>Goniothalamus</i> sp.) (1), leaves (1), [kind of fruit] (1), clothes (1), talcum powder (1), sun (1)
hamis	sun (6), air/smoke coming from the sun (2)
haʔit	rotting animal (4), animal (1), plantain squirrel ( <i>Callosciurus notatus</i> ) (1), Prevost’s squirrel ( <i>Callosciurus prevostii</i> ) (1), [kind of squirrel] (1), bats (1)
kameh	[kind of millipede A] (5), [kind of millipede B] (1), [kind of millipede C] (1), ipoh poison (1), [kind of bat] (1), forest (1)
kamloh	smoke from fire (3), old shelter (1), bathing (1) tubers ( <i>Dioscorea</i> spp.) (3), bearcat ( <i>Arctictis binturong</i> ) (2), new shelter (1), clean and dry clothes (1), fruit ( <i>Ficus chartacea</i> ) (1), forest (1), tree (1), animal (1), food (1), medicine to drink (1)
lspəs	
paleŋ	blood (5), raw meat (1), [kind of plant] (1), searching for tubers (1), sun (1)
paʔɔ̌ɔ̌	pouring/getting water (2), tuber ( <i>Dioscorea daunea</i> ) (2), mud (1), digging tubers in mud (1), cooking muddy tubers (1), wet or dirty clothes (1), rotting bamboo tube (1), soil (1), mushroom (1), petai ( <i>Parkia speciosa</i> ) (1), <i>Parkia timoriana</i> (1), sweat (1), urine (1), old shelter (1)
mi?	old shelter (2), soil (2), shelter (1), mushrooms (1), skin of a dead animal (1), rotten wood (1), bamboo for water (1), rotting leaf (1), head of macaque/leaf monkey (1)
bayɔ̌ɔ̌	
mi?	mushrooms (2), rotten wood (2), rotten mushrooms (1), old shelter (1), animal bones (1), durian seed (1), snakes (1), forest (1), searching for tubers (1), soil (1)
danəw	
mi?	snakes (2), soil (2), searching for tubers (1), digging tubers (1), mushrooms (1), sweat (1), rotten wood (1), walking in the forest (1), making fire (1), smoke (1)
huhũɔ̌ɔ̌	
mi?	soil (2), burning fire (1), [type of fire wood A] (1), [type of fire wood B] (1), [kind of flower] (1), [kind of fruit] (1), mushrooms (1), tree (1), walking in the forest (1)
latiŋ	
mi?	tree sap (1), leaves (1), garlic (1), soil (1), forest (1)
paŋtu?	

<sup>4</sup> The only exception here is the term *bayɔ̌ɔ̌* which, apart from describing smell, refers to color – a specific kind of white, e.g. of fog or old individual’s hair.

registers of speech. Talking about smell is a mundane activity which all members of the community engage in on a daily basis. What is more, smell is an important reference point in a number of areas of life, such as medicinal practices and rituals.

Formally, Maniq smell terms can be subdivided into stative verbs and noun phrases. The verbs can take verbal affixes, though most frequently they do not bear any morphology (excluding the apparent frozen morphology in *ls-pəs*, where the initial half-syllable has the shape of the iterative affix). A few of the verbs, namely *caŋes*, *caŋus* and *caŋə*, apart from being close semantically, are phonologically similar. They do not, however, show evidence of a productive derivational relationship.

As for the noun phrases, all of them are headed by the noun *mi?* ‘smell’. They appear to be lexical noun phrases since none of the modifiers, with the exception of *bayɔ̌p*<sup>5</sup>, occurs outside of the “mi?+...” phrase. For that reason, it is rather difficult to establish the word class affiliation of these modifiers, though elicited aspect-inflected forms for three of them (*danɔw*, *latiŋ* and *ŋətu?*) suggest that they might be verbs.

All of the above terms serve as phenomenon-oriented descriptions. The controlled activity of smelling as well as the uncontrolled experience of perceiving smell are both expressed by the verb *ɔ̌n* ‘to smell’. It is worth noting that the Maniq *ɔ̌n* forms a clear and distinct category uniquely relating to olfaction with no extensions into other sense modalities.

## Organization of the Smell Lexicon

Taking into account the large number of smell terms as well as the considerable range of exemplars associated with most of them, it is unclear what principles might underlie the organization of the smell lexicon. One way of gaining insight into that organization is to investigate the relationships between the smell terms by collecting similarity judgments from speakers, following a similar procedure used to study color lexica (Shepard & Cooper, 1992). Since the Maniq are a non-literate community, this task was carried out with the use of the triadic comparison method, which does not require reading. Following data collection, the results from 11 Maniq speakers were pooled together to create a similarity matrix analyzed with multidimensional scaling analysis.

## Stimuli and Method

Stimuli for the experiment were the 15 smell terms given in Table 1. The experiment was based on the triadic comparison method as discussed by Weller and Romney (1988). A complete triad test with 15 items would involve 455 triads, which would be time-consuming and tiring for

participants. For that reason, we have used a balanced incomplete block design ( $\lambda=1$ ) of 35 triads. The letter  $\lambda$  represents “the number of triads in which each pair of items occurs” (Burton & Nerlove, 1976, p. 249). To increase the reliability of the design without adding more triads, we followed the recommendation of Burton and Nerlove (1976) to administer two different triad compositions, with each composition randomly presented to half of the participants. Smell terms were randomly assigned a number and the triads were created following the directions of Burton and Nerlove. The only modification of Burton and Nerlove’s design was the randomization of the order in which triads were presented – items were randomized within and across triads to avoid frequent repetition of terms in close proximity.

## Participants

The participants were 11 Maniq speakers (6 male, 5 female) aged approximately 20-45 years. All were native speakers of Maniq, who also had a good command of Southern Thai, the unrelated majority language of the region.

## Procedure

Each participant was tested individually. The task was run exclusively in Maniq to preclude the influence of Southern Thai. Speakers were orally presented with 3 smell terms at a time and asked the following question: “Which one is not the same/similar?” (the meaning of the Maniq term *min*, from Thai *měuan* ‘same, similar’, has scope over both sameness and similarity). The response was coded on a response sheet and the next triad was presented until all triads were complete.

In order to ensure that the task was proceeding as intended, a series of precautions were taken. Before starting the task, the researcher informed the participants that they would be presented with words relating to smell. The critical question “Which one is not the same/similar?” was used each time with the initial triads to make sure the participants remembered what they were asked to do. As they became accustomed to the task, the question was repeated every few triads. Three objects (three similar leaves from the same plant) were placed in a row in front of the consultants to act as anchors to the words in the triad. In order to avoid a situation in which a consultant fell into a response set, words were assigned to objects sometimes from right to left and sometimes from left to right. When presenting a triad, target words were pronounced slowly several times with neutral intonation, unless a consultant gave a response immediately after hearing the triad once. Many consultants responded with the following phrases: “These are together” and “This one is alone” or “These are similar” and “This one is not similar”. In case of any uncertainties on the side of the speaker or the researcher, the triad was read out again and the question was repeated. On the rare occasions when the consultant could not make a choice after being asked the question several times, the researcher proceeded to the next triad and came back to the

<sup>5</sup> *Bayɔ̌p* is a stative verb occurring in a variety of syntactic contexts with a number of verbal affixes. Note, however, that whenever the word is used to denote smell, it occurs in the nonderived form.

problematic one at the end. All participants were able to complete the study.

## Results and Discussion

A 15x15 similarity matrix was constructed by summing over all participants the number of times each pair of smell terms was judged similar. The matrix served as input into the scaling procedure carried out with the use of the PROXSCAL algorithm in SPSS. The resulting two-dimensional solution yielded a stress value (Stress-I) of .098, a dispersion-accounted-for value of .99 and a Tucker's coefficient of congruence value of .995. Figure 1 shows the overall results from all 11 participants.

Figure 1: Two-dimensional MDS of 15 Maniq smell terms based on triadic comparison (N=11).

The distribution of smell terms is considerably more stretched on the first dimension. Items are more densely concentrated on the left-hand side, while the right-hand side is more sparsely populated, especially if we look at the almost empty area in the upper right quarter.

The first dimension is readily interpretable as distinguishing between pleasant and unpleasant smell terms, the former located on the right- and the latter on the left-hand side. Though the stimuli were words rather than actual smells, this aspect of the results is comparable with studies using odorants, which report the primary role of the hedonic dimension in smell perception and categorization (e.g. Dubois 2000; Schiffman, Robinson, & Erickson 1977). Pleasantness is also of great importance when considering neurophysiological responses to smells (cf. Yeshurun & Sobel 2010 for an overview) and there is some evidence suggesting this reflects the molecular structure of odorants (Khan et al., 2007).

The interpretation of the second dimension is less straightforward, yet a likely solution is the contrast of edibility vs. inedibility. Items at the bottom are associated

with food objects whereas those at the top are associated with nonfood objects. Again, this aspect appears to reflect odor perception since edibility was found to distinguish odorant samples (Chrea et al., 2004; Zarzo, 2008). An important caveat to this interpretation is that the focus is placed on the smell object rather than the smell quality itself. For instance, the terms *pale* or *ha?it* refer to raw or rotting animal meat, which are not edible within this community. Nevertheless, they refer to meat, which is an edible object.

Since many smell terms relate to multiple exemplars, some of which may be edible while others not, we focused on the smell term prototypes, which for the current purposes are defined as items listed by more than 1 speaker. Inspecting the plot, we see that most terms conform to the edibility distinction. All items in the upper part of the plot relate to exemplars which are considered to be inedible by the Maniq, e.g. *mi? huhu* (snakes and soil), *hamis* (sun and air/smoke coming from the sun), *kameh* (millipedes) and *kamloh* (smoke from fire). As for the opposite side, most items link to edible exemplars, e.g. *pale* (blood), *lspas* (tubers, bearcat), yet there are a few terms among whose prototypical exemplars we find inedible objects – *mi? bay* (old shelter and soil) and *mi? danow* (rotten wood). So, there is evidence consistent with viewing Dimension 2 in terms of edibility but a further examination is required to fully establish the facts.

A follow-up study could collect speakers' judgments on various possible semantic parameters, to see which best predicts the attested dimensions.

## Conclusions

This paper illustrates the richness and complexity of the domain of smell in Maniq society. The different methodologies employed provide insights into the smell lexicon, its underlying structure, and the deep cultural significance of different smell categories. Despite the fact that many cultures, especially those which are part of the developed world, are undergoing gradual deodorization, there appear to be a number of societies with a long tradition of vibrant interest in odor (cf. Classen, Howes, & Synnott 1994). As we hope to have demonstrated with this paper, Maniq adds to the literature regarding the special cultural value of smell across the world, and at the same time reinforces our observation that the Aslian-speaking communities of the Malay Peninsula provide a rewarding setting for studying such smell cultures and their linguistic elaboration of the domain (Burenhult & Majid, 2011). Moreover, it highlights the importance of looking beyond WEIRD people in our theories of cognition (Henrich et al., 2010).

Smell is an integral part of the intimate knowledge of the rainforest's fauna and flora shared by the tribe. What is more, for the Maniq, odor has a metaphysical dimension whereby it is treated as the projection of its source able to "act on its behalf". This is illustrated by the wind-appealing ritual involving the burning of *kasay* as well as the

medicinal practices of the group including both curing and prevention (the best example being the emission of smell to ward off the disease spreading with the odor of sun).

Contrary to the view that the language of odor is non-abstract and steeped in metaphors (Henning, 1916; Kant, 1798/2006; Sperber, 1974/1975), Maniq, and its Aslian brethren, possess rich smell vocabularies of over a dozen abstract terms. These terms are known to the whole speech community and are employed in everyday conversation.

Finally, the internal structure of the Maniq smell lexicon is remarkably similar to the dimensions of variance typically found in studies of odor categorization in speakers without an abstract olfactory lexicon. This suggests that odor lexica may reflect a pan-human olfactory space. Further investigation is needed to explore the extent to which olfactory language follows olfactory perception and cognition, and the extent to which perception and cognition might mirror language in the domain of olfaction.

### Abstract

Human infants develop a variety of attentional mechanisms that allow them to extract relevant information from a cluttered world. We know that both social and non-social cues shift infants' attention, but not how infants use these cues to learn basic events. With over 450 infants, four extensive eye-tracking studies in this thesis established a controlled paradigm for investigating how attention cues shape early learning. The results showed that infants' ability to learn about structures in their environment (i.e., predicting the appearance of audio-visual events and forming expectations about co-occurring features) is dependent on the presence and nature of attention cues. By 8 months, infants learned these events significantly better with social cues (e.g., eye gaze, infant-directed speech, expression of interest) than with non-social cues (e.g., flashing squares) or without any attentional cueing. Importantly, when presented with multiple events to learn and cued by a face to one specific event, infants learned the cued event and ignored the non-cued event. The last study found that familiar communicative social signals (i.e., an engaging face that spoke to the infant) boosted 9-month-olds' learning about cued events. In particular, the engaging face supported learning from non-social cues, providing evidence for a mechanism explaining how infants learn to learn from unfamiliar attention cues such as pointing or arrows. Our results showed that though social cues may temporarily detract attention away from certain learning events in the world, they appear to stimulate infants to display better learning about the cued event than when infants learn with other attention cues or on their own without attention cues.

**Keywords:** attention cues; pattern learning; infant eye-tracking; cognitive development; social cues.

### Introduction

The relationship between attention and learning is reciprocal: learning is enabled and facilitated by attentional selection, and attentional selection builds on previously learned knowledge. For example, studies with adults have shown that appropriate attentional selection can help filter distracters to learn about targets (e.g., Hillyard, Hink, Schwent, & Pinckton, 1973; Van Voorhis & Hillyard, 1977) and that learned knowledge about targets and distracters allows more efficient target selection among distracters (e.g., Chun & Jiang, 1998; Kruschke, 2011; Mazza, Turatto, Umiltà, & Eimer, 2007). This bi-directional relationship between attention and learning is highlighted in the developmental perspective, when considering such abilities in inexperienced learners (i.e., infants).

Human infants have to learn a great deal of information in a complex world that is filled with ambiguity. Not only are

many different features and dimensions present in the environment, but also they are often unrelated to any reinforcement or feedback. Selective attention, focusing on some information but ignoring other aspects, is a crucial component for learning, especially in situations involving uncertainty (e.g., Dayan, Kakade, & Montague, 2000). There are two broad solutions to this complexity and ambiguity inherent in the learning environment: (a) innate constraints on the cues selected for processing, or (b) rapid learning-to-learn mechanisms that assess cue-reliability and thus guide learning. In the bottom-up solution, there are environmental and innate biases that constrain what infants attend to (e.g., Brazelton, Scholl, & Robey, 1966; Johnson, Dziurawiec, Ellisc & Morton, 1991), and in the top-down solution, infants can sample their environment and quickly learn what sources of information make the most sense (e.g., Saffran, Aslin, & Newport, 1996; Fiser & Aslin, 2002). Mechanisms of learned information selection are generally considered top-down and thus may be tuned to specific task demands. Many experiments with older children and adults show that top-down selection produces efficient learning and allows for pre-activation of relevant neural circuits, which may lead to better processing of the stimulus (e.g., Driver & Frith, 2000). Would infants learn differently with different types of attention cues?

Both bottom-up and top-down (learned) attention cues shift infants' attention: social stimuli (e.g., eye gaze, infant-directed speech, faces), which infants learn to follow by four months of age, and non-social stimuli (e.g., bright lights/colors, motion), which capture infants' attention from birth. In following these stimuli, infants can develop attentional mechanisms for extracting relevant information from a cluttered multimodal world, because these stimuli can cue infants to the location of relevant events. In turn, relying on these attention cues can shape learning because what controls attention can gate processing (Moran & Desimone, 1985). Though it is well known that both social and non-social cues shift infants' attention, it is unclear how these attention cues differentially affect learning of basic events. We know that infants are capable of learning about the structure of their environment in the simplified laboratory setting. For example, infants recognize that certain sights and sounds belong together (e.g., toys dropping, cars driving, people talking, Bahrick, 2004; Lewkowicz, 2000) and track the co-occurrence of visual features (e.g., Fiser & Aslin, 2002; Kirkham, Slemmer, & Johnson, 2002). In the typical cluttered environment, however, infants are often presented with multiple events to

learn. How do infants know which events are important to learn? Would different attention cues similarly help infants select information to learn?

## Summary of Thesis Studies

The tight coupling of attention and learning, especially for the young learner, determines how information is selected, retained, and eventually applied. This thesis capitalized on recent advances in methodologies (i.e., eye-tracking) that allow for paradigms that include more ecologically valid environments with noise and distraction testing young age groups.

Learning from cues (specifically attention cues) is an ideal context for studying this interaction between selective attention and learning efficacy. The thesis investigated whether infants learn differently from different attention cues (or no cues), and how infants learn to learn from attention cues. In a distraction-filled environment, visual spatial attention cues (e.g., other's eye gaze or flashing lights) can highlight events in a particular location and facilitate processing of those events (see Posner, 1980). This is a critical aspect for the young learner, who may not know what to learn at a given moment. The components of a spatial cueing experimental paradigm include a cue, target, and distracter(s). Commonly, the cues shift attention to a particular location to prepare the viewer for the target event in that location. Cues can either attract attention (bright flashing lights, big moving objects) or shift attention from themselves to another location (learned attention cues: eye gaze, arrows).

My 3-year PhD investigated how different attention cues (or no cues) affect learning during infancy. My studies showed for the first time in one cohesive paradigm that the presence and nature of these attention cues mediate what infants learn about the structures in the environment (i.e., predicting the appearance of audio-visual events or forming expectations about co-occurring features). A sample of over 450 infants across four extensive eye-tracking studies (Wu & Kirkham, 2010; Wu, Gopnik, et al., 2011; Wu, Kirkham, et al., under revision) showed that by 8 months, infants learned the structures in their environment significantly better with subtle social cues (e.g., eye gaze, infant-directed speech) than with salient non-social cues (e.g., flashing squares) or without any attentional cueing. Importantly, when presented with multiple events to learn and cued by a face (rather than a flashing square) to one specific event, infants learned the cued event rather than the non-cued event. These results show that when naïve learners do not know what to learn, social objects (faces) shape the likelihood of learning cued targets, and that attending to social cues provides infants with an optimal strategy for learning appropriate events despite the presence of distractions.

**Study 1** In the first study, Experiment 1 used social cues to direct 8- and 4-month-old infants' attention to multimodal

events (i.e., animations of toys accompanied by specific sounds), while identical distracter events were presented in another location. Experiment 2 directed 8-month-olds' attention with colorful flashes to the same events. Experiment 3 measured 8-month-olds' baseline learning without attention cues. The test trials in all experiments played only the sounds previously associated with a particular animation, and looking time was measured to each now blank location that previously contained an object. Results showed that the 8-month-olds exposed to social cues learned about the cued audiovisual event (i.e., they predicted its appearance in the correct rather than incorrect cued location) (Figure 1). The 4-month-olds, however, displayed only general spatial learning from social cues (i.e., they looked to both correct and incorrect cued locations to predict its appearance), suggesting that infants *learn to learn* from a face stimulus between 4 to 8 months. Eight-month-old infants cued with the colorful flashes looked indiscriminately to both correct and incorrect cued locations during test (similar to the 4-month-olds learning from social cues) despite attending for equal duration to the training events as the 8-month-olds with social cues. Results from Experiment 3 (no learning) indicated that the learning effects from Experiments 1 and 2 resulted from exposure to the different cues and multimodal events. In summary, this first series of experiments shows that infants' attention to target events is captured equally well by both social and non-social cues, but learning is deeper and more precise with social cues. This study is published in the *Journal of Experimental Child Psychology* (Wu & Kirkham, 2010).

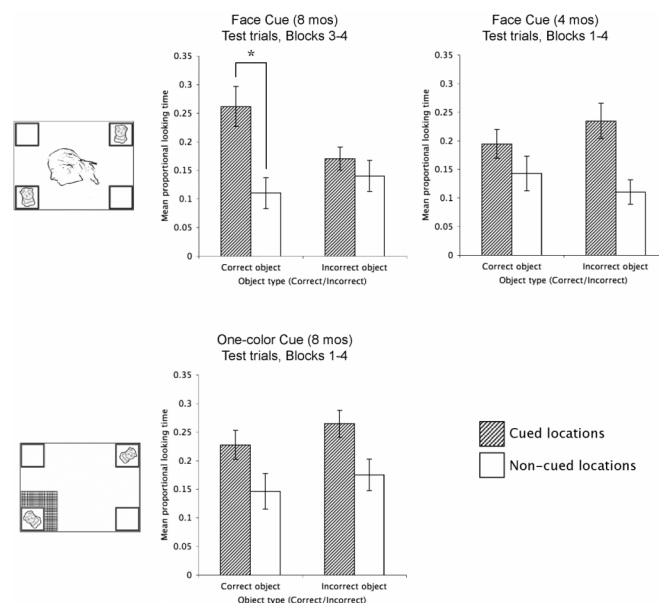

Figure 1: Stimuli and results from Study 1. Mean proportional looking times to locations during test trials from Blocks 3 and 4 in the Face Cue condition (8 months) and Blocks 1 to 4 in the Face Cue condition (4 months) and One-color Cue condition (8 months). The 8-month-olds in the Face Cue condition looked more to the cued correct object location, whereas the 4-month-olds in the same

condition looked longer to cued locations than to non-cued locations regardless of object–sound mappings. The 8-month-olds in the One-color Cue condition (flashing squares) also looked longer only to cued locations than to non-cued locations regardless of multimodal information.

\* $p=.01$

**Study 2** Study 2 used visual statistical learning as the dependent measure, and compared how infants learn from social cues to that with no cues. In laboratory experiments, infants can learn patterns of co-occurring visual features (e.g., Fiser & Aslin, 2002). Once infants learn the statistical regularities, however, how do they use the knowledge? In addition, which patterns do infants learn when presented with many options (as in the cluttered world outside of the laboratory)? In this study, infants were shown clusters of 3 shapes, where two always co-occurred and a third changed on every trial. Infants were either shown these shape patterns on their own (Experiments 1 and 2) or shown the pattern cued by a face (Experiment 3) or also with a distracter pattern in a non-cued location (Experiment 4). Test trials displayed shapes moving apart: either the co-occurring shapes (looking longer related to a preference for the inconsistent/violation of expectation) or the non-co-occurring shapes (looking longer related to a preference for the consistent). Tracking co-occurring units and inferring that they are larger fused units help identify integral object parts for object individuation, recognition, and categorization. Experiment 1 showed that 9-month-old infants interpret co-occurring features as larger fused units (i.e., infants looked longer when co-occurring features split apart). The other three experiments showed that social cues (compared to no cues) help 9-month-olds choose patterns among distracters during learning and test (Figure 2). These findings suggest that by 9 months, infants can use feature co-occurrence to learn about objects and that social cues shape such foundational learning in distraction-filled environments. In particular, though social cues may temporarily detract attention away from certain learning events in the world, they appear to stimulate infants to display the learning better in complex situations than when infants learn on their own without social cues. Task difficulty also mediates how inferences (made from visual statistical processing) are exhibited during test trials. This study is published in *Developmental Psychology* (Wu, Gopnik, et al., 2011).

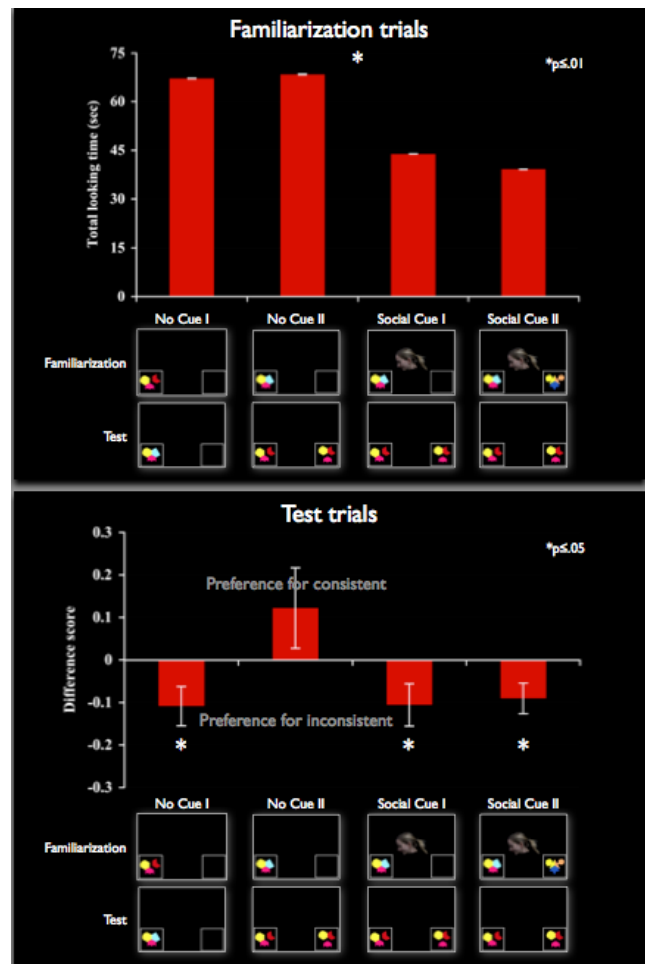

Figure 2: Stimuli and results from Study 2. The top half of the figure shows the total looking times to the target pattern for the familiarization trials across the four conditions (No Cue I, No Cue II, Social Cue I, and Social Cue II). Infants looked longer to the target pattern in the two No Cue conditions, and less in the two Social Cue conditions because they split their attention between the face and target pattern. \* $p\leq.01$  The bottom half of the figure displays the difference scores across four conditions (mean difference between proportional looking times for consistent minus inconsistent events during test). A negative value reflected a preference for the inconsistent splits (i.e., looking longer at events showing the separation of features that co-occurred rather than the separation of features that did not co-occur). Infants showed this preference in the easier test condition without a cue (No Cue 1), and with a social cue regardless of task difficulty. \* $p\leq.05$

**Study 3** Following up from these findings, that infants learn better from social than non-social cues, Study 3 investigated whether infants can *learn to learn* from typical non-social objects that are interactive like social cues (e.g., objects that move when infants look at it, e.g., Johnson, Slaughter, & Carey, 1998). The main procedure consisted of three phases: training, familiarization, and test. During the training phase, 9-month-olds interacted with a centrally presented teapot

(similar to Deligianni, Senju, Gergeley, & Csibra, 2011, who found that infants follow such interactive objects). Infants' fixations on the teapot caused it to jump or lift its lid. During the familiarization and test phases, infants were presented with the pattern events from Study 2, with the original face now replaced by the teapot. We found that if infants followed the teapot during familiarization, they seemed to have trouble learning about the cued event, only perhaps learning the cued location (general spatial learning similar to 4-month-olds cued by a face in Study 1). Infants who did not follow the teapot (and perhaps ignored this cue) seemed to learn about the non-cued event. While only preliminary observations can be made at this stage, this pilot study begins to address *how* infants learn to use cues, rather than describing cues they do or do not learn from.

**Study 4** In Study 1, the flashing square cue was unsuccessful at producing specific learning in infants (Wu & Kirkham, 2010). Study 4 investigated whether the pairing of familiar social cues with unfamiliar flashing cues could help infants learn from these novel flashing cues. Nine-month-old infants were eye-tracked during a Training phase, followed by a Generalization phase. In the Social Scaffolding condition, the Training phase consisted of an expressive face that spoke to the infant and then froze with a smile, while identical audio-visual animations appeared in diagonally opposite corners. At the same time, a red flashing square cued the infant to a specific target frame containing an object. In the Extended Practice condition, infants only saw the flashing square and multimodal events. The Generalization phase for both conditions displayed new audio-visual events with only the red flashing square cues. The test trials in each phase played one of the sounds previously associated with a particular animation, and looking time to each location was measured. In the Social Scaffolding condition, infants anticipated that the events would appear in the correct cued locations for both phases. In the Extended Practice condition, infants first displayed general spatial learning (replicating Experiment 2 in Study 1) during the Training phase, and then showed no learning during the Generalization phase (Figure 3). These findings suggest that initial exposure to familiar social cues can elicit and maintain specific learning from novel attention-orienting cues. Moreover, this could provide evidence for a mechanism explaining *how* infants and children can learn to learn from distal attention cues such as pointing fingers and arrows. This is an important first step towards elucidating an emerging ability to use familiar attention cues to support, enhance, and mediate learning about unfamiliar cues, going beyond documenting *which* cues guide attention and learning during infancy to proposing a mechanism for *how* this cascading learning effect occurs. Portions of this study are a CogSci proceeding and EuroCogSci proceeding (awarded Best Student Paper Prize), and is currently under revision for a journal submission.

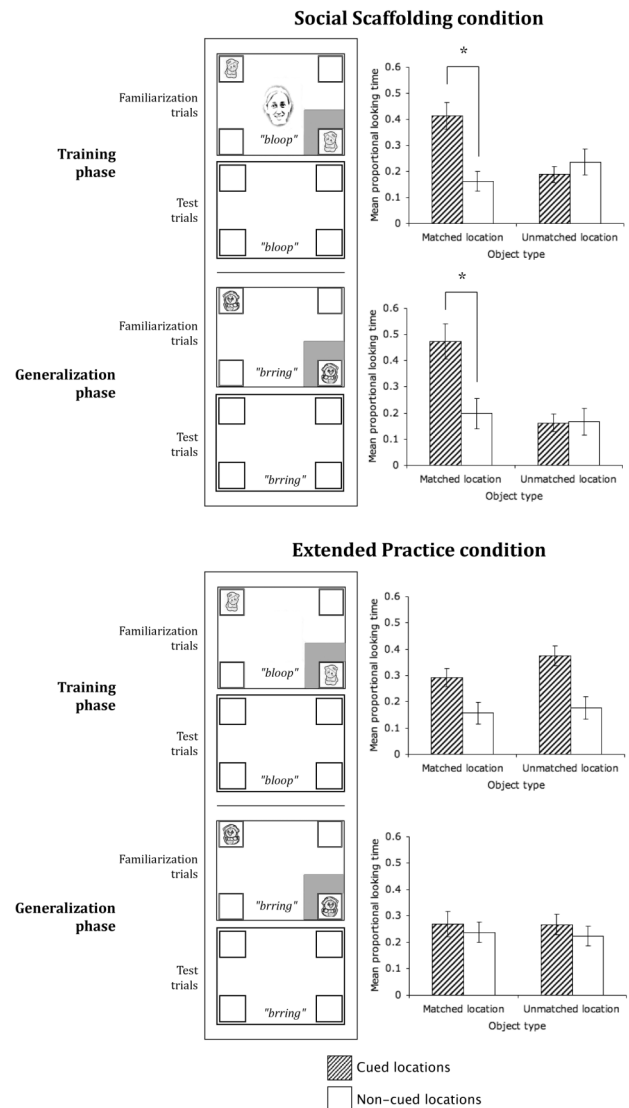

Figure 3: Stimuli and results from familiarization and test trials for both conditions in Study 4. All stimuli were in full color on a black background. When exposed to direct social signals paired with flashing squares, infants predicted objects would appear in matched cued locations (Social Scaffolding condition, Training phase). Infants continued learning specifically from flashing squares even after social signals were no longer presented (Social Scaffolding condition, Generalization phase). With only exposure to flashing squares, infants exhibited general spatial learning and no transfer of learning, suggesting that initial exposure to direct social signals is necessary to elicit and maintain specific learning from novel cues at this age.  $*p < .03$

## Conclusions

By studying how infants learn cued events (and do not learn distracter events) with attention cues, this thesis investigated the usefulness of attentional biases for infants' cognitive development. This research is important because it goes beyond describing singular events that infants can learn by exploring how they figure out *what* to learn in the

noisy environment. Investigating how infants learn to learn with cues provides a more accurate picture of infants' learning mechanisms in the rich natural environment. My thesis work contributed to the study of the optimal dynamics of selective attention and successful learning in typical development, which in turn would inform populations with learning difficulties. Though the studies in this thesis only investigated learning from visual spatial attention cues, research on the overall question of how one learns to learn among distraction is important for many areas of cognitive development. *Learning to learn* is essentially the interplay of gaining control over one's perceptual input based on previous experience (Aslin, 2008; Frank et al., 2009) and current interactions with the environment (Sarter, Givens, & Bruno, 2001). This is one way of describing how one gains expertise (Gopnik, 2009; Nodine, Kundel, Lauver, & Toto, 1996; Solso, 2001). We are trained to detect and learn from certain stimuli, whether it is learning from people (Bigelow, 1998; Csibra, 2010; Ghazanfar & Santos, 2004) or learning from other cues (e.g., arrows). With some rudimentary initial biases, infants *learn to learn* and become more adapted to function appropriately according to environmental norms.

Testament to the interdisciplinary contribution of this thesis, at least seven current projects on computational modelling, robotics, genetics, and atypical development are based directly on this work and dataset (please see CV). The large dataset (450+ infants) from this thesis is ideal for computational modelling and genetics projects, and the benchmark of typical behavior can be used to compare with data from atypical development.

This work also has led directly to the organization of two attention-learning workshops in London (Jan 2012 – organized by R. Wu, received £1818 to organize workshop) and Tokyo (March 2012 – organized by R. Wu, S. Shimojo, and T. Omori, funded by the Tamagawa-CalTech grant), encouraging discussions among computational modellers, developmental psychologists, neuroscientists, and roboticists to promote the emergence of this sub-field on the interaction of attention and learning.

## Acknowledgments

I owe a great deal of gratitude to my supervisors, Natasha Kirkham and Denis Mareschal for their guidance, dedication, and encouragement, as well as to the other collaborators on this project, Teodora Gliga, Alison Gopnik, Daniel Richardson, and Kristen Swan. Thank you to the Glushko-Samuelson Foundation and the Prize committee for the generous award, as well as providing travel grants to present this work at various Cognitive Science meetings. Thank you to Leslie Tucker and Marian Greensmith for help with data collection. This research was supported by a grant to NK from the British Academy, Grant No. SG-47879 and two grants to NK and RW from the University of London Central Research Fund.

## Abstract

For over 50 years expected value and expected utility theory has been challenged by behavioral findings in repeated and single plays of risky gambles. The inherent long-term nature of these models has been found to be at odds with preferences indicating short-term maximization in single play situations. With the present study we provide further evidence on the distinction between long-term and short-term oriented behavior. Evaluating experienced-based decisions over repeated and single play situations we demonstrate that both choice preferences and search behavior change in response to long and short-term framing. This suggests different cognitive approaches for single and repeated play situations, with single decisions often favoring risk-aversion and therefore the underweighting of rare events. These findings are in line with alternative models of risky choice as for example proposed by Lopes (1996) and also the literature on state-dependent foraging.

**Keywords:** Decisions from experience, information sampling; risky choice, single-play and repeated-play.

## Introduction

Over lunch nobel-laureate Paul Samuelson offered his colleague the following bet: Win 200\$ with a 50% chance or lose 100\$. To his surprise the colleague rejected the offer but mentioned that he would agree to a series of a hundred such bets. Samuelson (1963) considered the choice of his colleague irrational. He later showed how this pattern of choice is incompatible with expected-utility maximization. A series of bets, which individually are all unacceptable, should not be accepted. But is the behavior of Samuelson's colleague irrational?

The prevailing answer after 50 years of scientific debate seems to be unanimously no. However, very different theoretical explanations have been invoked. On one hand, it has been demonstrated that the behavior of

Samuelson's colleague can indeed be captured by models of expected utility theory when the decision is made over the aggregated outcome of repeated plays (Aloysius, 2007). On the other hand, "distinct process differences between the situations" (Wedell, 2011) have been emphasized. Particularly Lola Lopes argued in favor of a two-stage decision process in which the qualitative feature of "coming-out-ahead" plays an important role (Lopes, 1996; Lopes & Oden, 1999). Formally Lopes assumes next to decumulative weighting a second process that maximizes the probability of achieving an aspiration level.

Along the lines of Lola Lopes' explanation, Hills and Hertwig (2010) recently provided evidence for a decision strategy that focuses on winning most of the time. Hills and Hertwig used an alternative paradigm of risky choice – decisions from experience – in which the information about options is acquired in a prior inconsequential sampling phase. They found that the choice behavior of people who sampled less and evaluated options in shorter intervals – were best described by a "round-wise" decision strategy. Instead of aiming at the overall higher mean of both options, this strategy compares the options over all sampling transitions and tallies the wins. Consequently, this strategy favors the option with a higher probability of coming out ahead—i.e., the option that wins most of the time. The results of Hills and Hertwig (2010) indicate that distinct processes are indeed at work when people aim for either long-run expected value maximization or for short-run maximization that focuses on coming-out ahead.

The distinction between such strategies is prevalent also outside the field of human decision-making. For

example, risk sensitivity and state-dependent foraging explain why a bird that needs food regularly to avoid starvation should concern itself with short-term outcomes and not seek for the better long-term average, which may not come in time (e.g., Caraco, 1980; Houston & McNamara, 1999; Stephens, 1981). In the present study we build on these ideas by examining information search and decision making in single and repeated play situations.

### Behavioral Findings Under Repeated Plays

Behavioral studies have shown that in repeated-play situations—where people get to play the same gamble multiple times—people are more likely to act according to the principles of expected utility maximization (Wedell, 2011). Generally, under repeated plays, the preference for the option with the higher expected value is substantially increased (e.g. Montgomery & Adelbratt, 1982). In addition, repeated plays reduce a number of well-known decision anomalies including possibility and certainty effects (Keren & Wagenaar, 1987; Keren, 1991), violations of procedural invariance (Wedell & Böckenholt, 1990) and ambiguity aversion (Liu & Coleman, 2009).

The effect of repeated plays on choice preference has also been established in applied settings. Redelmeier and Tversky (1990, 1992) found that physicians make differential decisions for individual versus aggregated instances. Bernartzi and Thaler (1990) have also demonstrated the relevance of the single repeated play distinction for investment decisions.

### Present Study

The goal of the present study is to evaluate the effect of single and repeated plays in the context of decisions from experience. By incorporating an active sampling phase decisions from experience account for the lack of full information about the available options in real life; a quality that is neglected in the commonly used paradigm of decisions from description. Based on the findings of Hills and Hertwig (2010) we expect the contrast between repeated and single play to impact pre-choice information search in addition to preferences. Specifically we expect people in single play as compared to repeated play situations to draw fewer samples and have shorter evaluation intervals for the available options. We also expect a higher preference in single play situations for

options that have a higher probability of winning most of the time irrespective of expected. For repeated plays we expect the opposite pattern. Such findings would indicate an overall differential cognitive approach to single and repeated plays of the same gamble and speak in favor of choice models such as Lola Lopes' two-stage account.

Additionally, we are interested in the degree to which the pattern of results is dependent on the certainty of the available options. In much of the risky choice literature a risky high outcome option is paired with an option that offers a smaller but certain outcome. Thereby, the quality of “coming-out-ahead” is often confounded with certainty. However, given the prior assertions we would expect the pattern of results to be largely independent over cases where the secure option is certain (or only relatively secure).

Finally, we want to evaluate how the standard application of decisions from experience relates to situations where the single and repeated-play character is made salient. Decisions from experience have recently received much attention as they depart from decisions that are made based on full description of the options (see Hertwig & Erev, 2009). In this context it will be very telling to observe if the overall pattern of results in the paradigm used most often in the literature (following Hertwig et al., 2004) resembles more a single or repeated play instantiation.

## Method

**Participants** We collected data from 124 participants. The mean age of the sample was about 24.2 years, 85% were students of the University of Basel. Participants were rewarded either by course credit or a fixed payment of about 13\$. Every participant also received a performance-based bonus as a result of his or her choices.

**Materials** A set of 12 target problems was created (see table 1). Each problem required a choice between two gambles. Every gamble was comprised of two outcomes – one positive outcome and zero. One gamble posed a relatively secure ( $p > .7$ ) or certain chance ( $p = 1$ ) to win a positive outcome. The other gamble was substantially more risky ( $p \leq .15$ ). This riskier option was always superior in expected value (1.5 to 1.8 times as high). We refer to these two options as the low (L) and high (H) expected value options, respectively. For control purposes, we included two problems where the high outcome options had the lower expected value (C1,

Table1: Study problems

Problem	H	L
1	92 with $p=.05$	3 with certainty
2	34 with $p=.05$	1 with certainty
3	120 with $p=.05$	5 with $p=.70$
4	44 with $p=.05$	2 with $p=.70$
5	70 with $p=.10$	4 with certainty
6	16 with $p=.10$	1 with certainty
7	54 with $p=.10$	4 with $p=.75$
8	23 with $p=.10$	2 with $p=.75$
9	35 with $p=.15$	3 with certainty
10	21 with $p=.15$	2 with certainty
11	48 with $p=.15$	5 with $p=.80$
12	9 with $p=.15$	1 with $p=.80$
C1	0 with certainty	1 with $p=.75$
C2	0 with certainty	1 with certainty
C3	9 with $p=.10$	3 with $p=.75$
C4	7 with $p=.10$	2 with certainty

C2) and two problems where the supposedly high outcome option was actually a sure event of zero (C3, C4). Those problems were created to exclude participants showing unsystematic or extreme risk seeking behavior.

**Procedure** The experiment was entirely computer based. Participants were given verbal and visual instructions that explicitly explained the payoff modality according to their assigned experimental condition. Participants then made choices for three practice trials. On every problem the participants were able to sample from the two options as much and in whatever fashion they liked. They were instructed to proceed to the decision whenever they felt confident enough. Finally the participants made their decisions on all 16 problems (12 target and 4 control problems) in random order.

**Payoff Manipulation** The single and repeated play character was induced between-subjects through different payoff modalities. The payoff in the repeated play condition was determined by one hundred draws from one of the participant's chosen options. In the single play condition the payoff, one random sample was taken from

one the participant's chosen options and then this value was multiplied by one hundred. A third condition (neutral) corresponded to the payoff modality usually applied in the literature (Hertwig et al., 2004), with the payoff equivalent to one random draw from each option chosen by the participant. As the payoff in the neutral condition is based on only 16 draws all presented outcomes were multiplied by a fixed factor to equal the expected values in the other two conditions.

## Results

We applied two criteria to exclude participants showing extreme risk seeking or unsystematic behavior. First, we excluded participants that neither preferred the higher mean nor the higher median in the control problems C1 and C2 (see table 1). Second, we also excluded participants that did not sample at least once from every option. As a result the following analyses are based on 82 out of 124 participants. Inspection of control problems C3 and C4 reveals that this restriction very efficiently reduces zero EV choices, which can be regarded as an indicator for either extreme risk seeking or not very systematic behavior. The excluded participants chose the zero EV option in about 27% of the cases, whereas the included participants chose did not choose this option at all. Thus, the remaining participants showed neither extreme risk-seeking nor unsystematic behavior.

The main focus of this study is on the contrast between the single and repeated play conditions. Statistical tests are therefore mainly reported for this contrast. Additionally, comparisons for the neutral condition are reported to see where usual experimental instantiations of this paradigm fall in the context of salient single and repeated play situations.

Figure 2A illustrates choice patterns over the experimental conditions. In support of our predictions, H preferences increased for the repeated-play as compared to single-play situation ( $t_{42.4}=3.58$ ,  $p<.001$ ). H preference in the neutral condition resembled the pattern in the single-play condition ( $t_{53.1}=0.54$ ,  $p=.594$ ), but there was a difference for H choices between the neutral and repeated play conditions ( $t_{43.8}=-3.05$ ,  $p=.004$ ). This effect is not affected by the inclusion of the certainty of the L option in the prediction of H choices ( $\chi^2_{2}=.51$ ,  $p=.776$ ). Because none of the following analyses were influenced by a comparison of certain and uncertain gambles, the following results are collapsed over both problem types.

Figure 2B shows the information search behavior of the participants. Descriptively, it matches our predictions. The repeated-play condition elicited higher total sample sizes as well as longer evaluation intervals for the individual options (samples per transition: average number of samples taken per transition in the sampling sequence). However, only the contrast for total number of samples reaches statistical significance (total:  $t_{32.9}=2.28$ ,  $p=.029$ ; per transition:  $t_{31.8}=1.58$ ,  $p=.124$ ). Again the neutral condition closely resembled the single-play condition in both sampling variables (total:  $t_{49.1}=.52$ ,  $p=.609$ ; per transition:  $t_{52.1}=.85$ ,  $p=.40$ ), but was at least in terms of total sample size marginally different from the repeated-play situation (total:  $t_{37.9}=-1.85$ ,  $p=.072$ ; per transition:  $t_{34}=-1.07$ ,  $p=.29$ ).

So far we have shown that the payoff structure independently affected choice and information search in the predicted direction. However, we generally predicted that information search and choice behavior were likewise affected by the induction of a repeated play situation in that it was expected to elicit both a higher preference for the long run winner as well as higher total and per transition sample sizes. To demonstrate this, two additional analyses have to be carried out. First, it has to be shown that the contrast for H preference is not entirely caused by a sampling bias. Hertwig et al. (2004) showed how small sample sizes can systematically obscure rare outcomes in decisions from experience. When rare outcomes are obscured, the option that secures winning most of the time can also appear as the option with the

higher long run expectation. Second, an association between the choice preferences and the sampling behavior needs to be established. Therefore we tested if this pattern of results holds when the qualities of winning most of the time – represented by the higher median – and higher long run expectation – represented by the higher mean – do not coincide in respect to actually observed outcomes. Then we evaluate if the preference for the higher mean option is associated with the sampling behavior.

Figure 3 shows the proportions of choices that were consistent with the higher experienced mean. The separate lines distinguish cases where the experienced median and mean predict the same (dotted lines) or different (solid lines) choices. Focusing on the cases where the mean and median do not fall together, it is apparent that participants in the repeated play situation opted more often for the option with the higher experienced mean as compared to the single play situation ( $t_{49.1}=2.72$ ,  $p=.001$ ). Thus, the differences in choices do appear to be associated with different decision strategies and not simply differences in observed outcomes. The neutral condition again matches the single ( $t_{48.3}=.12$ ,  $p=.90$ ) but not the repeated play condition ( $t_{48.8}=-2.26$ ,  $p=.028$ ). Overall, the observed differences are all the more convincing given the pattern of results for cases where the experienced mean and median fall together. Independent of the payoff condition we observed strong preferences for the option with the higher experienced mean pointing towards very systematic

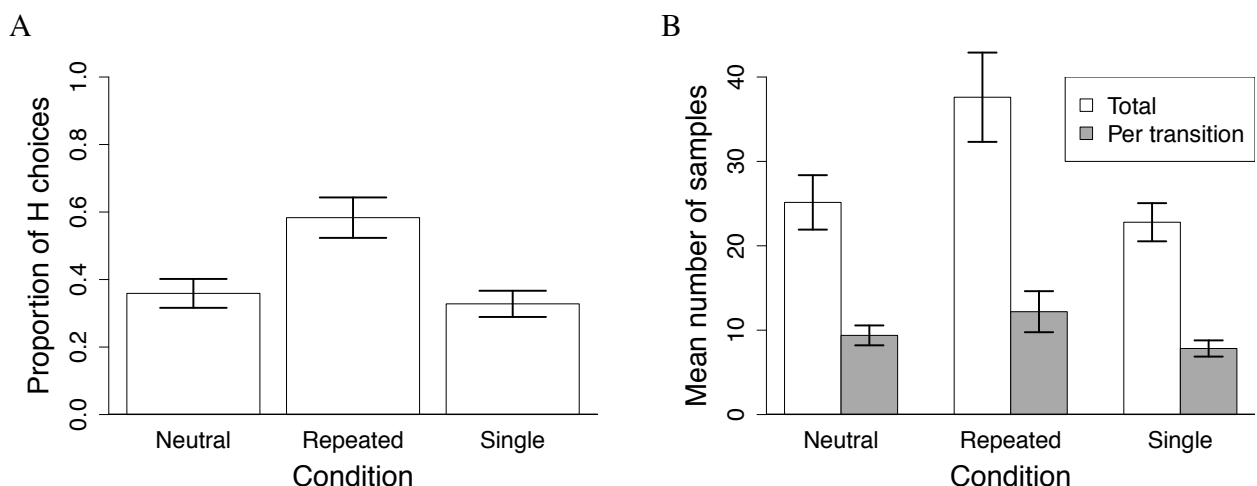

Figure 2: (A) Proportion of H choices as a function of the experimental condition. (B) Mean number samples in total and per transition in the sampling sequence as a function of the condition. Error bars represent standard error of the mean.

Figure 3: Higher mean choices as a function of the experimental condition.

behavior.

Now, is the shift in strategy use for the repeated play condition associated with changes in the sampling behavior? In line with our predictions we found this to be the case. Regressing higher mean choices on sample size and the group contrast of single and repeated play situations yields a significant interaction ( $t_{52} = -2.73$ ,  $p = .009$ ), while the main effect of the contrast vanishes ( $t_{52} = .54$ ,  $p = .59$ ). The same pattern was found for samples per transition (interaction:  $t_{52} = -2.36$ ,  $p = .022$ ; contrast:  $t_{52} = -0.33$ ,  $p = .746$ ). It was not possible to determine which of these sampling variables were more strongly associated with the strategy use because they were highly correlated ( $r = .83$ ). In sum, we thus were able to show, that the repeated play condition influenced both choice preference and sampling behavior.

## Discussion

The primary aim of our study was to use experience-based decisions to investigate information search and decision making over repeated and single plays. Based on prior findings of Hills & Hertwig (2010) we predicted that the situations of repeated and single plays would elicit information search behavior that has been found to be associated with short and long-term maximization, respectively. Our results confirm this prediction. Participants in the situation of repeated plays – particularly those that sampled more avidly and switched

less frequently between the options – exhibited higher preferences for the superior option in the long run. These results did not appear to be mediated by a simple sampling bias (Hertwig et al., 2004; Fox & Hadar, 2006). Rather, they were associated with different decision strategies.

We believe that our findings provide new evidence for the theoretical debate on single and repeated-play decisions. So far behavioral studies that separated these situations have focused entirely on decision outcomes. We extend this literature by showing that differences can also be demonstrated on more process-oriented measures such as information search. Our results imply that possibly more is changing over the situations of single and repeated play than the weighting of probabilities and outcomes (Aloysius, 2007), as suggested by unitary theoretical accounts, e.g. prospect theory (Kahneman & Tversky, 1979). We suggest that an overall different cognitive approach towards repeated plays is applied. These results appear to be consistent with theoretical accounts such as Lola Lopes' (1996, 1999) two-stage model.

Our findings also hold important insights for the literature on experienced-based decision making. On all of our measures, the standard payoff procedure resulted in behavior that resembled the condition where the single-play character was strongly emphasized. This might not appear surprising as in both cases only single draws were taken out of the chosen option. However, in the standard realization all decisions contribute to the overall payoff. Thus, the whole set of choices could be mentally combined (see Read, Loewenstein, & Rabin, 1999) and thereby the set of problems could more resemble a repeated play situation. In this context our findings suggest that under the standard paradigm of decisions from experience, all choices are evaluated independently. This finding might contribute in the explanation of the description-experience gap.

In conclusion, we find that single and repeated play situations impact more than just choice preferences. The way people search for information and specific decision strategies change as well. Our findings emphasize the distinction between long-term and short-term maximizing behavior in human decision-making - a distinction that is long established in the literature on animal foraging.

## Abstract

Self-to-object spatial relations are generally considered to be transient and supported primarily by perceptual processes. The present study investigates whether people can acquire stable self-to-object spatial relations that are not disrupted by disorientation. Participants either simultaneously or sequentially viewed the object locations from a learning position amidst a geometrically irregular array. Next they were blindfolded and pointed to the objects under three conditions: before turning (baseline), after rotating 240° (updating), and after disorientation (disorientation). Finally, all participants were taken to another room to perform judgments of relative direction (JRDs) among remembered object locations. The internal consistency of pointing among objects was disrupted by disorientation following simultaneous viewing but not sequential viewing. However, participants' memories of object-to-object relations were equivalent in the two viewing conditions. Together, these results suggest that people construct stable self-to-object spatial relations when they sequentially view each object of the irregular layout.

**Keywords:** self-to-object spatial relations; sequential learning; disorientation

## Introduction

In everyday life, people use self-to-object (egocentric) and object-to-object (allocentric) spatial relations to encode the location of objects or landmarks in the environment, navigate effectively to significant places, and reorient themselves when getting lost. In a self-to-object reference system, locations are represented with respect to the particular perspective of a perceiver, whereas in an object-to-object reference system, locations are represented within a framework external to the holder of the representation and independent of his or her position e.g., Easton & Sholl, 1995; Klatzky, 1998).

Generally, it is believed that self-to-object spatial relations are transient and supported primarily by the perceptual processes, and that object-to-object spatial relations are stable and can be preserved in the memory system (e.g., Burgess, 2006; Holmes & Sholl, 2005; Mou, McNamara, Valiquette, & Rump, 2004). When moving around the environment, if people navigate by means of the self-to-object spatial relations, one has to add a common vector to each individual target vector to compute the new egocentric coordinates of the target locations. If this updating process is disrupted through procedures that induce

a state of disorientation, the coherence of relative locations among different targets is reduced. Therefore, a disoriented participant's pointing response will show an inconsistency among different targets (disorientation effect). To the contrary, if people navigate by means of the object-to-object spatial relations, which remains the same regardless of people's movements, the state of disorientation cannot reduce the coherence of relative locations among different targets. Therefore, the consistency of the pointing response among different targets will be equal between oriented and disoriented participants (absence of disorientation effect). By measuring the standard deviation across target objects of the mean signed pointing errors (configuration error), the accuracy of the localization of each target in relation to the others can be assessed. Following this logic, recent research has indicated that people can navigate by means of either the transient self-to-object or stable object-to-object spatial representations (Holmes & Sholl, 2005; Mou, McNamara, Rump, & Xiao, 2006; Sargent, Dopkins, Philbeck, & Modarres, 2008; Waller & Hodgson, 2006; Wang & Spelke, 2000). In most situations, people acquire both self-to-object and object-to-object spatial representations, and can navigate by means of one of them according to the layout geometry or instruction (Xiao, Mou, & McNamara, 2009).

However, in all the previous research, which indicated that people were able to navigate by means of transient self-to-object spatial representations, the pointing responses of disoriented participants still had a relatively high consistency among different targets. The configuration errors in the disorientation condition were no more than 30°, which were much less than the expected configuration error of randomly pointing (approaching 104°). It is possible that disorientation does not totally disrupt the self-to-object spatial representations, and that the disoriented participants can still locate objects based on the impaired self-to-object spatial representations that persist in their memory. One of our recent experiments provided circumstantial evidence for this hypothesis (Xiao, et al., 2009). After visually learning object locations amidst, or at the periphery of an irregular array (see Figure 1), blindfolded participants pointed to the objects before turning (baseline), after rotating 240° (updating), and after disorientation (disorientation). In both learning conditions, the configuration error significantly increased after disorientation, indicating that the participants located objects by means of the self-to-object spatial relations. When explicitly instructed to use the object-to-

object spatial relations (e.g., “Please keep track of all of the locations of the objects relative to other objects while you are turning to face the ball.”), after the baseline pointing test and before rotation, the participants who learned at the periphery of the irregular array could follow the instruction to prevent the disorientation effect, while the participants who learned amidst the irregular array could not follow the instruction to prevent the disorientation effect. These results suggest that after visually learning object locations at the periphery of the irregular array, the participants established both self-to-object and object-to-object spatial relations, but updated self-to-object spatial relations during rotation by default. They could also update object-to-object spatial relations when required. However, after visually learning the object locations amidst an irregular array, the participants can only establish the self-to-object spatial relations. They may only represent minimally, if at all, object-to-object spatial relations, which cannot be used during rotation. Therefore, there is little possibility that the participants used the object-to-object spatial relations after disorientation. The disoriented participants can only locate objects by means of the self-to-object rather than the object-to-object spatial relations, suggesting that the self-to-object spatial relations are preserved, to some extent, over disorientation in memory.

In the object-to-object spatial relations, object locations are represented with respect to another object or set of objects, while in the self-to-object spatial relations object locations are represented with respect to the perceiver (e.g., Easton & Sholl, 1995; Klatzky, 1998; Mou, Xiao, & McNamara, 2008). If the perceiver takes him or herself as a stable object, and refers every other object location relative to him or herself, a special kind of object-to-object spatial representation is built, and can be well preserved in memory as another kind of object-to-object spatial representation. In other words, the perceiver establishes a stable self-to-object spatial representation. After disorientation, the perceiver can recover object locations by retrieving the remembered self-to-object spatial information. In Xiao et al. (2009), the participants visually learned object locations amidst the irregular array, where they could not perceive the whole layout from a single viewpoint. However, participants could directly view inter-object spatial relations between objects separated by small angular distances, and thus fragmentary object-to-object spatial representations might be acquired (Sargent, Dopkins, Philbeck, & Chichka, 2010). Attending to and memorizing neighboring object-to-object spatial relations might interfere with the acquisition of self-to-object spatial relations. Therefore, participants might develop unstable self-to-object spatial representations after they visually learned amidst the irregular array. There is a high possibility that participants will construct more stable self-to-object spatial representations through the new learning methods, by which they can only directly perceive the self-to-object spatial relations but not the inter-object ones, such as through sequential learning. Previous research has demonstrated that participants can learn spatial locations

by viewing one object at a time (e.g., Yamamoto & Shelton, 2007, 2009). Compared with visually learning object locations amidst the array, sequentially viewing each object prevents participants from directly perceiving any inter-object relations, but compels them to focus on each object’s location relative to themselves. Therefore, the acquisition of object-to-object spatial representations is maximally reduced and the salience of self-to-object spatial relations is enhanced, and the participants may develop stable self-to-object spatial representations and minimal object-to-object spatial relations.

In the present study, participants either sequentially or simultaneously viewed object locations from a learning position amidst the same irregular layout as in Xiao et al. (2009). After learning, all participants were blindfolded and pointed to object locations in baseline, updating, and disorientation conditions. Before rotating to a new heading in the updating condition, half of the participants were explicitly instructed to use object-to-object spatial relations during locomotion as in Xiao et al. (2009). At last, all participants were taken to another room to perform judgments of relative direction (JRDs), which have been commonly used to assess the memory of the object-to-object relations in an environment (e.g., Mou, et al., 2004; Shelton & McNamara, 2001; Waller & Hodgson, 2006). Because we hypothesized that participants would use self-to-object spatial relations to locate objects before and after disorientation when learning amidst the irregular layout, and that the participants would establish more stable self-to-object spatial relations following sequential viewing than by following simultaneous viewing, we expected that the configuration error in sequential viewing condition would be smaller than that in the simultaneous viewing condition, and that the disorientation effect would be absent in the sequential viewing condition but present in the simultaneous viewing condition. Meanwhile, since we hypothesized that the participants would establish minimal object-to-object spatial relations in both the simultaneous and sequential viewing condition, we expected that the participants could not use the object-to-object spatial relations during locomotion and after disorientation. As in Xiao et al. (2009), the participants could not follow the object-to-object instruction to prevent the disorientation effect after simultaneous learning of the layout. Because we predicted that the participants would use the stable self-to-object spatial relations after sequentially learning the layout, we expected that there will be no disorientation effect in both the object-to-object instruction and the non-instruction group. Because the participants established minimal object-to-object spatial relations, a floor effect might be present, and the performance on JRDs in the sequential learning group might be equivalent or inferior to that in the simultaneous learning group.

## Method

### Participants

Thirty-two university students (16 men and 16 women) participated in this experiment in return for monetary compensation.

### Materials

The irregular layout of Xiao et al. (2009) was used in this experiment. As illustrated in Figure 1, nine objects were presented on the floor in a cylinder that was located in an experiment room. The cylinder was 3.0 m in diameter, made by black fabric and reinforced cloth. Objects were chosen with the restrictions that they were visually distinct, fit with approximately 0.3 m on each side, were familiar to people, and shared no obvious semantic association. The scissors, the hat, and the brush were placed in a line. Participants were standing 1 meter away from the brush, facing the scissors. The floor was covered with gray carpet. Four lights were placed on the ceiling near the side of the cylinder to illuminate the area. They were placed at equal intervals and at equal distance from the center of the cylinder to minimize directional illumination cues.

Figure 1: Layout of objects used in the study.

Test trials were presented by a computer via wireless earphone. A joystick was used as the pointing apparatus.

### Procedures and Design

Before entering the study room, each participant was instructed to learn the location of objects for a spatial memory test and trained in how to use a joystick. After that, the objects that would be encountered in the experiment layout were presented individually to all participants and the name of each object was given. Then, the blindfolded participants were escorted to the study room and led to the learning position by the experimenter. The participant was then asked to remove the blindfold.

**Simultaneous Viewing** All nine objects were presented on the floor. Half of the participants viewed the layout for 30 s and then closed their eyes and named and pointed to each

object with one of their fingers. Throughout the learning phase, the participants were stationary at the learning position. They were allowed to turn their heads to review the layout but were required to maintain their body orientation.

**Sequential Viewing** The other half of the participants viewed each object presented alone for 3 s in a spatially random sequence. To control the viewing time, the participant was asked to close his/her eyes while the experimenter replaced the just-viewed object on the floor with a new object in a new location. After viewing the last object, the participant was asked to close his/her eyes and to name and point to each object with one of their fingers. The learning sequence of the objects was randomized.

In both learning conditions, the learning-pointing session was repeated until participants could fluently name and point to the correct object locations twice in a row. (Fluency and accuracy were determined by the experimenter's visual inspection of the pointing performance.) The number of repetitions needed to achieve the learning criterion was recorded. During training and learning, the participants were not aware of what particular tasks they would perform in the testing stage.

**Egocentric Pointing Tasks** After learning the layout, all of the participants put on the wireless earphone, and held the joystick against their front waist. All of the participants were blindfolded and tested in the order of the baseline, updating, and disorientation conditions. In the baseline condition, participants maintained their heading to the scissors. In the updating condition, participants rotated 240° by themselves (e.g., "Please turn right until you are facing the candle"). Half of the participants turned right to face the candle, and half turned left to face the ball. Within each group, immediately before rotation, half of the participants were explicitly instructed to use object-to-object spatial relations during rotation (e.g., "Please keep track of all of the locations of the objects relative to other objects while you are turning to face the candle"). The other half were not given this instruction. In the disorientation condition, the participants rotated in place for 1 minute. Then they pointed to the location of an object named by the experimenter (e.g., "Please point to the ball"). This rotation and pointing procedure was repeated until the absolute pointing error was larger than 90°. Then the participants were instructed to turn to face the ball (or candle) if they faced the candle (or ball) in the updating condition ("Please turn right until you believe you are facing the ball"). They were allowed to adjust their position by themselves if they thought they had drifted off the testing location while rotating. A recovery period was given before the final pointing test.

In each rotation condition, four blocks of trials were included, and each block involved pointing to all nine objects once in a random order. After hearing the warning indication ("Start"), the participants pulled the joystick trigger, and the target object was immediately announced (e.g., "Please point to the candle"). Then the participants used the joystick to point to the direction of the target object.

The *configuration error* was measured as in Xiao et al. (see Table 1), which defined as the standard deviation of the means per target object of the signed pointing errors, which indicated the internal consistency of pointing response among different targets. As pointing data is inherently circular data, circular statistics (e.g., Jammalamadaka & SenGupta, 2001) were used.

Table 1: Definitional Formulas for Dependent Variables

Variable	Formula
Signed pointing error for object $i$ on trial $j$	$e_{ij} = \text{judged direction} - \text{actual direction}$
Mean signed pointing error for object $i$	$\bar{e}_i = \frac{\sum_j e_{ij}}{T}$
Configuration error	$\sqrt{\frac{\sum_i \left( \bar{e}_i - \frac{\sum_i \bar{e}_i}{N} \right)^2}{N-1}}$

Note:  $T$  = number of pointing trials per object;  
 $N$  = number of target objects.

**JRDs Task** After finishing the egocentric pointing tasks, the blindfolded participants were escorted to another room to perform JRDs. They were allowed to remove the blindfold and take a short break before proceeding to the JRDs. The participants first initiated each trial by pressing a button of the joystick. Trials began with the imagined standing location and facing object given aurally (e.g., “Imagine you are at the mug facing the ball”). After having a clear mental image of where he or she was standing and what he or she was facing, participants pulled the joystick trigger, and the target object was immediately presented (e.g., “Please point to the scissors.”). Then the participants used the joystick to point to where the target would be if he or she occupied the standing location and facing the direction as presented. The participants were instructed to hold the joystick exactly in the front of his or her waist and to keep the joystick forward when he or she pointed.

The JRDs test included 8 imagined headings. To facilitate exposition, we arbitrarily labeled headings counterclockwise from  $0^\circ$  to  $315^\circ$  in  $45^\circ$  steps. The learning direction was defined as  $0^\circ$ . Because the geometry of the layout was irregular, there were little pairs of objects established the imagined heading parallel to above 8 directions. Therefore, the imagined heading established by any pair of objects varied within  $\pm 15^\circ$  (that is,  $0^\circ \pm 15^\circ$ ,  $45^\circ \pm 15^\circ$ ,  $90^\circ \pm 15^\circ$ ,  $135^\circ \pm 15^\circ$ ,  $180^\circ \pm 15^\circ$ ,  $225^\circ \pm 15^\circ$ ,  $270^\circ \pm 15^\circ$ , and  $315^\circ \pm 15^\circ$ ) was included in the 8 imagined headings (e.g., at the candle facing the mug established the imagined heading  $1.56^\circ$ , and were taken as the imagined heading  $0^\circ$ ). The participants were given a total of 48 trials, six trials at each

of eight imagined headings. The dependent measures were the angular error of the pointing response, measured as the absolute angular difference between the judged pointing direction and the actual direction of the target.

In both egocentric pointing and JRDs tasks, pointing accuracy but not speedy response was emphasized.

## Results

### Egocentric pointing

Configuration error on egocentric pointing were subjected to mixed-model analyses of variance (ANOVAs), with the rotation condition (baseline, updating, and disorientation) as the within subject variable, the viewing type (sequential, simultaneous) and object-to-object instruction (yes, no) as the between subjects variables. The results revealed no main effect or interactions of the object-to-object instruction. Data were therefore collapsed across this factor for subsequent analyses.

Figure 2: Configuration errors in egocentric pointing as a function of rotation condition and viewing type. Error bars are confidence intervals corresponding to  $\pm 1$  SEM.

The main effect of the rotation condition was significant,  $F(2, 60) = 13.13$ ,  $p < .001$ ,  $MSE = 24.92$ , the main effect of the viewing type was significant,  $F(1, 30) = 7.83$ ,  $p < .01$ ,  $MSE = 16.88$ , and the interaction of the rotation and the viewing type was significant,  $F(2, 60) = 6.09$ ,  $p < .005$ ,  $MSE = 24.92$ . As shown in Figure 2, three major findings were revealed. First, as in Xiao et al. (2009), the configuration error increased after disorientation when participants simultaneously viewed the layout, which indicated that participants had used the transient self-to-object spatial relations during rotation. This observation was supported statistically by a planned contrast comparing the participants' configuration errors in the updating condition with that in the disorientation condition following simultaneously viewing,  $F(1, 30) = 17.18$ ,  $p < .001$ ,  $MSE =$

59.05. Second, the configuration errors were equivalent before and after disorientation when participants sequentially viewed the layout, which indicated that participants used a kind of stable spatial relations before and after disorientation. This observation was supported statistically by a planned contrast comparing participants' configuration error for the updating condition with that for the disorientation condition following sequential viewing,  $F(1, 30) < 1$ . Third, the configuration errors were indistinguishable for simultaneous and sequential viewing in the baseline and updating conditions, but significantly higher for simultaneous viewing than for sequential viewing in the disorientation condition. These observations were supported statistically by planned contrast comparing participants' configuration errors for simultaneous viewing with those for sequential viewing at each rotation condition. There were no differences in the baseline and updating conditions,  $F_s(1, 30) \leq 1.39$ ,  $p_s \geq .24$ , but there was a significant difference in the disorientation condition,  $F(1, 30) = 15.01$ ,  $p < .001$ ,  $MSE = 43.69$ .

### JRDs

Performance data on JRDs were subjected to mixed-model analyses of variance (ANOVAs), with the imagined heading ( $0^\circ$  to  $315^\circ$  in  $45^\circ$  steps) as the within subject variable, viewing type (sequential, simultaneous) and object-to-object instruction (yes, no) as the between subjects variables.

Figure 3: Mean absolute angular errors in JRDs as a function of imagined heading and viewing type. Error bars are confidence intervals corresponding to  $\pm 1$  SEM.

Three major findings were revealed. First, as shown in Figure 3, the participants' performance on JRDs was indistinguishable for simultaneous viewing and sequential viewing, which indicated that participants had constructed object-to-object spatial representations of equivalent fidelity through simultaneous viewing and sequential viewing. This observation was supported statistically by no main effect or

interactions of the viewing type,  $F_s \leq 1.36$ ,  $p_s \geq .25$ . Second, the participants' performance on JRDs was sensitive to the imagined headings, as supported statistically by the significant main effect of the imagined heading,  $F(7, 210) = 3.75$ ,  $p < .001$ ,  $MSE = 147.10$ . Third, the instruction before the updating condition affected the participants' performance on JRDs. The performances on JRDs were more accurate for the participants following object-to-object updating instruction than those following no instruction. This observation was supported statistically by the main effect of instruction,  $F(1, 28) = 5.30$ ,  $p < .05$ ,  $MSE = 727.92$ . The interaction between the imagined heading and instruction was marginally significant,  $F(7, 196) = 1.93$ ,  $p = .067$ ,  $MSE = 147.10$ . The simple effect of instruction was significant within the headings of  $135^\circ$ ,  $180^\circ$ , and  $225^\circ$ ,  $F_s(1, 28) > 4.93$ ,  $p_s < .05$ , but not significant within the headings of  $0^\circ$ ,  $45^\circ$ ,  $90^\circ$ ,  $270^\circ$ ,  $315^\circ$ ,  $F_s(1, 28) < 2.21$ ,  $p_s > .14$ .

### Discussion

The absence of the disorientation effect has been interpreted as evidence that object-to-object spatial relations have been used during rotation (Holmes & Sholl, 2005; Mou, et al., 2006; Sargent, et al., 2008; Xiao, et al., 2009). However, in the present study, the absence of the disorientation effect following sequential viewing can unlikely be explained by using the object-to-object spatial relations. The participants' performance on JRDs was equivalent across sequential and simultaneous viewing, suggesting that the participants established equivalent object-to-object spatial relations among each viewing group. If the object-to-object spatial relations could be used in one viewing group, there is little possible that the object-to-object spatial relations could not be used in another group. If the participants in the sequential viewing condition used the object-to-object spatial relations to prevent the disorientation effect, the participants in the simultaneous viewing condition should also be able to use them to prevent the disorientation effect. However, in the simultaneous viewing condition, the disorientation effect consistently appeared, even when the participants were explicitly required to use the object-to-object relations during rotation. This result is consistent with Xiao et al. (2009), indicating that the participants could not have used the object-to-object but rather used self-to-object spatial relations to perform egocentric pointing during rotation and after disorientation. Therefore, it is unlikely that the participants could have used the object-to-object spatial relations to perform egocentric pointing in the disorientation condition following sequential viewing. The absence of the disorientation effect following sequential viewing can only be explained by using the stable self-to-object spatial relations.

As the transient self-to-object spatial representation, the stable self-to-object spatial representation may make use of a special polar coordinate system in which the origin is at the participant and the reference direction is participant's front. Object locations are specified by egocentric distance

and egocentric bearing. During locomotion, the sensory-perceptual input enables the participant to update multiple self-to-object spatial relations. Although the procedures that induce a state of disorientation will disrupt this updating process, and the coherence of relative locations among different targets will plummet if the participant still relies on the sensory-perceptual system; the participant could recover object locations by retrieving the remembered angular and distance information from the learning view. If the test heading misaligned with the learning view, a mental rotation process would be involved to align the remembered self-to-object spatial representation with respect to the test heading. This retrieving process is similar to retrieving object-to-object spatial representations (Mou, Fan, McNamara, & Owen, 2008; Mou, Xiao, et al., 2008). At this point, the differences between object-to-object and stable self-to-object spatial representations become less dramatic, because both representations could be preserved in memory and be retrieved from a novel heading after disorientation. However, unlike the object-to-object spatial relations, it is difficult to use the stable self-to-object spatial relations to judge inter-object spatial relations. Because every single object is represented with respect to the self, the participants have to compute an inter-object spatial relation, and this computation process will introduce error (Klatzky, 1998). Therefore, in present study, the participants in the sequential learning condition could use the stable self-to-object spatial relations to avoid disorientation effect, but could not use them to improve their JRDs performance. Their performance on JRDs was not superior to the simultaneous viewing condition.

In summary, the present research indicates that by sequentially viewing every object location from a learning position, the participants constructed stable self-to-object spatial relations which could be preserved over disorientation. These results suggest that self-to-object spatial relations are not only transient and supported primarily by perceptual systems, but can also be stable and preserved in memory.

## Abstract

The authors employ behavioral theories of human motivation and affect and present an explanation for why some computer-mediated collaborative learning is satisfying for a user. In a longitudinal experiment, participants were divided into four groups and solved two open-ended problems together using a video-conference system. Traditional metrics of usability and product acceptance were examined with respect to psychological variables such as personality, background knowledge, and feelings toward group members (mutual affect). The results show that group-level mutual affect is a strong predictor of system acceptability judgments, even after controlling for other pragmatic variables such as opinion convergence. It is proposed that evaluating one's experience with a computer-mediated collaborative system is a sensemaking process and that the variables that modulate this process also influence subjective judgments of usability and acceptability of a system.

**Keywords:** User satisfaction, user experience, mutual affect

Cultivating positive emotions among collaborators is essential for the success of groupware applications because shared positive affects promote group coordination, common ground, and group awareness—key ingredients for successful online collaboration (Carroll et al., 2006). But what design features are critical to generate positive mutual affects? Do mutual affects influence user experience primarily by elevating pragmatic qualities of group interaction, such as group communication and coordination?

To help improve computer-mediated collaborative learning (e.g., learning collaboratively via video conferencing), researchers have identified important variables, such as group awareness, common ground, shared visual information and teamwork coordination (Carroll et al., 2006). However, to make a “good” collaborative learning system, these pragmatic variables should be supplanted; the product should be not only useful but also *engaging* and *satisfying* for the users (Hassenzahl & Tractinsky, 2006; Norman, 2004). But to make an engaging and satisfying product, it is crucial to know how users come to evaluate their experiences with a collaborative system.

Conceptual frameworks such as information processing, affordance, and cognitive architecture have generated testable hypotheses and guidelines instrumental for single-user product design. However, these pragmatic variables are not entirely feasible in collaborative settings because of

added complexity inherent in group interaction (Grudin, 1994).

Here, we propose a conjecture that psychological models of sensemaking can provide a useful framework for user experience in a groupware setting much in the same way that affordance and cognitive architecture helped the evolution of single-user interfaces. We argue that the evaluation of one's experience is basically a sensemaking process, and the variables that intervene this process influence “user experience.”

To test our framework, we developed an experimental study, where 29 college students were divided into four groups and solved two problems together in a 2-month period using a video-conference system. We examined subjective metrics of usability and product acceptance with respect to other psychological variables such as personality, background knowledge and group-coherence. The results showed that a positive mutual affect among group members led to increased product acceptance, even after controlling for other pragmatic variables such as opinion convergence and communication effectiveness.

## User Experience as a Sensemaking Process

Klein et al. (2006) and Pirolli and Card (2005) provide models of sensemaking. The two models differ in specifics but share some basic properties. Sensemaking consists of dynamic processes of data selection and frame/schema revision. Relevant data are selected according to one's frame (prior knowledge/beliefs/mindsets), the data are interpreted and the frame is revised according to the interpretation. Sensemaking goes through cycles of this data selection/interpretation and frame/schema revision loop. Our central hypothesis is that user experience is a sensemaking process. “Experience” does not come to people unambiguously. Experience is selected, sensed, represented, and interpreted by people (Pirolli & Card, 2005). In this process, affects play critical roles as affect seeps into the evaluation of the data.

**Group-level Mutual Affect** The importance of affect in product design is well known, but affect in human-computer interaction has pertained to a specific product. We think that group-level mutual affect (e.g., feeling of closeness of group members) can also be an important factor because affects are contagious and affects coming from unrelated sources can be easily fused into the evaluation of a product.

Much research has shown that relatively simple manipulations of inducing a positive affect, such as viewing a comedy film for a few minutes or writing about happy events, influence subsequent decision making of unrelated objects (Clore & Huntsinger, 2007). Schwarz and Clore (1983) present one of the most stunning demonstrations of affect contamination. In their experiment, the researchers interviewed subjects about their general happiness with their lives. Subjects were selected randomly and telephone-interviews were conducted on either a sunny day or a rainy day. Those who had an interview on a sunny day gave higher happiness ratings than those who had an interview on a rainy day. When the link between mood and weather was made clear to subjects, the ratings made on the rainy day went up, indicating that subjects' ratings about happiness were partly due to their erroneous generalization of their unhappy mood on the rainy day.

A similar misattribution is likely to happen in the judgment of usability and acceptability. Usability and acceptability of a product will be judged by pragmatic, hedonic, and aesthetic features of the product (Hassenzahl & Tractinsky, 2006). However, in making an actual judgment, a user will *interpret* his/her memories of experience. In this process, affective experience with group members can contaminate their evaluation (Clore & Huntsinger, 2007).

In the experiment described below, we examined the extent to which mutual affects formed among collaborators influence their usability and acceptability judgments of a video-conference system.

## Experiment

In our 2-month-long experimental study, four groups of participants (seven to eight participants per group) met eight times using MeetingPlaza, a multi-party Web conferencing and collaboration system (<http://www.meetingplaza.com>); each group worked together to solve two different open-ended problems (i.e., how to improve the university and recommendations for freshman job search) [15], and wrote two one-page white paper proposals together as a group using MeetingPlaza.

MeetingPlaza has web-, file-, whiteboard- and application-sharing functions that facilitate collaborative communication. For example, the web-share function allows participants in different locations to view the same web site on their own computers at the same time. The file-sharing and application-sharing functions help people in remote locations to view and manipulate the same file together (e.g., an MS Word file). The participants were encouraged to write papers together using these sharing functions.

**Hypothesis.** On the basis of the theoretical background discussed previously, we formed the following hypothesis. Group-level mutual affect (e.g., feelings of closeness toward group members) influences subjective judgments of system usability and acceptability. In particular, those who have high positive group-level affect should give high acceptability and usability ratings even when other group-

level variables such as opinion convergence and communication effectiveness are controlled for.

Figure 1. MeetingPlaza.

conference system, as a user makes a system evaluation based on his/her memory of the experience with a product. Thus, positive mutual affect will be translated into positive product evaluation.

**Participants.** Thirty-two participants were recruited from the Texas A&M University community. They were assigned randomly to four groups. Three participants chose not to take part in the experiment after the first meeting. Thus, a total of 29 participants completed the two problem solving sessions (Table 1). Participants received a payment of \$144 (\$12 per hour for a total of 12 hours for their involvement). Bonus payments of \$24–\$48 were made to group members who produced the best and second-best white papers. In a separate experiment, 47 undergraduate students were recruited from the university psychology subject pool for the evaluation of the white papers submitted by the four groups.

Average age	21.1	
Note. Three participants dropped after the first meeting and the data from 29 participants were analyzed.		

*Note.* The participants received a payment of \$144. Bonus payments of \$24–\$48 were made to group members who produced the best and second-best white papers.

**Materials.** We employed five questionnaires to assess participants' mindsets (implicit beliefs on intelligence, morality and world), personality (neuroticism, extraversion and psychoticism), technological literacy (computer-literacy and Internet-literacy), and expectations (expected ease of use and expected usefulness of the product). These questionnaires, which were given at the orientation meeting, were adopted to isolate the effect of group-level mutual affect as much as possible.

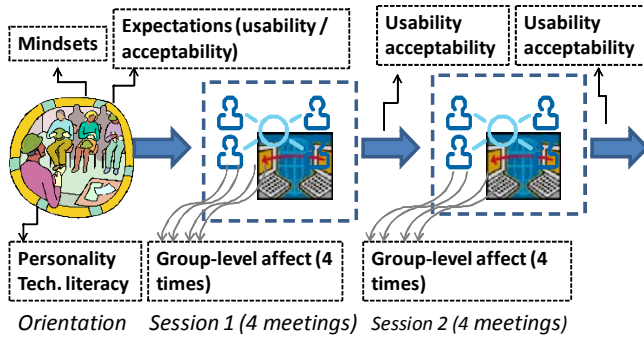

Figure 2. The logistics of the experiment.

Group-level coherence (affect, communication and opinion) was measured by electronic questionnaires given at the end of each meeting. Participants' subjective judgments of system usability and acceptability were collected three times in a two-month period, before using the system (at the orientation meeting), in the middle of using the system (after the fourth meeting), and at the end of the experiment (after the eighth meeting) (Figure 2). Participants' subjective judgments of system usability and acceptability were collected three times in a two-month period, before using the system (at the orientation meeting), in the middle of using the system (after the fourth meeting), and at the end of the experiment (after the eighth meeting) (Figure 2).

Below we explain the questionnaires used in the experiment.

**Implicit belief.** The implicit belief questionnaire assesses the extent to which people conceptualize intelligence, morality, or the world as a dynamic or fixed construct (Dweck, 1999). This questionnaire was included because people's implicit beliefs are known to influence their goal setting and learning experience.

**Personality.** Francis et al. (1992) developed an abbreviated version of the Eysenck personality questionnaire (EPQR), which has four dimensions (extraversion, neuroticism, psychoticism, and lie scale) with six questions each. The questionnaire assesses personality of a person with three dimensions, extraversion (high-low tendency to seek external stimulation), neuroticism (high-low level of negative affect), and psychoticism (high-low level of impulsiveness). Following the suggestion by Francis et al. (1992) we did not analyze lie-scale scores in the present experiment.

**Technology literacy.** The technology literacy questionnaire was developed for this experiment based on the digital literacy questionnaire by Hargittai (2009). Our questionnaire consists of two categories, computer literacy and Internet literacy, and a total of 10 questions. The computer literacy measure has four items related to knowledge about software (e.g., PowerPoint) and programming language (e.g., Java). Internet literacy consists of six items related to common Internet-based activities (e.g., tweeting or on-line shopping).

**Expected ease of use and expected usefulness of the product.** We modified Davis's Technology Acceptance

Model (TAM) (Davis, 1989) and developed questionnaires assessing expected ease of use and expected usefulness of the product (six questions for each). We included the term "expected" because our questionnaires were given shortly after MeetingPlaza was introduced to the participants but before they actually used the system.

**Usability.** We employed Lewis's Computer System Usability Questionnaire (CSUQ; 19 questions) (Lewis, 1995). The CSUQ consists of three factors, system usefulness, information quality, and interface quality. The pre-usability questionnaire was given at the orientation meeting shortly after participants were introduced to the system but before using the system. The post-usability questionnaire was given twice at the end of session 1 and at the very end of the experiment.

**Acceptability.** To measure participants' behavioral intention of adopting the video-conference system, we created 10 acceptability questions based on Davis et al., (1989) and Venkatesh and Morris (2003). These questions assessed participants' intention to continue to use MeetingPlaza if the system were made available to them.

**Group-level coherence.** We measured group-level coherence of individual members with three dimensions, mutual affect (e.g., how close do you feel with each member of your group?), opinion convergence (e.g., how close was your opinion with that of each member of your group?), and communication effectiveness (e.g., how effectively did you communicate with each member of your group?). Every participant rated how he/she felt about each group member at the end of every group meeting (a total of eight meetings), the ratings he/she gave to all group members were averaged over affect, communication effectiveness and opinion convergence dimensions, and these average values were treated as his/her group-level affect, communication effectiveness and opinion convergence (Strauss, 1997).

**Procedure.** The experiment consisted of four segments: orientation, session 1, session 2, and paper evaluation. Below, we describe the segments in chronological order (Figure 3).

**Orientation.** The orientation meeting was held in a large classroom. First, participants indicated their implicit beliefs, personality and technology literacy, and then the experimenter introduced MeetingPlaza. At this stage, participants were allowed to view MeetingPlaza, but they were not allowed to use the system. After this brief instruction, participants indicated their expected ease of use and expected usefulness of MeetingPlaza, along with their expected usability of the product (pre-usability) and their intention of using the product in the future (acceptability).

**Sessions 1 & 2.** Approximately 1 week after the orientation meeting, participants were assigned to four groups, and each group had its first on-line meeting using MeetingPlaza. In this segment, participants received extended instruction and demonstrations of MeetingPlaza functions and tested MeetingPlaza by themselves. Each group met twice a week, and discussed solutions for the assigned problems using MeetingPlaza. In one session,

participants as a group were required to write a one-page white paper describing ways to improve the university; in the other session participants as a group were required to write another white paper describing recommendations for job search for college freshmen. Each group was required to submit a paper at the end of the fourth meeting of each session. Each meeting lasted about 1 hour.

Figure 3. Four segments of the experiment

Session 2 was given 1 week after the end of session 1. The procedure of session 2 was identical to that described in session 1.

**Closings 1 & 2.** Two closing meetings, closing 1 and closing 2, were held at the end of sessions 1 and 2, respectively. In closings 1 and 2, participants filled out the usability and product acceptance questionnaires. Closing 2 was the final meeting.

**Paper evaluation.** In a separate experiment, 47 undergraduate students participated in the paper evaluation experiment (male=23, female=23, unknown=1) and rated the eight papers written by the four groups in six categories (creativity, implementation, coherence, effectiveness, cost, and communication) on a 0–100 scale. They were encouraged to rate the papers in the same way a professor grades their papers in a classroom.

## Results

All questionnaire responses were converted to a 0-1 scale such that the direction of the observed scores corresponded to the direction of the psychological dimensions in question. Thus, a high score corresponded to a high degree of the given dimension. This section begins with a summary of questionnaire responses, followed by a description of the longitudinal shifts of usability, product acceptability and group-coherence, and concludes with statistical analyses that examine the relationship between group-coherence and system evaluation.

**User profiles.** The responses on the 10 dimensions of the questionnaires (Figure 4) show that there were no ceiling or floor effects, except for the responses regarding expected ease of use and expected usefulness. This problem will be discussed in the next paragraph and later in the Results section. ANOVAs (analysis of variance) comparing the four groups in each of the ten user profile dimensions showed that the mean profile scores of the four groups were not statistically different:  $F(3, 25) < 2.2$ ,  $p > 0.11$ .

Note. The central mark and the edges of a box are the median and the 25<sup>th</sup> and 75<sup>th</sup> percentiles, respectively. The whiskers are the most extreme data points.

Figure 4. Boxplots for questionnaire responses.

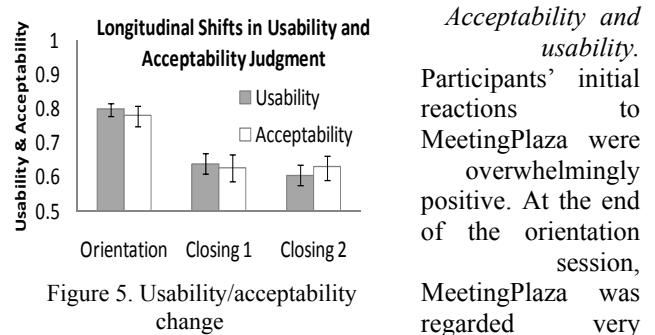

Figure 5. Usability/acceptability change

Participants' initial reactions to MeetingPlaza were overwhelmingly positive. At the end of the orientation session, MeetingPlaza was regarded very favorably (usability,  $M=0.80$ ,  $SD=0.11$ ; acceptability,  $M=0.78$ ,  $SD=0.17$ ; Figure 5). However, the ratings of MeetingPlaza dropped significantly at closing 1 (usability,  $M=0.64$ ,  $SD=0.64$ ; acceptability,  $M=0.63$ ,  $SD=0.21$ ) and closing 2 (usability,  $M=0.61$ ,  $SD=0.18$ ; acceptability,  $M=0.63$ ,  $SD=0.22$ ). Two 3 (sequence: orientation, closing 1, closing 2)  $\times$  4 (group: 1, 2, 3, 4) ANOVAs revealed that this drop occurred uniformly in all groups: usability,  $F(2, 50)=18.61$ ,  $MSE=0.02$ ,  $p<0.01$ ; acceptability,  $F(2, 50)=9.70$ ,  $MSE=0.02$ ,  $p<0.01$ . Neither the main effect of group nor the interaction between sequence and group was observed in both usability and acceptability measures:  $F$ 's  $< 1.5$ ,  $p > 0.24$ . These results suggest that MeetingPlaza created a positive impression on the college-age participants but the excitement dropped considerably once the participants used the product for problem solving, indicating that using the collaborative video-conferencing system was much more challenging than anticipated.

**Longitudinal shifts of group coherence.** The group-coherence scores (mutual affect, opinion convergence, communication effectiveness) all increased as the collaborative sessions progressed (Figure 6). Three sets of linear contrast analyses (shift; beginning, middle, end of the experimental sessions)  $\times$  (group; 1-4) applied to the three group-coherence measures revealed significant linear upward trends: communication effectiveness,  $F(1, 25)=7.72$ ,  $MSE=.01$ ,  $p<0.05$ ; opinion convergence,  $F(1, 25)=26.2$ ,  $MSE=.01$ ,  $p<0.001$ ; mutual affect,  $F(1, 25)=35.8$ ,

MSE=.01,  $p<.001$ , suggesting that our online meetings were indeed effective in developing a sense of common ground, better communication, and positive feelings. There was no interaction effect of group and shift:  $F's<1.0$ .

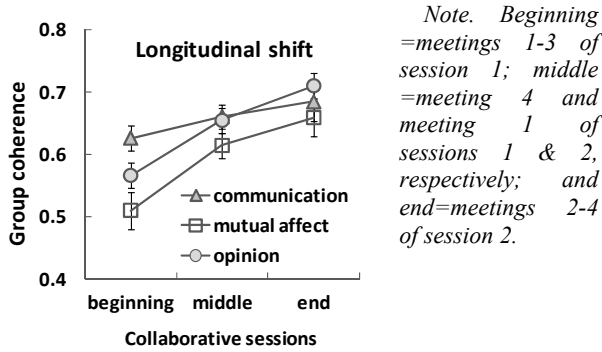

Figure 6. Longitudinal shifts of group coherence

**Evaluation of the hypothesis.** Regression analyses were employed to investigate the link between group-level affect and system evaluation. Both step-wise regression and regular multiple regression were adopted to ameliorate the problem of multicollinearity. In the step-wise regression procedure, the forward selection method was applied with the entry criterion of 0.1 to ensure that all relevant predictors were included in the regression models.

The step-wise regression analyses using group coherence variables suggest that mutual affects influenced system acceptability scores significantly;  $\beta=.52$ ,  $p<0.01$ ,  $R^2=.27$ ; but other group coherence variables—opinion convergence and communication effectiveness—did not influence acceptability scores,  $p>.1$ . The impact of the mutual affect variable remained strong on the system acceptability measure even after controlling for the effects of all other personal variables [mindsets (intelligence, morality, world); personality (neuroticism, extraversion, psychoticism), technology literacy (computer-literacy, Internet-literacy)];  $\beta=.48$ ,  $p=.05$ ; but not the usability scores;  $\beta=.35$ ,  $p=.15$ .

The results from multiple regression analyses were analogous to those found in the step-wise regression analyses. Even after the communicative variables—communication effectiveness and opinion convergence—were forced into the models, the strongest predictors were still mutual affect; the correlation between mutual affect and acceptability was significant after the effects of communication effectiveness and opinion convergence were partialled out ( $r=0.45$ ,  $p<0.05$ ).

**Cohort effects.** The predictor, group-level mutual affect, was evaluated with the data obtained from individual participants. Because MeetingPlaza is a collaboration tool, the impact of this variable should be scrutinized with respect to the properties obtained from each group. For this reason, we employed hierarchical linear regression models and estimated the beta coefficients of the mutual affect variable for each group and investigated if the impact of mutual affects remain robust after controlling for other group-specific properties—the ratio of female and male

participants in each group and the white paper evaluation score that each group received (Table 2).

Table 2. Hierarchical Linear Regression Model

Individual layer:

$$Y_{ij} = \beta_{0j} + \beta_{1j}X_{ij} + u_{ij}$$

Group layer:

$$\beta_{0j} = \gamma_{00} + \gamma_{01}W_j + u_{0j}$$

$$\beta_{1j} = \gamma_{10} + \gamma_{11}W_j + u_{1j}$$

Note. Subscript  $j$  denotes group ID and  $Y_{ij}$  represents the acceptability score obtained from participant  $i$  of group  $j$ .  $\beta_{0j}$  and  $\beta_{1j}$  are intercepts and slopes of the regression line of group  $j$ , respectively.  $u$ 's are error terms.  $\gamma_{00}$  is the overall mean of the acceptability scores and  $\gamma_{10}$  is the mean of the slopes of the four groups.  $W_j$  represents group-specific values (e.g., either the female-male ratio of group  $j$  or the problem solving score of group  $j$ ) and  $\gamma_{11}$  is the coefficient for predictor  $W_j$ .

Note. The problem-solving performance was measured by the average paper evaluation score that each group received in a separate experiment.

Figure 7. 95% high density intervals of  $\beta_{1j}$  estimated for each group

Our hierarchical models had two layers, individual and group (Table 2). The model assumes that the coefficients  $\beta_{1j}$  of mutual affects ( $X_{ij}$ ) vary for each group and are modulated by a group-specific properties (problem-solving scores or female-male ratios). Note that the “group-level mutual affect” variable  $X_{ij}$  was included in the individual layer

because the values of this variable were calculated for individual participants. The values of group-specific variable  $W_j$  (e.g., problem-solving scores or female-male ratios) were calculated for each group, not for each participant. Because we had only four groups, the intervals of  $\beta_{1j}$  were estimated by a Bayesian method where the coefficients ( $\gamma$ ) in the group layer were treated as non-informative hyper-parameters and posterior distributions were obtained by the Markov Chain Monte Carlo algorithm with 1000 iterations (Gelman & Hill, 2007).

The results, which are summarized in Figure 7, suggest that even after the two group-specific properties (female-male ratios and problem-solving scores) were taken into account, the impact of mutual affect remained robust, as the 95% high density intervals of the coefficients  $\beta_{1j}$  were above 0 in all cases, suggesting that the effect of mutual affect occurred on top of the group-specific properties.

## Discussion

In computer-mediated collaborative learning, the focus has been to enhance pragmatic functionality of the system. The present study shows that fostering positive emotions among collaborators is no less important. The results suggest that mutual affects shared among collaborators influence the evaluation of product acceptability even after personal variables, such as personality and background knowledge, were taken into account, implying that the influence of mutual affect on a video-conferencing system is far reaching than previously thought. Because the effect of mutual affect was stronger than that of pragmatic variable such as group-level communication and opinion convergence, it is likely that mutual affects were fused into users' experience with the system.

Note that the fact that affective experience can be misattributed does not mean that affect is irrelevant in enhancing the functionality of a collaborative learning system. Positive emotions can unleash creative and flexible thinking (Isen, 2008) and shared feelings have a multiplicative effect on collaborators because emotions are highly contagious.

A considerable progress has been made in the area of affective computing of intelligent tutoring systems, primarily thanks to the pioneering studies by D'Mello, Graesser, and Conati (Conati & Maclaren, 2009; D'Mello et al., 2007). We suggest that similar affect detection technologies help advance groupware applications. In a large computer-based collaborative situation, it is difficult to assess participants' affective states in real time. A collaborative groupware system that can trace users' affective state can facilitate group participation and learning.

## Abstract

Evidence for human learning without awareness of what is learned has been sought in serial reaction time (SRT) tasks in which, unknown to participants, the locations of stimuli follow a particular rule or sequence (Willingham, Nissen & Bullemer, 1989). A number of criticisms have been levelled at such tasks, including a lack of adequate control for sequential effects and a discrepancy in sensitivity between measures of implicit and explicit knowledge about the task (Jones & McLaren, 2009; Shanks & St. John, 1994). In this study we provide a novel, two-choice SRT paradigm whereby the locations of the response stimuli are sometimes predicted by a separate set of stimuli on screen. A color-filled square appears before each stimulus requiring a response, with participants informed this is simply a fixation point to prepare for the next trial. Two out of eight colors are predictive on 80% of trials, and performance on these consistent trials was faster than on the other six colors that were equally likely to result in either of the two possible responses. All these trial types were faster and more accurate than the remaining inconsistent 20% of trials for the predictive colors, which also produce more errors than control colors. A prediction task and interview followed the task, on which participants performed at near (slightly below) chance levels. We suggest that this task is a useful tool for studying associative learning in humans, as it provides reliable effects that appear to demonstrate implicit learning with relatively brief training.

**Keywords:** Associative learning; implicit learning; SRT task

## Introduction

In 1994 Shanks and St. John published their seminal review of implicit learning in *Behavioral and Brain Sciences*. Their conclusion was that implicit learning in humans had not yet been conclusively demonstrated. One paradigm that seemed to hold some promise in this regard was the SRT task pioneered by Willingham, Nissen and Bullemer (1989). In this task participants had to simply respond to one of four possible stimulus locations by pressing a spatially compatible key. Unknown to them, the sequence in which the stimulus locations were presented was not random but instead repeated a particular ordering. Willingham et al found that participants trained on such a sequence learned to respond faster than controls, yet were unable to say much about the sequence or, importantly, to predict the next stimulus location given a number of preceding trials. Shanks and St. John analysed this result, and others like it, and concluded that whilst the prediction task was potentially a sufficiently sensitive method of assaying participants' knowledge of the sequence, the evidence suggested that the non-significant findings on the

prediction task had more to do with a lack of power than a lack of knowledge. Subsequent reviews of more recent evidence (e.g. Lovibond and Shanks, 2002; Shanks and Lovibond, 2002; Mitchell, De Houwer and Lovibond, 2009) have seen no reason to change this conclusion.

In this paper we attempt to provide the evidence needed to prove that learning can take place without awareness of what is being learned. We do this using a variant of the SRT task employed by Jones and McLaren (2009) developed by Aitken (1996) which, instead of using the preceding trials to determine the later ones, uses a separate stimulus to predict which of the location stimuli will be presented next. A colored square presented between two stimulus locations is the predictor stimulus, and which of the two stimulus locations changes from an open to a filled circle is what determines the response required. If the left circle fills, then a left key press is needed and if the right-hand circle fills then a right key press is appropriate. The colored square is presented just before a response is required (while both circles are unfilled) so that it can predict which response will shortly be needed. Rather than run a separate control group, we follow Cleeremans (1993) in using a within-subject control. Thus some colors are never predictive (they have a random relationship with the stimulus location) whereas others are correlated with the response needed on the next trial.

The detailed design of this paradigm was dictated by our assumption of a dual-process mechanism for human learning. Following McLaren, Green and Mackintosh (1994), we conceptualized learning as being driven by two quite different sets of processes, one Cognitive in nature, employing conscious, controlled, rule-based symbolic processes, the other Associative in nature, automatic in operation and based on simple algorithms that capture the correlations between events. The challenge, then, was to arrive at a paradigm that would readily allow learning on an associative basis but would be much less amenable to rule-based cognition. The Aitken SRT paradigm allows for a parameterization that meets these requirements. We used 8 colors in total, but made only 2 of them predictive (one left, one right). Thus, 6 out of the 8 bore no relationship to the next stimulus location to occur. Following the technique used by Posner and Snyder (1975), the 2 predictive colors were themselves only 80% reliable. Hence, if one of them typically predicted a left response would be the next needed, 20% of the time it was followed by a stimulus location that

required a right response. Our rationale for doing this was that it would make conscious detection of the contingencies in play much harder. Due to 6 of the 8 colors being non-predictive, the overall prediction rate possible in this experiment is a mere 57.5% if complete knowledge of the contingencies is assumed, and no stimulus is an entirely reliable predictor of anything. In these circumstances, we expected it to be very difficult to notice which colors had some predictive value. Any attempt to "work out" what was going on in this fast paced task, with many different colors involved, would overtax working memory and severely impair performance on the main, SRT task, which should lead to this type of strategy being quickly rejected.

We also used the fact that there were 6 non-contingent colors to configure a design in which half the blocks were control blocks, and the other half experimental. The latter included the 2 contingent colors and 2 of the non-contingent, whereas the control blocks had the other 4 non-contingent colors in them. Control and Experimental blocks were alternated. This meant that for much of the time our participants were not experiencing any contingency between the colored square and the stimulus location / response required. It also allowed us to define two, somewhat different, within subject controls for our experimental manipulation. The first are the control colors in the experimental blocks: these have the advantage of sampling our participants' behavior under similar circumstances to those in force for the contingent, experimental colors. The second are the colors in the control blocks: these have the advantage of sampling behavior over an entire block without any distortions caused by the contingent colors. The control blocks were given exactly the same sequence of right and left responses as the corresponding experimental blocks. Thus, any sequential effects, caused by a particular run of right and left responses, will be controlled for by these blocks. As we shall see, this proved to be a useful aspect of our design.

Despite our efforts to prevent conscious rule-based learning, the parameters chosen for this design should nevertheless support strong associative learning. The colors occur just before the stimulus location is presented and the response required, and feedback is available shortly afterward. Thus, given that there is a reliable contingency between a clearly perceived stimulus and stimulus location / response, it should be easily learned. We ensured that the colors were presented boldly at fixation and gave our participants good reason to be looking there at the start of each trial. If this type of learning is automatic, and stimulus specific, then there should be little difficulty in learning the association between the two predictive colors and their correlated stimulus locations / responses.

## **Method**

### **Participants**

The study was conducted with 32 participants, randomly divided into two groups (n=16 in each) who performed the task with slightly different parameters (different distances

between the stimuli on screen). The participants were all first year psychology students at the University of Exeter, aged from 18 to 22 years old, who were rewarded with a course credit in return for their participation.

### **Materials**

An Apple iMac computer was used to run the experiment, with participants seated roughly 50cm from the screen. The display during blocks contained two white, outline circles and a white, outline square on a black background. The circles were 1.9cm in diameter, and the square was 1.9cm in width. The square was positioned directly in the centre of the screen for both groups. One group saw the circles positioned 2.2cm to the right and left of the centre of the screen, consistent with the distance separating the two-choice SRT task stimuli in Jones & McLaren (2009). The other group saw the same size white circle outlines placed 7.5cm from the right and left of the centre of the screen, following the stimulus locations specified in Aitken (1996).

The predictor stimulus was a colored filled square 1.9cm in width that filled in the white square outline. A choice of eight possible colors: red, green, blue, yellow, pink, orange, brown and teal were used. The response signal was a white filled circle 1.9cm in diameter that replaced either the right or left outline circle during the trials. The participants were instructed to press the spatially compatible "x" key on a QWERTY keyboard if the target stimulus appeared on the left, and the ">" key if the stimulus appeared on the right.

### **Design**

The experiment consisted of a two-choice SRT task conducted over one session that lasted approximately an hour. The task consisted of 20 alternating blocks, half of which were control blocks and half experimental, each with 120 trials. The ordering of the blocks was counterbalanced across participants. On both experimental and control blocks participants received a random ordering of equal amounts of right and left response stimuli. In the experimental blocks participants saw four colors (red, green, blue, yellow) as the filled square predictor stimulus. One of these colors preceded a right circle fill with an 80% contingency, and another color appeared before the left circle filling 80% of the time. The other two colors in the experimental block occurred with equal probability before a right or left circle fill. The colors were randomized for each participant and the experimenter was blind to which colors were predictive, and which response they predicted. During control blocks, all four colors (pink, orange, brown, teal) were equally likely to occur before a right or left response signal. Each color that could appear in a block appeared on an equal number of trials in that block, and all trials were constructed so that a color would not repeat itself on the next trial.

### **Procedure**

Participants were instructed to fixate on the colored square and then to simply respond as quickly and accurately as possible to the white circle fills. They were told to use the

colored square to bring their focus back to the centre of the screen and therefore improve their overall performance on the task by avoiding bias to one side or the other. They were informed that the colors changed to attract their attention back to the centre of the screen: no mention was made of any contingencies or the role of the colored square as a predictive or instructive stimulus.

On each trial the square would fill with the stimulus color and remain on screen until the computer detected a response. A variable interval in the range of 250-500ms would then occur before the white circle response signal appeared on screen. Reaction time was measured from this stimulus' appearance on screen until a key press was detected. A 250ms response-stimulus interval (RSI) then followed before the appearance of the next colored square stimulus during which the screen was blank except for the square and circle outlines. On each trial the stimuli remained on the screen until the participant had responded or was timed-out for not having pressed a key within 4.25s.

If participants pressed an incorrect key or were timed-out then the trial terminated and the computer issued a short 'beep' sound. Following each block, participants rested during a 30 second break in which they were shown their average reaction time (in milliseconds) and their accuracy (as a percentage) for the block of stimuli just completed. They were also informed whether these scores were better or worse than those from the previous block. At the end of the 20<sup>th</sup> block, participants were instructed to fetch the experimenter.

A short verbal interview asking general questions about the task was given, and participants were then assessed to determine the extent of their knowledge about the contingencies during the experiment. They were first asked to describe any relationship that they had noticed between the colors and the circle fills. Then a prediction task was conducted that closely followed the procedures employed in the main task they had just experienced. Thus, participants were instructed to attend to a colored square at fixation in the middle of two outline circles, but now had to make a prediction about which circle they thought would fill by pressing the appropriate key. They were told that the circles would not fill, and that no response would be considered an error, apart from pressing keys other than the two response keys, and that there was no time limit on making their choice. The prediction task was presented as two short blocks of 16 trials per block, with each color from both control and experimental blocks occurring twice in each block in a randomized order.

## Results

Results were computed for both errors and RTs, with four Stimulus Types compared across Blocks and at the different Distances between the two response signals. Those colors that had an 80% contingency with a right or left circle fill (the Experimental colors) are split into both their Consistent and Inconsistent presentations. For example, if a red square preceded a right circle fill on 80% of the trials, those

responses would be Consistent, whilst when a red square was followed by a left circle fill on the other 20% of trials this would be Inconsistent with the trained contingency. The two other colors in the experimental block form one control set (denoted Control – Experimental Block) for within-subject comparison, as do the four control colors from the control blocks (Control – Control Block). Trials following an error were excluded from both RT and error analyses. The RT and error data are shown in Figures 1 and 2, respectively.

Figure 1. Average RT in msecs for different Stimulus Types.

Figure 2. Proportion of errors for different Stimulus Types.

ANOVAs were conducted on both RT and proportion of errors, with Block, Distance and Stimulus Type as the independent variables. Blocks were collapsed into fours for the analyses, so each Block comprised two Experimental blocks and two Control blocks. The Distance of the stimulus did not have a main effect on the RTs,  $F(1,30) = .27$ ,  $p = .61$ , nor on the errors,  $F(1,30) = .56$ ,  $p = .46$ . Distance did not interact with any other variable, and therefore the location of the response stimuli was not a significant factor in determining learning of the color contingencies.

Figure 1 shows the average RT and proportion of errors for the four Stimulus Types, the main effect of Stimulus Type was significant for both the RTs,  $F(3,90) = 17.45, p < .001$ , and errors,  $F(3,90) = 3.72, p = .014$ . Both RTs and errors follow the same ordinal pattern, which was examined in more detail with a set of planned contrasts. Faster responses and fewer errors were made on Experimental Consistent trials. The difference between Experimental Consistent and Inconsistent trials is significant for both RTs,  $F(1,30) = 33.15, p < .001$ , and errors,  $F(1,30) = 5.463, p = .026$ , with Inconsistent stimuli responded to more slowly and with lower accuracy. Experimental Consistent stimuli are also responded to faster than both Control stimuli from Experimental,  $F(1,30) = 34.46, p < .001$  and Control blocks,  $F(1,30) = 6.173, p = .019$ , this trend is also apparent in the errors, but it is significant only in the RTs.

Experimental Inconsistent trials are slower than Control stimuli from Experimental blocks in RTs,  $F(1,30) = 4.85, p = .035$ , and show a trend toward more errors,  $F(1,30) = 3.34, p = .078$ . Experimental Inconsistent trials are also slower and less accurate than Control stimuli from the Control blocks, significantly so in RTs,  $F(1,30) = 14.51, p = .001$ , and again demonstrating a trend in the errors,  $F(1,30) = 4.05, p = .053$ . It seems therefore that learning of the contingencies occurred, with performance averaged across the experiment showing faster and more accurate responses to those trials that were predicted 80% of the time by the preceding color. This is further highlighted by the decrement in performance for those trials inconsistent with the learnt relationship, causing participants to make more errors and respond slower to these stimuli than both the Consistent stimuli and the Control stimuli.

The Control stimuli are interesting, in that they significantly differ from one another in the RTs,  $F(1,30) = 9.16, p = .005$ , although not in the errors,  $F(1,30) = .62, p = .44$ . Control stimuli from the Experimental blocks are responded to more slowly than Control stimuli from the Control block. We suspect that this is due to the presence of the Consistent and Inconsistent stimuli in the Experimental Block. It is not that more errors are being made (overall) in the Experimental blocks, instead, it may be that the conflict that occurs on inconsistent trials engages mechanisms that produce more cautious responding, though we note that this cannot simply be a speed-accuracy trade-off as the error rate is, if anything, lower for the Control block stimuli than for Control stimuli from the Experimental Blocks.

Block has a significant main effect in RTs,  $F(4,120) = 9.26, p < .001$ , and errors,  $F(4,120) = 19.02, p < .001$ . With practice, participants got faster at the task but exhibited something of a speed-accuracy trade-off, making more errors progressively throughout the experiment. Block did not interact with Stimulus Type in the RT analysis, thus Experimental Consistent stimuli in Experimental Blocks were responded to faster than Control stimuli in Control Blocks, which were in turn responded to faster than Control stimuli in Experimental Blocks, and all are faster than Experimental Inconsistent stimuli. The relative positions of

Inconsistent and Consistent stimuli are reversed in Block 1 in the errors, however, and the interaction between Block and Stimulus Type for errors is significant,  $F(12,360) = 2.68, p = .002$ . Thus, in this case, the Consistent / Inconsistent difference emerges over blocks.

The structured questionnaire and prediction task were completed by half of the participants, eight at each Distance value. The other participants were simply asked to pick which colors were predictive: they were invited to select two colors from the eight possible candidates. 14 of the 16 felt able to make the attempt, and out of the 28 responses that were generated 6 were correct (7 would be expected by chance).

The results of the structured questionnaire for the other 16 participants who completed the prediction task show that of the 32 responses, 8 were correct. If we take it that there are two predictive colors, and do not require the participant to remember which predicted left and which predicted right, then if we ask the participants to pick two colors out of the eight, the expected number of colors selected correctly is 0.5. With 16 participants taking part the total number of colors correctly selected is expected to be 8 by chance, and it is exactly 8, approximately evenly distributed across the different responses (right or left) and Distances.

Turning now to the prediction task itself, each participant experienced 32 trials in total. 8 of which involved the two predictive colors. Taking into account the requirement to give the appropriate response for the color, we can expect 4 correct responses by chance to these 8 presentations. Inspection of Figure 3 shows that the distribution of correct responses across participants is approximately binomial at each Distance, and is centered at a mean of 4 or less.

Figure 3. The number of correct responses participants gave for Consistent – Predictive colors. Data presented from 8 participants who performed the task with 2.2cm Distance (open bars) and 8 participants who performed the task with 7.5cm (solid bars) between response stimuli.

The actual means are 3.5 and 4 for Distances of 2.2 cm and 7.5 cm respectively, neither of which differ significantly from chance, and neither of which exceed mean chance

expectation. Our conclusion, based on these data, is that our participants do not know which colors are predictive, and do not know what they predict. This is in accord with their self-reports at the end of the experiment: they claimed to be unaware of any contingency between the color of the central square and the response that followed.

## General Discussion

Our basic claim is that our participants' behavior was affected by the contingencies between color and stimulus location / response in the absence of any conscious knowledge on their part about these contingencies. That their behavior was affected is beyond doubt; the effect is statistically highly significant and, by the standards of these things, rather easy to obtain after relatively little training. We believe that these characteristics make this paradigm a good candidate for studying associative learning in humans. In particular, the highly reliable difference between Consistent and Inconsistent responses to the contingent colors is noteworthy, and our results suggest that this difference is made up of a disadvantage for Inconsistent trials and an advantage for Consistent trials.

Our use of two different types of within-subject control enables us to be confident that the advantage for Consistent trials and the disadvantage for Inconsistent trials are real. They also allow us to speculate about the effect of having these types of trial in a block. In some ways the most appropriate controls are those colors used as controls in the Experimental blocks. They are subject to the same local conditions, in terms of motivation, mood etc., and so provide an appropriate baseline for comparison with Consistent and Inconsistent responses to the contingent stimuli. We included the separate control blocks because we suspected that simply having some predictable trials in a block might alter our participants behavior, and also to provide a control for sequential effects. This last was accomplished by using exactly the same sequence of left and right responses in paired Control and Experimental blocks, the only difference between the two was in what colors were used in the block, and how they were paired with responses. Thus, in a Control block our participants would have exactly the same sequence of responses to make, but no useful information from the colored squares that were presented to help (or hinder) them. The fact that our contingent stimuli also differ from these controls on Consistent and Inconsistent trials gives us considerable confidence that there is no hidden artifact responsible for our results.

The difference between the Experimental control stimuli and the Control block control stimuli is also revealing. We hypothesize that this difference, with Experimental block controls performing worse than Control block controls, is due to the conflict experienced on Inconsistent trials leading to a greater cautiousness on some trials (perhaps best described as some kind of post-stimulus presentation checking process) that does not shift performance in terms of any speed – accuracy trade-off. By this we mean that the

slower RTs do not lead to higher accuracy, but instead reflect an additional “cost” that is incurred in task performance. It is difficult to speculate any further on what the exact nature of this cost might be, but one possibility is that perceptual information specifying which stimulus location had occurred might continue to be gathered post-decision on some proportion of trials as part of the checking process. If this mostly occurred on trials where the decision was the correct one (which given the low absolute error rates of our participants is quite likely), then it would have relatively little impact on the error rate but a significant impact on RTs. This analysis can only apply if the chance of engaging the checking process is unrelated to the probability of making an error, and low enough to result in a low frequency of occurrence on trials that result in an error. In these circumstances our RT measure would be much more sensitive to such a process than the error estimate (because the latter would be based on so few data points), so a result in the RTs alone would be quite possible. All speculation aside, this result is, as far as we are aware, a novel one, and opens up a new line of enquiry that may well be related to recent work by Verbruggen et al (in press).

Now we turn to some consideration of the arguments that may be raised to suggest that our prediction test results do not prove that our participants had no conscious knowledge of the contingencies. The most obvious is that the prediction test results apply to only half the participants. This objection is of no concern, as the effects we report, i.e. the advantage for Consistent vs. Inconsistent, the advantage for Consistent trials relative to both types of Control trial and the disadvantage for Inconsistent trials are all significant if only the 16 participants who were given the prediction test are included. We've included all our data because this gives the best estimate of the pattern of performance on the main task, and because it gives the best estimate of the ability of participants to pick the contingent colors during the structured interview. Another objection that might be raised is that the prediction task itself is flawed, in that it a) takes place after the main task by which time participants have forgotten which are the contingent colors and b) is not sufficiently like the main task to help them recall this information. Our response is that our participants appear to have learned to respond faster to Consistent trials relatively early in the experiment, certainly by the time they reached the 6<sup>th</sup> block, and appear to have had no trouble remembering this information (if that was how they were doing it) from block to block from then on. And our prediction task used the same room, same computer, same display, same stimuli presented in a very similar fashion, it was simply the response requirements and consequent presentation rate (and feedback) that were different to the main task. If our participants consciously knew which were the contingent stimuli, this should have acted as a salient reminder of that information.

Perhaps more troublesome for our analysis is the objection that, whilst our prediction test does attempt to assess the correct information (Shanks & St. John, 1994), it

does not do so sensitively enough. We only gave two blocks of 16 trials each, compared to the 20 blocks of 120 trials each for the main task. Is this really a fair test of our participants' knowledge about the color-response contingencies? To which question our answer has to be "yes". The point here is that, in order to be effective in determining RT to respond to the stimulus location, participants' knowledge must be of the categorical variety if the idea of "conscious knowledge" is to mean anything different to "there's been some change in behavior". They must know that this color predicts this location / response, even allowing for a caveat to the effect that this prediction will not always be valid. In other words, they must know, when faced with the appropriate stimulus input, that some colors are predictive and that others do not seem to be. Only then can conscious knowledge produce the desired pattern of results. If this were the case, then our 8 trials for the contingent colors should be more than adequate to detect this type of categorical knowledge. If they get all 8 correct, then this is significantly better than chance on an individual basis. Even allowing for only some of the participants being aware of the contingencies, the means over all 16 participants who took the test should produce overwhelming evidence of such knowledge if only as many as 4 were aware of the contingencies. But we do not even have means that are greater than chance to report for our prediction test, let alone means approaching significance.

Another possibility is that the effect observed in the RTs might be due to our participants being aware of the contingencies on very few trials during the experiment (and then they forget), and that we have simply not given enough trials in the prediction task to capture any of these trials. This is implausible. Firstly, once the contingencies are explicitly coded – then this should in itself increase the probability of noticing them again until it becomes a frequent occurrence. Secondly, even a rate as low as say 1 trial in every 8 of the predictive colors (i.e. 2.5 on average a block in training) would produce a mean on our prediction test of 4.5 that is significantly different to that observed ( $Z=2.27$ ,  $p<.05$ ). And the effect on these individual trial RTs would have to be large (approx 40msec). There is no evidence for such a bimodal distribution in our data.

It would seem, then, that we have good evidence for implicit performance on our task. It is still possible that we may have not demonstrated implicit learning, if we adopt a position that results from a stringent application of the Shanks and St. John criteria (our thanks to Tony Dickinson for pointing this out). Imagine that during training on some trials our participants became aware of the contingencies, but then forgot this prior to being asked. They would have learned the contingencies, but not implicitly. This learning might then give rise to performance that reflected the learning, but still without conscious knowledge of the contingencies so that they passed our prediction test. This type of implicit performance, based on a form of implicit memory, would explain our results. In the limit, it is almost impossible to discount this type of critique, but we think

that it lacks plausibility when applied to our paradigm. There is not much to learn, just that two colors predict responses, and if participants were to become repeatedly aware of this (so that learning could occur), it's hard to see why they would forget this so easily.

Our conclusion, then, is that we have demonstrated learning in human participants without conscious awareness of what has been learned. This robust effect has been accomplished in a single, one-hour session with relatively few participants. These considerations suggest that this paradigm is ideally suited to the study of implicit processes, and we hope to report the results of further investigations with this paradigm in the near future.

## Abstract

We investigate how the degree to which a context constrains the words that could occur in a sentence affects the processing of the word that does occur. Roland et al. (2012) found that processing was facilitated when target words were more semantically similar to word alternatives that could have appeared. Because this effect is independent of word predictability, it suggests that comprehenders may have separate expectations for words and more general semantic features. We show that the semantic similarity effect is modulated by the degree of contextual constraint. We found that facilitation due to semantic similarity was greater when contexts were less constraining, and lower when contexts were more constraining, independent of word predictability. We interpret these results as suggesting that in highly constraining contexts, comprehenders may expect specific words, and face difficulties when these expectations are violated, while in less constraining contexts, they may have more general expectations for semantic properties shared between the words that could occur.

**Keywords:** sentence processing; semantic similarity; predictability; entropy; contextual constraint; expectation-based language comprehension

## Introduction

In expectation-based models of sentence comprehension, contextual information has an enormous effect on how words are integrated into sentences. These models predict that the degree of difficulty a reader encounters in integrating a new word into a sentence is either entirely or in large measure a function of how predictable that word is given prior context (e.g., Levy, 2008). Presumably this is because predicted words are activated by context in advance of when they are encountered, making them easier to retrieve from memory or because predictable words are easier to integrate into the representations being constructed during comprehension. The effect of predictability on processing time has been observed in many studies (e.g., Bicknell, Elman, Hare, McRae, & Kutas, 2010; Ehrlich & Rayner, 1981; Frisson, Rayner, & Pickering, 2005; Staub, 2011; DeLong, Urbach, & Kutas, 2005; Federmeier, Wlotko, De Ochoa-Dewald, & Kutas, 2007; Otten & Van Berkum, 2008; Van Berkum, Brown, Zwitserlood, Kooijman, & Hagoort, 2005).

The relationship between a word's predictability and the amount of effort required to process it has been formalized in a number of computational models of language processing known as surprisal models (e.g., Boston, Hale, Patil, Kliegl, & Vasisht, 2008; Hale, 2001; Levy, 2008; Padó, Crocker, & Keller, 2009). In these models, the amount of cognitive effort required to integrate a word into a sentence depends on the negative log probability of that word given its preceding context. Surprisal models have had considerable success in predicting differences in reading times based on a word's predictability given its preceding context.

As it turns out, the amount of processing effort associated with integrating a word into a sentence cannot be entirely reduced to its predictability given its preceding context. Roland, Yun, Koenig, and Mauner (2012) examined the effects of the semantic cohort of a target word (i.e., the other words that could appear in the same position/context as the target word) on the processing of a target word. They found that words that are more semantically similar to their semantic cohort are easier to process when word predictability and other factors are controlled for. This result is important because it points to a limitation in expectation-based computational accounts of sentence processing that claim that a word's probability given its context is the sole predictor of processing effort (e.g., Levy, 2008). The results we present further constrain expectation-based accounts of sentence processing by showing that the effect of semantic similarity between a target word and its semantic cohort interacts with the degree of constraint provided by context.

The findings of Schwanenflugel and LaCount (1988) motivate the possibility that the benefits of semantic similarity on word integration might be modulated by contextual constraint. Schwanenflugel and LaCount found that unpredictable words that were semantically related to the most predictable word that could occur in the same position were processed faster than other equally unpredictable words that were also semantically unrelated to that most predictable word. What is crucial for this discussion is that the benefit of shared semantic information was not consistently observed for all unpredictable words. Shared semantic information only facilitated the processing of unpredictable words when contexts were weakly constraining.

To illustrate why the benefit of shared semantic similarity to other words activated by the preceding context would be greatest when a target word is unpredictable and its context is only weakly constraining, consider the sentence contexts in examples (1) and (2), for which we have obtained word completions (this study will be described in greater detail later).

- (1) The gladiator jabbed the African tiger with  
(2) The aborigine attacked the angry lion with

Figures 1a-b: Probability distributions for semantic cohorts for Examples (1) and (2).

In both contexts, an instrument noun is most likely to be the next word. However, the types of instruments in the semantic cohort differed across contexts. For context (1), instruments like *sword*, *spear*, *stick*, *knife*, and *spike* were mentioned. These instruments share a typical property, i.e., all can be used as “pokers”. In contrast, instruments like *sword*, *spear*, *knife*, *stick*, *fire*, *net*, *whip*, and *rock*, which were mentioned for context (2), have few salient characteristics that are common to instruments of attacking. This difference in the degree of shared characteristics suggests that context (1) places greater restrictions on the range of possible instruments than context (2). Using responses obtained from a completion study, we illustrate the distribution pattern of the probabilities of possible instruments for each context. In comparing Figure 1a to Figure 1b, two things become apparent. First, the most probable instruments for jabbing are more likely than the most probable instruments for attacking. Second, the probabilities of the jabbing semantic cohort drop more sharply than do the probabilities of the attacking semantic

cohort. One way of quantifying the greater degree of constraint provided by the jabbing context is to note that the top three items have a combined probability of .55. In the attacking context, even the first 6 items do not match that combined probability.

## Hypotheses and Prediction

Based on the findings of Schwanenflugel and LaCount (1988), we predict that the semantic similarity effect found by Roland et al. (2012) will be stronger in more weakly constraining contexts and weaker in highly constraining contexts. While Schwanenflugel and LaCount only examined the processing of unpredictable words, we do not expect interactions with word predictability, since Roland et al. found no interaction between similarity and predictability.

## Entropy as a measure of contextual constraint

In order to measure the effects of contextual constraint, we need a measure to quantify the degree of contextual constraint. Recall that in a more constraining context, there are larger differences in the probabilities of cohort members, because a small subset of the possible words is more likely, while the others are unexpected. Alternatively, in a less constraining context, there are a larger number of words that are more or less equally likely. We will use Entropy (H), a standard measure from information theory shown in Equation 1, to reflect these differences in the distributions of the probabilities the cohort members. Entropy is higher when the choices are more similar in probability, as in low constraint contexts, and is lower when choices are less similar in probability, as in more highly constraining contexts.

$$H(X) = - \sum_{i=1}^n p(x_i) \log p(x_i) \quad \text{Equation 1}$$

## Experiment to Generate Reading Times

**Participants** One hundred thirty native English-speaking undergraduates from the University at Buffalo received partial course credit for participation.

**Materials** We constructed 3 sets of 60 active declarative sentences with optional prepositional phrases similar to those in Example (3). Sets were differentiated by having an instrument noun that was highly likely (e.g., *sword*), moderately likely (e.g., *spear*), or unlikely (e.g., *spike*). To avoid wrap-up effects on instrument reading times (Just & Carpenter, 1980), all sentences included sentence-final phrases like *in the Colosseum*. Presentation regions are indicated in example (3) by vertical lines (|).

- (3) The gladiator |jabbed |the African tiger |with |a sword/spear/spike |in |the Colosseum.

Selection of target instruments was based on responses from a listing study in which 42 participants produced five instruments for sentence fragments like (1) and (2). Cloze probabilities for highly likely, moderately likely and unlikely instruments were  $M = .23$ ,  $S.D. = .06$ ,  $M = .10$ ,  $S.D. = .04$  and  $M = .02$ ,  $S.D. = .01$ , respectively. Results of plausibility rating revealed that all instruments were plausible. Co-occurrence frequencies between target verbs and instrument prepositional phrases, counted using the British National Corpus (BNC) (Burnard, 1995), were very low ( $M = .03$ ,  $S.D. = .03$ ), and separate modeling showed that the frequency with which each verb occurred with an instrument phrase played no role in our results.

Experimental sentences were counterbalanced across six presentation lists, each consisting of 10 experimental sentences for each level of predictability. To obscure systematicities, these sentences were intermixed with 90 distractor sentences with varied syntactic structures (e.g., subordinate clause, adverbial phrase, or relative-clause sentences) and prepositional phrases with different prepositions (e.g., *on*, *in*, or *from*). Finally, because participants judged whether each sentence made sense, 33% of the total number of trials were designed not to make sense.

**Procedure** Participant-paced, region-by-region reading was accompanied by a secondary make-sense judgment task. This task was used to increase sensitivity to subtle semantic effects that might not be observed in a straight reading paradigm. Trials were divided into two blocks with a two-minute break between blocks to lessen fatigue.

**Dependent Variables** While the primary dependent variable was the reading times for sentences that participants continued to judge acceptable, we examined “No” judgments to ensure that they did not differ as a function of instrument likelihood. Across conditions, percentages of “No” responses adjusted for remaining chances to say “No” (see Boland, Tanenhaus & Garnsey, 1990) were low (under 5% in all conditions) and their variances were small. “Yes” reading times for instrument noun phrases were filtered for outliers such that reading times greater than 4,000 ms or less than 200 ms were omitted. Filtering resulted in the removal of 27 of 3723 (0.7%) reading times.

### Measuring Effects of Predictability, Semantic Similarity, and Contextual Constraint

The goal of the modeling was to investigate how contextual constraints modulated the effect of semantic similarity. Reading times were submitted to a linear mixed-effects model for analysis using the R statistics program (version 2.14.0, R Development Core Team, 2011) using lme4 (version 0.999375-42, Bates & Maechle, 2011). Fixed factors consisting of Predictability, Similarity, Constraint, Length, and Frequency, described in more detail below, were used to predict reading time variances. Participants and

items were random factors. Fixed effects terms that did not contribute significantly to the fit of the model, including all 4-way and 5-way interactions, were removed. We simplified the initial fully crossed and fully specified random effects structure to yield the maximally justified random effect structure, as discussed by Jaeger (2009) and Baayen, Davidson, and Bates (2008). Outliers with a standardized residual at a distance greater than 2.5 standard deviations from zero were removed (Baayen, 2008).

### Model Predictors

**Predictability** We used log-transformed cloze probabilities from the above-mentioned listing study to estimate predictability. Each of the five responses was weighted by its order of mention. If an instrument was a participant’s first choice, it was weighted 5, if it was the second choice, it was weighted 4, and so on.

**Similarity** We measured the degree of semantic similarity between each target instrument and each member of its semantic cohort (i.e., the other words produced in the above-mentioned listing study) using Latent Semantic Analysis (LSA) cosines (Deerwester, Dumais, Furnas, Landauer, & Harshman, 1990) with a semantic space created from the BNC. LSA cosines were weighted by their cohort-frequencies to determine the average semantic similarity of a target instrument with its semantic cohort. Average LSA cosines between targets and their semantic cohorts ranged from .08 for the lowest similarity to .54 for the highest similarity. Our measure of semantic similarity differs from that used by Schwanenflugel and LaCount (1988), in that they compared the target word with only the most likely word, rather than with all of the words in the semantic cohort. In addition, they used human similarity judgments, while we used LSA cosines as a measure of similarity.

**Constraint** We used the entropy of the probability distribution of all possible instruments for a context to measure the degree of constraint provided by the preceding context. Entropy values ranged between 2.55 for the most constraining contexts and 5.02 for the least constraining contexts, with a mean of 3.88.

**Length** The lengths of instrument noun phrases were included as an additional factor to control for any potential reading time differences which might be due to this perceptual factor. Length was measured in number of characters, including spaces. Lengths ranged from 5 to 16 characters, with a mean of 8.36 characters.

**Frequency** We log-transformed the raw frequencies of the head nouns of the instrument noun phrases, which were obtained from the BNC. Base 10 log-transformed frequencies ranged from 0 to 4.56 (i.e., occurring between 1 and ~36K times in the BNC), with a mean of 2.85. Because frequency was correlated with Length ( $r = .65$ ) and

Predictability ( $r = .31$ ), we residualized Frequency for Length and Predictability, so that the predictors would only reflect the component of frequency that did not overlap with length and predictability. All other predictors had correlations of less than 0.30.

## Model Results and Discussion

We provide a summary of the linear mixed-effect regression model in Table 1 and a graphical representation of the interaction between Similarity and Constraint in Figure 2.

**Length** Longer words took longer to read. This is consistent with previous findings showing the effects of length (e.g., Juhasz & Rayner, 2003). Besides the interactions discussed below, there was a 3-way interaction between Length, Frequency, and Constraint. This was due to length effects being larger for low constraint, low frequency items and high constraint, high frequency items, and smaller for low constraint, high frequency items and high constraint, low frequency items. This possibly due to idiosyncrasies within our items, since we did not attempt to make sure that the same range of target word lengths were found in all conditions.

**Frequency** Unsurprisingly, more frequent words were read faster than less frequent words. This too is consistent with previous studies (e.g., Ashby et al., 2005; Juhasz & Rayner, 2003; Kliegl, Grabner, Rolfs, & Engbert, 2004; Staub, 2011). Frequency interacted with a number of other predictors as discussed below.

**Predictability** Consistent with many previous studies (Ashby, Rayner, & Clifton, 2005; Bicknell et al., 2010; DeLong et al., 2005; Ehrlich & Rayner, 1981; Federmeier et al., 2007; Frisson et al., 2005; Otten & Van Berkum, 2008; Rayner & Well, 1996; Staub, 2011; Van Berkum et al., 2005), more predictable instruments were processed more quickly.

There was a 3-way interaction between Predictability, Frequency, and Constraint, as well as a 2-way interaction between Predictability and Frequency, and a marginally significant 2-way interaction between Predictability and Constraint. These are due to low frequency unpredictable words taking longer to read in low constraint contexts than would be expected from the simple effects of frequency and predictability (i.e., when all factors combine to give the comprehender the least amount of help in predicting the word). This may have resulted in the model underestimating the reading times for low frequency unpredictable words in low constraint contexts, giving the appearance of a lack of a frequency effect for highly predictable words in low constraint contexts.

Table 1: Summary of fixed factors from the linear mixed-effect regression model, when the effects of random variables were maximized, for predicting reading times of that target noun.

	Estimated Coefficient	S.E.	<i>t</i> -value
Intercept	713.72 (713.64)	17.51	40.75

Similarity x Frequency x Length	-55.33 (-12.90)	2.54	-2.35
Constraint x Frequency x Length	-26.41 (-29.67)	2.84	-4.82

Note: All predictors are centered. Parenthetical values below the coefficients are standardized coefficients from an alternate version of the model with standardized predictors. *t*-values with an absolute value greater than 2 are significant at an alpha level of .05 (Gelman & Hill, 2007).

**Similarity** Instruments were read faster when they were more similar to the members of their semantic cohort than when they were less similar. This result replicates Roland et al.'s (2012) results. There was also a 3-way interaction between Similarity, Frequency, and Length and a 2-way interaction between Similarity and Length. These interactions were due to the effect of similarity being larger for longer words and smallest for short, high frequency words. These are both consistent with the notion that similarity effects are due to spreading activation during processing, as the slower reading times for longer words provide more chance for activation to spread between pre-activated words, and short, fast words, being read quickly, provide the least time.

**Constraint** There was no main effect of contextual constraint. Importantly however, Constraint interacted with Semantic Similarity, just as hypothesized. We analyzed this interaction by performing separate analyses on the data where one standard deviation was either added or subtracted from the values for each of the predictors in the interaction to create models reflecting low and high conditions for each predictor, respectively (Aiken and West 1991). There was an effect of Semantic Similarity when Entropy was high (i.e., low constraint contexts) (Estimated coefficient = -500.28, S.E. = 103.43, t-value = -4.84), but no effect of Semantic Similarity when entropy was low (i.e., high constraint contexts) (Estimated coefficient = -34.14, S.E. = 85.70, t-value = -0.40). The estimated high and low reading times are shown in Figure 2. The fact that Semantic Similarity did not facilitate the integration of instruments in strongly-constraining contexts is consistent with Schwanenflugel and LaCount's (1988) results. In addition, there was a 3-way interaction between Similarity, Constraint, and Length, with the similarity effects in the low constraint conditions being larger for longer words than for shorter words. Again, this is consistent with the notion that the added reading times of longer words allows more time for activation to spread between pre-activated words.

Figure 2: Interaction of Contextual Constraint and Similarity using standardized coefficients.

## General Discussion

We found that semantic similarity between a target word and its semantic cohort has a stronger effect on processing when the context provides fewer constraints on what may appear in the target position. Alternatively, the effects of semantic similarity become weaker as the context becomes more constraining. The effect of contextual constraint on the degree to which semantic similarity affects processing has important implications for models of processing. Roland et al. (2012) suggested two possible causes for the semantic similarity effect: spreading activation between the representations for the words that comprehenders were anticipating, and the possibility that expectations for words and expectations for semantic features could have independent effects on comprehension difficulty. Our results suggest that the nature of comprehenders' expectations may vary with the degree of contextual constraint. In a highly constraining context (i.e., low entropy), there is no effect of semantic similarity, and comprehension difficulty appears to be primarily determined by the predictability of the target word. If the target word is expected, it is easy to process. If the target word is unexpected, it is difficult to process.

On the other hand, in a less constraining context, semantic similarity and predictability both influence processing. Not only are more predictable words easier to process, but so are words that are more similar to the other members of the semantic cohort. Words are most difficult to process when they are both unexpected and semantically distant from their semantic cohort.

One possible explanation for why contextual constraint modulates the influence of semantic similarity for unpredictable words is that in a highly constraining context, comprehenders may be expecting specific words, and face difficulty when the expectations turn out to be wrong. In a less constraining context, comprehenders may have less specific expectations – anticipating semantic features in common between a set of possible words (in addition to, or as an alternative to anticipating specific words). Thus, they face less difficulty when the target word turns out to be something other than the most likely word – as long as the target word shares some level of semantic similarity with the other likely possible words. Overall, our data suggests that word predictability, semantic similarity, and contextual constraint all have an impact on language comprehension.

## Abstract

The words that children learn can be characterized as a semantic network, with links connecting related words. Recent analyses have shown these networks to have small-world structure, with a few highly-connected hub words facilitating short paths between otherwise distant words. This structure contributes to network robustness, and differences in structure can predict differences in language learning outcomes. While previous studies have shown that semantic network structure reflects linguistic input structure, we provide the first evidence that it is related also to children's own language learning biases. Two-year old children who show a mutual-exclusivity bias have significantly more hub-like networks than children who do not, even when they know the same number of words. This finding contributes to our understanding of both semantic networks and the origins of mutual exclusivity.

**Keywords:** word learning; mutual exclusivity; semantic networks; language acquisition

## Introduction

Although the earliest analyses of human memory and learning concerned the learning of lists of unrelated words (Ebbinghaus, 1885/1962), researchers quickly discovered that the words people learn in more natural contexts are intricately connected. Vocabularies were conceptualized as richly structured networks, with links connecting semantically related words (Collins & Loftus, 1975). These connections play an important role in both learning and memory, and can be observed empirically in semantic priming experiments. Because activation spreads from words to their semantic neighbors, presenting a word, even subliminally, leads to faster processing of related words (Anderson, 1983). Even two-year old infants show semantic priming, suggesting that vocabularies have network structure early in language learning (Arias-Trejo & Plunkett, 2009).

Recently, the application of graph-theoretic methods to the study of these networks has begun to provide insight into their structural properties. For instance, Hills, Maouene, Maouene, Sheya, & Smith (2009a) analyzed the semantic network structure of 130 nouns typically learned before 30 months. Compared to randomly-connected control networks, these semantic networks showed significant small-world structure, in which most words are sparsely connected, but a few are highly-connected hubs. This kind

of structure results in networks robust to malfunction (e.g. forgetting a word; Albert, Jeong, & Barabási, 2000), and can help to explain some of the remarkable efficiency of human semantic memory (Raaijmakers & Shiffrin, 1981). Further, semantic networks lacking this structure are associated with slower language-learning, characterizing the vocabulary structure of late talkers (Beckage, Smith, & Hills, 2011). But why do children learn these words? Why do semantic networks have this structure?

Undoubtedly, one answer to this question is that structure comes from the environment. Because children learn words from the language they hear, language input is a strong predictor of the words that children will learn. For instance, the frequency with which a child hears a word in isolation can predict how likely a child is to learn that word (Brent & Siskind, 2001). Similarly, the semantic networks constructed from corpora of both adult-directed and child-directed language have many of the same structural properties as networks constructed from the words 30-month-old children are likely to know (Hills, et al., 2009a; Steyvers & Tenenbaum, 2005).

But perhaps a more complete explanation of the origin of semantic network structure is that it emerges from an interaction between structure in the linguistic environment and the child's own learning system. Because children are not unbiased samplers of linguistic input, their attentional and learning biases mediate the link between language input and language learned (Hudson Kam & Newport, 2005; Smith, 2000). For instance, children who learn to attend to shape are likely to learn shape-based categories, and those who learn to attend to other properties (e.g. material) learn other kinds of words (Colunga & Sims, 2011; Smith, Jones, Landau, Gershkoff-Stowe, & Samuelson, 2002). Can word-learning biases predict and explain semantic network structure? In this paper, we consider the case of disambiguation through mutual exclusivity.

In the disambiguation task, a child is presented with a novel object among one or more familiar object competitors. The child then hears a novel label (e.g. 'can you find the dax?') and is asked to select an object. Both toddlers and adults reliably select the novel object as the target of the novel label (Markman & Wachtel, 1988; Golinkoff, Hirsh-Pasek, Bailey, & Wenger, 1992), and studies with infants suggest that this disambiguation may arise as early as 18 to 22.5 months (Halberda, 2003; Mather & Plunkett, 2009). Preferential

mapping of novel labels to novel objects over known objects, which we will refer to as mutual exclusivity (ME), could arise for a number of reasons, and its mechanism of action is the topic of significant debate (e.g. Diesendruck & Markson, 2001; Golinkoff et al., 1992; Markman & Wachtel, 1988). We explore this question in the general discussion, but will sidestep it here and instead consider the potential consequences of mutual exclusivity for semantic network structure.

Mutual exclusivity is a mechanism by which children can leverage prior knowledge to learn new words *in the context of known objects*. Consequently, children who show mutual exclusivity should have vocabularies that echo this kind of contextual structure. For these children, learning *fork* should ease the acquisition of *spoon*, *bowl*, and *plate*. In contrast, learning *fork* should have little effect on the acquisition of *dog* and *coat*. Thus, we propose that mutual exclusivity can help explain small-world structure of semantic networks, and those children who show mutual exclusivity will have more hub-like networks than those who do not. We begin by reporting empirical data from a disambiguation task with 24-month-old children, continue by describing a semantic network analysis of these children's vocabularies, and conclude with a discussion of how these results inform our understanding of the relationship between mutual exclusivity and vocabulary development, as well as the origins of mutual exclusivity itself.

## Experiment

### Method

**Participants.** Forty two-year-olds ( $M = 24.75$  months; range = 24-26; 20 female) participated. All were typically developing children from households in which parents reported English to be the dominant language. A subset of 34 infants ( $M = 24.9$  months; range = 22.4-27.5; 16 female) participated in the followup analysis (explained below).

**Stimuli.** Nine familiar objects (e.g. boat, glasses) were used in the warm-up trials. Twenty-five familiar (e.g. brush, cup) and 8 novel objects (e.g. massager, platypus) were used in the referent-selection task.

**Procedure.** Parents first completed the MCDI (Fenson, Dale, Reznick, Bates, Thal, & Pethick, 1994) and an SES measure (Hollingshead, 1975). After this, each child participated in three warm-up trials. On warm-up trials, the experimenter set a tray containing three familiar objects on the table, initially covered by an occluder. The experimenter asked for the target object (e.g. "which one is the dog?") three times: once while the items were occluded, again after lifting the occluder, and again three seconds later while pushing the tray towards the infant. The first reach, point, or grab, was scored as a response. On these trials, infants were praised for correct responses and corrected when necessary.

Subsequently, each child participated in sixteen referent-selection trials. On each trial, the experimenter presented a tray containing two familiar objects and one novel object.

The procedure was identical except that children received neutral feedback on all trials. On half the trials, the experimenter asked for a familiar object, while on the other half she asked for a novel object (e.g. *modi*, *taju*).

## Results and Discussion

Each participant made a total of 16 choices, picking 8 targets on familiar trials, and 8 targets on novel trials. Any trial on which the child did not know the label for the familiar target, or the label for one of the familiar distractors, was excluded from analysis. The proportion of targets correctly chosen on these remaining trials was then analyzed to determine the child's success in the task. Overall, children performed quite well, selecting the correct target on both familiar ( $M_f = .83$ ,  $t(39) = 15.31$ ,  $p < .001$ ) and novel trials ( $M_n = .545$ ,  $t(39) = 5.87$ ,  $p < .001$ ) at greater than chance levels. Thus, as a group, 24-month-old children used mutual exclusivity for disambiguation. Familiar trial performance, however, was significantly higher than novel trial performance ( $t(39) = 6.88$ ,  $p < .001$ ).

Because the central question in this study is about the relationship between learning mechanisms and vocabulary development, we measured both vocabulary size (MCDI - Fenson, et al., 1994) and mother's education (Hollingshead, 1975), a potential correlate of rich language input. Mother's education was reliably correlated with performance on familiar trials ( $r = .33$ ,  $p < .05$ ), but not novel trials ( $r = .01$ , *n.s.*), and vocabulary size was not significantly correlated with performance on either kind of trial ( $r_f = .19$ , *n.s.*;  $r_n = .15$ , *n.s.*). In the semantic network analysis to follow, we show that *vocabulary structure* is reliably related to novel trial performance. Because neither mother's education nor *vocabulary size* predict ME in this data set, the relationship between ME and structure is likely to be quite robust.

But perhaps this analysis is unfair. While most of the children had high levels of success on familiar trials, a few children did not perform as well. Since these children knew the words for all three objects on these familiar trials, their low levels of performance indicate that they may not have understood the task. Thus, for the same reason that response time analysis typically uses only correct response trials, excluding these children from individual-level analyses may give clearer correlations. In order to determine whether a child's performance was significantly better than expected by chance, we modeled chance behavior on each trial as random selection of one of the three objects.

The probability of success expected by chance is given by a binomial distribution with probability  $\frac{1}{3}$ . Consequently, a child should be counted as performing differently from chance if he or she made enough correct selections to be outside the 95% confidence interval for a binomial distribution. A child who made 8 choices, for instance, needed to make at least 5 correct choices to be counted as performing better than expected by chance. Each child's number of correct selections on familiar trials was thus submitted to a binomial test. Six of the 40 children were found to have performance levels on the familiar trials

indistinguishable from chance, and were thus excluded from further analysis. This left a subset of 34 children who could confidently be assumed to have understood the task. Figure 1 shows novel and familiar trial performance for children both from the full set, and from this reduced subset.

We also performed a similar analysis on novel trials, dividing children into two categories: those who reliably showed evidence of using mutual exclusivity (ME), and those who did not. Seventeen children were classified as ME users, and seventeen were classified as Nonusers. We are not arguing that ME is a binary phenomenon, but rather perform this binary split for technical reasons. Binarization loses some information separating children within the ME users category, but it also cleans up noise that may not meaningfully separate nonusers. Quantitative differences at or below chance levels are more likely to be generated by noise than they are to be generated by meaningful process differences, and thus are likely to dilute linear correlations. In subsequent analyses, because mutual exclusivity is analyzed as a binary phenomenon, we use Spearman's  $\rho$ , a non-parametric measure of correlation. In all cases, correlations were stronger for this binary measure.

In this subset, mother's education was still correlated with performance on familiar trials ( $r = .36, p < .05$ ), as was vocabulary size ( $r = .39, p < .05$ ). Neither mother's education nor vocabulary size predicted performance on novel trials ( $\rho = -.11, n.s.$ ;  $\rho = .08, n.s.$ ). In the analyses that follow, we compare the semantic network connectivity of ME users and nonusers. Because use of mutual exclusivity was uncorrelated with vocabulary size, differences in network connectivity are unlikely to be a simple reflection of network size. Further, because mother's education predicted performance on familiar, but not novel, trials, a relationship between ME and vocabulary structure arising from language input must come from more specific properties not indexed by mother's education in this sample.

Figure 1: Proportion of correct choices by participants in both the familiar and novel conditions. Dark blue bars show the complete sample, light red bars the subset. Error bars indicate  $\pm 1$  standard error.

## Semantic Network Analysis

To understand how use of mutual exclusivity contributes to the structure of children's vocabularies, we formalize these vocabularies as semantic networks. In semantic networks, vertices represent the words that children know, and edges represent semantic relationships among these words. In any such analysis, the first step is to formalize 'semantic relatedness' – the relationship used to link two words.

Previous analyses have used a number of successful metrics of connectivity: co-occurrence in CHILDES (e.g. Beckage, Hills, & Smith, 2011), frequency of free-association by adults (e.g. Steyvers & Tenenbaum, 2005), and common perceptual and conceptual features (e.g. Hills, et al., 2009b). In our analysis, we adopt and extend the last approach, connecting two words if they share a number of common semantic features. Features were drawn from the set of McRae feature norms (McRae, Cree, Seidenberg, & McNorgan, 2005). McRae and colleagues asked 725 adults to freely list up to 14 features of 541 English nouns. The number of features shared by two words gives a measure of their semantic relatedness.

Although participants could generate any features they liked, McRae et al. (2005) subsequently divided the generated features into 4 categories: perceptual features accessible to the 5 senses (e.g. "has fur," "tastes sweet"), functional features (e.g. "used for writing," "is edible"), encyclopedic features (e.g. "is expensive"), and taxonomic features (e.g. "a crustacean"). Following Hills et al. (2009b), we analyze only features of the first and second kind, as these are the features likely to be available to two-year-old children. We create two different networks for each child: one in which connectivity is defined by *perceptual* feature overlap, and one in which connectivity is defined by *functional* feature overlap. This is because overlapping perceptual features indicate a very different kind of relatedness than overlapping conceptual features.

Hills et al. (2009b) analyzed the clusters produced by each of these kinds of networks to quantify these different kinds of relatedness. Defining connectivity by *perceptual* feature overlap produced networks that were dense, highly connected, put words into more than one category, and produced categories that were overly inclusive relative to human judgments (e.g. MCDI categories, Fenson, et al., 1994). In contrast, *functional* feature overlap produced networks that were sparser, had smaller, better defined categories, and were better at discriminating among near-category members. In general, words connected in the *functional* network are more likely to be encountered in a relational context, facilitating learning by mutual exclusivity (e.g. *cake-carrots*, *boots-coat*). In contrast, words connected in the *perceptual* networks are less likely to be encountered in such situations, and learning one is thus less likely to facilitate learning the other through mutual exclusivity (e.g. *sheep-sofa*, *pencil-stick*). Thus, we can test a specific prediction about how mutual exclusivity builds vocabulary structure: it facilitates the acquisition of *functionally* related words.

Figure 2: Two 7-vertex networks with different connectivity structures. The left network has a high clustering coefficient and a low degree centrality. The right network has a low clustering coefficient, but a high degree centrality.

In addition to using these two kinds of features to define connectivity, we measure their resulting structure in two different ways. These different connectivity measurements represent different ways in which mutual exclusivity could build structure. Consider the networks in Figure 2.

The first network (2a) has many local clusters, triangles in which any vertices with a common neighbor are likely to be neighbors themselves. One might predict mutual exclusivity to facilitate this kind of structure because using one word (e.g. *scarf*) to learn a semantic neighbor (e.g. *sweater*) should make a common neighbor even easier to learn (e.g. *coat*). This structure is measured by *clustering coefficient* (Equation 1), which has previously been used to distinguish the vocabulary structures of early and late talkers (Beckage, Hills, & Smith, 2011).

$$C = \frac{1}{|V|} \sum_{i=1}^{|V|} \frac{2|\{e_{jk}\}|}{d(v_i)(d(v_i) - 1)} \quad v_j, v_k \in N_i, e_{jk} \in E \quad (1)$$

In contrast, the second network (2b) does not have any local clusters, but rather has a single highly salient *hub*: a single vertex with many neighbors. This kind of structure might be even more likely to arise through mutual exclusivity, as learning the *hub* word (*bowl*) makes each of its neighbors easier to learn (*spoon*, *tray*, *cup*). This kind of structure is measured by *degree centrality* (Equation 2). This measure is new to semantic network analyses, but is a mainstay of social network science (Freeman, 1979), and measures the structural property intuitively most likely to be related to learning words through exclusion.

$$D = \frac{\sum_{i=1}^{|V|} [d(v^*) - d(v_i)]}{(|V| - 1)(|V| - 2)} \quad (2)$$

Thus, we test two hypotheses in the following analysis: mutual exclusivity should predict connectivity structure in *functional* but not the *perceptual* networks, and it should manifest more strongly in high *degree centrality* should than in *clustering coefficient*.

## Method

To construct semantic networks for each child, we used all words which are both measured by the MCDI, and for which McRae and colleagues collected feature norms. This resulted in a list of 130 nouns, encompassing animals, food, clothing, vehicles, etc. For a full list, see Hills et al. (2009b). Each child's semantic network was constructed by adding one vertex for each word on that child's productive MCDI. Vertices were connected if they shared a minimum number ( $w$ ) of semantic features. To be consistent with Hills et al. (2009b), we set this features threshold to all possible values 1-4. At  $w = 3$ , for instance, two words were connected only if they shared three or more semantic features. However, networks become increasingly sparse as  $w$  increases, and we thus urge caution in interpreting results at high thresholds.

Two networks were created for each child, one network in which only *perceptual* features defined connectivity, and one network in which only *functional* features were used to define connectivity (see above). Networks were defined by their set of vertices  $V$  and the set of edges  $E$  that connected them. A vertex's degree ( $d(v)$ ) is defined as the number of other vertices to which it is connected by an edge. These connected vertices are called neighbors, and together define a node's neighborhood ( $N$ ).

Once each network was constructed, two properties of its connectivity structure were measured. The first, clustering coefficient ( $C$ ), measures the proportion of vertices with a common neighbor that are also neighbors of each other. (Equation 1). The second, degree centrality ( $D$ ), measures the proportion of edges connected to a single dominant *hub* vertex (Equation 2). These measures of structure trade off, with high degree centrality necessitating a low clustering coefficient. Both measures always range between 0 and 1, and thus are independent of the size of a child's vocabulary. They are measures of structure independent of size.

## Results and Discussion

As in the analysis above, children were divided into two groups: Mutual Exclusivity Users who performed better than chance on the novel trials of the disambiguation task, and Nonusers who did not. Again, we reiterate that this is not a theoretical commitment, but rather a tool for noise reduction. The structure of each child's individual semantic networks – both perceptual and functional – was used to predict that child's category of mutual exclusivity usage.

Before presenting the results of network analyses, we recapitulate that vocabulary *sizes* were quite comparable between these groups. The 17 ME Users produced an average of 408.3 words on the MCDI while the 17 Nonusers produced an average of 388.1 ( $t(32) = .37, n.s.$ ). They also did not differ in the number of words they knew from the set of 130 used in the network analysis ( $M_u = 92.6, M_n = 88.1, t(32) = .51, n.s.$ ). However, the particular words they knew, and the semantic relationships among them, proved to be importantly different.

Figure 3 shows correlations between measures of network structure and the mutual exclusivity category to which each individual child belonged. For perceptual networks, constructed by connecting words by shared perceptual features (e.g. “has fur,” “tastes sweet”), neither clustering coefficient nor degree centrality were related to use of mutual exclusivity at any feature overlap threshold (Figure 3, left column). As predicted, perceptual networks, in which connections are not a good proxy for words likely to occur in contrastive contexts, have structures not well predicted by use of mutual exclusivity.

In contrast, for functional networks, those constructed by connecting words by shared relational, functional features, mutual exclusivity was a significant predictor of degree centrality when 2 or more overlapping features defined a connecting edge ( $w = 2$ ). At this threshold, children who used mutual exclusivity at above-chance levels had semantic networks with higher degree centrality ( $\rho = .34, p < .05$ ; Figure 3, bottom right). This same threshold is shown by Hills et al. (2009a) to best separate semantic categories in this set of words. Use of mutual exclusivity did not reliably predict clustering coefficient, but did show a positive trend, particularly at overlap threshold 3 ( $\rho = .28, p = .1$ ; Figure 3, top right). This trend should be interpreted cautiously, however, as conceptual networks were quite sparse at  $w = 3$ , having at most 12 edges.

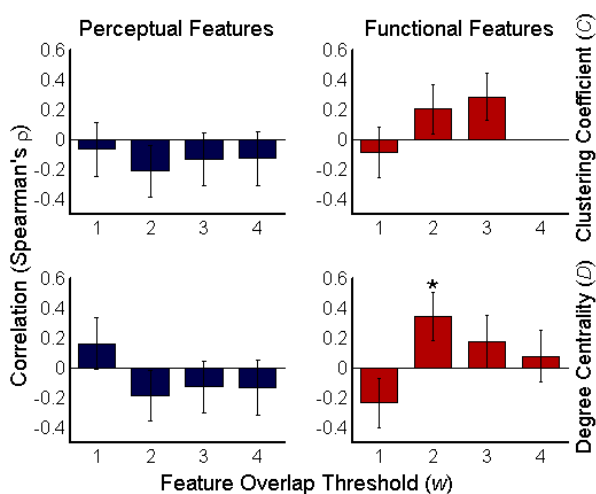

Figure 3: Correlation between network structure and mutual exclusivity performance. The top row shows correlations clustering coefficient, the bottom row for degree centrality. The left column shows perceptual features, the right shows functional. Individual bars shows correlations when particular thresholds ( $w$ ) define the minimum number of overlapping semantic features required to connect two words. Error bars show  $\pm 1$  standard error as measured by 1000 samples of bootstrap resampling (Lunnenborg, 1985). Mutual exclusivity was significantly correlated with degree centrality in the functional networks and showed a non-significant trend towards correlation with correlation coefficient in these same networks. As predicted, ME was uncorrelated with perceptual network structure.

Thus, the semantic network structures of children who reliably exhibit mutual exclusivity are predictably different from those of children who do not. Even though these children know the same number of words, the words they know are different. Semantic networks of ME users are characterized by more hub-like structure, a consequence of the kind of word learning facilitated by exclusion. Importantly, these differences are likely to matter (Beckage, Smith, & Hills, 2011). Differences in connectivity structure lead to differences in network robustness, with the networks of mutual exclusivity structure perhaps protecting them against forgetting and aiding future learning (Albert, Jeong, Barabási). These results represent a first step in understanding how children’s own learning mechanisms build the structure of their semantic networks.

## General Discussion

While the words that children learn are, of course, a function of the linguistic input to which they are exposed (Brent & Siskind, 2001; Hills et al., 2009a), this link is likely to be moderated by children’s own attentional and learning mechanisms (Hudson Kam & Newport, 2005; Smith, 2000). For instance, children learn to extend newly-learned object words to categories on the basis of particular feature dimensions. Normatively, children learn a bias to attend to shape, and this bias leads them to learn more categories organized by shape (Smith et al., 2002). However, children may learn a different bias, and consequently learn different words in the future (Colunga & Sims, 2011). We show that use of mutual exclusivity may play a similar role. Children who robustly use mutual exclusivity are likely to learn new words functionally related to words they already know. As atypical semantic network structure is related to slower language learning (Beckage, Smith, & Hills, 2011), these results point to a potential intervention for late-talking children. Learning to disambiguate the meanings of new words through exclusion could help late-talkers to catch up.

These results also lead to two further insights about mutual exclusivity and its role in vocabulary development. While mutual exclusivity is often thought to be critical to early word learning, its relationship to vocabulary size is unclear. For every study that finds a significant correlation between mutual exclusivity and vocabulary size (e.g. de Marchena, Eigsti, Worek, Ono, & Snedeker, 2011; Mervis and Bertrand, 1994), another finds no correlation between the two (e.g. Halberda, 2003; Mather & Plunkett, 2009). These results help to shed light on this inconsistency by pointing out that the relationship between vocabulary development and mutual exclusivity may be found not in size but in structure. While we do not mean to argue that mutual exclusivity is required for rapid word learning, we do suggest that their relationship can be better understood by considering semantic network structure.

Finally, these results may shed light on the origins of mutual exclusivity itself. Thus far, we have argued that mutual exclusivity builds vocabulary structure. But

vocabulary structure may also build mutual exclusivity. One can think of mutual-exclusivity as an overhypothesis, a probabilistic rule about the general structure of word-object mappings derived from the structure of individual word-object mappings (Kemp, Perfors, & Tenenbaum, 2007; Mervis & Bertrand, 1994). For instance, mutual exclusivity may have its roots in an understanding that labels are often contrastive, pointing to differences between otherwise similar objects. If this is true, vocabularies that make this overhypothesis more probable should lead to stronger mutual exclusivity biases. Thus, one can think of the hub-like structures characteristic of ME users in our sample as not only arising from mutual exclusivity, but helping to construct it as well. Hub words, which are connected to many semantically-related neighbors, may play an important role in discovery of this higher-order regularity. Thus, mutual exclusivity may operate much like the shape bias: being both built from regularities in the structure of linguistic input, and helping children to discover further regularities (Smith, et al., 2002). A deep understanding of the connection between mutual exclusivity and vocabulary structure, then, will come from understanding a three part relationship: how ME contributes to structure, how structure contributes to ME, and language input contribute to both.

### Acknowledgments

We are grateful to Cody Stitzel for her help coding the MCDI data, and to all of the members of the Smith, Yu, and Shiffrin labs whose feedback helped to improve this work. This work was supported by a NSF GRF to DY.

## Abstract

The study of cognitive development hinges, largely, on the analysis of infant looking. But analyses of eye gaze data require the adoption of *linking hypotheses*: assumptions about the relationship between observed eye movements and underlying cognitive processes. We develop a general framework for constructing, testing, and comparing these hypotheses, and thus for producing new insights into early cognitive development. We first introduce the general framework – applicable to any infant gaze experiment – and then demonstrate its utility by analyzing data from three studies investigating the role of attentional cues in infant learning. Finally, we discuss general implications for construction and testing of quantitative linking hypotheses.

Keywords: eye movement data; infancy methods; Bayesian data analysis; learning; attention

## Introduction

The study of infant cognitive development hinges, largely, on the analysis of infant looking data (Aslin, 2007). Since Fantz’s (1964) landmark demonstration of visual memory in 2-month-old infants, researchers have used his habituation technique, and other eye-movement methods, to ask deep theoretical questions about the ontogeny and development of human cognition. But analysis of eye-movements, like analysis of other high-dimensional cognitive measures (e.g. fMRI, EEG) carries particular challenges (Yu, Yurovsky, & Xu, 2012). In order to connect observed eye-movements to underlying cognitive processes, one must define a linking hypothesis that relates them (Aslin, 2007; Teller, 1984).

Every eye gaze paradigm used to study infant cognition commits to a particular *linking hypothesis*. In habituation studies, decreased looking is hypothesized to indicate encoding, and recovery of looking indicates discrimination of a novel stimulus (Gilmore & Thomas, 2002). In violation of expectation studies, increased looking is hypothesized to indicate noticing a surprising event. Intermodal preferential looking studies hypothesize that a difference in looking time to one sound-object mapping over another indicates a difference in their associations. Critically, these linking hypotheses are *qualitative*; they assert that a relationship exists, but do not specify its *quantitative*, metric properties.

Why should we prefer quantitative linking hypotheses? They help us, in several ways, to move from asking *if* a phenomenon occurs, to asking *how* and *why*. First, quantitative linking hypotheses allow researchers to clearly and unambiguously specify the assumptions and

mechanisms in their theories. As theories grow in complexity, correctly deriving their (sometimes counterintuitive) predictions can become difficult. Formalizing theories makes such prediction tractable (Shiffrin, 2010). Second, without quantitative predictions it can be impossible to distinguish competing theoretical accounts of the same data, fueling debates about “rich” (conceptual) vs. “lean” (perceptual) theoretical explanations (e.g., Spelke, 1998). Third, quantitative linking hypotheses allow researchers to test the same theoretical model across experiments, integrating multiple datasets within one self-consistent framework (Aslin, 2007; Schöner, & Thelen, 2006; Shiffrin, 2010).

Developmentalists who measure eye-movements, however, face several challenges to the construction of quantitative linking hypotheses. First, control of eye-movements is complex, and saccades are moderated by multiple systems (Aslin, 2007). Thus, quantitative linking hypotheses may need to integrate interacting mechanisms. Second, although fixation duration is likely related to learning, their relationship may not be a simple linear one. Instead, learning and looking may be linked non-monotonically, with a preference for familiarity appearing first, and a preference for novelty developing with further experience (Hunter & Ames, 1988). Linking hypotheses must be flexible enough to accommodate this kind of complexity. Third, early development is a time of rapid change, and the variability among infants of the same age may be surprisingly high. Thus, using the same linking hypothesis for each infant may distort true relationships in the data (Siegler, 1987). Because one cannot know apriori whether one’s data is best analyzed as one group, or two, or three or more, construction of linking hypotheses must adaptively accommodate this kind of variability.

Building on a growing body of statistical tools in Bayesian non-parametrics, this paper presents a rigorous, principled, empirically successful framework for the construction of quantitative linking hypotheses that meets the three challenges reviewed above. To demonstrate the utility of this framework, we analyze data from a set of experiments investigating the role of social and non-social cues in infant multi-modal learning (Wu & Kirkham, 2010). This analysis shows how quantitative linking hypotheses can provide leverage in understanding the development and operation of infant learning mechanisms. We begin by presenting the general framework, demonstrating its robustness in simulation studies, and then present the empirical data.

## General Model Framework

In any eye-tracking experiment, infants are exposed to stimuli that encode some structure of theoretical interest, and the researcher measures the influence of this structure on their behavior. For instance, in word-learning experiments, infants are exposed to consistent pairings between words and objects, and their discrimination for consistent vs. inconsistent mappings is measured (e.g. Yu & Smith, 2011). However, we are typically interested not in the change in observed behavior, but rather in the cognitive processes it implicates (Aslin, 2007). Quantitative linking hypotheses let us describe these processes directly.

For each infant, on each trial, the researcher observes some eye-gaze data ( $D$ ), and the researcher's goal is to determine the model ( $M$ ) that best explains these observed eye-movements ( $P(M|D)$ ). This can be formalized as a problem of Bayesian inference. The researcher can specify several possible models, each making different predictions about the gaze data likely to be observed ( $P(D|M)$ ). The researcher may also prefer simpler models apriori, in accord with Ockham's razor ( $P(M)$ ). These properties can then be combined via Bayes' rule to infer the model that best describes the infants' cognitive processes (Equation 1).

$$P(M|D) \propto P(D|M)P(M) \quad (1)$$

We present a graphical model (Figure 1) for connecting hypothesized cognitive models to observed eye gaze data. On each trial of an experiment, an infant ( $i$ ) is exposed to some experimental stimuli ( $e$ ) and produces observed eye movements ( $d$ ). This observed gaze data is encoded as proportion of dwell time over a set of hypothesized areas of interest (AOIs). The inference framework discovers the set of underlying cognitive processes ( $s$ ) that operate on the stimuli to generate the observed data. Intuitively, this is essentially a regression problem: inference finds the relationship between predictor variables ( $s, e$ ) and observed outcomes ( $d$ ). Because gaze data are a distribution over AOIs rather than a single continuous variable, we connect predictors to outcomes via the Dirichlet distribution ( $\theta$ ).

Figure 1: A graphical model for inferring the cognitive processes ( $s$ ) responsible for generated eye movements ( $d$ ) under particular experimental conditions ( $e$ ).

The introduction identified three challenges for quantitative linking hypotheses: multiple processes may drive eye-movements, linking functions may be complex, and a group of infants may be heterogeneous. This framework meets all three challenges. Because  $s$  can encode any hypothesized cognitive model, the contributions of multiple processes can be estimated together without forcing a dichotomy (Anderson, 2011). Nonetheless, if a process has little effect, this is found via the prior on parameter values  $\sigma$  (Figuerido, 2002). Second, cognitive processes and observed eye movements need not be linked in a simple, linear way. In this framework, the cognitive model  $s$  can encode any functional link. For simplicity, and to minimize assumptions, we do so through arbitrary degree polynomials (see Jackson & Sirois, 2009). Again, the model parameter prior ( $\sigma$ ) facilitates discovery of the most parsimonious linking function, penalizing complex polynomials.

Formally, each cognitive model parameter  $s$  is modeled as a draw from a 0-mean normal distribution whose standard deviation has a non-informative prior, making high values unlikely (Jeffreys, 1961). Each infant's data are modeled as a draw from a Dirichlet distribution over the AOIs whose parameters are defined as the exponentiated product of the cognitive model parameters and experimental settings  $e$  (Equations 2). This allows model parameters to be negative. A specific formulation is presented in the next section.

$$\begin{aligned} \sigma &\sim \frac{1}{|\sigma|} \\ s &\sim N(0, \sigma^2) \\ \theta_z &= e^{(s_z \times e)} \\ d &\sim \text{Dir}(\theta_z) \end{aligned} \quad (2)$$

Finally, infants in a sample may come from two or more different kinds of groups, (e.g. slow and fast learners: Yu & Smith, 2011). This framework automatically and adaptively determines the number of groups of infants, and the infants who belong to each group. Each distinct group is best represented by a different cognitive model. The estimation of unique groups is performed using the Chinese restaurant process (Aldous, 1985), which has been used successfully to determine unique groups in adult experiments (Navarro, Griffiths, Steyvers, & Lee, 2006). Clusters are discovered in this process by treating participants by analogy to customers in a Chinese restaurant. As each customer enters, he sits at each occupied table ( $z$ ) with probability proportional to the number of occupants, but also chooses a new table with some small probability ( $\alpha$ ). This implements a rich-get-richer scheme in which groups that account for the behavior of many infants become favored, and the most parsimonious number of groups is discovered. A hyper parameter ( $\gamma$ ) prevents us from having to make a direct decision about the probability of choosing a new table (Equations 3). Each cluster has different cognitive parameter values ( $s$ ).

$$\begin{aligned} \alpha &\sim \text{Exp}(\gamma) \\ z &\sim \text{CRP}(\alpha) \end{aligned} \quad (3)$$

## Case Study: Attentional Cues and Infant Learning

To demonstrate how this framework’s utility in a concrete case, we applied it to data from a set of studies investigating the role of attentional cues in infant multi-modal learning. In each experiment, 8-month-old infants watched videos in which sounds and objects’ on-screen locations were reliably related. When objects appeared in the top-left and bottom-right boxes, one sound was heard. When they appeared instead in the top-right and bottom-left boxes, a different sound was heard (Figure 2). In some conditions, infants were cued to one of the two objects. Subsequently, infants were exposed to test trials on which they heard a sound from training, but all four boxes were blank. If infants had learned sound-location regularities, they were expected to attend preferentially to locations consistent with each sound.

Submitting these test preferences to ANOVAs, Wu and Kirkham found reliable multi-modal learning only in the presence of the Face cue (2a), but not when infants were cued with a flashing square (2b) or received no cue (2c). We reanalyze this data to reveal significantly more structure, and to provide new insights into infant learning.

To this end, we define quantitative linking hypotheses for these experiments, formally specifying the connection between the observed eye-movement data ( $d$ ), observable experimental conditions ( $e$ ), and the unobservable, hypothesized cognitive processes ( $s$ ). By analogy to regression, the data are the dependent variable, experimental conditions are the independent variables, and the cognitive processes parameterize these independent variables. On each trial of the experiment – whether training or testing – infants saw a black screen containing four boxes, one in each corner of the screen (Figure 2). Thus, we define five areas of interest (AOIs): one for each of the four boxes, and a fifth to capture all other looks (including off-screen looks).

Figure 2: Training and testing trials from Wu & Kirkham (2010). In the Face condition (2a), a centrally-located face directed infants’ attention to one of the boxes. In the Square condition (2b), a red flashing square highlighted one of the boxes. In the No Cue condition (2c) only the multi-modal regularity was present. On test trials (2d), all boxes remained empty while infants heard a sound from training.

The total data ( $d$ ) for an individual infant is thus the entire set of gaze proportions observed on each trial. Formally, this is a matrix in which rows correspond to trials, columns to AOIs, and each cell to the proportion of looking to a particular AOI on a particular trial. This whole matrix is the outcome to be predicted from the experimental conditions ( $e$ ) and hypothesized cognitive processes ( $s$ ).

Next we specify the experimental conditions on each trial. While all four boxes were empty on test trials, on training trials two of the four boxes contained pictures of animals (Figure 2a-c). These are coded with binary indicator variables *salient* specifying whether a box ( $b$ ) contains a picture. Further, in the Face and Square conditions (Figure 2a-b), one of the boxes was highlighted by an attentional cue. We similarly define an indicator variable *cued*.

$$\begin{aligned} \text{salient}(b) &= \begin{cases} 1 & \text{box } b \text{ contains stim} \\ 0 & \text{otherwise} \end{cases} \\ \text{cued}(b) &= \begin{cases} 1 & \text{box } b \text{ cued} \\ 0 & \text{otherwise} \end{cases} \end{aligned} \quad (4)$$

In addition to the visual stimuli, each trial also included a sound that could alter looking patterns if infants learned sound-location contingencies. To formalize this learning process (below), we encode infants’ experience with these contingencies in the experimental conditions ( $e$ ). Thus, we let *contingent* be the cumulative time an infant has fixated a given box ( $b$ ) in the presence of a particular sound ( $n$ ). So, on trial  $t$  that plays sound  $n_t$  and on which we observe data  $d_t$ , where  $\delta(i, j)$  is Kronecker’s delta function,

$$\text{contingent}_t(b, n_t) = \sum_{r=1}^{t-1} \delta(n_r, n_t) \cdot d_r(b) \quad (5)$$

Last, we define cognitive processes that act on experimental condition variables to produce observed gaze data. First, infants may have a baseline preference for some locations over others. Thus, we include a preference constant  $p_b$  for each AOI, allowing the contributions of the other variables to be estimated relative to proper baselines. Second, an infant’s preference for a box may be altered by the presence of an object (*salient*), or the presence of an attentional cue (*cued*). We let the strength of these factors be linearly scaled by parameters  $l$  and  $c$  respectively, which function like slope terms in linear regression.

Finally, in these experiments, the question of interest is whether infants learn to associate sounds with objects/locations. We define the effect of association between a sound and location as a change in preference for that location through exposure to the contingent sound. Specifically, we define association between a sound and location as a function of time spent fixating that location in the presence of that sound (*contingent*). To avoid making assumptions about the association function (e.g. that it is linear, or monotonic), we let association between box  $b$  and sound  $n$  on trial  $t$  be an arbitrary degree polynomial function of cumulative looking time to  $b$  while hearing  $n$ .

Since polynomials can approximate any functional form, this is a general solution (Jackson & Sirois, 2009). As in testing for higher-order terms in standard regression, polynomial coefficients are pushed down to zero by model priors if they do not contribute to predictive power.

$$assoc_t(b, n) = \sum_{o=1}^o a_o \cdot [contingent_t(b, n)]^o \quad (6)$$

After formally specifying the experimental conditions and hypothesized cognitive process that act on this input, we can infer the effect of each hypothesized factor on infant the gaze data. As in regression, differences in parameters across conditions help us understand whether and how different cues affect infant multi-modal learning. To infer parameter values, we perform Bayesian inference in the model specified in Figure 1. Because this model has non-conjugate priors, we use an MCMC sampling algorithm that alternates Metropolis-Hastings updates with Split/Merge steps for cluster assignment (Jain & Neal, 2007). Sampling estimates the true distribution for each of these parameters, producing a set of credible intervals (similar to confidence intervals) that can be used to determine the likelihood that parameters are non-zero, as well as their likely range (Kruschke, 2011). Clustering was relatively insensitive to  $\gamma$ , so we let  $\gamma = 1$ .

## Simulations

In order to ensure that it behaves as expected, we validate the analysis in a set of simulation studies by generating gaze data from a known cognitive model and trying to recover its parameters. In these simulations, we show that this framework can deal with all three challenges for quantitative linking hypotheses: non-homogenous samples of infants, interactions among multiple cognitive processes, and non-linear functions linking learning to looking.

Infants in Wu & Kirkham’s (2010) study were simulated in training and testing trials like those in their experiments. Each simulated infant was exposed to four consecutive blocks, each consisting of six training trials and a test trial. On each training trial, objects appeared in two of the boxes (top-left and bottom-right, or top-right and bottom-left), and the lower box was cued. Each configuration of objects also co-occurred with a unique sound. Each of the two configurations occurred three times in each block of training trials, and order was randomized within a block. After all six training trials, infants saw one test trial where the screen was empty, but one of the two sounds was heard. Simulated infants then saw three more blocks, and each sound was tested twice in random order across the four test trials.

### Simulation 1

In Simulation 1, we generated gaze data from known models in which the infants in a sample were drawn from a mixture of one, two, three, or four distinct groups. Formally, the 30 infants on each run were drawn from a multinomial distribution with equal probability for each group.

Parameters for each group were drawn randomly without replacement from *cued* –  $c$ : {0, 1, 2, 3}, *salient* –  $l$ : {0, 1, 2, 3}, and *contingent* –  $a_1$ : {0, .2, .4, .6}. Baseline AOI preferences for each box were drawn uniformly from  $[-2, -1]$  and off-screen preference was drawn from  $[.5, 1.5]$ . These values were representative of those found in the empirical analysis (next section).

Across all 120 simulations (30 runs at each group size), the correct number of groups was identified in all but 1. On one run at group size 4, the analysis identified only 3 clusters. Further, individual infants were almost always assigned to the right group. Group assignment was perfect when the number of true groups was 1 or 2, and less than a quarter of one percent ( $<.0025$ ) of infants were misclassified at the higher group numbers. Thus, this framework deals well with heterogeneous groups of infants.

### Simulation 2

Simulation 2 tested the framework’s ability to recover correct quantitative parameter values when multiple processes interacted to produce eye movements. This time, all infants were drawn from one group, but group parameters were parametrically manipulated to sample the space of parameters recovered in the analysis of Wu & Kirkham’s empirical data. Six unique parameter values were chosen for each hypothesized cognitive processes, and one simulation was run at each combination. Baseline preferences on each run were drawn as in Simulation 1. Figure 3 (next page) shows parameter estimates and true values for each combination of parameter values. Inference was successful:  $r^2$  values were exceedingly high.

Figure 3: Best fit lines for true and inferred parameter values for each of the three factors hypothesized to affect infant gaze patterns in the experimental data.

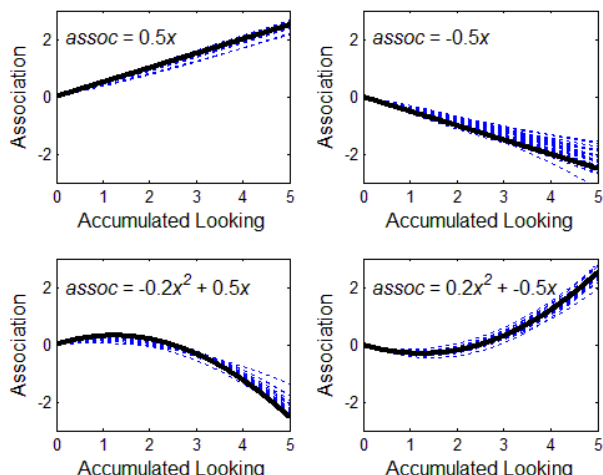

Figure 4: True functions (solid) and 30 inferred functions (dashed) for each learning function tested in Simulation 3.

### Simulation 3

Simulation 3 tested the framework’s ability to recover non-monotonic learning functions, for instance, a preference for familiarity followed by novelty. On each run of the simulation, 30 infants were generated with one of four possible learning functions: linear increasing, linear decreasing, u-shaped up, and u-shaped down (Figure 4). All other model parameters were drawn as in Simulation 2. Bayesian 95% credible intervals for estimated parameters were analyzed to determine how often a 0-valued parameter was estimated to be non-zero (0%) and how often a non-zero parameter was estimated to be 0 (2.5%). Thus, both Type I and Type II error rates were low (Kruschke, 2011).

### Empirical Analysis

We now apply the same inference procedure to gaze data from real infants. Instead of comparing the effects of different attentional cues on raw looking patterns, as in standard analyses (e.g. ANOVAs), inferring cognitive model parameters for each condition lets us analyze the effects of cues directly on attention and learning.

### Method

Inference was performed using the same model as in the Simulations above. Infants each saw a series of training and testing trials, and gaze data on each trial were coded as a proportion of looking to each on-screen box as well as a fifth AOI for all other looks (Figure 2). As before, inference recovered the joint distribution for all parameters ( $s$ ) explaining looking as a function of experimental conditions. Full parameter descriptions are in the Simulation section. Gaze data included 26 infants in the No Cue condition, 29 infants in the Face condition, and 30 infants in the Square condition (see Wu & Kirkham, 2010 for full details).

Before presenting the results, we review Wu & Kirkham’s ANOVAs for test trial looking. These analyses showed associative learning only in the Face condition. In contrast, infants in the No Cue condition showed no learning, and

infants in the Square condition preferred the cued locations, but did not learn to sound-location associations.

### Results and Discussion

Inference yields full posterior distributions for all cognitive model parameters, estimating the contribution of each factor in the context of all other factors. We focus on two key factors: attention to the cue ( $c$ ) and the association function ( $assoc$ ). Figure 5 shows estimated parameter values for both factors for infants in each experimental condition.

First, in no condition were infants best described as a single homogeneous group. Two distinct groups were identified in the Face and No Cue conditions, and four groups were found in the Square Condition. Thus, even within one condition, infants learned and used cues differently. Second, all learning functions were linear; credible intervals for all association coefficients  $\geq 2$  overlapped 0 in all conditions. Thus, Figure 5 shows the first-order association coefficient ( $a_1$ ) for each group.

Finally, we turn to the parameter values and their implications. First, all infants in the No Cue condition appeared to be learning ( $a_1 > 0$ ), although approximately  $\frac{2}{3}$  had low association values, indicating that they learned slowly. The Face condition had a comparable number of equally fast learners, and these fast learners did not show evidence of using the cue ( $c \approx 0$ ). However, the larger, slow group of learners did use the cue, and learned faster than the slow learners in the No Cue condition. Learners had two routes into learning the regularity: quickly and directly, or slowly and indirectly. This detailed level of structure underlies and explains Wu & Kirkham’s coarser analysis.

The Square condition also had a small group of fast learners who used the cue. However, in contrast to the other conditions, approximately  $\frac{1}{2}$  of the infants did not learn, and these infants all used the cue ( $c > 0$ ). These results directly confirm Wu and Kirkham’s hypothesis that the flashing square may interfere with learning by competing for attention, and that only the fastest learners may be able to learn from these kinds of competing cues. Together, these results both confirm the major findings from the standard analysis and provide deeper insight into how attentional cues guide (or interfere with) infant multi-modal learning.

Figure 5: Posterior distributions for *cue* ( $c$ ) and *association* ( $a_1$ ) parameters for infants from Wu & Kirkham (2010). Each circle indicates a cluster, and its size indicates the proportion of infants in that condition in that cluster. Circles are centered at median parameter values, and dashed lines indicate 68% credible intervals, akin to  $\pm 1$  SE.

**Non-monotonic learning functions.** Simulation 3 showed that this framework can recover non-monotonic functions linking learning to looking when appropriate for the data (Hunter & Ames, 1988). However, no such functions appear in the Empirical Analysis above. Why? One possibility is that non-monotonic linking functions arise in a different kind of experiment or at a different age. An alternative possibility is that non-monotonic linking functions are seen when infants' baseline preferences are not controlled. In our analyses, we included a set of parameters  $p_b$  to encode baseline preferences for each location. When these parameters were not included, we *did* find non-monotonic linking functions in all conditions. Thus, we propose that, at least in some cases, observation of non-monotonic linking functions may be an artifact of different baseline preference rather than a core property of the learning system itself.

**Competing Hypotheses.** One strength of quantitative linking hypotheses is that they facilitate direct comparison of competing theories for the same data. In the previous sections, we argued that changes in looking preferences over the course of these experiments arise from associations between heard sounds and fixated locations, and modeled this learning with the *assoc* function. Alternatively, preferences could change over time through habituation; infants' preferences could change as a function of looking to a location independent of the concurrent sound. We tested this directly, by modeling habituation as an arbitrary-degree polynomial function of cumulative looking time to a location (Equation 7). However, 95% credible intervals for *habit* parameters overlapped 0 in all conditions, out this explanation for the data. Thus, quantitative looking hypotheses allowed us to directly compare two hypothetical explanations of this data and to choose the best alternative.

$$habit_t(b) = \sum_{o=1}^o h_o \cdot \left( \sum_{r=1}^{t-1} d_r(b) \right) \quad (7)$$

## General Discussion

Infant researchers have made tremendous progress by using eye gaze data to ask questions about early cognition and development. The majority of this work has used *qualitative* linking hypotheses, but we propose that even faster progress can be made through model-based analyses using *quantitative* linking hypotheses (Aslin, 2007; Teller, 1984). While quantitative linking hypotheses have been proposed for specific experiments (e.g. Gilmore & Thomas, 2002; Yu & Smith, 2011), this paper presents a general framework applicable to all eye movement experiments. We hope this work will facilitate asking and answering future questions about early cognitive processes and their development.

## Abstract

The words that children learn can be characterized as a semantic network, with links connecting related words. Recent analyses have shown these networks to have small-world structure, with a few highly-connected hub words facilitating short paths between otherwise distant words. This structure contributes to network robustness, and differences in structure can predict differences in language learning outcomes. While previous studies have shown that semantic network structure reflects linguistic input structure, we provide the first evidence that it is related also to children's own language learning biases. Two-year old children who show a mutual-exclusivity bias have significantly more hub-like networks than children who do not, even when they know the same number of words. This finding contributes to our understanding of both semantic networks and the origins of mutual exclusivity.

**Keywords:** word learning; mutual exclusivity; semantic networks; language acquisition

## Introduction

Although the earliest analyses of human memory and learning concerned the learning of lists of unrelated words (Ebbinghaus, 1885/1962), researchers quickly discovered that the words people learn in more natural contexts are intricately connected. Vocabularies were conceptualized as richly structured networks, with links connecting semantically related words (Collins & Loftus, 1975). These connections play an important role in both learning and memory, and can be observed empirically in semantic priming experiments. Because activation spreads from words to their semantic neighbors, presenting a word, even subliminally, leads to faster processing of related words (Anderson, 1983). Even two-year old infants show semantic priming, suggesting that vocabularies have network structure early in language learning (Arias-Trejo & Plunkett, 2009).

Recently, the application of graph-theoretic methods to the study of these networks has begun to provide insight into their structural properties. For instance, Hills, Maouene, Maouene, Sheya, & Smith (2009a) analyzed the semantic network structure of 130 nouns typically learned before 30 months. Compared to randomly-connected control networks, these semantic networks showed significant small-world structure, in which most words are sparsely connected, but a few are highly-connected hubs. This kind

of structure results in networks robust to malfunction (e.g. forgetting a word; Albert, Jeong, & Barabási, 2000), and can help to explain some of the remarkable efficiency of human semantic memory (Raaijmakers & Shiffrin, 1981). Further, semantic networks lacking this structure are associated with slower language-learning, characterizing the vocabulary structure of late talkers (Beckage, Smith, & Hills, 2011). But why do children learn these words? Why do semantic networks have this structure?

Undoubtedly, one answer to this question is that structure comes from the environment. Because children learn words from the language they hear, language input is a strong predictor of the words that children will learn. For instance, the frequency with which a child hears a word in isolation can predict how likely a child is to learn that word (Brent & Siskind, 2001). Similarly, the semantic networks constructed from corpora of both adult-directed and child-directed language have many of the same structural properties as networks constructed from the words 30-month-old children are likely to know (Hills, et al., 2009a; Steyvers & Tenenbaum, 2005).

But perhaps a more complete explanation of the origin of semantic network structure is that it emerges from an interaction between structure in the linguistic environment and the child's own learning system. Because children are not unbiased samplers of linguistic input, their attentional and learning biases mediate the link between language input and language learned (Hudson Kam & Newport, 2005; Smith, 2000). For instance, children who learn to attend to shape are likely to learn shape-based categories, and those who learn to attend to other properties (e.g. material) learn other kinds of words (Colunga & Sims, 2011; Smith, Jones, Landau, Gershkoff-Stowe, & Samuelson, 2002). Can word-learning biases predict and explain semantic network structure? In this paper, we consider the case of disambiguation through mutual exclusivity.

In the disambiguation task, a child is presented with a novel object among one or more familiar object competitors. The child then hears a novel label (e.g. 'can you find the dax?') and is asked to select an object. Both toddlers and adults reliably select the novel object as the target of the novel label (Markman & Wachtel, 1988; Golinkoff, Hirsh-Pasek, Bailey, & Wenger, 1992), and studies with infants suggest that this disambiguation may arise as early as 18 to 22.5 months (Halberda, 2003; Mather & Plunkett, 2009). Preferential

mapping of novel labels to novel objects over known objects, which we will refer to as mutual exclusivity (ME), could arise for a number of reasons, and its mechanism of action is the topic of significant debate (e.g. Diesendruck & Markson, 2001; Golinkoff et al., 1992; Markman & Wachtel, 1988). We explore this question in the general discussion, but will sidestep it here and instead consider the potential consequences of mutual exclusivity for semantic network structure.

Mutual exclusivity is a mechanism by which children can leverage prior knowledge to learn new words *in the context of known objects*. Consequently, children who show mutual exclusivity should have vocabularies that echo this kind of contextual structure. For these children, learning *fork* should ease the acquisition of *spoon*, *bowl*, and *plate*. In contrast, learning *fork* should have little effect on the acquisition of *dog* and *coat*. Thus, we propose that mutual exclusivity can help explain small-world structure of semantic networks, and those children who show mutual exclusivity will have more hub-like networks than those who do not. We begin by reporting empirical data from a disambiguation task with 24-month-old children, continue by describing a semantic network analysis of these children's vocabularies, and conclude with a discussion of how these results inform our understanding of the relationship between mutual exclusivity and vocabulary development, as well as the origins of mutual exclusivity itself.

## Experiment

### Method

**Participants.** Forty two-year-olds ( $M = 24.75$  months; range = 24-26; 20 female) participated. All were typically developing children from households in which parents reported English to be the dominant language. A subset of 34 infants ( $M = 24.9$  months; range = 22.4-27.5; 16 female) participated in the followup analysis (explained below).

**Stimuli.** Nine familiar objects (e.g. boat, glasses) were used in the warm-up trials. Twenty-five familiar (e.g. brush, cup) and 8 novel objects (e.g. massager, platypus) were used in the referent-selection task.

**Procedure.** Parents first completed the MCDI (Fenson, Dale, Reznick, Bates, Thal, & Pethick, 1994) and an SES measure (Hollingshead, 1975). After this, each child participated in three warm-up trials. On warm-up trials, the experimenter set a tray containing three familiar objects on the table, initially covered by an occluder. The experimenter asked for the target object (e.g. "which one is the dog?") three times: once while the items were occluded, again after lifting the occluder, and again three seconds later while pushing the tray towards the infant. The first reach, point, or grab, was scored as a response. On these trials, infants were praised for correct responses and corrected when necessary.

Subsequently, each child participated in sixteen referent-selection trials. On each trial, the experimenter presented a tray containing two familiar objects and one novel object.

The procedure was identical except that children received neutral feedback on all trials. On half the trials, the experimenter asked for a familiar object, while on the other half she asked for a novel object (e.g. *modi*, *taju*).

## Results and Discussion

Each participant made a total of 16 choices, picking 8 targets on familiar trials, and 8 targets on novel trials. Any trial on which the child did not know the label for the familiar target, or the label for one of the familiar distractors, was excluded from analysis. The proportion of targets correctly chosen on these remaining trials was then analyzed to determine the child's success in the task. Overall, children performed quite well, selecting the correct target on both familiar ( $M_f = .83$ ,  $t(39) = 15.31$ ,  $p < .001$ ) and novel trials ( $M_n = .545$ ,  $t(39) = 5.87$ ,  $p < .001$ ) at greater than chance levels. Thus, as a group, 24-month-old children used mutual exclusivity for disambiguation. Familiar trial performance, however, was significantly higher than novel trial performance ( $t(39) = 6.88$ ,  $p < .001$ ).

Because the central question in this study is about the relationship between learning mechanisms and vocabulary development, we measured both vocabulary size (MCDI - Fenson, et al., 1994) and mother's education (Hollingshead, 1975), a potential correlate of rich language input. Mother's education was reliably correlated with performance on familiar trials ( $r = .33$ ,  $p < .05$ ), but not novel trials ( $r = .01$ , *n.s.*), and vocabulary size was not significantly correlated with performance on either kind of trial ( $r_f = .19$ , *n.s.*;  $r_n = .15$ , *n.s.*). In the semantic network analysis to follow, we show that *vocabulary structure* is reliably related to novel trial performance. Because neither mother's education nor *vocabulary size* predict ME in this data set, the relationship between ME and structure is likely to be quite robust.

But perhaps this analysis is unfair. While most of the children had high levels of success on familiar trials, a few children did not perform as well. Since these children knew the words for all three objects on these familiar trials, their low levels of performance indicate that they may not have understood the task. Thus, for the same reason that response time analysis typically uses only correct response trials, excluding these children from individual-level analyses may give clearer correlations. In order to determine whether a child's performance was significantly better than expected by chance, we modeled chance behavior on each trial as random selection of one of the three objects.

The probability of success expected by chance is given by a binomial distribution with probability  $\frac{1}{3}$ . Consequently, a child should be counted as performing differently from chance if he or she made enough correct selections to be outside the 95% confidence interval for a binomial distribution. A child who made 8 choices, for instance, needed to make at least 5 correct choices to be counted as performing better than expected by chance. Each child's number of correct selections on familiar trials was thus submitted to a binomial test. Six of the 40 children were found to have performance levels on the familiar trials

indistinguishable from chance, and were thus excluded from further analysis. This left a subset of 34 children who could confidently be assumed to have understood the task. Figure 1 shows novel and familiar trial performance for children both from the full set, and from this reduced subset.

We also performed a similar analysis on novel trials, dividing children into two categories: those who reliably showed evidence of using mutual exclusivity (ME), and those who did not. Seventeen children were classified as ME users, and seventeen were classified as Nonusers. We are not arguing that ME is a binary phenomenon, but rather perform this binary split for technical reasons. Binarization loses some information separating children within the ME users category, but it also cleans up noise that may not meaningfully separate nonusers. Quantitative differences at or below chance levels are more likely to be generated by noise than they are to be generated by meaningful process differences, and thus are likely to dilute linear correlations. In subsequent analyses, because mutual exclusivity is analyzed as a binary phenomenon, we use Spearman's  $\rho$ , a non-parametric measure of correlation. In all cases, correlations were stronger for this binary measure.

In this subset, mother's education was still correlated with performance on familiar trials ( $r = .36, p < .05$ ), as was vocabulary size ( $r = .39, p < .05$ ). Neither mother's education nor vocabulary size predicted performance on novel trials ( $\rho = -.11, n.s.$ ;  $\rho = .08, n.s.$ ). In the analyses that follow, we compare the semantic network connectivity of ME users and nonusers. Because use of mutual exclusivity was uncorrelated with vocabulary size, differences in network connectivity are unlikely to be a simple reflection of network size. Further, because mother's education predicted performance on familiar, but not novel, trials, a relationship between ME and vocabulary structure arising from language input must come from more specific properties not indexed by mother's education in this sample.

Figure 1: Proportion of correct choices by participants in both the familiar and novel conditions. Dark blue bars show the complete sample, light red bars the subset. Error bars indicate  $\pm 1$  standard error.

## Semantic Network Analysis

To understand how use of mutual exclusivity contributes to the structure of children's vocabularies, we formalize these vocabularies as semantic networks. In semantic networks, vertices represent the words that children know, and edges represent semantic relationships among these words. In any such analysis, the first step is to formalize 'semantic relatedness' – the relationship used to link two words.

Previous analyses have used a number of successful metrics of connectivity: co-occurrence in CHILDES (e.g. Beckage, Hills, & Smith, 2011), frequency of free-association by adults (e.g. Steyvers & Tenenbaum, 2005), and common perceptual and conceptual features (e.g. Hills, et al., 2009b). In our analysis, we adopt and extend the last approach, connecting two words if they share a number of common semantic features. Features were drawn from the set of McRae feature norms (McRae, Cree, Seidenberg, & McNorgan, 2005). McRae and colleagues asked 725 adults to freely list up to 14 features of 541 English nouns. The number of features shared by two words gives a measure of their semantic relatedness.

Although participants could generate any features they liked, McRae et al. (2005) subsequently divided the generated features into 4 categories: perceptual features accessible to the 5 senses (e.g. "has fur," "tastes sweet"), functional features (e.g. "used for writing," "is edible"), encyclopedic features (e.g. "is expensive"), and taxonomic features (e.g. "a crustacean"). Following Hills et al. (2009b), we analyze only features of the first and second kind, as these are the features likely to be available to two-year-old children. We create two different networks for each child: one in which connectivity is defined by *perceptual* feature overlap, and one in which connectivity is defined by *functional* feature overlap. This is because overlapping perceptual features indicate a very different kind of relatedness than overlapping conceptual features.

Hills et al. (2009b) analyzed the clusters produced by each of these kinds of networks to quantify these different kinds of relatedness. Defining connectivity by *perceptual* feature overlap produced networks that were dense, highly connected, put words into more than one category, and produced categories that were overly inclusive relative to human judgments (e.g. MCDI categories, Fenson, et al., 1994). In contrast, *functional* feature overlap produced networks that were sparser, had smaller, better defined categories, and were better at discriminating among near-category members. In general, words connected in the *functional* network are more likely to be encountered in a relational context, facilitating learning by mutual exclusivity (e.g. *cake-carrots*, *boots-coat*). In contrast, words connected in the *perceptual* networks are less likely to be encountered in such situations, and learning one is thus less likely to facilitate learning the other through mutual exclusivity (e.g. *sheep-sofa*, *pencil-stick*). Thus, we can test a specific prediction about how mutual exclusivity builds vocabulary structure: it facilitates the acquisition of *functionally* related words.

Figure 2: Two 7-vertex networks with different connectivity structures. The left network has a high clustering coefficient and a low degree centrality. The right network has a low clustering coefficient, but a high degree centrality.

In addition to using these two kinds of features to define connectivity, we measure their resulting structure in two different ways. These different connectivity measurements represent different ways in which mutual exclusivity could build structure. Consider the networks in Figure 2.

The first network (2a) has many local clusters, triangles in which any vertices with a common neighbor are likely to be neighbors themselves. One might predict mutual exclusivity to facilitate this kind of structure because using one word (e.g. *scarf*) to learn a semantic neighbor (e.g. *sweater*) should make a common neighbor even easier to learn (e.g. *coat*). This structure is measured by *clustering coefficient* (Equation 1), which has previously been used to distinguish the vocabulary structures of early and late talkers (Beckage, Hills, & Smith, 2011).

$$C = \frac{1}{|V|} \sum_{i=1}^{|V|} \frac{2|\{e_{jk}\}|}{d(v_i)(d(v_i) - 1)} \quad v_j, v_k \in N_i, e_{jk} \in E \quad (1)$$

In contrast, the second network (2b) does not have any local clusters, but rather has a single highly salient *hub*: a single vertex with many neighbors. This kind of structure might be even more likely to arise through mutual exclusivity, as learning the *hub* word (*bowl*) makes each of its neighbors easier to learn (*spoon*, *tray*, *cup*). This kind of structure is measured by *degree centrality* (Equation 2). This measure is new to semantic network analyses, but is a mainstay of social network science (Freeman, 1979), and measures the structural property intuitively most likely to be related to learning words through exclusion.

$$D = \frac{\sum_{i=1}^{|V|} [d(v^*) - d(v_i)]}{(|V| - 1)(|V| - 2)} \quad (2)$$

Thus, we test two hypotheses in the following analysis: mutual exclusivity should predict connectivity structure in *functional* but not the *perceptual* networks, and it should manifest more strongly in high *degree centrality* than in *clustering coefficient*.

## Method

To construct semantic networks for each child, we used all words which are both measured by the MCDI, and for which McRae and colleagues collected feature norms. This resulted in a list of 130 nouns, encompassing animals, food, clothing, vehicles, etc. For a full list, see Hills et al. (2009b). Each child's semantic network was constructed by adding one vertex for each word on that child's productive MCDI. Vertices were connected if they shared a minimum number ( $w$ ) of semantic features. To be consistent with Hills et al. (2009b), we set this features threshold to all possible values 1-4. At  $w = 3$ , for instance, two words were connected only if they shared three or more semantic features. However, networks become increasingly sparse as  $w$  increases, and we thus urge caution in interpreting results at high thresholds.

Two networks were created for each child, one network in which only *perceptual* features defined connectivity, and one network in which only *functional* features were used to define connectivity (see above). Networks were defined by their set of vertices  $V$  and the set of edges  $E$  that connected them. A vertex's degree ( $d(v)$ ) is defined as the number of other vertices to which it is connected by an edge. These connected vertices are called neighbors, and together define a node's neighborhood ( $N$ ).

Once each network was constructed, two properties of its connectivity structure were measured. The first, clustering coefficient ( $C$ ), measures the proportion of vertices with a common neighbor that are also neighbors of each other. (Equation 1). The second, degree centrality ( $D$ ), measures the proportion of edges connected to a single dominant *hub* vertex (Equation 2). These measures of structure trade off, with high degree centrality necessitating a low clustering coefficient. Both measures always range between 0 and 1, and thus are independent of the size of a child's vocabulary. They are measures of structure independent of size.

## Results and Discussion

As in the analysis above, children were divided into two groups: Mutual Exclusivity Users who performed better than chance on the novel trials of the disambiguation task, and Nonusers who did not. Again, we reiterate that this is not a theoretical commitment, but rather a tool for noise reduction. The structure of each child's individual semantic networks – both perceptual and functional – was used to predict that child's category of mutual exclusivity usage.

Before presenting the results of network analyses, we recapitulate that vocabulary *sizes* were quite comparable between these groups. The 17 ME Users produced an average of 408.3 words on the MCDI while the 17 Nonusers produced an average of 388.1 ( $t(32) = .37$ , *n.s.*). They also did not differ in the number of words they knew from the set of 130 used in the network analysis ( $M_u = 92.6$ ,  $M_n = 88.1$ ,  $t(32) = .51$ , *n.s.*). However, the particular words they knew, and the semantic relationships among them, proved to be importantly different.

Figure 3 shows correlations between measures of network structure and the mutual exclusivity category to which each individual child belonged. For perceptual networks, constructed by connecting words by shared perceptual features (e.g. “has fur,” “tastes sweet”), neither clustering coefficient nor degree centrality were related to use of mutual exclusivity at any feature overlap threshold (Figure 3, left column). As predicted, perceptual networks, in which connections are not a good proxy for words likely to occur in contrastive contexts, have structures not well predicted by use of mutual exclusivity.

In contrast, for functional networks, those constructed by connecting words by shared relational, functional features, mutual exclusivity was a significant predictor of degree centrality when 2 or more overlapping features defined a connecting edge ( $w = 2$ ). At this threshold, children who used mutual exclusivity at above-chance levels had semantic networks with higher degree centrality ( $\rho = .34, p < .05$ ; Figure 3, bottom right). This same threshold is shown by Hills et al. (2009a) to best separate semantic categories in this set of words. Use of mutual exclusivity did not reliably predict clustering coefficient, but did show a positive trend, particularly at overlap threshold 3 ( $\rho = .28, p = .1$ ; Figure 3, top right). This trend should be interpreted cautiously, however, as conceptual networks were quite sparse at  $w = 3$ , having at most 12 edges.

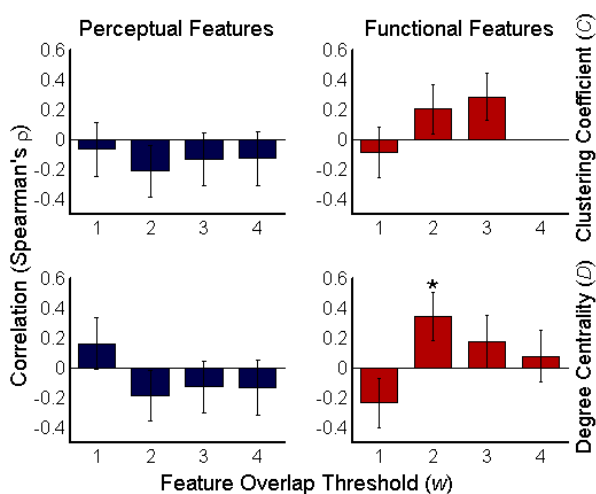

Figure 3: Correlation between network structure and mutual exclusivity performance. The top row shows correlations clustering coefficient, the bottom row for degree centrality. The left column shows perceptual features, the right shows functional. Individual bars show correlations when particular thresholds ( $w$ ) define the minimum number of overlapping semantic features required to connect two words. Error bars show  $\pm 1$  standard error as measured by 1000 samples of bootstrap resampling (Lunnenborg, 1985). Mutual exclusivity was significantly correlated with degree centrality in the functional networks and showed a non-significant trend towards correlation with correlation coefficient in these same networks. As predicted, ME was uncorrelated with perceptual network structure.

Thus, the semantic network structures of children who reliably exhibit mutual exclusivity are predictably different from those of children who do not. Even though these children know the same number of words, the words they know are different. Semantic networks of ME users are characterized by more hub-like structure, a consequence of the kind of word learning facilitated by exclusion. Importantly, these differences are likely to matter (Beckage, Smith, & Hills, 2011). Differences in connectivity structure lead to differences in network robustness, with the networks of mutual exclusivity structure perhaps protecting them against forgetting and aiding future learning (Albert, Jeong, Barabási). These results represent a first step in understanding how children’s own learning mechanisms build the structure of their semantic networks.

## General Discussion

While the words that children learn are, of course, a function of the linguistic input to which they are exposed (Brent & Siskind, 2001; Hills et al., 2009a), this link is likely to be moderated by children’s own attentional and learning mechanisms (Hudson Kam & Newport, 2005; Smith, 2000). For instance, children learn to extend newly-learned object words to categories on the basis of particular feature dimensions. Normatively, children learn a bias to attend to shape, and this bias leads them to learn more categories organized by shape (Smith et al., 2002). However, children may learn a different bias, and consequently learn different words in the future (Colunga & Sims, 2011). We show that use of mutual exclusivity may play a similar role. Children who robustly use mutual exclusivity are likely to learn new words functionally related to words they already know. As atypical semantic network structure is related to slower language learning (Beckage, Smith, & Hills, 2011), these results point to a potential intervention for late-talking children. Learning to disambiguate the meanings of new words through exclusion could help late-talkers to catch up.

These results also lead to two further insights about mutual exclusivity and its role in vocabulary development. While mutual exclusivity is often thought to be critical to early word learning, its relationship to vocabulary size is unclear. For every study that finds a significant correlation between mutual exclusivity and vocabulary size (e.g. de Marchena, Eigsti, Worek, Ono, & Snedeker, 2011; Mervis and Bertrand, 1994), another finds no correlation between the two (e.g. Halberda, 2003; Mather & Plunkett, 2009). These results help to shed light on this inconsistency by pointing out that the relationship between vocabulary development and mutual exclusivity may be found not in size but in structure. While we do not mean to argue that mutual exclusivity is required for rapid word learning, we do suggest that their relationship can be better understood by considering semantic network structure.

Finally, these results may shed light on the origins of mutual exclusivity itself. Thus far, we have argued that mutual exclusivity builds vocabulary structure. But

vocabulary structure may also build mutual exclusivity. One can think of mutual-exclusivity as an overhypothesis, a probabilistic rule about the general structure of word-object mappings derived from the structure of individual word-object mappings (Kemp, Perfors, & Tenenbaum, 2007; Mervis & Bertrand, 1994). For instance, mutual exclusivity may have its roots in an understanding that labels are often contrastive, pointing to differences between otherwise similar objects. If this is true, vocabularies that make this overhypothesis more probable should lead to stronger mutual exclusivity biases. Thus, one can think of the hub-like structures characteristic of ME users in our sample as not only arising from mutual exclusivity, but helping to construct it as well. Hub words, which are connected to many semantically-related neighbors, may play an important role in discovery of this higher-order regularity. Thus, mutual exclusivity may operate much like the shape bias: being both built from regularities in the structure of linguistic input, and helping children to discover further regularities (Smith, et al., 2002). A deep understanding of the connection between mutual exclusivity and vocabulary structure, then, will come from understanding a three part relationship: how ME contributes to structure, how structure contributes to ME, and language input contribute to both.

### Acknowledgments

We are grateful to Cody Stitzel for her help coding the MCDI data, and to all of the members of the Smith, Yu, and Shiffrin labs whose feedback helped to improve this work. This work was supported by a NSF GRF to DY.

## Abstract

It has been widely acknowledged that the interpretation of logical metonymies involves the interpretation of covert events (*begin the book* → *reading / writing*). Whether this implicit content is part of our lexicon or rather derives from general pragmatic inference, it is currently subject of debate. We present results from a probe recognition experiment, providing novel evidence in support of early metonymy processing, consistent with the hypothesis that covert events are retrieved from knowledge of typical events activated by lexical items.

**Keywords:** Logical metonymy; generalized event knowledge; qualia structure; covert events; probe recognition.

## Logical metonymy:

### lexicon, world knowledge, typical events

In logical metonymies, an event-subcategorizing verb is combined with an entity-denoting patient. Contrast the German non-metonymic “long variant” (Ex. 1) with the metonymic “short variant” (Ex. 2), which is understood to have the same meaning:

1. Peter begann das Bier **zu trinken**. (“long variant”)  
Peter began the beer **to drink**.  
Peter began **drinking** the beer.
2. Peter begann das Bier. (“short variant”)  
Peter began the beer. → drinking the beer

In (2), the event-subcategorizing verb *beginnen* (begin) combines with an entity, *das Bier* (the beer), but the clash is resolved and the interpretation constructed by the recovery of a covert event which mediates between matrix verb and object (e.g. *begin* → *drinking the beer*).<sup>1</sup> The reconstruction of the covert event has well-known behavioral correlates – processing metonymic sentences is more costly than processing non-metonymic ones (Pykkänen & McElree, 2006; Baggio, Chroma, Lambalgen, & Hagoort, 2010).

On the level of theory, logical metonymies pose a challenge to compositionality (Partee, ter Meulen, & Wall, 1993; Baggio, Lambalgen, & Hagoort, 2012) and therefore touch on a foundational principle to language research. One of the points

<sup>1</sup>This presumed process, namely the coercion of the object into an event associated with it, explains the use of the term “metonymy”.

of debate is where covert events are retrieved from. The two main accounts of logical metonymy have suggested that covert events are part of our lexical knowledge (“lexical hypothesis”) or that they are retrieved through post-lexical inferences triggered by our general world knowledge and communication principles (“pragmatic hypothesis”).

We present experimental evidence in support of a third hypothesis, namely that covert events are retrieved from knowledge of typical events stored in our long-term memory. A previous self-paced reading study (Zarcone & Padó, 2011) had presented evidence for generalized event knowledge integration in logical metonymy, but its results were relying on a strong methodological assumption, namely that the same cognitive processes are used to interpret “long variants” (Ex. 1) and “short variants” (Ex. 2). The present study uses a probe recognition paradigm in order to avoid this assumption. Additionally, the new paradigm allows us compare reaction times for low and high inter-stimulus intervals to assess the time course of metonymy interpretation in more detail. We find evidence for early, expectation-driven processing for metonymy as opposed to later, strategy expectancy generation, which points towards a central role of generalized event knowledge in logical metonymy interpretation.

## Covert events from lexical knowledge

Pustejovsky (1995) and Jackendoff (1997) provide an account of logical metonymy which we call the “lexical hypothesis”: Logical metonymy is a type mismatch between the (semantic) subcategorization of a metonymic verb for an event and the entity denoted by the object on the other side, which requires the integration of an event to be resolved. The event is retrieved from complex lexical entries (qualia structures) associated with the object in the mental lexicon. In particular, the “agentive quale” (the event that brings about the object) and the “telic quale” (the main purpose of the object) are the relevant components of the qualia structure which can be retrieved as covert events in metonymic contexts.

Being part of the mental lexicon, qualia model linguistic knowledge – in opposition to world knowledge and pragmatic inferences. Psycholinguistic work has identified experimental correlates for the lexical hypothesis (see Pykkänen and McEl-

ree (2006) for a review), however processing studies have focused predominantly on the type mismatch and have largely ignored the question of what covert events are accessible to metonymic interpretation and what their nature is (lexical vs. pragmatic).

The lexical hypothesis provides an economical solution to the problem of covert event retrieval, and it seems very plausible that we associate typical events with lexical items referring to entities in our mental lexicon. However, this solution seems to undergenerate the range of potential interpretations for logical metonymy. Consider the following examples:

3. John is a famous wrestler. He really enjoys a good fight.  
(→ fighting)
4. John is a wrestling fan. He really enjoys a good fight.  
(→ watching)

These examples show a few shortcomings which seem to be associated with this account: first, *fight* is an event-denoting item and, since metonymy is typically claimed to arise from a type clash, we wouldn't expect an event reconstruction here, nevertheless *watching* seems to be the normal scenario involving wrestling fans and wrestling fights; secondly, qualia structures are only defined for artifacts, but not for event-denoting items such as *fight*; lastly, a mechanism to select one or another event depending on the agent involved (e.g. *wrestler* vs. *wrestling fan*) is not specified. Facts like this are well known at least since Lascarides and Copestake (1998), who claim that qualia structure alone (as defined in Pustejovsky (1995)) is not enough to explain the range of reconstructed events in metonymic sentences, which instead derive from the contribution of wider contextual information.

### Covert events from pragmatic inferences

An alternative approach (the "pragmatic hypothesis") has argued that metonymy resolution is driven by dynamic inferences based on context and world knowledge rather than static lexicon entries. This model assumes that lexico-conceptual representations are atomistic (Fodor & Lepore, 1998) and that metonymic event reconstruction derives from post-lexical pragmatic inferences (Cartson, 2002; R. D. de Almeida & Dwivedi, 2008; R. G. de Almeida et al., 2009). Without resorting to lexical atomism, Asher (2010) similarly models logical metonymy in terms of general discourse principles for presupposition accommodation. This approach has the advantage of placing logical metonymy within a broader picture of inference-driven processes, and it accounts for the most problematic cases for strict lexicalist models. However, it currently lacks a concrete characterization of the type and organization of knowledge involved in metonymy interpretation.

### Covert events from generalized event knowledge

Recent work on *generalized event knowledge* (McRae & Matsuki, 2009) has shown that inferential world knowledge about typical scenarios plays an early and crucial role in sentence

comprehension processes. There is solid experimental evidence that language understanding makes extensive use of global plausibility information and event knowledge (e.g. Altmann and Kamide (1999)). McRae and Matsuki (2009) established that speakers make use of prototypical knowledge about events (generalized event knowledge) when rapidly building expectations about upcoming input. Generalized event knowledge is assumed to be built from first and second-hand experience: for instance, we learn that a scenario of *washing hair* typically includes a shampoo, a sink, a bathroom, and happens indoor; a scenario of *washing car* would include different elements (an outdoor environment, a hose). Such scenarios are available in our memory and can be cued by linguistic input, e.g. "action verbs as well as nouns referring to agents, patients, instruments, locations, and events" (McRae & Matsuki, 2009). Generalized event knowledge can be also thought as default information associated with lexical items, according to the proposal in Lascarides and Copestake (1998).

Generalized event knowledge can provide the basis for a third account of covert event recovery in logical metonymy, suggesting that covert events are retrieved from knowledge of typical events stored in our long-term memory. Similarly to the lexical hypothesis, this third hypothesis links objects to associated events. The difference between the accounts is that the lexical hypothesis associates each noun with a fixed set of events, whereas the picture for generalized event knowledge is more flexible. In many cases, our experience will comprise events that do not correspond to classical qualia – in the case of cars, we know that cars need to be filled up, that they need to be washed, and that many people lease their cars. Word meaning is tied up to this sort of scenario knowledge, which typically contains the qualia as a proper subset. This is not always true, however – people will only have rich representations for events and objects that they are familiar with. For example, Matsuki et al. (2011) found that U.S. college undergraduates were not familiar with the event of "dusting off" and failed to build expectations about plausible scenarios. Also, some events which are part of our generalized event knowledge for a given entity (a few examples from our experimental materials: *pizza - deliver, fix - car, peel - apple*) do not fit well with the traditional qualia roles.

It follows that the picture painted by generalized event knowledge is also considerably different regarding the status of this knowledge: There is no distinction between linguistic and world knowledge. Resorting to world knowledge is an element of similarity with the pragmatic hypothesis, from which our proposal however differs with regards to an important aspect. The "pragmatic hypothesis" assumes that metonymic event reconstruction is carried out by general communication or discourse based devices, like many other types of pragmatic inferences; contrastively, generalized event knowledge is activated immediately during sentence processing. Consequently, the metonymic event reconstructions can be based on exactly the same type of knowledge responsible for generating predictions during on-line language comprehension and for the

Table 1: Example materials for the self-paced reading study (Zarcone & Padó, 2011) and the present probe recognition study.

	Self-paced reading	Probe recognition	
		Sentence	Probe
high-typicality agent	Der <i>Konditor</i> begann, die <i>Glasuren</i> <b>aufzutragen</b> . The baker started the icing <b>to spread</b> .	Der <i>Konditor</i> begann mit der <i>Glasuren</i> . The baker started with the icing.	<b>AUFTRAGEN</b>
low-typicality agent	Das <i>Kind</i> begann, die <i>Glasuren</i> <b>aufzutragen</b> . The child started the icing <b>to spread</b> .	Das <i>Kind</i> begann mit der <i>Glasuren</i> . The child started with the icing.	<b>AUFTRAGEN</b>
high-typicality agent	Das <i>Kind</i> begann, die <i>Glasuren</i> <b>zu essen</b> . The child started the icing <b>to eat</b> .	Das <i>Kind</i> begann mit der <i>Glasuren</i> . The child started with the icing.	<b>ESSEN</b>
low-typicality agent	Der <i>Konditor</i> begann, die <i>Glasuren</i> <b>zu essen</b> . The baker started the icing <b>to eat</b> .	Der <i>Konditor</i> begann mit der <i>Glasuren</i> . The baker started with the icing.	<b>ESSEN</b>

predicate-argument thematic fit (McRae & Matsuki, 2009). We regard the account proposed here as a generalization of purely lexicalist approaches, which is able to provide a more dynamic model of covert event interpretation triggered by event knowledge associated with lexical items, while keeping it distinct from other, genuinely pragmatic processes.

### Evidence from self-paced reading

While type clashes and type shifting have received great attention in the experimental literature on logical metonymy, there is comparatively little work on the source of covert events (lexical vs. inferential). Offline work (Lapata, Keller, & Scheepers, 2003; Zarcone & Padó, 2010) has established that the range of interpretations for metonymy is larger than predicted from qualia structure. In an important online study, Frisson and McElree (2008) “assume that coerced senses are computed from a broader range of properties than the Qualia structure of the complement noun”. In order to exclude the possibility that increased processing costs in logical metonymies might be determined by competition between different possible interpretations, they carried out an eye-tracking experiment, contrasting (a) sentences like *The teenager began the novel*, where one interpretation is strongly preferred (*reading*), (b) sentences like *The waitress started the coffee*, where multiple interpretations are plausible (*drinking*, *preparing*) and possibly competing, and (c) base forms of (a) and (b) like *The teenager read the novel*. However, the authors do not commit to a specific hypothesis regarding the range of covert events.

Zarcone and Padó (2011) have suggested *generalized event knowledge* as an alternative source of interpretation, providing results from a self-paced reading experiment. The study capitalized on the verb-final word order in German subordinate phrases, by likening the recovery of a covert event in a “short variant” metonymy (Ex. 2) to the process of building expectations about the sentence-final event in its “long variant” (Ex. 1) and by analyzing reaction times for long variants, where the event was explicit.

The self-paced experiment contrasted a high-typicality agent condition with a low-typicality agent condition (*Der Konditor / das Kind hörte auf, die Glasuren aufzutragen*. - *The baker / the child finished spreading the icing*). In the high-typicality condition the target event was cued by the preceding agent-patient pair (*baker-icing*), creating rich expectation on the upcoming event. The experiment found that these expecta-

tions in fact yield a facilitation effect and shorter reading times for the target verb compared to the low-typicality condition.

Also, a crucial difference with Frisson and McElree (2008) is that in this study the same patient noun is used in different context conditions, in order to restrict variability due to item idiosyncrasies. Thus, the experiment in Zarcone and Padó (2011) provided evidence towards a generalized event knowledge account of logical metonymy. However, it was heavily based on the assumption that the same cognitive resources are involved when recovering covert events in logical metonymies and when predicting sentence-final sentences (Lapata et al., 2003). This assumption is of course debatable.

### Experiment

The goal of the present study is to strengthen the case for generalized event knowledge in logical metonymy by avoiding any assumptions about the relative processing of “short variant” and “long variant” sentences. We employ a different experimental paradigm, namely probe recognition, and concentrate on unequivocally metonymical experimental materials. More specifically, we build “short variant” sentences from the items used in the self-paced reading study, contrasting two typicality conditions as before. The main difference is in the cued event, which is now not part of the sentence but is presented as a probe after the metonymical sentence. The old and new materials are contrasted in Table 1.

Crucially, in the probe recognition study the probe is not part of the test sentence: to enhance this and avoid sentence completion effects (i.e. that participants would be influenced by verb-final word order in German subordinate phrases and perceive the probe as part of the sentence), the *zu* particle was omitted. Since the cued event is never part of the sentence, participants are required to answer “no” for all probes. To balance the responses, the material sentences are complemented by fillers for which the answer is “yes” (see below for details).

Our expectation is that in the high-typicality condition (*baker-icing-spread*), the covert event *spread* is cued by the agent-patient combination, causing participants to require longer decision latencies to recognize that the verb was not part of the sentence than in the low-typicality condition (*child-icing-spread*), where the cued event is a different one (*eat*).

A second element of novelty is the addition of a second factor: inter-stimulus interval (ISI). Contrasting a short and a long ISI can provide insights about the nature of covert event

Table 2: Triplets for *Glasur (icing)*.

	Agent	Patient	Event
high-typicality triplet	Konditor	Glasur	auftragen
	baker	icing	spread
	Kind	Glasur	essen
low-typicality triplet	child	icing	eat
	Kind	Glasur	auftragen
	Konditor	icing	spread
	baker	Glasur	essen
		icing	eat

retrieval: at longer ISI, an expectancy strategy is employed (strategic expectancy generation) and participants tend to use the input received to generate a potential set of upcoming targets whose processing is facilitated (Becker, 1980; Ferretti, McRae, & Hatherell, 2001; Van Der Meer, Krüger, & Nuthmann, 2005); an effect at a short ISI would suggest that covert events are available online and early on during processing.

### Creation of Materials

As mentioned above, we adapted the German materials from the self-paced reading experiment in Zarcone and Padó (2011) for the probe recognition task. In the earlier study, elicitation tasks were used to tap into generalized event knowledge scenarios when preparing materials for the self-paced reading experiment, according to an established method in research on generalized event knowledge (see also McRae, Hare, Elman, and Ferretti (2005)).

**Event elicitation** We elicited typical events for a set of 50 patients in German, by asking 20 participants in a web experiment to generate verbs in response to typical patients (“list the things that these objects have done to them”). Space for 10 responses per item was provided and no time limit was imposed. For each item, we chose four events from those named early by many participants (i.e., those with highest mean reciprocal rank measure), ensuring that the four events referred to different scenarios. Then we paired each patient to the infinite form of its four selected verbs (200 patient-event pairs): e.g., the four events selected for *Auto (car)* were *fahren* (drive), *reparieren* (fix), *verkaufen* (sell), *waschen* (wash).

**Agent elicitation** We elicited typical agents for the resulting 200 patient-event pairs from 10 participants in a web experiment (“list who typically performs these actions”). For each item, space was provided for 10 responses; no time limit was imposed. From the initial list of 200 patient-event pairs, we extracted 24 patients paired with 2 events each, and per each patient-event combination we selected one of the best agents (those named early by many participants, i.e. with highest mean reciprocal rank measure), obtaining 48 agent-event-patient high-typicality triplets.<sup>2</sup> 48 low-typicality triplets were obtained by crossing agents between the two events in the

high-typicality triplets, for a total of 96 agent-event-patient triplets (48 high-typicality, 48 low-typicality). Table 2 shows examples for high- and low-typicality triplets.

**Test sentences** The aim of the probe recognition task was to replicate the results from the self-paced reading tasks with strictly metonymical sentences. For this reason, we only used “short version” main clause sentences (Ex. 2) constructed with metonymical verbs, as shown on the right-hand side in Table 1.

### Method

**Participants** Thirty-six students of Universität Stuttgart volunteered to participate in the experiment and were paid for their participation. All participants were native speakers of German and had normal or corrected-to-normal vision.

**Procedure** On each trial, a sentence appeared in the middle of the screen and the participants were to press a key after reading it. Pressing the key elicited the presentation of the probe word with a short (100 ms) or long (900 ms) inter-stimulus interval (ISI). The participants were instructed to decide as quickly and accurately as possible whether or not the probe appeared in the sentence by pressing the green or the red key respectively. The green key was the left key for left-handed participants and the right key for right-handed participants, so that the “no” answers were always given with the non-dominant hand.

Responses and decision latencies for each probe were recorded. The experimental session lasted approximately 30 minutes; participants were allowed to take two breaks during the experiment, one after the first third of sentences and one after the second third.

Each participant saw all 48 sentence-probe combinations, half of them in the high-typicality condition and the other half in the low-typicality condition. The experimental items were intermixed with 72 filler items, which were the same for both lists. Since the 48 test probes in each list were never in the sentence (i.e. the answer was “no”), 60 of the fillers did include the probe in the sentence and 12 did not, for a total of 60 “yes” answers and 60 “no” answers in each list.

**Design** The study employed a 2x2 mixed factorial design. One factor, inter-stimulus interval (ISI: long / short), was varied between subjects, the other factor, typicality (TYP: high / low), was varied within subjects.

### Results

All participants scored better than 95% correct on the probe recognition task. Data points corresponding to the wrong answers and outliers ( $> 2.5$  SD from the mean) were excluded from the analysis (2% of the data points). The mean of reading times on the sentences preceding the probes was 2629 ms (SD 1280). At both short and long ISI, mean decision latencies were longer for the high typicality condition (Table 4).

We examined the effect of ISI and typicality on decision latencies through 2 x 2 by-subject ( $F_1$ ) and 2 x 2 by-item ( $F_2$ ) analyses of variance, which yielded main effects of

<sup>2</sup>An additional sensibility verification test was run, in order to check that low-typicality triplets were, although not typical, still sensible (i.e., did not violate any selectional restriction). See Zarcone and Padó (2011) for more details on the pre-tests).

Table 4: Mean decision latencies (dl, measured in ms).

	low typicality		high typicality		
ISI	Mean dl	SD	Mean dl	SD	Mean diff.
short	969	296	1026	363	+57
long	1735	351	1746	362	+12

ISI ( $F_1(1, 35) = 111.03, p < .001; F_2(1, 47) = 2553, p < .001$ ) and of typicality ( $F_1(1, 35) = 7.7616, p = .009; F_2(1, 47) = 6.02, p = .015$ ). The difference in decision latencies between low and high typicality is larger for the short ISI condition, but the interaction fails to reach significance.

Mixed-effect models have been shown to be more powerful for reading studies, because they allow on the one hand for separating random effects of item and participant, and on the other hand for taking into account trial-to-trial longitudinal dependencies between individual observations, by including covariates such as response latencies at preceding trials. Following the procedure suggested by Baayen, Davidson, and Bates (2008); Baayen and Milin (2010), we performed a mixed-effect analysis using as covariates the order of presentation (rank-order of a trial in its experimental sequence), the reading times at the sentence preceding the probe and the decision latencies at preceding probe. The mixed-effect analysis (Table 3) shows a number of significant effects. Most important for our current purpose is the marginally significant interaction of ISI and typicality (shown in boldface), which indicates that the effect of typicality indeed diminishes for longer inter-stimulus intervals.

## Discussion

In our experiment, high typicality agents in logical metonymies cue covert events that are coherent with the generalized event knowledge scenario associated with those agents and with the given patient. Cued events were integrated in the sentence meaning and were therefore more difficult to reject as probes, leading to significantly longer decision latencies for the high typicality condition than for the low typicality condition. This supports the hypothesis that covert events can be predicted by generalized event knowledge scenarios, which constitute a broader range of interpretation than traditional qualia-based accounts, which are typically a subset of them. Elicitation tasks were used to retrieve two generalized event knowledge scenarios per item, and in some cases these did

not correspond to traditional qualia roles: the events used for *pizza* were *baking* and *delivering*, the events for *apple* were *picking* and *peeling*, the events for *car* were *driving* and *fixing*.

The emergence of the effect at long ISI could indeed be explained as a result of an expectancy strategy (that is, pragmatic inferences driven by the perceived need to perform the task), but the effect at short ISI provides evidence for early integration of generalized event knowledge, suggesting that covert event interpretation emerges early on in processing. Firm conclusions on this point require further investigation, but there is clear parallelism to short SOA effects of generalized event knowledge typicality in Ferretti et al. (2001).

The early emergence of the typicality effect in Zarcone and Padó (2011) and in the current experiment is in contrast with the "inference hypothesis" (if by inference we mean a post-lexical late-onset process), in that covert events emerge early on in processing. Promising work on ERPs (Baggio et al., 2010; Schumacher & Weiland, 2011) can therefore be of crucial importance in the near future to shed new light into more fine-grained processes involved in covert event resolution.

In the current experiment, we were able to replicate the activation effect for events which can be plausibly assumed to be present in generalized event knowledge observed in Zarcone and Padó (2011). By using a different experimental paradigm, we avoided the need to compare "long" and "short" variants. The parallel outcome of the two experiments provides evidence for a picture of language processing in which metonymic event reconstruction is carried out by the same resource – i.e., general event knowledge – which is normally employed for predicate-argument integration during on-line comprehension of non-coercion sentences.

To test this hypothesis, we are currently running a further experiment with non-metonymic verbs and the same probe recognition design used in this study. There exists indeed a long standing tradition of experiments contrasting coercion conditions and control conditions which do not involve coercion (Traxler, Pickering, & McElree, 2002; R. D. de Almeida & Dwivedi, 2008; Frisson & McElree, 2008), and in such studies the question of coercion plays a central role. We have sidestepped this issue in our experiments so far, but our next step will directly address this question by contrasting the same sentence-probe combinations illustrated above with sentences containing a non-coercion predicate (e.g. *The man rolled a cigarette*), such that the probe (e.g., *smoke*) expresses an event

part of the general knowledge activated by the sentence (e.g., smoking is the purpose of rolling a cigarette). Our model predicts no significant differences in decision latencies between the non-coercion sentences of the new experiment and the coercion sentences of the present study, given that the same general event knowledge is responsible for on-line expectation activation during sentence comprehension. In other terms, we expect that both with *The man rolled a cigarette* and with *The man enjoyed a cigarette*, general event knowledge activates the cued event of smoking, irrespective of the presence or not of a coercive predicate.

## Conclusion

We have provided evidence in support of the hypothesis that generalized event knowledge can predict covert event interpretation. Also, the current study constitutes a further step towards a characterization of the phenomenon of logical metonymy within the broader frame of early online integration of typical event knowledge in comprehension.

## Abstract

Computational modeling has served a powerful tool for studying cross-situational word learning. Previous research has focused on convergence behaviors in a static environment, ignoring dynamic cognitive aspects of concept change. Here we investigate concept drift in word learning in story-telling situations. Informed by findings in cognitive neuroscience, we hypothesize that a large ensemble of sparse codes flexibly represents and robustly traces drifting concepts. We experimentally test the population coding hypothesis on children's cartoon videos. Our results show that learning the meanings of words over time is hard, especially when the concept evolves slowly, but the sparse population coding can handle the concept drift problem effectively while hypothesis elimination and simplistic parametric models have difficulty.

**Keywords:** Cross-situational word learning; statistical language learning; concept drift; meaning change; population coding.

## Introduction

Children learn the meaning of words rapidly and robustly across multiple situations (Smith & Yu, 2008). Computational modeling has served a powerful tool for precise investigation of the hypothesized mechanisms of word learning. Many computational models of word learning have been used to simulate and account for the observed patterns such as reference disambiguation, blocking, and long-term memory (Frank *et al.*, 2009, Kachergis *et al.*, 2010; Vlach & Sandhofer, 2010).

Existing computational models for word learning can be broadly divided into hypothesis elimination and associative learning (Fazly *et al.*, 2010). In the hypothesis elimination approach the learning process consists of eliminating incorrect hypotheses about word meaning, on the basis of a combination of a priori knowledge and observations of how words are used to refer to aspects of experience, until the learner converges on a single consistent hypothesis. For instance, Siskind (1996) presented an efficient algorithm for keeping track of just the necessary and possible components of word-meaning hypotheses consistent with a set of examples. A weakness of this approach is that some logically possible hypotheses may be ruled out a priori or the concepts cannot be recovered once they are eliminated.

Another approach to computational modeling of word learning is associative learning. Yu (2005), for example, studied a word-object association model in a unified framework of lexical and category learning. This model demonstrated the emergence of patterns observed in early word learning. Xu and Tenenbaum (2007) proposed a

probabilistic model of word learning. The Bayesian account aims to explain inductive learning at the level of computational theory rather than to describe psychological processes involved. Fazly *et al.* (2010) uses a probabilistic framework to propose an incremental associative model that deals with referential uncertainty. The proposed model is demonstrated to converge over time on the most likely meaning of the word in CHILDES data sets. However, this model does not incorporate alignment ambiguity and it is not clear how the model behaves if the concept drifts in the course of learning.

Concept drift is a fundamentally important phenomenon in language acquisition. It means that the statistical properties of the target concept, which the learner is trying to learn, change over time (Widmer & Kubat, 1996). For example, a child might think that all birds can fly until he/she observes an ostrich, at which time the child revises the concept of bird. This causes problems because the learning process needs some mechanisms to unlearn or revise the learned concepts. Simple hypothesis elimination cannot account for this since it lacks a mechanism for recovering the eliminated concepts. Both the associative learning and its probabilistic versions have difficulties since they strive to model global patterns, not modeling local patterns that might be necessary at a later stage.

Here we propose a computational model of word learning that deals with concept drift under alignment ambiguity and referential uncertainty. The model borrows ideas from neuroscience and uses a population coding (Pouget *et al.*, 2000; Ma *et al.*, 2006). We propose a sparse population-code network in which meanings of the words are represented as a large collection of sparse microcodes. Since each microcode is sparse, it describes a general concept. There are many of the microcodes and, thus statistically, only a few parts of them are updated on a single observation, maintaining stability by the remaining microcodes in the population. We test this population coding hypothesis on naturalistic children's cartoon video data. To make the experiments more realistic, we use state-of-the-art image processing techniques to represent the scene as a bag of image patches. This is contrasted with the previous studies of cross-situational word learning in which the scene representation adopts hand-coded semantic features. Our experimental results show that learning the meaning of words over time is hard, especially when the concept is drifting slowly. We demonstrate that the sparse population coding can handle the concept drift problem effectively

while simplistic parametric models have difficulty in dealing with the problem.

## Materials and Experimental Setup

### Video Data Sets

We used a series of children’s cartoon videos, *Maisy*, consisting of 6 episodes. Each episode plays for 48 to 105 minutes and the total play time is 475 minutes. From this video set, we prepared a total of 972 utterance-scene pairs as described in the following subsections. Cartoon videos provide naturalistic story-telling situations that children face in language acquisition (Zhang & Kang, 2011). An additional advantage of cartoons is that its image processing is relatively easy, allowing for automated generation of a large data set to study the long-term learning behavior in situated word learning.

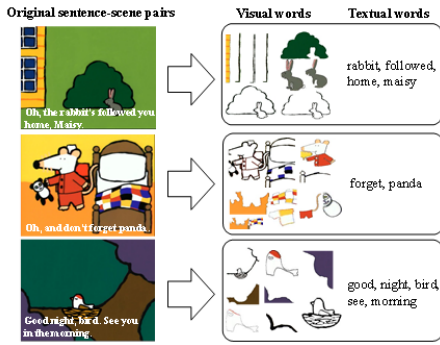

Figure 1: Examples of utterance-scene representation

### Utterance-Scene Representation

The material for cross-situational learning consists of utterance-scene pairs, where each pair is represented as a vector of the form

$$\mathbf{x}(t) = (\mathbf{w}(t), \mathbf{v}(t)) = (w_1, \dots, w_{|\mathbf{w}(t)|}, v_1, \dots, v_{|\mathbf{v}(t)|})$$

Here,  $|\mathbf{w}(t)|$  and  $|\mathbf{v}(t)|$  are the number (vocabulary size) of textual words and visual words in the  $t$ -th example, respectively. Figure 1 shows the examples of utterance-scene pairs extracted from the original videos. The following subsection describes how the textual words were processed.

### Language Processing

We collected all utterances in the text captions of the video set, which amounts to approximately 2,800. Removing simple utterances such as ‘Hi’ gives a total of 972 sentences. We determined the vocabulary for textual words by computing the standard TF-IDF (term-frequency and inverse-document-frequency) values. TF-IDF gives higher weights to the terms that frequently occur and are uncommon between episodes. This results in 1,049 words. We chose the top 448 textual words which defines the utterance vocabulary. The sound modality was not used in the experiments.

### Image Processing

We extracted image frames from the video, one frame for each of the 972 sentences extracted by language processing. Out of a stream of image frames played for the duration of speech of an utterance, we chose the image frame corresponding to the start of the utterance. This results in an image corpus of 972 scenes. Each scene was described by a subset of 7,520 image patches (i.e., visual words), each composed of the SIFT (scale-invariant feature transform) features and the color histogram extracted as follows. To define the visual words, we first used the MSER (maximally stable extremal region) feature extractor to segment and extract salient and informative regions from the images. SIFT was then used to find salient features in the extracted regions. The resulting features are grouped by K-means clustering to remove redundancy.

### Experimental Paradigm

Given the set of learning examples  $D_N = \{(\mathbf{w}(t), \mathbf{v}(t)) \mid t = 1, \dots, N\}$ , the goal of the learner is to form the concepts in the training set by finding the relationships between the words and the visual words (i.e. image patches). Learning proceeds incrementally, i.e. the examples are presented in sequence. Each time an example is presented the learner updates its model before the next example comes in.

Figure 2(b) shows the paradigm we adopt in this study. As indicated by the connections between textual words and those between visual words, we consider the fully interconnected relationship between different words and visual words. Note that this paradigm is contrasted with the standard paradigm shown in Figure 2(a), where the learner is to learn the relationship between the words and the referents or meanings, but do not attempt to learn the relationship among the words or among the referents.

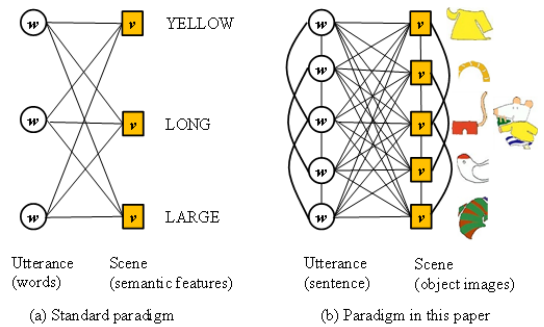

Figure 2: Experimental paradigms in comparison

## The Model

### Concept Representation

Meaning of words can be defined as a set of contexts in which word occurs in running text (Burgess & Lund, 1998) or represented in network connectivity revealed by statistical analysis of a text corpus (Steyvers & Tenenbaum,

2005). The textual domain can be extended to include the visual domain by taking into account the full contexts in which the word and images (visual words) co-occur in scenes (Zhang, 2008). Figure 3 illustrates this type of concept representation we adopt in this work. Here, the concept of MOUSE, for example, is defined as a collection of words ( $w$ -nodes), i.e. {yellow, run, dark, tall}, and a collection of visual words or visual patches ( $v$ -nodes) linked to the ‘mouse’-node in the figure. Thus, we consider the learner to acquire the visually-grounded linguistic concepts or the joint vision-language concepts, similar to the perceptual symbol systems *a la* Barsalou (1999).

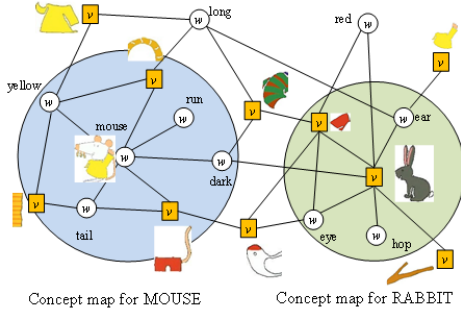

Figure 3: The concept of a word is defined by other words  $w$  as well as visual words  $v$ . In this representation the concepts are defined as a relationship among the primitives (words and visual words).

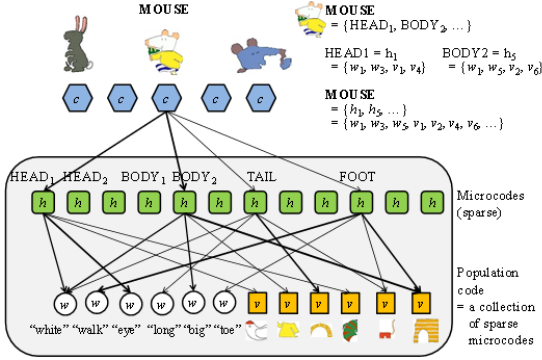

Figure 4: Sparse population coding scheme

### Sparse Population Coding

We represent the joint vision-language concept using sparse population codes. Figure 4 shows the basic units of the coding scheme, i.e. microcodes. Each microcode represents a prototype, exemplar, or common pattern for a set of similar examples. For instance, a microcode  $h = \{\text{'white'}, \text{'eye'}, v_1, v_4\}$  represents a class of objects (or concept HEAD1 as indicated in the figure) that have white eyes and image features of  $v_1$  and  $v_4$ , where  $v_1$  and  $v_4$  are image patches. The textual words, ‘white’ and ‘eye’, and the visual words,  $v_1$  and  $v_4$ , are instances of the textual and visual word vocabulary, respectively. Since the number of words or visual words chosen to define the specific microcode is small compared to their vocabulary size, this is a sparse

coding scheme. Typically we use a large number of microcodes to describe complex concepts.

The population of sparse microcodes can be considered as a three-layer network as shown in Figure 4. The first (bottom) layer consists of the  $w$ -nodes for words (e.g. “white”) and the  $v$ -nodes for visual words (image patches). The second (middle) layer represents the  $h$ -nodes for microcodes or micro-concepts such as HEAD1. A formal concept is represented as an ensemble of micro-concepts (or microcodes), as indicated by  $c$ -nodes at the third (top) layer of the network. This network can be learned from the data. Before describing the learning procedure we see the statistical background underlying this representation.

### Finite Mixture Model Formulation

Formally, a large collection of microcodes represents the empirical distribution of the concepts in the form of a finite mixture model (McLachlan & Peel, 2000). To see this, we suppose that the density of data  $\mathbf{x} = (\mathbf{w}, \mathbf{v})$  can be written in the form:

$$P(\mathbf{x} | \theta) = \sum_{j=1}^M \alpha_j f_j(\mathbf{x} | h_j) \quad (1)$$

where  $f_j(\mathbf{x} | h_j)$  are densities and  $\alpha_j$  are nonnegative quantities that sum to one:

$$0 \leq \alpha_j \leq 1 \quad (j=1, \dots, M) \quad \text{and} \quad \sum_{j=1}^M \alpha_j = 1.$$

Equation (1) is called  $M$ -component finite mixture density. Roughly, the configuration of the microcode defines the shape of the mixture component  $f_j(\mathbf{x} | h_j)$  and the weight associated with the microcode defines the mixing weight  $\alpha_j$ . We denote the complete collection of all distinct parameters occurring in the mixture model by  $\theta = (\boldsymbol{\alpha}, \mathbf{h})$ , where  $\boldsymbol{\alpha} = (\alpha_1, \dots, \alpha_M)$  and  $\mathbf{h} = (h_1, \dots, h_M)$ . We note that by designing the microcodes  $h_j$  appropriately to be the parameters of the component density  $f_j(\mathbf{x} | h_j)$ , the mixture density can be represented by the sparse population code.

In other words, if the microcode has an associated component density  $f_j(\mathbf{x} | h_j)$ , the distribution of the data set  $D_N = \{\mathbf{x}(1), \dots, \mathbf{x}(N)\}$  can be represented by the population code:

$$\begin{aligned} &P(\mathbf{w}(1), \mathbf{v}(1), \dots, \mathbf{w}(N), \mathbf{v}(N) | \theta) \\ &= P(\mathbf{x}(1), \dots, \mathbf{x}(N) | \theta) = \prod_{t=1}^N \sum_{j=1}^M \alpha_j f_j(\mathbf{x}(t) | h_j) \end{aligned} \quad (2)$$

which is a sum of  $M^N$  products of component densities. Each term in the summation is interpreted as the probability of obtaining a given one of the MN possible divisions of the observations among the groups.

### Learning Algorithm

Learning proceeds incrementally by observing each utterance-scene pair in sequence. On each observation of an

example  $(\mathbf{w}, \mathbf{v})$  the learner predicts and updates the meanings or concepts  $\theta$ . This is an inductive process and can be formally described as Bayesian inference:

$$P_t(\theta | \mathbf{w}, \mathbf{v}) = \frac{P(\mathbf{w}, \mathbf{v} | \theta) P_{t-1}(\theta)}{P(\mathbf{w}, \mathbf{v})} \quad (3)$$

At each time step  $t$ , the prior distribution  $P_{t-1}(\theta)$  of the hypothesis  $\theta$  is updated to the posterior distribution  $P_t(\theta | \mathbf{w}, \mathbf{v})$  of the hypotheses by computing the likelihood function  $P(\mathbf{w}, \mathbf{v} | \theta)$  and normalizing by

$$P(\mathbf{w}, \mathbf{v}) = \sum_{\theta'} P(\mathbf{w}, \mathbf{v} | \theta') P_{t-1}(\theta') \quad (4)$$

to make  $P_t(\theta | \mathbf{w}, \mathbf{v})$  back to a probability distribution. The posterior is then used as the prior for the next time step. Making the data set explicit, we can rewrite (3) in a recursive form:

$$\begin{aligned} P_t(\theta | \mathbf{w}(t), \mathbf{v}(t), \mathbf{w}(1:t-1), \mathbf{v}(1:t-1)) \\ = \frac{P(\mathbf{w}(t), \mathbf{v}(t) | \theta) P_{t-1}(\theta | \mathbf{w}(1:t-1), \mathbf{v}(1:t-1))}{P(\mathbf{w}(t), \mathbf{v}(t) | \mathbf{w}(1:t-1), \mathbf{v}(1:t-1))}, \end{aligned} \quad (5)$$

where  $\mathbf{w}(t)$  and  $\mathbf{w}(1:t-1)$  denote the word vector at time step  $t$  and the sequence of word vectors from time step 1 to  $t-1$ , respectively. Expectation-maximization (EM) style algorithms are usually used to solve the estimation problem (McLachlan & Peel, 2000). In the following we describe the method we implemented as a sparse population coding network. Recall that  $\theta = (\boldsymbol{\alpha}, \mathbf{h})$ , i.e. the concepts are represented as a collection of microcodes  $\mathbf{h}$  with weights  $\boldsymbol{\alpha}$  in the network. The population code is a mechanistic representation for psychological processes since it describes the memory encoding and decoding mechanisms more explicitly than simplistic parameter tuning models.

We first describe the learning algorithm in pseudocode and then explain it.

```

1  $H(0) \leftarrow \{\}, V_T \leftarrow \{\}, V_I \leftarrow \{\}$ 
2  $t \leftarrow 1$  ; prior  $P_{t-1}(\theta)$ 
3 Perceive  $\mathbf{x}(t) = (\mathbf{w}(t), \mathbf{v}(t))$ 
4  $E = \{h_1, \dots, h_m\} \leftarrow \text{Sample}(\mathbf{x}(t))$  ; microcodes
5  $V_T \leftarrow V_T + \{\text{new } w's\}, V_I \leftarrow V_I + \{\text{new } v's\}$ 
6  $H \leftarrow H + E$  ; accommodation
7 Repeat
8    $H' \leftarrow \text{Predict}(H)$  ; sampling prior  $P_{t-1}(\theta)$ 
9    $\mathbf{x}' \leftarrow \text{Generate}(H')$  ; likelihood  $P(\mathbf{x} | \theta)$ 
10   $H'' \leftarrow \text{Correct}(H', \mathbf{x}', \mathbf{x}(t))$  ; assimilation
    (resampling)
11   $H \leftarrow H''$ 
12 Until reconstruction_satisfactory( $\mathbf{x}(t)$ )
13  $H(t) \leftarrow H$  ; posterior  $P_t(\theta | \mathbf{x}(t))$ 
14  $t \leftarrow t+1$ 
15 Go to 3
```

Given an utterance-scene instance (line 3), a subset of words and a subset of visual words are selected to build a

microcode (line 4). For each utterance-scene pair, a number  $m$  of microcodes are generated randomly and repeatedly (line 4). Duplications are permitted and, in fact, the number of duplications represents the strength of the code (we will use this later on in decoding the referents or meanings of the words). The set  $E$  of new microcodes is then added to the existing set  $H$  of microcodes (line 6). This step is equivalent to accommodating new memory elements. Then the model is trained to tune or assimilate the incoming concepts into the existing concepts (lines 7-12). First, a collection  $H'$  of the microcodes is sampled to be used to generate an example  $\mathbf{x}'$ . The generated example is then compared to the training example. The difference is used to correct the model  $H$  or the population code. This results in the update of the posterior distribution (line 13).

The algorithm consists of basically three steps: i) sampling new microcodes (line 4), ii) merging them with the old (existing) population of microcodes (line 6), and iii) resampling of the whole microcode population (line 10) to correct the conflicts and interferences. To correct predictive errors in an unsupervised way, the algorithm test-generates the samples from the current model (lines 8 and 9) and compare the resulting data with the perceived data (line 10).

## Connection to Probabilistic Models of Cognition and Monte Carlo

Recall that the population of sparse codes approximates the probability distribution of the examples if the population size is big. Recall also that the learning algorithm is implemented by repeatedly sampling the sparse codes (microconcepts or hypotheses) like a Monte Carlo simulation does. In terms of Bayesian inference the learning algorithm updates the distribution of the concepts from prior to posterior distribution by Monte Carlo simulation. Shi *et al.* (2010) suggested that exemplar models are a successful class of psychological process models that can be used to perform a sophisticated form of Monte Carlo approximation. The similarity of the sparse coding representation with the exemplar model suggests that our sparse population code model offers a concrete process model of Bayesian cognition.

## Simulations and Results

### Parameter Setting for Experiments

Experiments were performed using the following parameter settings. Given a new observation, 10 new sparse codes were sampled and added to the population. Each microcode consists of three textual words and one visual word. 5 iterations of error correcting steps were executed to tune the whole population code to the new observation. To see the effects of memory capacity we experimented with two sizes of populations:  $|H| = 100, 500$ . When the population size exceeds the memory capacity, we replace 10 microcodes with the lowest weight values by 10 new microcodes. We define two scores for measuring the similarity between visual and textual concepts as follows:

$$S(w, v) = \frac{1}{\sum_{h \in H_w} \alpha(h)} \cdot (|H_v|)^{\frac{1}{2}} \cdot \sum_{h \in H_v} \alpha(h) \text{ and } S(w) = \sum_{h \in H_w} \alpha(h)$$

where  $\alpha(h)$  is the weight of microcode  $h$ , and  $H_w$  and  $H_v$  are the subsets of  $H$  consisting of the microcodes with textual word  $w$  and visual patch  $v$ , respectively.

### Vocabulary Growth

Figure 5 shows the growth of visual and textual vocabularies as learning proceeds. When the memory size is unlimited (left), the size of both visual words and textual words increases continuously (linearly). When the maximum memory capacity is set to be limited to 500 (right), the size of visual words increases first and then decreases while the number of textual words grow continuously but in two stages of fast growth and then slow growth. The difference in vocabulary growth pattern seems in part due to the difference in vocabulary size of visual and textual words, i.e. in this experimental setting, 7520 visual words and 448 textual words were used for candidates.

Figure 5: Growth of vocabulary. (left) unlimited memory size. (right) limited memory size.

### Word Learning in Concept Drift

Figure 6 shows the trace of concept memory for the 4 separate focus objects which appear in all episodes.

Figure 6: Emergence, extinction, and re-emergence of concepts in drift. (left) larger memory capacity ( $|H| = 500$ ). (right) smaller memory capacity ( $|H| = 100$ ).

The results show the emergence, extinction, and re-emergence of different visual concepts as the video runs. If the memory size is relatively big (500 in this case), the concepts do not extinct totally and remain in the backend to re-emerge when new similar observations are made. In contrast, when the memory size is small (100 in this case), the concepts disappear entirely from the memory,

suggesting the difficulty of the problem, especially if the memory capacity is small. However, this problem can be solved by dynamically varying the population size to balance exploration and exploitation. In contrast to this sparse population coding approach, a localist, eliminative method would have a fundamental difficulty in recovering once-eliminated concepts due to its lack of associative connections between concepts.

Figure 7: (left) Emergence patterns of concepts for different memory size. Plotted are the weight values for the specific visual concept shown. (right) Emergence of different visual concepts for given three textual concept (rabbit, bird, and mouse).

Figure 7 shows the change of concepts in the course of learning. (left) shows the change of weight distribution for the specific visual concept (patch 2 in Figure 6) shown. (right) is the reverse, i.e. the query is given by a textual word (rabbit) and the graph shows how the corresponding image concept changes as learning proceeds. It can be observed that, since the concept of rabbit drifts, different types of rabbit images and, sometimes very different (and wrong) images, are retrieved by the same word.

### Concept Generalization and Specialization

Figure 8 shows the joint vision-language concept maps around the ‘rabbit’ as they evolve over the 6 episodes. The maps (a)-(d) are the snapshots after watching 1, 2, 4, 6 videos, respectively. Note that the map contains visual words as well as textual words. We observe that the connectivity of the visual-linguistic map grows as more episodes are learned. Careful examination of the map shows the role of visual words or concepts for the specialization and generalization of the textual concepts and vice versa. For example, in Figure 8(a) we observe that a visual word connects the three textual words of ‘enjoy’, ‘lunch’, and ‘rabbit’ together. This adds an additional, visually-grounded, connection (association) between the words ‘enjoy’ and ‘lunch’. We also observe that the word ‘rabbit’ is connected to multiple images, again grounding and refining the meaning of the textual word. Formally, the former is the one-image to many-words relationship and the latter is the many-images to one-word relationship. This again shows the effect of visual generalization of the textual words and that of visual specialization, respectively, which cannot be observed in language-only concept maps (Zhang & Kang, 2011).

# The role of recent versus future events in children's comprehension of referentially ambiguous sentences: Evidence from eye tracking

## Abstract

Findings from recent eye-tracking studies suggest that adults prefer to rely more on recently seen events than possible future events during sentence comprehension: When the verb in an NP1-VERB-ADV-NP2 sentence was referentially ambiguous between a recent action and an equally possible future action, adults fixated the target of the recent action more often than the not-yet-acted upon object (Knoeferle & Crocker, 2007; Knoeferle, Carminati, Abashidze, & Essig, 2011). We examined whether this preference for the recent event generalizes to five-year-old children. In an eye-tracking study, five-year-olds were presented a display with an animal and two other objects. On the next picture frame, the animal was depicted as performing an action (e.g., a horse galloped to a blue barn). Next, a spoken sentence referred either to an event involving the acted upon target object (the blue barn) or to an equally plausible future action event (e.g. galloping to the red barn). At the adverb in NP1-VERB-ADV-PP sentences, children fixated more often the recent (vs. future) event target. This result replicates the findings from the adult studies and suggests that, just like adults, children rely more on the recent event than expectations of an event that could happen next. At the same time, visual context effects of the recent events were subtly delayed for children (vs. adults). For adults, the recent-event preference emerged during the verb; for children, by contrast, it emerged post-verbally during the adverb. Thus, similar attentional mechanisms underlie visual context effects in both 5-year old children and adults but their time course differs.

**Keywords:** eye tracking; child language comprehension; visual context; depicted events.

## Introduction

Adults have been shown to rapidly and efficiently integrate all sorts of contextual cues during real-time spoken language comprehension. Referential contrast between objects can incrementally influence syntactic disambiguation (e.g., Tanenhaus, Spivey, Eberhard, & Sedivy, 1995), as well as semantic interpretation (Sedivy et al., 1999). Object affordances (Chambers et al., 2004) and depicted events (Knoeferle et al., 2005; Knoeferle et al., 2008) can also rapidly affect structural disambiguation.

Sometimes contextual information can even permit adult comprehenders to actively derive expectations about upcoming information. One source of evidence for predictive processes has been “anticipatory” eye movements to target objects (i.e., eye movements to objects just before they are mentioned). Verb selectional restrictions (Altmann & Kamide, 1999), compositional noun and verb meaning

and associated world knowledge (Kamide et al., 2003a,b), prosody (Weber et al., 2006), and information structure (Kaiser & Trueswell, 2005) can each restrict the range of target objects that can be mentioned next, as evidenced by participants inspecting a target object before its mention relative to a control condition.

Like adults, children have also been shown to derive expectations about upcoming information. When children (aged 10-11) listened to a sentence in which the verb *eat* restricted the domain of reference to edible objects, they fixated the only edible object in context shortly after hearing *eat* and before that object was actually mentioned (Nation, Marshall, & Altmann, 2003). This was true for both (verbally and visually) less-skilled children as well as for normally developing children although the former (vs. the latter) made more and shorter fixations to the edible object.

At first glance this might give the impression that child and adult language comprehension and expectation formation are governed by similar mechanisms. Results from another study with younger children (mean age of 4.7), by contrast, suggest marked differences between child and adult language comprehension. In a study by Trueswell et al. (1999), children either heard a locally structurally ambiguous sentence such as *Put the frog on the napkin in the box* or an unambiguous sentence such as *Put the frog that's on the napkin in the box*. For the ambiguous sentence, the prepositional phrase *on the napkin* can either modify the noun indicating the location of the frog, or attach into the verb phrase and specify the destination of the action. Children saw either only one possible referent for *frog* in the 1-referent condition (e.g. a frog on the napkin, an empty napkin, a distractor object and a box) or two referents in the 2-referent condition (e.g. a frog on the napkin, another frog, an empty napkin and a box). A 2-referent context should bias comprehenders to look at the frog on the napkin upon hearing *on the napkin* rather than to the empty napkin.

However, five-year old children frequently looked at the *incorrect* destination (the empty napkin) in both one-referent and two-referent contexts. Adults, by contrast, looked first at the correct target (the frog on the napkin) when hearing *Put the frog on the napkin* and then to the correct destination (the box) rather than the empty napkin in a context with two frogs. These findings were taken as support for the claim that children – unlike adults – incorrectly interpreted the prepositional phrase *on the napkin* as the destination for *put*, and that they were unable

to use the referential contrast (between two frogs) for structural disambiguation. Moreover, children's actions indicated that they never revised this initial misanalysis: On 60% of the trials they performed an action that involved the incorrect destination (e.g., moving a frog to the empty napkin before putting it in the box).

Accordingly, at least some aspects of 5-year-old children's and adults' real-time language comprehension appear to differ. What is not clear, however, is to what extent children's (vs. adults') use of (visual) context for spoken language comprehension is indeed limited, and, more broadly, what demarcates child-adult comprehension differences. Perhaps 5-year-old children and adults are not that dissimilar in their comprehension mechanisms and only employ different (attention) mechanisms in a few isolated instances. Alternatively, children at that age still differ fundamentally from adults in how they use (visual) contextual cues for language comprehension. This is an interesting research question since processing accounts of situated language comprehension (e.g., Knoeferle & Crocker, 2006, 2007) will ultimately want to accommodate language processing from infancy to young-adulthood to older age.

Existing findings suggest similarities in how children versus adults process language in (visual) context, but there are also some differences. Just like adults, infants as young as six months of age can track moving objects with their gaze (Richardson & Kirkham, 2004). 36-month-olds also exhibit adult attention behavior in that they shift their visual attention more quickly to a target picture when they hear *blue car* in a context with a blue and a red car than when the context shows a blue car and a blue house (Fernald, Thorpe, & Marchman, 2010). This suggests that they can rapidly use linguistic input to fixate relevant referents. In younger children, by contrast, this behavior is not yet apparent. Furthermore, when 19-months-old infants listened to nouns as they saw matching (vs. mismatching) objects, their event-related brain potentials to the noun exhibited an N400 (a negativity approximately 400 ms after stimulus onset, see Kutas & Hillyard, 1984) that was larger for mismatches than matches. That negativity was also found in adults, but the scalp distribution and latency of that effect differed in children relative to adults (Friedrich & Friederici, 2004). In summary, it is unclear to what extent children throughout language development and adults share the same mechanisms in language comprehension, language-mediated visual attention, and visual context effects on comprehension.

The present research contributes to this emerging evidence about real-time situated language processing in children by examining how recently-depicted action events guide children's visual attention and spoken language comprehension. We know that adults can rapidly draw on recent action events in informing language comprehension and in interrogating visual context (Knoeferle & Crocker, 2007). Participants saw a character (a waiter) move toward an object, interact with it (e.g., polish candelabra), and move

away from it. They then listened to an utterance that referred either to the recent action (polishing the candelabra: simple past tense: *Der Kellner polierte kürzlich die Kerzenleuchter*, "The waiter recently polished the candelabra") or to an equally plausible action that hadn't yet been performed (e.g., polishing crystal glasses; present tense with future meaning: *Der Kellner poliert sogleich die Kristallgläser*, "The waiter will soon polish the crystal glasses"). At the verb *poliert* . . . ('polish...') the comprehension system and visual attention had a choice between anticipating the recent action target versus anticipating (and thus inspecting) the target of the as-yet-unseen future action. Adult participants preferentially anticipated the target of the recent (vs. the other, future) action, a gaze pattern that continued even as future tense information became available through the adverb (e.g., *sogleich*, 'soon'). Verb meaning and future tense information did not elicit expectations of future events, and adults relied on the recently inspected events. Recent research has replicated these results with real-world stimuli. In addition, the recent-event preference replicated even when both 'recent' and 'future' events were equally frequent but tense effects were then more pronounced (i.e., participants always saw one action before and another action after sentence comprehension, Knoeferle, Carminati, Abashidze, & Essig, 2011).

The present experiment used eye tracking to see to what extent 5-year-olds can also rely on recent events in directing their visual attention and language comprehension. To this end, 5-year-olds saw clipart depictions such as a horse and two stables, one red and one blue (see Fig. 1). The horse moved to the blue stable (Fig. 1b). Subsequently the child would hear *Das Pferd galoppierte gestern zu der blauen Scheune*, (literal translation: "The horse galloped yesterday to the blue barn", "Yesterday, the horse galloped to the blue barn") or *Das Pferd galoppiert morgen zu der roten Scheune* (literal translation: "The horse gallops tomorrow to the red barn", "Tomorrow, the horse will gallop to the red barn"). If 5-year-olds rely on recent events with the same time course as adults, then we should see them inspect the target of the recent event (the blue barn) more often than the target of the future event (the red barn) during the verb and post-verbal adverb. While tense information is available post-verbally, there was only a (non-reliable) tendency for tense effects post-verbally in the adults (Knoeferle & Crocker, 2007, Experiment 3; Knoeferle et al., 2011, Experiment 1). Inspections to the target of the future event (the red barn) in children should thus only increase as that target is mentioned.

## Experiment

### Participants

24 kindergarten children (10 4-year-olds and 14 5-year-olds, range: 4-5;9) took part in the Experiment and received a small toy for their participation. All participants had German as their only mother tongue and normal or

corrected-to-normal vision. All were unaware of the experiment purpose. Children and one of their parents gave informed consent.

## Materials and Design

There were sixteen items, and two sentence conditions (Figure 1 and Table 1). Each item consisted of a series of three clipart scenes and four sentences. We created the pictures by using commercially available clipart and graphics programs. The first frame of the scene displayed a central animal agent (a horse) and two objects (e.g., a blue barn and a red barn, Figure 1a). The objects on either side of the animal were identical mirror images that only differed in their color or size (e.g., red barn, blue barn). The verb of the sentence (e.g., *galoppieren* ‘gallop’, see example in Table 1) was always a motion verb. Both of the two objects (e.g. the blue barn and the red barn) were equally plausible targets of the event (e.g. horse-galloping). However, the agent approached only one of the two objects (e.g. galloping to the blue barn, Figure 1b) and then moved back to another center position (Figure 1c). Each frame was presented for 1500 ms. The sentence could either refer to a past event (Table 1a, *Das Pferd galoppierte gestern zu der blauen Scheune*. ‘The horse galloped yesterday to the blue barn.’) or a future event (Table 1b, *Das Pferd galoppiert morgen zu der roten Scheune*. ‘The horse gallops tomorrow to the red barn.’) Figure 1a’-c’ and Table 1a’-b’ were the counterbalanced version in which the red barn was the target of the recent action. Therefore, each object was the target of a past and a future action once. This ensured that visual characteristics of the post-verbally referenced target object contributed equally to each critical condition.

We also counterbalanced the presentation side of each object. As shown in Figure 1, the blue barn was on the left side and the red barn was on the right side. In the counterbalancing version (not shown), the red barn was on the left side and the blue barn was on the right side.

In addition to the 16 experimental items, we created 8 filler items to ensure that children were exposed to a range of other sentence structures and actions. The two conditions of the sentence (past vs. future tense), the counterbalancing of the target object, and the counterbalancing of the target

object presentation side led to eight basic lists. Lists were pseudo-randomized and each participant saw an individually randomized version of one of the eight experimental lists.

## Procedure

An EyeLink1000 remote eye-tracker with a sampling rate of 500 Hz monitored participants’ eye movements. Images were presented on a 22" LCD color monitor at a resolution of 1680×1050 pixels concurrently with a spoken sentence. We only tracked the right eye, but viewing was binocular. At the beginning of the experiment, each child was instructed to play a game. In this game, children were asked to inspect the images and to listen to the sentences. After each trial, they heard a question about the previous sentence and were asked to try to answer it correctly.

Each trial started with the display of a series of three frames which depicted an action (e.g., Fig. 1a-c). Each of the three frames in Fig. 1 was presented for 1500 ms (totaling 4500 ms). After that, the third image remained on the screen and the sentence was played via speakers. Five hundred milliseconds after the offset of the sentence, a spoken question asked for the target object of the verb in the previous sentence (for example, *Wohin galoppierte das Pferd?/Wohin galoppiert das Pferd?* ‘Where did the horse gallop?/Where does the horse gallop?’). Participants’ task was to answer the question by naming the correct destination.

At the start of the experiment, each participant was shown two example image sequences and sentences. Next, participants were set up and calibrated manually using a five-point fixation stimulus. The black dot that is used to calibrate adults was replaced by a smiley face to attract children’s attention. The EyeLink software validated calibration; if validation was poor, the calibration procedure was repeated until validation was good. Between the individual trials, participants saw a centrally-located smiley on the screen which they were asked to fixate. This allowed the eye-tracking software to perform a drift correction if necessary. The entire experiment lasted approximately 25 minutes.

Table 1: Example item sentences

Picture	Condition	Sentence
Figure 1a-c	Past tense	(a) <i>Das Pferd galoppierte gestern zu der blauen Scheune..</i> The horse galloped yesterday to the blue barn.
	Future tense	(b) <i>Das Pferd galoppiert morgen zu der roten Scheune.</i> The horse gallops tomorrow to the red barn.
Figure 1a’-c’	Past tense	(a’) <i>Das Pferd galoppierte gestern zu der Roten Scheune..</i> The horse galloped yesterday to the red barn.
	Future tense	(b’) <i>Das Pferd galoppiert morgen zu der blasuen Scheune.</i> The horse gallops tomorrow to the blue barn.

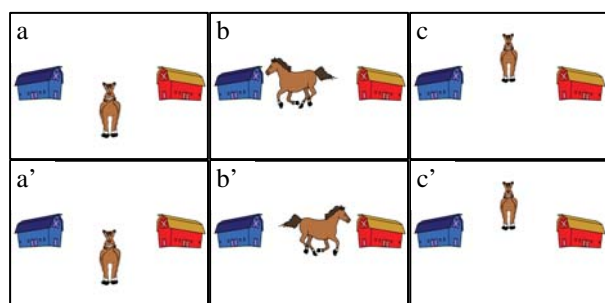

Figure 1: Example item pictures. In Figure 1 a-c, the horse gallops to the blue barn. To counterbalance visual characteristics of the target (e.g., its color), the horse gallops to the red barn in Figure 1 a'-c'.

## Analysis

For the purpose of inferential analyses, we defined three time windows: an exact verb region (from verb onset until its offset); the extended adverb region (from verb offset until adverb offset) and the PP region (from preposition onset until sentence end). We coded participants' fixations to four areas of interest in the scene: the agent (e.g., the horse in Figure 1); the recently acted upon object (e.g., the red barn in Figure 1a-c); the future object (e.g. the blue barn in Figure 1a-c); and the background. Of those, the recent and future objects were our target areas of interest.

The proportions of fixation on the target areas of interest (the recent and the future targets) were entered into log-ratio analyses (c.f., Arai, van Gompel & Scheepers, 2007; Carminati, van Gompel, Scheepers, & Arai, 2008; Knoeferle et al., 2011). We computed mean log gaze probability ratios for the recent object relative to the future object  $\ln(P(\text{future target})/P(\text{recent target}))$  for each condition and for each time window. Then we entered the log probability ratios into a one-factor (*tense*) ANOVA. Separate models were fitted for log-ratios averaged over participants and items respectively. We report the *p*-values for these analyses. To test whether the log probability ratios of each condition differs significantly from zero, we conducted simple *t*-tests. We adjusted the significance level of the *p*-values using the Bonferroni correction.

For the descriptive overview of the time course of the eye-movement data, we divided the utterance from sentence onset into time slots of 250 ms each. For each time slot and target object, we computed the number of fixations that fell within a given time slot. Then we plotted the mean proportion of fixation counts per time slot separately for each sentence condition and each target object.

## Results

Figures 2a) and 2b) plot the mean proportion of fixations to the two objects in the future and past tense conditions using time slots of 250ms. Figure 3 zooms in on one region of

interest and presents the mean log gaze probability ratios ( $\ln(P(\text{future target})/P(\text{recent target}))$ ) per condition for the adverb region.

Figures 2a) and 2b) illustrate an overall preference for fixating the acted-upon object rather than the not-acted-upon object from the offset of the verb until well into the NP2, irrespective of tense condition. As illustrated in Figure 2, the preference for looking at the acted-upon object is much reduced and reverses as children hear the second noun phrase in the future compared to the past tense condition.

In agreement with the descriptive pattern, the inferential analysis revealed no significant main effect of tense at both the verb and the adverb region. To test whether children had a preference to inspect one of the two targets, we examined whether the intercept was significantly different from zero. At the verb region this was not the case. By contrast, simple *t*-tests confirmed that log probability ratios of both the future tense condition and the past tense condition by subjects ( $ps < 0.05$ ) and of the past tense condition by items ( $p < 0.005$ ) were significantly different from zero for the adverb region (see Figure 3). This corroborates the findings from the descriptive analysis and indicates that children looked more often at the recently-acted-upon object than at the not-yet-acted-upon object in both the past and future tense conditions. For the PP region, by contrast, analyses confirmed that the children inspected the target objects as they were named (both  $ps < 0.002$ ).

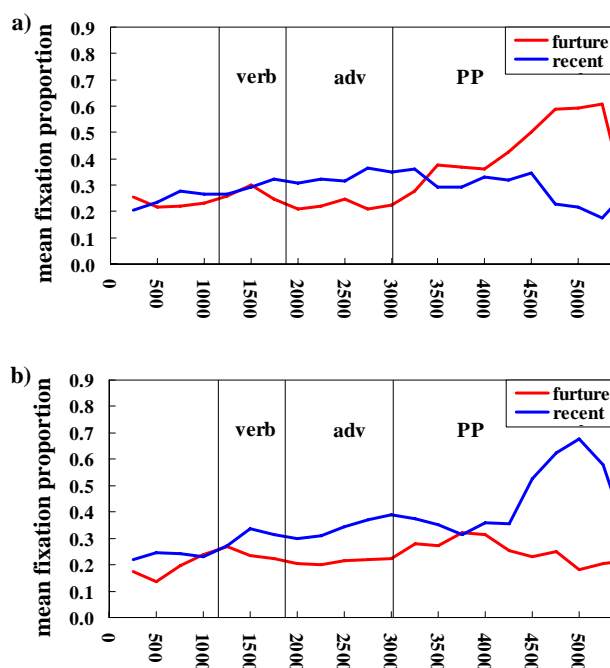

Figure 2: Eye movements to the target of the recent event (recent target: blue lines) and the target of the future event (future target: red lines) from sentence onset to sentence end for a) future tense condition and b) past tense condition

Figure 3: Children's mean log gaze probability ratios ( $\ln(P(\text{future target})/P(\text{recent target}))$ ) per condition for the adverb region (Error bars represent the standard error of the mean log gaze probability ratios)

## Discussion

The present research assessed whether 5-year-old children resemble adults in how and when they make use of recently-inspected clipart events during spoken language comprehension. We conducted an eye-tracking experiment in which we monitored 5-year-olds' eye movements to target objects in a clipart picture as they listened to related sentences. The children saw an animal move towards one of two equally plausible objects (e.g., the horse would gallop to the blue barn when a blue and a red barn were depicted). When the motion verb in an ensuing spoken sentence referred either to that recent action or to another action that hadn't yet happened, children preferred to inspect the target of the recent event (e.g., the blue barn) over the target of the as-yet-unseen but plausible other event (e.g., the red barn).

This finding confirmed clear similarities in how children and adults (Experiment 3 in Knoeferle & Crocker, 2007) direct their visual attention during spoken language comprehension: both of these participant groups preferred to inspect the recent-event (vs. future-event) target. The time course of visual attention, however, was delayed for children relative to adults. While adults in Experiment 3 by Knoeferle and Crocker (2007) began to inspect the recent-event target more often during the verb, the recent-event inspection preference only emerged post-verbally for children.

One open question is what underlies the recent-event preference in both children and adults. The experiment procedure introduced a frequency bias for the recent events. While participants in Experiment 3 by Knoeferle and Crocker (2007) and in the present study saw an event before each experimental trial, they never saw a post-sentence future event acted out. The procedure of never depicting the future event may have created a within-experiment

frequency bias toward relying more on recently depicted than on equally plausible future events for comprehension. It is possible that this bias led participants to preferentially inspect the recent (vs. future) event target.

Indeed, statistical regularities play an influential role in a range of cognitive processes for both children and adults. At 8 months of age, children can already use statistical regularities in linguistic input to segment words in fluent speech (Saffran, Aslin, & Newport, 1996). Statistical factors also play a role in children's visual attention to novel (vs. known) object patterns. When circles appeared in a pattern, infants at 11 months inspected novel (vs. known) circle sequences longer; by contrast, that behavior was not yet present at 8 months of age (Kirkham, Slemmer, Richardson, & Johnson, 2007, Experiment 1). For adults, statistical regularities play a role in language processing and other cognitive and motor processes. Adults' short-term linguistic experience can modulate their language production (Kaschak, Loney, & Borreggine, 2006; Haskell, Thornton, & MacDonald, 2010) and sentence reading (Wells, Christiansen, Race, Acheson, & MacDonald, 2009). It also affects adults' action execution (e.g., Chapman, Gallivan, Wood, & Milne, 2010) and visual perception (e.g., Chun & Jiang, 1999).

For the recent-event inspection bias in adults, however, frequency biases appear to play no causal role. When recent and future events were performed equally frequently within the experiment, effects of tense appeared somewhat earlier than in Knoeferle and Crocker (2007, Experiment 3), during the post-verbal adverb. By contrast, adults' recent-event inspection bias during the verb remained largely unchanged (Knoeferle et al., 2011, Experiment 2).

To what extent this preference generalizes to 5-year-olds when both recent and future events are equally frequent is unclear. What is clear, however, is that children, like adults, rapidly used recently inspected clipart events during comprehension, but that the time course of these event effects was delayed in children. For accounts of situated language comprehension (e.g., Coordinated Interplay Account, Knoeferle & Crocker, 2006, 2007), the present findings together with the other results that we discussed suggest that the closely temporally coordinated interplay of language comprehension, visual attention, and visual context effects on comprehension has a developmental basis.

## Acknowledgments

This research was funded by the Cognitive Interaction Technology Excellence Center (German Research Foundation, DFG). We thank Linda Krull and Eva Mende for their assistance with preparing the stimuli and collecting data. We thank Maria Nella Carminati for advice regarding the analyses and Helene Kreysa for help with the Experiment

Builder software. We also thank all the participating families and students for their support.

## Abstract

Bayesian orthodoxy posits a tight relationship between conditional probability and updating. Namely, the probability of an event  $A$  after learning an event  $B$  should equal the conditional probability of  $A$  given  $B$  prior to learning  $B$ . We examine whether ordinary judgment conforms to the orthodox view. In three experiments we found substantial differences between the conditional probability of an event  $A$  supposing an event  $B$  compared to the probability of  $A$  after having learned  $B$ . Specifically, supposing  $B$  appears to have less impact on the credibility of  $A$  than learning that  $B$  is true. Thus, Bayesian updating seems not to describe the relation between the probability distribution that arises from learning an event  $B$  compared to merely supposing it.

**Keywords:** belief updating, reasoning, probability

## Introduction

Let  $Pr_1$  represent the beliefs of an idealized agent who is considering at time 1 the credibilities of events over an outcome space  $\Omega$  (finite, for simplicity). Suppose that for some event  $B \subseteq \Omega$  with  $Pr_1(B) > 0$  experience intervenes at time 2 to convince the agent that  $B$  is (definitely) true. What new distribution  $Pr_2$  should embody the agent's revised beliefs? The Bayesian response (Hacking, 2001, Ch. 15) is that  $Pr_2$  should be the result of conditioning<sup>1</sup>  $Pr_1$  on  $B$ , that is:

(1) BAYESIAN UPDATING:

If  $B \subseteq \Omega$  is learned between times 1 and 2 (and nothing else relevant is learned) then for all events  $A \subseteq \Omega$ ,  $Pr_2(A) = Pr_1(A | B)$  (provided that  $Pr_1(B) > 0$ ).

It is easy to check that  $Pr_2$  as defined by (1) is a genuine probability distribution and that  $Pr_2(B) = 1$  (as expected). Also, (1) is a consequence of compelling axioms on belief change (Gärdenfors, 1988, §5.2), and its violation exposes the agent to sure-loss betting contracts (Harman, 1999, §4.12).

<sup>1</sup>By conditioning we refer to simple or strict Bayesian updating, rather than associative learning.

Such normative virtues suggest a psychological question. One way of formulating (1) is that *supposing* an event  $B$  should have the same impact on the credibility of an event  $A$  as *learning*  $B$ . Is this true for typical assessments of chance? For example, is the judged probability of a Democratic victory in 2012 *supposing* that Hilary Clinton is the vice presidential candidate the same as the judged probability of a Democratic victory in 2012 after *learning* that Clinton, as a matter of fact, is the vice presidential candidate?

The foregoing question is orthogonal to the provenance of conditional probability in the mind, that is, to the way such probabilities are mentally computed. Thus, even if people fail to respect the standard definition:

$$Pr(A | B) \stackrel{\text{def}}{=} \frac{Pr(A \cap B)}{Pr(B)}$$

it is still possible for (1) to hold.<sup>2</sup> All that matters is whether the same degree of confidence in event  $A$  is reached when supposing event  $B$  compared to learning it. On the other hand, recent literature on conditional reasoning has suggested a difference between supposing vs. learning the antecedent of a conditional (Oaksford & Chater, 2007). We investigated the difference between learning and supposing in three experiments.

## Experiment 1

### Participants

Forty undergraduates (27 female, mean age 19.4 yrs, SD = 1.3) from Princeton University participated in exchange for course credit.

<sup>2</sup>An earlier study focussed on the fidelity of the standard definition (above) to the numbers people report as conditional probabilities (Zhao, Shah, & Osherson, 2009).

## Materials

Five decks of cards served as stimuli, each with 20 cards. Each card presented an animal and a colored square on one side and was blank on the other side. The animal was marked on the bottom half of the card and could be either a dog or a duck. The colored square was marked on the top half and could be either green or yellow. Thus, each deck contained four types of cards: green dog, green duck, yellow dog, and yellow duck. Table 1 summarizes the respective frequencies of the types of cards for each deck.

Table 1: Number of cards in each deck used in Experiment 1.

Deck	Green Dog	Green Duck	Yellow Dog	Yellow Duck
1	5	4	6	5
2	9	2	6	3
3	4	8	2	6
4	7	8	2	3
5	3	3	6	8

## Procedure

There were two conditions in the experiment: *learn* and *suppose*, each with 20 participants. In both conditions, the five decks were presented to the participant in random order. For each deck, the experimenter first showed the cards to the participant, with the animals and colors in plain view. Cards were presented briefly (around 0.5 second apiece) to prevent counting. After all cards in the deck were presented, the participant shuffled the deck, drew one card at random, and put it on the table blank side up. Thus, neither the participant nor the experimenter knew what the card was.

The procedure then differed between the two conditions. In the *learn* condition, the experimenter covered the card drawn from the deck, turned the card over while still covered, and then revealed one half of the card to the participant. Whether the animal or the color was thereby revealed was randomly determined. If the revealed half was an animal then the participant estimated the probability that the unrevealed half was a certain color; whether they were asked for the probability of “green” versus “yellow” was determined randomly. If the revealed half was a color then the participant estimated the probability that the unrevealed half was a certain animal; whether they were asked for the probability of “dog” versus “duck” was determined randomly. The covered half was never revealed to the participant. This procedure was repeated for all five decks.

The *suppose* procedure was identical to the foregoing up to placing one card from the shuffled deck face down on the table. In the *suppose* procedure, neither side of the card was revealed, and the experimenter proceeded instead to ask a question of the form: “What is the probability that so-and-so appears on the card supposing that such-and-such appears?” The content of the question (so-and-so and such-and-such) was determined by yoking each *suppose* participant to the immediately preceding participant, who was in the *learn* con-

dition. Specifically, if for decks 1 through 5 the *learn* participant was asked for the probabilities of  $A_1 \dots A_5$  upon learning  $B_1 \dots B_5$  then the *suppose* participant was asked for the conditional probabilities  $Pr(A_1 | B_1) \dots Pr(A_5 | B_5)$  in the order corresponding to the presentation of the five decks to the *learn* participant.

Thus, the first participant was assigned to the *learn* condition, the second to the *suppose* condition (and yoked to the first participant), and likewise for succeeding pairs of participants. The crucial difference was that participants in the *learn* condition estimated  $A$  after learning  $B$ , whereas participants in the *suppose* condition estimated  $A$  while supposing  $B$ .

## Results and Discussion

We computed three statistics over the five probabilities that a given participant produced, namely, (a) the average of the five raw responses, (b) the average absolute deviation from 0.5, and (c) the average absolute deviation of a response from the objective probability of the event under consideration (where the objective probability was derived from the composition of the deck employed in that trial). Statistic (b) quantifies confidence inasmuch as extreme probabilities signify presumed knowledge about an event whereas 0.5 represents ignorance. The statistics produced by the two groups were then compared via paired  $t$ -tests. There were thus 20 pairs, defined by yoking each *suppose* participant to his/her *learn* participant.

As seen in row (a) of Table 2, the average responses across the 20 *learn*-*suppose* pairs were virtually identical [ $t(19) = 0.60$ ,  $p = 0.56$ ,  $d = 0.13$ ]. Row (b) shows, however, that the absolute deviation from 0.5 was reliably greater for the *suppose* group compared to *learn* group [ $t(19) = 2.61$ ,  $p = 0.02$ ,  $d = 0.58$ ]. The absolute deviation from objective probability also differed reliably between the *learn* and *suppose* conditions [ $t(19) = 4.15$ ,  $p < 0.001$ ,  $d = 0.93$ ] with more accurate responses from the *learn* participants; see row (c). Moreover, in 16 of the 20 pairs, *learn* participants were more accurate than *suppose* participants ( $p = 0.01$  by binomial test).

Table 2: Comparison of *learn* and *suppose* groups in Experiment 1

Statistic	Learn	Suppose	$p$
(a) Raw estimate of $Pr(A B)$	0.50(0.10)	0.49(0.12)	0.56
(b) Abs. dev. from 0.5	0.14(0.05)	0.19(0.06)	0.02
(c) Abs. dev. from $Pr(A B)$	0.09(0.05)	0.16(0.08)	0.00

Means for the two groups, relative to various statistics. Standard deviations are given in parentheses;  $p$ -values reflect paired  $t$ -tests ( $N = 20$ ). (Abs. dev. = Absolute deviation)

The results of Experiment 1 thus suggest limitations to the Bayesian model of updating, at the descriptive level. To check the robustness of our findings, we repeated Experiment 1 with new decks, involving different frequencies of the four events.

## Experiment 2

### Participants

A new group of forty undergraduates (26 female, mean age 19.5 yrs, SD = 1.8) from Princeton University participated in exchange for course credit.

### Materials and procedure

The procedure was identical to Experiment 1 except for the use of five different decks shown in Table 3.

Table 3: Number of cards in each deck used in Experiment 2.

Deck	Green Dog	Green Duck	Yellow Dog	Yellow Duck
1	9	2	1	8
2	2	8	9	1
3	7	1	3	9
4	3	8	7	2
5	8	3	2	7

### Results and Discussion

We computed the same statistics as in Experiment 1; see Table 4. As before, there was virtually no difference in the average responses of the suppose versus learn groups. And once again, suppose participants were less accurate than learn participants in terms of absolute deviation from the objective value; 16 of the twenty learn/suppose pairs showed this pattern ( $p = 0.01$  by binomial test). This time, however, learn rather than suppose participants issued more extreme probabilities; see row (b) of Table 4.

Table 4: Comparison of learn and suppose groups in Experiment 2

Statistic	Learn	Suppose	$p$
(a) Raw estimate of $Pr(A B)$	0.50(0.14)	0.48(0.10)	0.53
(b) Abs. dev. from 0.5	0.23(0.05)	0.18(0.06)	0.00
(c) Abs. dev. from $Pr(A B)$	0.13(0.04)	0.21(0.08)	0.00

Means for the two groups, relative to various statistics. Standard deviations are given in parentheses;  $p$ -values reflect paired  $t$ -tests ( $N = 20$ ). (Abs. dev. = Absolute deviation)

Why did suppose participants issue more extreme probabilities than learn participants in Experiment 1 while the reverse is true in Experiment 2? Tables 1 and 3 report the objective distributions of the cards in the two experiments, and reveal greater extremeness for the second experiment compared to the first. So, the switch in extremeness might be a corollary to the greater accuracy of the learn compared to suppose groups.

In sum, the results of Experiment 2 reveal once again a gap between learning and supposing that is not foreseen by Bayesian updating.

## Experiment 3

In Experiments 1 and 2, probabilities were grounded in frequencies and therefore *extensional*. The third experiment was

designed to evaluate the impact of learning versus supposing in an *intensional* setting involving probabilities of non-repeatable events. In particular, participants in the third experiment specified their confidence (as a probability) that Bill Clinton won/lost a specified state given that he won/lost another state in the 1992 presidential election.

### Participants

A new group of sixty undergraduates (41 female, mean age 20.4 yrs, SD = 1.9) from Princeton University participated in exchange for course credit.

### Materials

A deck of 50 cards served as stimuli. One side of a given card was marked with a U.S. state, the other side left blank.

### Procedure

As in the previous experiments, there was a learn and a suppose condition, each with 20 participants. In both conditions, the participant examined the deck then shuffled it and placed two cards face down on the table (without looking at them). Despite the appearance of randomness, the experimenter examined but then ignored the contents of the cards, and instead asked about two states from a pre-selected list. The list consisted of 20 swing states (electoral outcome not easily predictable); the two swing states figuring in a given trial were drawn randomly from the list.<sup>3</sup>

In the learn condition the experimenter picked up one of the two drawn cards and looked at its underside (preventing the participant from seeing the content). The state was announced (actually, the announced state was preselected from the list of 20 swing states), and then the electoral outcome for that state was determined by consulting a website. Specifically, with the participant watching, the experimenter discovered the outcome for that state via <http://uselectionatlas.org/RESULTS/>, and showed the result to the participant. Note that the participant was only shown whether Clinton won or lost the specified state; information about other states was masked. The experimenter then examined the underside of the remaining card, announced this second state (actually, preselected from the list of swing states), and asked the participant to estimate the probability of Clinton winning or losing that state. The framing of the question in terms of winning or losing was consistent with the outcome for the first state. For example, if Clinton won the first state then the participant estimated the probability of Clinton winning the second state, and likewise for losing. The two cards were then put aside, never revealed to the participant. This procedure was performed five times per participant.

In the suppose condition, each participant was yoked to the immediately preceding learn participant. To start the trial, the experimenter announced that it was a winning (or losing) round, meaning that the participants were to estimate the

<sup>3</sup>The swing states were taken to be AL, AZ, GA, ID, IN, KS, KY, LA, MI, MN, MO, MS, MT, NC, ND, NM, OH, TN, VA, WV.

probability that Clinton won (or lost) the second state, supposing that he won (or lost) the first state. The choice of framing (win/lose) appeared to be random, but in fact matched the questions in the learn condition. To finish the trial, the participant shuffled the deck and placed two cards face down on the table (without looking). The experimenter pretended to look at the undersides of the two cards and asked the participant to estimate the probability of Clinton winning (or losing) the second state supposing that he won (or lost) the first state. The two states were yoked to those in the learn condition. The two cards were then set aside, never revealed to the participant. This procedure was performed five times (yoked to the preceding learn participant).

A third group ( $N = 20$ ) served as a control condition in which just  $Pr(A)$  was estimated (no conditioning event  $B$  was evoked). In this condition, each participant was yoked to the preceding suppose and learn participants, and gave probabilities to the five states that were target events  $A$ . For each trial, the experimenter announced that it was a winning (or losing) round, meaning that the probability to be estimated was that Clinton won (or lost) the state in question. The framing was yoked to the questions in the suppose and learn conditions. The participant then shuffled the deck and placed one card face down on the table. The experimenter pretended to look at the card and asked the participant to estimate the probability of Clinton winning (or losing) the state. The procedure was performed for each of the five states.

## Results and Discussion

As seen in row (a) of Table 5, the average responses of the learn participants were reliably higher than those of the suppose participants [ $t(19) = 4.41$ ,  $p < 0.001$ ,  $d = 0.99$ ]. Row (b) shows that the learn group offered more extreme probabilities than the suppose group [ $t(19) = 3.11$ ,  $p < 0.01$ ,  $d = 0.69$ ].

Table 5: Comparison of learn and suppose groups in Experiment 3

Statistic	Learn	Suppose	$p$
(a) Raw estimate of $Pr(A B)$	0.64(0.09)	0.53(0.10)	0.00
(b) Abs. dev. from 0.5	0.21(0.06)	0.15(0.06)	0.00
(c) Quadratic penalty	0.18(0.08)	0.25(0.08)	0.02

Means for the two groups are presented, relative to various statistics. Standard deviations are given in parentheses;  $p$ -values reflect paired  $t$ -tests ( $N = 20$ ). (Abs. dev. = Absolute deviation)

To quantify the accuracy of the probability assigned to event  $A$  upon learning or supposing  $B$ , we computed the *quadratic penalty* for  $Pr(A)$ . To illustrate, the quadratic penalty for  $Pr(\text{wins Virginia})$  is  $(1 - Pr(\text{wins Virginia}))^2$  in the event that Clinton won Virginia, and it is  $(0 - Pr(\text{wins Virginia}))^2$  in case he lost. (Note that the conditioning event  $B$  was true in every case.) Thus, low penalty signifies accuracy of a stochastic forecast whereas high penalty signifies inaccuracy; assigning the noncommittal probabil-

ity 0.5 guarantees a penalty of 0.25, indicating ignorance. The quadratic penalty was introduced by Brier (1950); see Predd et al. (2009) for a justification of its use in measuring accuracy. For every participant, we computed her average quadratic penalty over the five trials. Row (c) of Table 5 shows that learners were closer to the truth than supposers were [ $t(19) = 2.57$ ,  $p = 0.02$ ,  $d = 0.58$ ]. This holds for 17 of the 20 pairs of participants ( $p = 0.01$  by binomial test). It is striking that the mean quadratic penalty for the suppose group is almost exactly 0.25, the accuracy level guaranteed by issuing 0.5 probabilities.

We note that a majority (60%) of the pairs figuring in the experiment had consistent outcomes in the election (Clinton winning both or losing both). For the learn condition, the average probabilities assigned to consistent and inconsistent pairs were 0.72 and 0.50, respectively, whereas they were 0.55 and 0.48 for the suppose condition. A two-way ANOVA reveals a reliable interaction, the difference between the learn probabilities exceeding that for the suppose probabilities [ $F(1, 19) = 17.7$ ,  $p < .001$ ]. Since a majority of pairs were consistent (as noted above), these facts explain the lower quadratic penalty for learn participants, and highlight their greater sensitivity to the conditioning event  $B$ .

Finally, in the control condition, the average raw estimate of  $Pr(A)$  was 0.51 ( $SD = 0.13$ ). This is close to the 0.53 estimate of  $Pr(A | B)$  in the suppose group [ $t(19) = 0.51$ ,  $p = 0.61$ ,  $d = 0.12$ ] but reliably different from the 0.64 estimate of the learn group [ $t(19) = 4.09$ ,  $p < 0.001$ ,  $d = 0.91$ ]. The quadratic penalty for the control condition was 0.29 ( $SD = 0.09$ ), reliably different from learn [ $t(19) = 4.18$ ,  $p < .001$ ,  $d = 0.94$ ] but not suppose [ $t(19) = 1.50$ ,  $p = 0.15$ ,  $d = 0.34$ ]. These results indicate once again that the conditioning event  $B$  had greater impact on the judgements of the learn participants compared to suppose.

## General Discussion

Bayesian updating (1) seems not to describe the relation between the probability distribution that arises from learning an event  $B$  compared to merely supposing it. For, in our three experiments, the probabilities that issue from learning  $B$  are more accurate than those resulting from conditioning, and they also differ in their deviation from 0.5. In Experiment 3, moreover, the average probabilities in the two groups differed significantly.

In the latter experiment, learn participants seem to have made greater use of the conditioning event  $B$  than did suppose participants. This is revealed by the greater difference in updated compared to prior probabilities for  $A$  in the learn compared to the suppose conditions. Specifically, learn estimates were reliably higher than the prior, suggesting that learn participants interpreted a win [loss] of one swing state to increase the chance of a win [loss] of another. In contrast, suppose participants' estimates of  $Pr(A | B)$  were almost identical to the control group's  $Pr(A)$ .

Insensitivity to  $B$  may reflect a deficit of imagination, the

suppose participants being unable to simulate the effect of genuinely believing *B*. In fact, Bayesian updating imposes a heavy burden on the reasoner's ability to foresee the impact of experience. Suppose that lions are discovered roaming your neighborhood; can you anticipate the probabilities you would attach to other events if such startling circumstances actually came to pass? Analogous difficulties arise when attempting to predict future affective states (Wilson & Gilbert, 2003).

At the normative level, the Bayesian doctrine (1) is supported by the considerations mentioned in the introduction, yet it remains contentious (see, e.g., Bacchus, Kyburg, and Thalos (1990)). Recent work has begun to provide a necessary critique of Bayesian inference (Jones & Love, 2011). The Bayesian doctrine may also prove to be unsuited to situations in which the agent, albeit rational, loses track of her position in time or space (Arntzenius, 2003). But the debate about (1) might be of limited relevance to the typical transition from one probability distribution to another. Such transitions need not depend on adding an event *B* to one's beliefs without probabilistic qualification. Rather, experience might lead us to revise our confidence in *B* without driving it to zero or one. The rule proposed by Jeffrey (1983) is suited to this kind of case. Recent work has begun to examine Jeffrey's rule from the psychological point of view (Over & Hadjichristidis, 2009; Zhao & Osherson, 2010).

## Introduction

The research described below is unique within both cognitive science and computer science (especially in AI and HCI-related variants) as, to the best of our knowledge, it is the first to combine the issues of humor generation and emotion recognition in an interaction between humans and computers. We present the first conversational system which recognizes user emotions and on this basis decides whether or not to use humor in response.

## Humor and Emotions

This research is based on an assumption that what can work well in interactions between humans can also be beneficial for HCI. It was demonstrated that humor can induce positive moods and reduce negative moods in humans; see Dybala (2011); Dybala et al. (2010c) for a summary. This leads to the conclusion that it should perform the same role in HCI. This was shown in existing research, however, only to some extent. While non-computer-science related research usually considers the humor-emotion relationship in what we defined as three-stage chains, i.e. emotive state I → humorous stimulus → emotive state II, in HCI, all research so far focuses only on doublets, i.e. humorous stimulus → emotive reaction (for more details regarding this approach see Dybala et al., 2010a). Our research bridges this gap and is the first in HCI in which not only emotions following but also those preceding humorous acts were taken into consideration (Dybala, 2011).

## Components

The system developed in our research is named MAS-Punda. Punda is the name of our pun generator (Dybala et al., 2008), and MAS stands for “multiagent system”, as it is composed of multiple intelligent agents: 1) a conversational agent, 2) an emotion recognition agent and 3) a humor generator.

### Conversational Agent

The first agent in our research is Maru-chan, a conversational agent for Japanese (Takahashi, 2009). The agent uses the Internet to extract word associations for users' utterances, and then uses them to generate a relevant response (Dybala et al., 2010d). For more details, see Dybala, Ptaszynski & Sayama (2012a), Dybala (2011).

### Emotion Recognition Agent

The second agent used in our research is Ptaszynski's et al. Emotion Recognition Agent (2010). Besides performing the decisive role in the multi-humoroid, it is also used in automatic evaluation of the system. The agent uses databases with emotive expressions and emotive elements for Japanese. It performs two types of text analysis: 1) it detects if a sentence is emotive, and 2) it determines the type and valence of the conveyed emotion(s). For more details, see Dybala (2011) and Dybala et al. (2010c).

### Humor Generation Agent

The second agent used in this research is Pundalin, a pun generator for Japanese (Dybala et al., 2008), which also uses the Internet. This agent represents the class of “humoroids”, defined by Dybala et al. (2009d). Against a user utterance, the agent generates phonetic candidates for puns, selects the most appropriate, and then integrates it into an adequate humorous response. In the generation step, the agent uses phonetic patterns based on an innovative classification of Japanese puns, proposed by Dybala (2011). For more details about this agent, see (Dybala, 2011; Dybala et al., 2010c).

### Multiagent Emotion Aware Joking System

The agents described above were merged to create a multiagent humor-equipped joking conversational system. It represents a high level class of humoroids, defined and named by Dybala et al. (2010d) as “multi-humoroids”. Basing on existing literature (see above), we assumed that in HCI, the computer agent can use humor to make the interlocutor feel better. In order to do that, first the system detects human emotions (performed by ML-Ask), and on this basis makes a decision whether a joke should be told.

To summarize the decision rules used in this experiment, the assumptions were that: 1) if a human's emotive state is negative or neutral, the agent can use humor in order to make him / her feel better, and 2) otherwise, the response is generated by the non-humorous agent. If ML-Ask decides that a joke should be told, the response is generated by the joke generator. If ML-Ask decides otherwise, the response is generated by the Maru-chan (Dybala et al., 2010c).

### Evaluation Experiments

The multiagent system was evaluated using a novel chatterbot evaluation methodology proposed by Dybala et al.

(2010b). In this particular case we conducted two experiments: user-oriented and automatic.

### User-oriented evaluation

In the first experiment we asked 13 users to perform conversations with Maru-chan and MAS-Punda in order to compare their performance in a questionnaire completed afterwards. Some results are summarized in Table 1.

Table 1. User-oriented evaluation experiment results

A) Did the agent try to make the conversation more interesting?, B) Did you find the conversation interesting?, C) Did the agent try to make you feel better?, D) Did the agent use humor in appropriate moments?, E) Describe your feelings towards the agent after the interaction (sum), F) Which agent was better?, cont? – do you want to continue the dialogue? (option to choose)

Question	A	B	C	D	E	F	cont?
Maru	1.69	2.08	1.69	1.00	-9	38%	2
MAS	2.85	2.69	2.69	2.45	+8	62%	5

### Automatic evaluation

In the second experiment, the chat logs acquired in the first experiment were analyzed by the ML-Ask agent to investigate user emotions and their changes during the conversations. Some results are summarized in Table 2.

Table 2. Automatic evaluation experiment results

	Maru-chan			MAS-Punda		
Emotiveness	91 (average: 7.0 per utt.)			125 (average 9.6 per utt.)		
Valence	to positive		to negative	to positive		to negative
	68%		32%	94%		6%
Final emotion	pos.	neg.	neutr.	pos.	neg.	neutr.
	69%	31%	0%	85%	0%	15%

### Summary and Future Directions

The experiments showed that the humor- and emotion-equipped multiagent system was evaluated as better, more interesting and, perhaps most importantly, making users feel better than the baseline agent. This leads to the conclusion that our goal to construct a conversational system able to properly react with humor to users' emotions was achieved.

That said, there is still much to be done in this area. Currently we are working on a user-adaptive humor sense model, which should lead to personalization of the system (Dybala et al., 2009b). We also plan to construct a metaphor processing agent and implementing it into our system.

# Meta-Representational Competence as an Aspect of Spatial Intelligence

Mary Hegarty (hegarty@psych.ucsb.edu)

Department of Psychology, University of California, Santa Barbara  
Santa Barbara, CA 93106 USA

## Abstract

Meta-representational competence (diSessa, 2004) encompasses ability to choose the optimal external representation for a task and to use novel external representations productively. Research on this aspect of spatial intelligence reveals large individual differences in ability to adaptively choose and use external visual-spatial representations for a task. This research suggests that we should not just think of interactive external visualizations as ways of augmenting spatial intelligence, but also consider the types of intelligence that are required for their use.

**Keywords:** Spatial ability; intelligence; external representations.

## Introduction

The concept of spatial intelligence brings to mind measures of individual differences in spatial ability, which measure performance in tasks (e.g., mental rotation, paper folding) involving the storage and manipulation of internal spatial representations. While this is certainly a central aspect of spatial intelligence, with developments in information technologies, spatial thinking increasingly involves interacting with external visualizations. For example, medical students now learn three dimensional (3-D) anatomy by interacting with computer visualizations that they can rotate at will, scientists gain insight into their data by visualizing and interacting with multidimensional plots, and chemists use a variety of external representations, including 3-D physical and virtual models and 2-D diagrams, to reason about the structures and reactive properties of molecules. While new technologies are typically seen as means of augmenting human intelligence, this paper considers the ways in which they also make new demands on our intelligence.

diSessa (2004) coined the term *meta-representational competence* to encompass ability to choose the optimal external representation for a task, use novel external representations productively, and invent new representations as necessary. This competence goes beyond the capacity to understand the conventions of a particular type of representation (such as a graph, map, or diagram). It is a form of metacognition about visual-spatial displays. diSessa was mostly concerned with children's native representational competence in using and inventing scientific representations, and how to foster this in instruction. In this paper, I consider meta-representational competence as a component of adult spatial intelligence.

## Using Representations

In one line of research inspired by the use of new technologies in medicine, I and my colleagues have found large individual differences in use of interactive visualizations (Cohen & Hegarty, 2007; Keehner, Hegarty, Cohen, Khooshabeh & Montello 2008; Stull, Hegarty & Mayer, 2009). In a series of studies, participants were given the opportunity to manipulate a virtual 3-D object while accomplishing a spatial task, namely inferring the appearance of a cross section of the 3-D object. On each cross section trial, participants were shown a picture of the 3-D object with a line drawn through it, and an arrow pointing to the line and their task was to draw the cross section that would result if the object were sliced at the line and one was viewing the cross section from the direction of the arrow.

The most common use of the virtual object was to rotate it to the view of the object that one would see if one was viewing it from the perspective of the arrow. Rotating the external visualization in this way relieves the participant of the need to mentally rotate the object or mentally change his or her perspective with respect to the object. Participants who used the model in this way had better performance, but many students did not use the model. In general, there were large individual differences in ability to discover how to best use the virtual object, ability to actually manipulate it, and ability to benefit from the most task-relevant view of the object.

We are finding similar results in current studies on use of 3-D models in chemistry (Stull, Hegarty, Dixon & Stieff, submitted). In these studies the task (for chemistry students) is to translate between different diagrams of molecules that use different conventions to depict the 3-D structure of molecules in the two dimensions of the printed page, and depict the molecule from different spatial perspectives. On each trial participants are given one diagram of a molecule and their task is to draw a different diagram of the same molecule. The most common use of the model is to first match it to the perspective of the given diagram, then rotate it to match the perspective of the diagram to be drawn, and then draw this diagram. However, when they are provided with a concrete 3-D model of the molecule, many students do not use the model and perform poorly on the representation translation task. These studies indicate that ability to use an external representation is not always a given, and provide evidence for individual differences in adult meta-representational competence.

## Choosing Representations

Another aspect of meta-representational competence is choosing the most effective representation for a given task. We have examined this aspect in the domain of meteorology. The design of a weather map, such as its complexity or the relative salience of different depicted variables, can have significant effects on performance of map comprehension tasks (Canham & Hegarty, 2010; Fabrikant, Rebich-Hespanha & Hegarty, 2010; Hegarty, Canham & Fabrikant, 2010). However, when given a choice of displays, people do not always choose the optimal display for their task. In a series of studies we asked naïve undergraduate students and experienced weather forecasters to perform read-off and inference tasks with maps that varied in complexity (the number of displayed variables) and realism (the extent to which they looked like their real-world referents). We also asked our participants to choose (from a set of maps varying in complexity and realism) the maps that they would prefer to use when accomplishing these tasks.

Both naïve students and experienced forecasters performed the tasks more efficiently with simple maps that displayed only the task-relevant information and naïve students were more accurate with these displays. When asked to choose which map they would prefer to use, or the map with which they would be most efficient, the majority also chose these relatively simple maps. However about one third of naïve students and expert weather forecasters chose more realistic and complex weather maps than they needed, even though complexity and realism impaired performance (Hegarty, Stull & Smallman, in press; Hegarty, Smallman, Stull & Canham, 2009). More generally, surveys of undergraduate students indicate that they prefer realistic, animated, and detailed displays over more abstract, static, and sparse displays for a range of tasks (Hegarty, 2010; Hegarty et al., 2009).

## Conclusions

It is important to consider the broader context of these research findings. For example, efficiency may not be an individual's paramount goal when he or she chooses a visual display. There is also a tradeoff between the time required to find or design the most efficient display and the time saved by using that display. Finally, complex displays that are less efficient in the short term may lead to a more elaborated understanding of the situation represented by the display

Nevertheless, these studies highlight the fact that although new visualization technologies have the potential to augment human spatial intelligence, intelligence is also required for their use. With the current interest on how to foster spatial intelligence, (National Research Council, 2006) and increased availability of complex visualizations, they suggest that more attention should be paid to teaching people to use, design, and critique external spatial representations, in addition to training their internal visualization abilities.

## Abstract

The integration of artificial intelligence (AI) within cognitive science (CogSci) necessitates further elaborations on, and modelings of, several indispensable cognitive criteria. We approach this issue by emphasizing the close relation between artificial general intelligence (AGI) and CogSci, and discussing, particularly, “rationality” as one of such indispensable criteria. We give arguments evincing that normative models of human-like rationality are vital in AGI systems, where the treatment of deviations from traditional rationality models is also necessary. After conceptually addressing our rationality-guided approach, two case-study systems, NARS and HDTP, are discussed, explaining how the allegedly “irrational” behaviors can be treated within the respective frameworks.

**Keywords:** Rationality; intelligence; AGI; HDTP; NARS

## Motivations and Background

For more than five decades, artificial intelligence (AI) has always been a promising field of research on modeling human intelligence. The success of projects like IBM’s Watson (Ferrucci et al., 2010), for instance, increases the hopes in achieving not only language intelligence but also inference mechanisms at a human-level and paves the way for solving more baffling tasks. However, AI has turned into a vague, un-specific term, in particular because of the tremendous number of applications that belong, in fact, to seemingly orthogonal directions. Philosophers, psychologists, anthropologists, computer scientists, linguists or even science fiction writers have disparate ideas as to what AI is (or should be). The challenge becomes more obvious when AI is looked at from a CogSci perspective, where the focus is mainly on explaining processes of general cognitive mechanisms (not only on how one or another intelligence task can be solved by a computer). We think that from a CogSci perspective the kind of intelligence characterizing classical AI problems is not yet exhaustive enough. Solutions to most of the problems are not cognitively inspired: neither do they consider essential cognitive mechanisms (or general intelligence results) nor do they show the biological plausibility of the solutions.

*Artificial General Intelligence* (AGI) refers to a research direction that takes AI back to its original goals of confronting the more difficult issues of human-level intelligence as a whole. Current AGI research explores all available paths, including theoretical and experimental computer science, cognitive science, neuroscience, and innovative interdisciplinary

methodologies (Baum, Hutter, & Kitzelmann, 2010). Here, we approach cognition in AGI systems by particularly promoting “rationality” as one of such indispensable criteria, and analyze some divergent, sometimes seemingly irrational, behaviors of humans.

In this article, our goal is twofold. We first concern ourselves with explicitly allocating ideas from AGI within CogSci. Second, we give a conceptual account on some principles in normative rationality-guided approaches. After explaining our approach at a general level, we explain how two cognitively inspired systems, namely NARS and HDTP, have the potential to handle (ir)rationality. We conclude by giving some remarks and future speculations.

## Why AGI?

In current AGI research, there are approaches following different paths, including those (1) inspired by the structure of human brain or the behavior of human mind, (2) driven by practical demands in problem solving, or (3) guided by *rational principles* in information processing. We are concerned with the latter approach, which has at least three essential advantages. One advantage of the rationality-guided approach, from an AGI perspective, is that it is less bound to exactly reproducing human faculties on a functional level. Another advantage is that it gives AI the possibility of being established in a way similar to other disciplines, where it can give a theoretical explanation to intelligence as a process that can be realized both in biological systems and computational devices. The third advantage of the rationality-guided approach is that it is not limited to a specific domain or problem.

## Rationality

The term *rationality* is used in a variety of ways in various disciplines. In CogSci, rationality usually refers to a way a cognitive agent deliberatively (and attentively) behaves in, according to a specific normative theory. The prototypical instance of cognitive agents that can show rational behavior is humans, who so far are also the ultimate exemplar of generally intelligent agents. When modeling intelligence, it is reasonable to initially take the remarkable abilities of humans into account with respect to rational behavior, but also their apparent deficiencies that show up in certain tasks.

Surprisingly little attention has been paid so far in AI towards a theory of rationality. A reason might be that the concept of rationality was too broad in order to be of interest to AI, where for a long time usually relatively specific cognitive abilities were modeled and heuristics were suggested. Moreover, an artificial cognitive agent is usually intended to reproduce rational behavior, not to act in seemingly irrational ways. Consequently, AI researchers are not interested in results of some *classical rationality puzzles*. Still, we think that a move towards integrating AGI in CogSci cannot ignore rationality issues, neither the remarkable abilities nor the originalities human subjects show in rationality tasks.

### Traditional Models of Rationality

Different models of rationality use significantly different methodologies. Clustering such models according to the underlying formalism usually results in at least the following four classes: (1) logic-based models (Evans, 2002), (2) probability-based models (Griffiths, Kemp, & Tenenbaum, 2008), (3) heuristic-based models (Gigerenzer, 2008), and (4) game-theoretically based models (Osborne & Rubinstein, 1994). Several of these models have been proposed for establishing a *normative theory of rationality*, normally by judging a belief as rational if it has been obtained by a formally correct application of the respective reasoning mechanism, given some background beliefs or knowledge (cf. e.g. also (Gust et al., 2011; Wang, 2011)). Therefore, such theories of rationality are not only intended to model “rational behavior” of humans, but to postdictively decide whether a particular belief, action, or behavior is rational or not. Nonetheless, although a conceptual clarification of rational belief and rational behavior is without any doubts desirable, it is strongly questionable whether the large number of different (quite often orthogonal) frameworks makes this task easier, or if the creation of a more unified approach wouldn’t be recommendable. From our perspective, basic cognitive mechanisms seem to offer a basis for such an endeavor.

### Some Rationality Challenges and Puzzles

Although the models mentioned above have been proven to be quite successful in modeling certain aspects of intelligence, all four types of models have been challenged. For example, in the famous Wason selection task (Wason & Shapiro, 1971) human subjects fail at a seemingly simple logical task (cf. Table 1.a). Similarly, Tversky and Kahneman’s Linda problem (Tversky & Kahneman, 1983) illustrates a striking violation of the rules of probability theory in a seemingly simple reasoning problem (cf. Table 1.b). Heuristic approaches to judgment and reasoning try to stay closer to the observed behavior and its deviation from rational standards (Gigerenzer, 2008), but they fail in having the formal transparency and clarity of logic-based or probability-based frameworks with regard to giving a rational explanation of behavior. Game-based frameworks can be questioned due to the various forms of optimality concepts in game-theory that can support different “rational behaviors” for one and the same situation.

In order to make such challenges of rationality theories more precise, we discuss some aspects of the famous Wason selection task and the Linda problem in more detail.

**Wason Selection Task** This task shows that a large majority of subjects are seemingly unable to evaluate the truth of a simple rule of the form “*if p then q*” (Wason & Shapiro, 1971). In the version depicted in Table 1.a, this rule is represented by: “*If on one side of the card there is a D, then on the other there is the number 3*”. According to classical logic, in order to assign a truth-value to this rule, subjects need to turn D and 7. What is interesting is the fact that a slight modification of the content of the rule to a setting more familiar from daily life, while keeping the structure of the problem isomorphic, makes subjects perform significantly better, as e.g. shown in (Cosmides & Tooby, 1993).

Table 1: a. A description of the Wason selection task. b. An abbreviated version of the Linda problem setting.

<b>a. Wason Selection Task (Wason &amp; Shapiro, 1971):</b>
Every card which has a D on one side has a 3 on the other side (and knowledge that each card has a letter on one side and a number on the other side), together with four cards showing respectively D, K, 3, 7, hardly any individuals make the correct choice of cards to turn over (D and 7) in order to determine the truth of the sentence. This problem is called “selection task” and the conditional sentence is called “the rule”.
<b>b. Linda Problem (Tversky &amp; Kahneman, 1983):</b>
Linda is 31 years old, single, outspoken and very bright. She majored in philosophy. As a student, she was deeply concerned with issues of discrimination and social justice, and also participated in anti-nuclear demonstrations.
(F): Linda is active in the feminist movement.
(T): Linda is a bank teller.
(T&F): Linda is a bank teller and is active in the feminist movement.

**Linda Problem** With respect to the Linda problem (Tversky & Kahneman, 1983) it seems to be the case that subjects have problems to prevent the so-called *conjunction fallacy*: subjects are told a story specifying a particular profile about someone called Linda. Then, some statements about Linda are shown and subjects are asked to order them according to their probability (cf. Table 1.b). 85% of subjects decide to rank the statements “*Linda is a bank teller and is active in the feminist movement*” (T & F) as more probable than the statement “*Linda is a bank teller*” (T). This ranking conflicts with the laws of probability theory, because the probability of two events (T & F) is less than or at most equal to the probability of one of the events (e.g. (T)).

### Classical Resolution Strategies of Irrationality

Many strategies have been proposed to address the mentioned challenges, ranging from the use of non-classical logics to model subjects’ behavior in the Wason selection task (Stenning & van Lambalgen, 2008), to considerations involv-

ing reasoning in semantic models instead of (syntactic) deductions (Johnson-Laird, 1988) in the case of the Wason selection task. With respect to the Linda problem it has been argued that pure probability theory is not appropriate for addressing the problem properly, but a foundation of the analysis of this problem in coherence theories would be necessary (Pfeifer, 2008). Another resolution strategy applicable to both puzzles is to question whether tasks were appropriately phrased in the respective experiments. In the Wason selection task the “if-then” rule presented in natural language is usually not equivalent to its interpretation in classical logic, and in the Linda puzzle the term “probable” can be interpreted differently by the subjects (Gigerenzer, 2005). In any case, although there are many proposals to address the challenges, there is no generally accepted rationality concept available yet. Moreover, specific frameworks can address specific challenges, but do not generalize to the breadth of the mentioned problems.

For a generally intelligent cognitive system a question that can be raised is: *which principles of rationality can be transferred to and modeled in AGI systems, in order to achieve intelligence on a human scale?* We will argue for models that link rationality to the ability of humans to establish analogical relations (continuing a line of reasoning started in (Besold et al., 2011)), and to the ability to adapt to the environment by making good use of previously obtained experiences.

### Non-Standard, CogSci-Based Approaches

The two examples discussed above definitely show that humans have sometimes problems to apply rules of classical logic correctly (at least in rather abstract and artificial situations), and to reason according to the Kolmogorov axioms of probability theory. Nonetheless, the most that can be concluded from the experiments is that human agents are neither classical deduction machines nor probability estimators, but perform their indisputable reasoning capabilities by other means, necessarily linked to their cognitive capacities.

#### Resolving the Selection Task by Cognitive Mechanisms

As mentioned above, subjects perform better (in the sense of more according to the laws of classical logic) in the Wason selection task, if content-change makes the task easier to access for subjects. We think that the performance of subjects has a lot to do with the ability of subjects to establish appropriate analogies. Subjects perform badly in the classical version of the Wason selection task, probably because they fail to establish a correct analogy. Therefore, subjects fall back to other (less reliable) strategies to solve the problem. In a content-change version of the task the situation is different, because subjects can do what they would do in an everyday analogous situation. In short, the success or failure of managing the task is crucially dependent on the possibility to establish a meaningful analogy.

Another related resolution is to study the mode of the inference that should underly a normative theory of rationality. When a system has sufficient knowledge and resources

(with respect to the problems to be solved), an axiomatic logic (such as classical logic) can be used, which treats the available knowledge as axioms, and derives theorems from them to solve a given problem. When the system has insufficient knowledge, it has no absolute truth to be used as axioms, so has to follow some “non-axiomatic” logic, whose premises and conclusions are all revisable by new evidence. In Wason’s task, the expected results are the ones assuming an axiomatic system, while the actual results may be consistent with a non-axiomatic one. Therefore, the “mistake” here is mainly the misunderstanding between the psychologists who run the tests and the subjects who take the tests. In this artificially structured experiment, it is valid for the psychologists to assume sufficient knowledge and resources, therefore to expect the application of an axiomatic type of inference mechanism. Their mistake, however, is the failure to see the result as coming from another type of inference. On the side of subjects, since non-axiomatic reasoning is used more often in everyday life, most of them fail to understand the experiment setting as a testing of their capacity of using an axiomatic inference mechanism. This explains why many subjects admit their mistake afterwards, and do better in the content-change task (as soon as they realized that the expected way of reasoning is not their default one, they have less problem to adapt to follow it).

#### Resolving the Linda Problem by Cognitive Mechanisms

Here, a natural explanation of subjects’ behavior is that there is a lower degree of coherence of Linda’s profile plus the statement “*Linda is a bank teller*” in comparison to the degree of coherence of Linda’s profile plus the statement “*Linda is a bank teller and is active in the feminist movement*”, as in the conjunctive statement, at least one conjunct of the statement fits quite well to Linda’s profile. *Coherence* (Thagard, 2002) is a complicated concept that needs to be discussed in more detail (as does its connection to notions like the idea of representativeness proposed as an explanation for the Linda problem by Tversky and Kahneman themselves), but it can be mentioned that coherence is important for the successful establishment of an analogical relation, as well as for guiding adaptation of obtained knowledge and experiences. In order to make sense out of the task, subjects tend to rate statements with a higher probability where facts are arranged in a theory with a higher degree of coherence. Also, this can be thought of as a form of coherently adapting beliefs, which also depends heavily on subjects’ experiences rather than on their knowledge of Kolmogorov axioms of probability theory.

### Modeling Rationality: Case Studies

Formal and computational models in CogSci can be roughly divided into two major types: *descriptive* and *normative*. A descriptive model explains how a system actually works, and its establishment is based on empirical data. A descriptive model’s quality is evaluated according to its behavior’s *similarity* to that of humans. A normative model, on the other hand, specifies how a system should work, and its estab-

lishment is based on certain general principles or postulates. Such a normative model's quality is evaluated according to its behavior's *coherence* with these basic assumptions. Though the two types of models are closely related, they are still built and evaluated differently (Wang, 2011). When building a model of rationality, a central issue is the selection of the assumptions on which the model is based, since all conclusions about the model are derived from, and justified against, these assumptions.

In the following, we give two examples for cognitively inspired systems: NARS and HDTP. Both stand in a certain tradition to classical cognitive architectures like the well-known models ACT-R (Anderson & Lebiere, 1998) and SOAR (Laird, Newell, & Rosenbloom, 1987), because they attempt to model cognition in breadth and not relative to highly specialized abilities. Nevertheless, because NARS and HDTP stand in a tradition of modeling the competence aspect of general intelligence, they attempt to integrate a bunch of different human-inspired reasoning abilities, and they try to integrate these abilities in uniform models, they also differ significantly from the mentioned classical cognitive architectures. We briefly introduce NARS and HDTP and discuss how they can account for "irrational" behaviors in tasks, such as the Selection Task and the Linda problem.

**AGI with Relative Rationality (NARS)** NARS (Non-Axiomatic Reasoning System) is an AGI system designed under the assumption that the system usually has insufficient knowledge and resources with respect to the problems to be solved, and must adapt to its environment. Therefore, the system realizes a "relative rationality", that is, the solutions are the best the system can get *under the current knowledge-resource restriction* (Wang, 2011). Since this system has been described in a book (Wang, 2006) and many papers (most of which are available at the the last author's website<sup>1</sup>), here we only briefly explain the treatment of the "Selection Task" and "Conjunction Fallacy" in NARS.

Since NARS has insufficient knowledge and resources, its beliefs are not "absolute truth" but summary of the system's experience. Especially, the *truth-value* of a statement measures its *evidential support*, and the evidence can be either *positive* or *negative*, depending on whether the evidence agrees with the statement. Concretely, for statement "*If on one side of the card there is a D, then on the other there is the number 3*", the D card always provides evidence (positive if the other side is 3, otherwise negative); the 3 card may provide positive evidence (if the other side is D); the 7 card may provide negative evidence (if the other side is D); the K card provides no evidence. To determine the truth-value of the statement, all cards except K should be checked, but due to insufficient resources, the system may fail to recognize all evidence. In this case, D is the easiest, while 7 the hardest. This result is consistent with the common responses of human beings. It is labeled as "irrational", because in classical logic

the truth-value of a statement only depends on the existence of *negative* evidence, and whether there is *positive* evidence does not matter. Furthermore, classical logic does not consider resource restriction at all. For a detailed discussion on evidence and truth-value in NARS, see (Wang, 2009).

In NARS, the meaning of a concept, such as "Linda" or "feminist bank-teller", is determined by the available information about it, in terms of how it relates to other concepts, as far as the system knows. For a given concept, such information may be either *extensional* (indicating its instances or *special cases*) or *intensional* (indicating its properties or *general cases*). To decide the extent to which a concept, "Linda", is a special case of another one, "bank-teller" or "feminist bank-teller", the system will consider all available evidence. In this example, the most accessible evidence about all three concepts are *intensional* (i.e., about their properties), so the system reaches its conclusion by checking if Linda has the properties usually associated with "bank-teller" and "feminist bank-teller", respectively. Since according to the given information Linda has more common properties with "feminist bank-teller" than with "bank-teller", her "degree of membership" is higher to the former than to the latter. This is judged as a "fallacy" when probability theory is applied *extensionally* to this situation, so only the *base rates* matters, while the properties do not. For a detailed discussion on the categorization model in NARS, see (Wang & Hofstadter, 2006).

In summary, as soon as a normative model of rationality or intelligence makes more realistic assumptions, many "heuristics", "bias", and even "fallacies" follow from them. In the above examples, there are strong reasons for assuming that the truth-value of a statement should depend on both positive and negative evidence (rather than negative only), and the meaning of a concept should depend on both extensional and intensional relations (rather than extensional only). We believe these examples mainly show the limitations of traditional models (classical logic, probability theory), rather than human errors. The practice of NARS and similar systems shows that it is possible for a new normative model to explain and reproduce similar results in a unified way.

**Rationality Through Analogy (HDTP)** As a second case study, we want to sketch how *Heuristic-Driven Theory Projection* (HDTP), an analogy-engine, can be used to implement some crucial parts of our cognitively-based theory of rationality (for an expanded elaboration cf. e.g. (Besold et al., 2012)). HDTP is a framework for computing analogical relations between two domains that are axiomatized in many-sorted first-order logic (Schwering, Krumnack, Kühnberger, & Gust, 2009). It provides an explicit generalization of the two domains as a by-product of establishing an analogy. Such a generalization can be a base for concept creation by abstraction. HDTP proceeds in two phases: in the *mapping phase*, the source and target domains are compared to find structural commonalities, and a generalized description is created, which subsumes the matching parts of both domains. In the *transfer phase*, unmatched knowledge in the source domain

<sup>1</sup>At <http://www.cis.temple.edu/~pwang/papers.html>.

is mapped to the target domain to establish new hypotheses. HDTP is therefore similar in spirit to the well-known Structure-Mapping Engine (SME) (Falkenhainer, Forbus, & Gentner, 1989), e.g. with respect to the mentioned mapping and transfer phases and the symbolic representation of domains. Nevertheless, HDTP also differs significantly from SME, e.g. with respect to the strong expressive power of the underlying domain theories (many-sorted first-order logic in HDTP vs. propositional logic in SME), the establishment of the analogy relation as a by-product of an abstraction, and the massive usage of heuristics differ from the ones used in SME.

HDTP implements a principle (by using heuristics) that maximizes the coverage of the involved domains (Schwering et al., 2009). Intuitively, this means that the sub-theory of the source (or the target) that can be generated by re-instantiating the generalization is maximized. The higher the coverage the better, because more support for the analogy is provided by the generalization. A further heuristics in HDTP, for which the motivation is to prevent arbitrary associations, is the minimization of substitution lengths in the analogical relation, i.e. the simpler the analogy the better (Gust, Kühnberger, & Schmid, 2006). There is a trade-off between high coverage and simplicity of substitutions: An appropriate analogy should intuitively be as simple as possible, but also as general and broad as necessary, in order to be non-trivial. This kind of trade-off is similar to the trade-off that is usually the topic of model selection in machine learning and statistics.

The modeling of the Wason selection task with HDTP is quite simple as long as appropriate background knowledge is available, in case an analogy should be established, or the lack of appropriate background knowledge prevents analogy making, in case no analogy should be established. In other words, the availability of appropriate resources in form of background knowledge is crucial. If appropriate background knowledge for an analogous case is missing, then there is no chance to establish an analogical relation or a potential analogy (with low coverage and complex substitutions) is misleading the subject. Hence, subjects have to apply other strategies. This is the situation when subjects are confronted with the original Wason selection task based on properties of cards. Most subjects have problems to establish a meaningful analogy with a well-known domain due to the high degree of abstractness of the task itself. In the other case, if there is a source theory with sufficient structural commonalities, then the establishment of an analogical relation is straightforward. This happens if the task is changed in the following way: the rule that needs to be checked is now: *“If someone is drinking beer in a bar, he / she must be older than 21”*. In the experiment, subjects can choose between “drinking beer”, “drinking coke”, “25 years old”, and “16 years old” (Cosmides & Tooby, 1993). In the corresponding experiments, subjects behave significantly better than in the original selection task. With analogy making the improvement of the subjects in mastering the task can be explained. They can establish an analogy between the sketched set-up of the

experiment and a standard situation in daily life, in which they would simply do the necessary actions to check whether there is someone who is drinking beer in the bar without being older than 21: check people who are drinking beer, and check what people are drinking who are 16. As both situations are very similar to each other, the generalization is straightforward, substitutions length are minimal, and coverage is high.

The Linda problem is structurally different in comparison to the Wason selection task. In an analogy making context, an explanation of subjects’ behavior in terms of coherence maximization is promising. Coherence aspects of input theories are crucial for establishing analogies in several ways. Roughly speaking, the statement *“Linda is a bank teller”* has less coherence with Linda’s profile than the statement *“Linda is a bank teller and is active in the feminist movement”*. Therefore, it is easier to establish an analogy between Linda as given in Linda’s profile and Linda as described in *“Linda is a bank teller and is active in the feminist movement”* than in the pure “bank teller” case. Notice that from an abstract point of view the coherence-based resolution of the task is rather similar with the intensional interpretation of the task in NARS, where “feminist bank teller” has a higher degree of membership with Linda’s profile than “bank teller”.

## Conclusion and Future Work

There are multiple models of rationality, each with its own assumptions and applicable situations. The traditional models are based on certain idealized assumptions, and thus are limited to the domains where the latter are satisfied. Since human cognition has evolved in and is usually used in realistic situations where those idealized assumptions do not hold, those models of rationality are not universally applicable, and violations should not be deemed “irrational” per se. The seemingly irrational behaviors are there not because the intelligent systems (e.g. humans) are irrational, but because the traditional normative theories do not cover rationality very well.

Instead, we believe what is needed are new models of rationality that are based on more realistic assumptions and developed in a more holistic framework. Such models should be able to provide an adequate and feasible positive account of actual human rationality, also accommodating particularities of human-style reasoning. Such a framework could form a cornerstone of a closer connection between AGI and CogSci, embedding important parts of the AGI program within a CogSci context, whilst making the more general methods and theories of AGI accessible to the CogSci side.

The overall appeal for a “more cognitive” view on rationality models and systems is infrequent, but not unusual. Amongst others, already Kokinov (2003) reaches the conclusion that the concept of rationality as a theory in its own right ought to be replaced by a multilevel theory based on cognitive processes involved in decision-making. On the more technical side, there is a growing body of evidence that analogy engines (like HDTP) and general-purpose reasoning engines (like NARS) can be used for implementing these cognitive

mechanisms and, thus, also as foundations of a rationality-guided approach to general intelligence.

This paper should merely be considered as a point of departure, leaving questions for future research galore. For example with respect to the present proposal concerning HDTP, it seems recommendable to figure out to which extent different types of coherence concepts can be integrated into the framework. In particular, the challenges mentioned above need to be addressed, and a formal treatment of coherence needs to be fleshed out. Furthermore, an implementation of coherence principles for retrieval, mapping, and re-representation purposed in the analogy making process needs to be formulated. Concerning NARS, amongst others the following issues would merit work and effort: real-time temporal inference, procedural inference, and self-control. Regarding competing theories for rationality, clarifying to what extent cognitive capacities and limitations have already been taken into account (implicitly as well as explicitly) when designing the theories, and to what extent the classical frameworks can be re-instantiated by a cognitively-based approach, has to be considered one of the principal questions for future research. Finally, on a fundamental conceptual level, a broader definition of rational beliefs is still needed.

## Abstract

This study is a first attempt at formalizing the concept of *Musical Relevance* from a cognitive and computational perspective. We elaborate on Sperber and Wilson's Relevance Theory, and extend it to account for musical cognition, involving both listening and understanding. Our claim is that the application of the concept of *Cognitive Relevance* to music would permit us to partially explain hearers' behavior and composers' choices. A computational model of Musical Relevance could also contribute to the formulation of a general computational theory of musical cognition. In turn, formulating an algorithm to compute Musical Relevance can shed light on the computational nature of the broader cognitive principle of relevance. We propose to unify Relevance Theory with the Generative Theory of Tonal Music, in order to compute Musical Relevance. We started implementing a system to test the proposed approach over simple examples and report about the results in a preliminary experimentation.

**Keywords:** Relevance Theory; Computational Approach; A Generative Theory of Tonal Music; Tonal Pitch Space.

## Introduction

The *Relevance Theory* was initially formulated as cognitive-pragmatic theory of communication (Sperber & Wilson, 1986); lately it has been viewed and developed as a general theory of human cognition (Wilson & Sperber, 2004; Caruthers, 2006). The relevance of an input to an individual (or a cognitive system) is defined as the ratio between the cognitive effect and the processing effort. In the authors words:

“a.) Other things being equal, the greater the positive cognitive effects achieved by processing an input, the greater the relevance of the input to the individual at that time. b.) Other things being equal, the greater the processing effort expended, the lower the relevance of the input to the individual at that time.”

An input is relevant for a cognitive agent in a given context when it can be related with the information registered in memory and accessible, and when this relation yields a “positive cognitive effect”.<sup>1</sup> Relevance of an input is a continuous (non-categorical) variable. The concept is comparative and non quantitative: e.g., “x is more relevant than y, for P in the context C”.<sup>2</sup> The greater the cognitive effects are, the greater

<sup>1</sup>“A positive cognitive effect is a worthwhile difference to the individual's representation of the world: a true conclusion, for example. False conclusions are not worth having. They are cognitive effects, but not positive ones” (Wilson & Sperber, 2004).

<sup>2</sup>On the comparative/quantitative notion of relevance, and on Carnap's distinction of comparative and quantitative concepts, see (Sperber & Wilson, 1986).

the relevance of a given input is (*ceteris paribus*); on the other side, the smaller is the processing effort, the greater is the relevance of a given input (*ceteris paribus*).

It is a matter of fact that Relevance Theory has a lot of opponents. For example, in a footnote Jerry Fodor let us know that according to his opinion a Relevance Theory doesn't even exist: “As for a theory of relevance, saying that if we had one it would solve the frame problem is as pointless as saying that if we solved the frame problem, that would give us a theory of relevance: Both are true, of course, because ‘assessing relevance’ and ‘framing’ are two terms for the same thing. [...] If cognition is to attain true beliefs with any efficiency, it's got to be the case both that what's importantly relevant is generally in the frame, and that what's not importantly relevant generally isn't. Maybe meeting these conditions is tractable within the assumptions of Classical theories, but I don't know of any current proposal for a cognitive architecture, Classical or otherwise, that seems likely to tract it” (Fodor, 2000, p. 114). Fodor takes correctly Sperber and Wilson's theory as a semantic-pragmatic theory of linguistic comprehension, and he poses the question of how a cognitive system can attain true beliefs in an efficient way. However, if we conceive that Relevance Theory can be a general theory of (human) cognition, we have to remark that not all mental representations have a truth-based semantics, and mental representations of music seem to be a good candidate for representation without truth value (Acotto, 2011 (in press)). So, the efficiency of the cognitive system faced with non-semantic representations has to be analyzed with different criteria than those that Fodor has in mind.

One chief problem with Relevance Theory is the difficulty to formalize it: however, in a restricted and formal domain like music, this seems to be possible and psychologically plausible. Modeling musical relevance we have to shift from a “subjective” concept of relevance to an “objective” one: instead of modeling the musical relevance for a given individual in a given context, we'll model the relevance for an idealized listener familiar with the Western tonal music idiom. That is, we are presently concerned with a restricted subset of all possible music.

In their original formulation of Relevance Theory Sperber and Wilson (1986) do not propose any method for calculating relevance, so we had to provide relevance with a quantitative counterpart to design a computational model. This is a key contribution of the present work.

The formulation of an algorithm to compute Musical Relevance would lead to improve the general computational nature of the cognitive principle of relevance: “Human cognition tends to be geared to the maximization of relevance” (Wilson & Sperber, 2004). If Relevance Theory is empirically plausible, and if the musical mind yields a kind of thought comparable with other forms of mental life, Relevance Theory can apply to the musical thinking as well. In order to explore such hypothesis, we propose to put together Relevance Theory and Lerdahl and Jackendoff’s Generative Theory of Tonal Music, GTTM (Lerdahl & Jackendoff, 1983).<sup>3</sup>

The GTTM describes the musical comprehension of a hearer familiar with the Western tonal idiom. It postulates the existence of mental representations of music, structured on five levels: first the musical surface, then two horizontal structures (meter and grouping), and finally two hierarchical structures, the time-span reduction and the prolongational reduction, which can be formalized as binary branching trees (Hamanaka, Hirata, & Tojo, 2006). Generative Theory of Tonal Music finds in Lerdahl’s Tonal Pitch Space theory a partial readjustment (Lerdahl, 2001), especially concerning the formalization and the quantification of the musical dimensions.

Although other musicological theories exist that are related to musical salience (e.g., by Deliège (1996)), we chose the notion of relevance by Sperber and Wilson because it seemed to be more naturally suited to a computational implementation. A major assumption is that it allows formalizing and quantifying musical relevance via the computation of the musical cognitive effect and of the processing effort. We presently do not explore the connections of our work with related investigations of a notion similar to Musical Relevance and grounded on information theory (Conklin & Witten, 1995; Pearce, Conklin, & Wiggins, 2004): we defer to future work the exploration on such links.

The paper is structured as follows: we first qualify Musical Relevance as the ratio between the cognitive effect and the processing effort, and explore both cognitive (musical) effect and (musical) processing efforts. We then provide an example to show how such concepts fit to the musical context. Then a preliminary experimentation is illustrated, and the results are reported and discussed. Finally we conclude by pointing out present limitations and future works.

## Computing Musical Effect

According to Relevance Theory, in order to be more relevant than another, a music excerpt has to offer a greater cognitive/emotional effect than another one requiring the same pro-

cessing effort; alternatively, a musical excerpt has to require a minor processing effort than another one that yields the same effect. The Musical Relevance (*MR*) is defined as the ratio between the Musical Effect (*ME*) and Processing Effort (*PE*): that is,  $MR = ME/PE$ .

GTTM individuates three types of tonal tension: *surface*, *sequential* and *hierarchical* tension. Some experimental tests have been carried out, confirming that sequential tension is not sufficient to represent the effective musical understanding, and that hearers perceive hierarchical tension as well (Lerdahl & Krumhansl, 2007). The Musical Effect yielded by the tonal tension is complemented by the tonal attraction:<sup>4</sup> in other words, the “forces” that constitute musical effect are both *tensional* and *attractive*. In order to calculate the musical effect some rules can be applied, that were devised as Tonal Pitch Space Rules (Lerdahl, 2001). The following rules can be used to compute the musical effect.

### Surface tension rule

$$T_{diss}(y) = scale\_degree + inversion + non\_harmonic\_tones \quad (1)$$

where the tension score of the target chord  $y$  is computed as the sum of three elements *scale\_degree*, *inversion* and *non\_harmonic\_tones*. *scale\_degree* is 1 if  $3^\wedge$  or  $5^\wedge$  is present in the melodic voice, 0 otherwise; *inversion* is 2 if  $3^\wedge$  or  $5^\wedge$  in the bass, 0 otherwise; *non-harmonic tone* is 3 if a pitch class is a diatonic non-chord tone, 4 if it is a chromatic non-chord tone, 0 otherwise.

### Sequential tension rule

$$T_{seq}(y) = \delta(x_{prec} \rightarrow y) + T_{diss}(y) \quad (2)$$

where  $y$  is the target chord,  $x_{prec}$  is the chord that immediately precedes  $y$  in the sequence,  $T_{seq}(y)$  is the tension associated with  $y$ , and  $\delta(x_{prec} \rightarrow y)$  is the distance from  $x_{prec}$  to  $y$ .

### Hierarchical tension rule

$$\begin{aligned} T_{loc}(y) &= \delta(x_{dom} \rightarrow y) + T_{diss}(y); \\ T_{glob}(y) &= T_{loc}(y) + T_{inh}(x_{dom}) \end{aligned} \quad (3)$$

where  $y$  is the target chord,  $x_{dom}$  is the chord that directly dominates the prolongational tree;  $T_{loc}(y)$  is the local tension associated to  $y$ ;  $\delta(x_{dom} \rightarrow y)$  is the distance from  $x_{dom}$  to  $y$ ;  $T_{glob}(y)$  is the global tension associated to  $y$ ;  $T_{inh}(x_{dom})$  is the sum of the values of the distances inherited by the chords that dominate  $x_{dom}$ .

### Melodic attraction rule

$$\alpha(p_1 \rightarrow p_2) = \frac{as_2}{as_1} \cdot \frac{1}{n^2} \quad (4)$$

where  $p_1$  and  $p_2$  are pitches, with  $p_1 \neq p_2$ ;  $\alpha(p_1 \rightarrow p_2)$  is the attraction of  $p_1$  to  $p_2$ ;  $as_1$  is the anchoring strength of  $p_1$  and

<sup>3</sup>It is noteworthy that Musical Relevance model is not directly committed to the GTTM for computing the effect and the effort. E.g., we could employ different theories descending from (Meyer, 1956), such as (Narmour, 1990, 1992) and (Huron, 2006). However, Narmour’s Implication/Realization theory does not account for the *hierarchical* structure (i.e., binary branching tree) of music perception (Margulis, 2005, p. 688), and the same holds for Huron’s Expectation theory.

<sup>4</sup>The model by Lerdahl and Krumhansl is a quantitative theory of tonal tension made out of four components: “1. A representation of hierarchical (prolongational) event structure. 2. A model of tonal pitch space and all distances within it. 3. A treatment of surface (largely psychoacoustic) dissonance. 4. A model of voice-leading (melodic) attractions” (Lerdahl & Krumhansl, 2007).

$as_2$  is the anchoring strength of  $p_2$  in the current configuration of the basic space;  $n$  is the number of semitone intervals between  $p_1$  and  $p_2$ .<sup>5</sup>

*Harmonic attraction rule*

$$\alpha_{rh}(C_1 \rightarrow C_2) = c \cdot \frac{\alpha_{rvl}(C_1 \rightarrow C_2)}{\delta(C_1 \rightarrow C_2)} \quad (5)$$

where  $\alpha_{rh}(C_1 \rightarrow C_2)$  is the harmonic attraction of  $C_1$  toward  $C_2$ ; the constant  $c = 10$ ;  $\alpha_{rh}(C_1 \rightarrow C_2)$  is the sum of the attraction of the leading voices for all the voices in  $C_1$ ;  $\delta(C_1 \rightarrow C_2)$  is the distance of  $C_1$  a  $C_2$ , with  $C_1 \neq C_2$ .

Such rules have found an experimental corroboration in (Lerdahl & Krumhansl, 2007). We assume that these rules represent a good approximation of the musical effect in the overall computation of musical relevance.

For sake of simplicity and because of the greater complexity of music, in this paper we are concerned with melodic music only. Even though this is a clear simplification, and it is the first step of a more complete and complex model, our present work allows us to make experimental tests and to compute a musical relevance score for simple melodies.

## Computing Processing Effort

Concerning the *PE*, no methods to calculate it are given nor suggested in (Lerdahl & Jackendoff, 1983) nor in (Lerdahl, 2001). Nevertheless, following GTTM we can surely identify a vertical, hierarchical, dimension of the *PE* represented by the binary branching trees of the musical structure. Against the “concatenationism” hypothesis (Davies, 2011), musical surface is not enough to understand music, and the structural properties of a melody are a key element for its understanding. We can then assume that at least a great portion of the *PE* is involved in detecting the structural properties of the heard melody.

Figure 1: Structure of the toy melody represented in the GTTM notation, by Katz and Pesetsky (2009).

How to compute the binary branching trees that represent the hierarchical musical structure? In their reinterpretation

<sup>5</sup>In our implementation we adopted a correction to handle the case of repeated notes, with  $p_1 = p_2$ , that otherwise would produce a division by zero. Since the underlying rationale is that in case of repeated notes the ratio  $\frac{1}{n^2}$  should approach 1, we presently set the value of  $n$  to 0.9.

of the GTTM, Katz and Pesetsky observe that in the GTTM time-span trees the more relevant information is the hierarchical distance from the root of the tree (see Figure 1). This distance is measured through a Root Distance (*RD*) number: “The *RD* number of an event  $e$  in a structure  $K$ ,  $RD(e)$ , is the number of nodes that nonreflexively dominate the maximal projection of  $E$  (i.e.  $eP$ ) in  $K$ ” (Katz & Pesetsky, 2009).

Figure 2: Structure of the toy melody in the standard linguistic notation.

The reinterpretation of Lerdahl and Jackendoff’s theory is made within the framework of generative linguistics, where the concept of “projection” plays a central role: “A constituent whose head is  $H$  is called a projection of  $H$ , and is conventionally labeled  $H'$  (‘H-bar’) if it is dominated by another projection of  $H$ ; and  $HP$  otherwise.  $HP$  is called the maximal projection and  $H'$  is called an intermediate projection of  $H$ .  $H$  itself is sometimes called the zero-level projection of  $H$ ”. As it is showed in Figure 2, the linguistics notation allows a graphic translation of the structure of the GTTM.<sup>6</sup>

We will take into consideration the *RD* number of each sound event as a part of the *PE* (we increase by 1 the *RD* numbers). So, we shall measure the *PE* by using the rules of time-span reduction formulated in GTTM.

## An example with melody

Searching for a first implementation of our model, we focus initially on the case of the melodies, in particular the leading voice of the toy melody, and illustrated in Figure 3.

Since we are considering a melody, we only make use of the *melodic attraction rule* (please refer to Equation 4), since the other rules are concerned with events where multiple notes are present at a time.

**Music effect** Since melodic attraction is between each two musical events, an attraction number is not referred to a single

<sup>6</sup>“Variations in the notation with which one expresses a theory can influence one’s thinking about the actual topics under investigation. Even when different sorts of diagrams represent exactly the same information (as is the case here), the differences among them may reflect and reinforce differing working hypotheses or hunches about the kinds of phenomena one expects to model. Differences of this sort between GTTM and common practice in linguistics arise in two important domains: the relevance of projection level and the amount of information that project from terminal nodes to the constituents that they head.” (Katz & Pesetsky, 2009)

Figure 3: The leading voice of the toy melody.

Figure 4: The three levels of the toy melody time-span reductions.

pitch, but represents a transition between two adjacent pitches  $x$  and  $y$ . The attraction values (i.e. the musical effect) between each two notes in the toy melody are as follows:

$$\begin{aligned}
 \alpha(C \rightarrow D) &= 0.125 \\
 \alpha(D \rightarrow E) &= 0.375 \\
 \alpha(E \rightarrow F) &= 0.667 \\
 \alpha(F \rightarrow G) &= 0.375 \\
 \alpha(G \rightarrow A) &= 0.007 \\
 \alpha(A \rightarrow B) &= 0.25 \\
 \alpha(B \rightarrow C) &= 2.0 \\
 \alpha(C \rightarrow D) &= 0.125 \\
 \alpha(D \rightarrow C) &= 0.5
 \end{aligned}$$

**Processing Effort** In order to calculate the  $PE$ , we compute the  $RD$  numbers by following the binary branching tree: for each pair of events the  $PE$  will be the average of the two  $RD$  numbers (augmented by a unit). To compute processing effort implies the possibility to automatically “reduce” a given melody to its more fundamental schema, as it is shown in Figure 4.

This kind of reduction relies on a set of “preference rules”. However, these are not easily implemented because if there are cases where multiple rules are triggered at the same time, unfortunately in the GTTM no criteria are proposed to resolve such conflicts. Deepening the computation of the  $PE$  component of  $MR$  will be one major focus of future work.

**Musical Relevance** We can now calculate the musical relevance of the transition from one event to another in a melody (without considering, for the moment, the relevance of similarity). As each note has a value of  $PE$ , but the attraction value

Figure 5: Excerpt from the Piano Sonata in C minor (KV. 457) by W.A. Mozart.

Figure 6: Excerpt from the “Petit pièce” from the Opus 68 n.5 by R. Schumann.

is between two events, we’ll calculate the average  $PE$  of each couple of notes, and then we’ll calculate the relevance (the ratio between  $ME$  and  $PE$ ) of the passage from one musical event to another.

## Experimental Assessment

In order to provide the proposed approach with an experimental assessment, we devised the following experimental setting.

We implemented a system that computes the *Musical effect* ( $ME$ ) component in the equation  $MR = ME/PE$ . We studied how the computed musical effect differs by varying two simple melodies.

A core hypothesis of the experimentation is that melodies by historical composers maximize  $ME$ , and  $MR$  as well.<sup>7</sup> Let us consider the *cognitive constraints* by Lerdahl (1988), that postulates that ‘good’ music is composed according to the cognitive nature of human mind/brain. By following this theoretical framework we stipulate that the original melodies from historical composers have higher  $ME$  than ‘experimental’ variations composed by ourselves.

In this setting, we expect the system to compute lower  $ME$  for our variations; also, we expect it to be able to distinguish between grammatical and ‘ungrammatical’ variations, by assigning lower scores to ungrammatical ones.

**Experimental setting** We selected the music excerpts illustrated in Figures 5 and 6. Such pieces were chosen in order to capture (and test the system in) two widely different experimental conditions. In particular, they can be thought of as two paradigmatic examples of themes opposite in spirit. The first one is rather percussive and jumps over the main degrees of the C minor key. On the other side, the second one is a typical *cantabile* theme: it is more regular under a rhythmic viewpoint, and the melody mostly moves stepwise.

<sup>7</sup>In accord with the given definition, music relevance ( $MR$ ) grows *ceteris paribus*— as the music effect ( $ME$ ) grows, and vice versa it decreases *ceteris paribus*— as the processing effort ( $PE$ ) grows. Since we added new events by interleaving existing events with new ones, this makes the input more complex. Then we know in advance that new nodes will produce further levels to the reduction tree, thus increasing the  $PE$  component. That is, we know *a priori* that by increasing  $PE$  and by decreasing  $ME$ , the final  $MR$  will result reduced.

Table 1: The Musical Effect scores for the six considered pieces.

<i>Excerpt</i>	<i>Score</i>
Mozart excerpt	0.4259
Mozart Var 1	0.3888
Mozart Var 2	0.3267
Schumann excerpt	0.3182
Schumann Var 1	0.2460
Schumann Var 2	0.1877

Therefore, different musical aspects are accounted for by the considered excerpts.

We then elaborated two variations for each excerpt (Figure 7). In both cases the first variation (indicated as *Var 1* in Figure 7-a) and 7-b)) is only slightly different from the original excerpt. As regards as the second variation, the Mozart excerpt has been modified in a ungrammatical fashion (see *Var 2* in Figure 7-a)), whilst Schumann excerpt has been modified through the insertion of musically plausible notes that transform it into a rhythmically regular arpeggio (see *Var 2* in Figure 7-b)).

The implemented system takes in input the excerpts encoded as MIDI files, and computes the associated musical effect –through the formula in Equation (4)– as the sum of the melodic attraction between each two music events:

$$ME_{excerpt} = \left[ \frac{\sum_{i=1}^{excerpt.length-1} \left( \frac{as_{i+1}}{as_i} \cdot \frac{1}{n^2} \right)}{excerpt.length} \right]$$

By adding new notes we expected a reduction in the musical effect. Furthermore, since the second variation of each input excerpt was more different from each ‘original’ source, we expected to observe a decrease in the musical effect and, relatedly, in musical relevance.

**Results** In accord with our intuition, the implemented system computed the maximum ME scores for the original excerpts, reduced scores for each first variation, and the lowest scores for both second variations. The final figures are reported in Table 1.<sup>8</sup> Provided that this experimentation represents only the very first step towards a psychological validation (that would require considering in how far the results approach human responses), the results seem to corroborate Lerdahl’s hypothesis. Tonal music is governed by an attraction-based syntax. This sort of attraction, which is maximally exploited by composers and which is maximal in the original music excerpts, is at least partly grasped by the proposed model. Further work is needed to investigate whether and how classical western tradition as a whole ‘incorporates’ a criterion to maximize the Musical Effect (independently of the associated processing effort).

<sup>8</sup>The material employed in the experimentation (MIDI files, printable scores and Lilypond sources) along with the results file is available at the URL <http://www.di.unito.it/~radicioni/datasets/cogsci12/>.

Also, if we compare the original excerpts (Figure 5 and 6), the system accounts for the greater ‘dramatical’ salience of Mozart’s excerpt (which is a first theme of a C minor sonate). Schumann’s excerpt is a simple piece: its value results perhaps from the balance between its simple effect and its structural simplicity.

## Conclusions

The paper illustrates a modeling attempt, and an initial implementation of a complex phenomenon such as relevance-guided music understanding. The presented implementation only accounts for the musical effect; coping with the computation of the processing effort is left for future work.

Due to such limitation we considered for experimentation only melodies with differing surface, but with similar underlying structures. Notwithstanding this limitation, the preliminary experimentation provided some evidence that the musical effect captures meaningful aspects of Western tonal music.

Another relevant point for completing the Musical Relevance model involves dealing with musical similarity. Similarities and repetitions in music are a frequent and important structural phenomenon. They affect important musical features like style (Meyer, 1989), but they permit also to affirm that without similarity there would be no music, since similarity is a center of gravity for perception and comprehension (Cambouropoulos, 2009). Similarities and repetitions influence musical effect, and therefore they have impact on the cognitive relevance of a piece of music. The relevance of a musical event  $E_2$  should be a function both of the relevance of the similar event  $E_1$ , and of the relevance of  $E_2$  as taken in isolation. The similarity increases the relevance of a musical event; otherwise, similarities should be avoided for the risk to diminish the relevance effect. Starting from existent systems for computing musical similarity (Meredith, Lemström, & Wiggins, 2002; Radicioni & Botta, 2006), in future works we will focus on detecting similar patterns in music pieces.

## Acknowledgments

This work has been partly supported by the project *Speak2Home*. We are grateful to two anonymous reviewers for their valuable advices that helped to substantially improve the work, and to Jelle Gerbrandy for discussions on some subtle aspects of the paper.

## Abstract

Previous research has found a connection between spatial cognition and success in STEM areas and that spatial cognition skills can be trained using video games. The present study explores whether a relationship exists between non-trained spatial cognition skills and video game performance. Non-video game players first completed four spatial cognition tasks and then played two video games, Tetris and Unreal Tournament (UT). Results showed significant correlations between performance on UT and mental rotation, paper-folding, and the Race dynamic spatial task. In contrast, Tetris performance only correlated with paper-folding. These results indicate that performance on action video games such as UT may be related to more spatial skills than Tetris.

**Keyword:** spatial cognition, video games

## Objective and Rationale

The goal of the present study is to examine the relationship between video game performance and performance on tests of static and dynamic spatial skills. The rationale is that (a) spatial skills may be instrumental for success in science, technology, engineering, and mathematics (STEM), and (b) video game playing may be related to the development of spatial skills.

## Spatial Cognition and STEM Areas

In a longitudinal study Wai, Lubinski, and Benbow (2009) examined the connection between adolescents' spatial ability and later achievement in STEM fields (i.e., science, technology, engineering, and mathematics). Cognitive ability measures of mathematical, verbal, and spatial ability for 400,000 participants from the Project TALENT data bank of 9<sup>th</sup>-12<sup>th</sup> grades were compared to follow-up academic data from 11 years later. Three major conclusions were made from this study: (1) high spatial ability was found among almost all adolescents who went on to achieve educational and occupational credentials in STEM areas; (2) spatial ability was critical for students in the general population as well as those deemed

intellectually talented; and (3) restricting talent searches to verbal and mathematical ability may miss many spatially gifted individuals. If we wish to encourage students to go into STEM fields the educational system may need to adapt to include spatial measures in talent assessment as well as to include interventions and training that encourage the development of spatial skills.

Studies in different areas of STEM have shown different spatial abilities are used on these tasks. For physics, Kozhevnikov, Hegarty, and Mayer (2002) found that there was a significant correlation between students' spatial abilities and accuracy on kinematic problems. Further research by Kozhevnikov, Motes, and Hegarty (2007) found several differences between high- and low-spatial students and the answer they gave to physics problems. High-spatial students could integrate several motion parameters while low-spatial students only considered one. High-spatial students used kinematic graphs as abstract representations of motion while low-spatial students interpreted graphs as being picture-like representations. For representations of the problems, high-spatial students could reorganize representations of spatial problems into other corresponding representations while low-spatial students used multiple, uncoordinated representations of the same problems. Eye-tracking also showed that high-spatial students made eye movements that corresponded to elements of the problem while low-spatial students did not. The researchers suggested this is due to the high-spatial individuals visualizing the correct movement produced when the two movement components were integrated.

To help improve performance in engineering, Sorby and Baartmans (2000) developed a 10-week course to help teach spatial visualization skills to freshman engineering majors who were identified as having lower scores on the Purdue Spatial Visualization Test: Rotations (PSVT:R). Twenty-four students took the course while 72 acted as the control group. During the course students were taught topics such as rotations of objects, cross-sections of solids, and translation and scaling. Those who participated in the course showed significant gains on the PSVT:R beyond simple practice effects. Furthermore, after later analyzing the transcripts for the all of the 96

students, the researchers found that students who took the course scored higher on later graphics courses and had higher retention rates in the graphically oriented engineering program.

While higher spatial ability often facilitates STEM learning for novices, experts in the field often do not use spatial strategies when solving problems. For example, Stieff (2007) found that students used mental rotation strategies when determining if molecular diagrams were identical or enantiomers. In contrast, experts typically used an analytical strategy to complete the task. Uttal and Cohen (in press) propose that spatial ability actually acts as a gateway to getting into STEM fields. While experts develop contextualized spatial abilities and can also use prior semantic knowledge, novices must rely on de-contextualized spatial abilities. Therefore spatial training such as Sorby and Baartmans's (2000) can be used to help novices develop these skills and prevent dropout.

### **Video Games and Spatial Cognition**

Spence and Feng (2010) propose that if students possess poor spatial skills, they will avoid learning in academic areas that require spatial cognition, such as STEM subjects. Similar to verbal or mathematic ability, we must try to improve spatial ability through training either through early education or through play. Research has shown that video games can be used to improve spatial cognition skills. Terlecki et al. (2008) found long lasting, transferable effects on spatial skills after participants were trained using Tetris. For the study, both control and experimental subjects were given a mental rotation task (MRT) once a week over a 12 week period. Participants in the experimental condition also played Tetris for one hour a week while the control participants played Solitaire. At the end of the 12 weeks, large improvements were found for both the repeat MRT exposure control group and the video game training group. Participants in the videogame training condition, however, showed significantly greater transfer effects on the Guilford-Zimmerman Spatial Visualization Task (Guilford & Zimmerman, 1947) and the Surface Development Test (SDT) (Ekstrom, French, & Harman, 1976).

Feng, Spence, and Pratt (2007) also found improvement on a mental rotation task after participants played a first-person shooter action game called Medal of Honor: Pacific Assault. First-person shooter games involve simulated combat in which the player competes against other players or computer controlled enemies. Improvement in mental rotation correlated with improvement on a useful-field-of-view task (UFOV). The authors suggest that the improvement in mental rotation was due to improving lower level attention skills.

Furthermore, Subrahmanyam and Greenfield (1994), in a study on improving both dynamic and static skills in school aged children, found that those with the best initial

spatial skills were best at playing the video game. The researchers proposed that strong dynamic spatial skills helped the participants master a game while practice strengthened weak dynamic spatial skills. The fact that already existing strong dynamic spatial skills facilitate game mastery relates back to Uttal and Cohen's (in press) argument that spatial ability can act as a gateway to STEM areas. In these training studies students/participants are completing these training regimes either because they are being paid or as part of a class exercise. In the real world there is no external motivator to encourage individuals to continue playing video games if they find them too difficult, perhaps due to a lack of spatial ability, or because they find video games unappealing in general. Studies with expert video game players that display high spatial and visual attention skills are also dealing with individual that were self-selected game players (Feng et al., 2007). These individuals may have become regular game players because they possessed higher relative spatial skills to begin with. This could be causing a Matthews effect in which individuals with higher spatial skills enjoy playing action video games therefore they play more of them and further improve their spatial abilities. The question then becomes whether lacking preexisting spatial ability could affect video game performance and therefore affect the motivation to continue playing.

### **Present Study**

The present study examines the relationship between performance on static spatial tasks (i.e., mental rotation and paper-folding) and dynamic spatial tasks (i.e., race task and interception task) on the one hand and novice performance on commercial video games (i.e., Unreal Tournament and Tetris) on the other. Prior research by Terlecki et al. (2008), Feng et al. (2007) and Subrahmanyam and Greenfield (1994), have found that playing video games can increase performance on tasks involving different cognitive skills. However, no study has explored how an individual's performance on any of these cognitive tasks may relate to their ability to play video games.

**Participants.** The participants were 69 college students from the University of California, Santa Barbara (44 women, 25 men). Ages ranged from 18 to 27 years old with a mean age of 19.29 years. All participants were classified as non-video game players, meaning that that did not regularly play commercial video games during their free time.

**Materials and Procedure.** The experiment took place over two sessions that were scheduled within two days of one another. In the first session, participants first filled out a survey assessing their video game usage to remove

any regular video game players. Next, they completed battery of tests including two dynamic spatial tasks and two static spatial tasks. All tasks included in the battery were administered on computers using electronic versions. Static spatial ability was assessed using a version of the Shepard and Metzler (1970) mental rotation test (MRT) and the paper-folding test (Ekstrom et al., 1976). The first cognitive task that participants completed was paper-folding. During the task, on each item, a series of pictures is presented demonstrating how a piece of paper is being folded. The last picture on the left includes circles that signify where holes are punched all the way through the folded piece of paper. To the right of the vertical line are five figures with possible configurations for the holes in the paper once it has been completely unfolded. Participants indicated which of the five figures they believed had the correct configuration by pressing the corresponding key (i.e., 1-5). Participants had 3 minutes for each of the 2 sets of 10 trials.

The paper-folding task was followed by the mental rotation task, in which two 3D block figures were presented simultaneously. The participants were asked to indicate whether the two items were the same or different (i.e., mirror-reversed images). On some trials the block figure on the right hand side of the screen was a version of the left figure rotated in depth varying by 20° intervals. Participants completed a total of 120 trials for this task.

Dynamic spatial skills were assessed using variations of the Race2 and Interception tasks as described by Hunt et al. (1988). Specifics for the Race2 task were taken from D'Oliveira (2009). During the Race task, two oval objects (one black, one white) race horizontally toward their own finish lines, as exemplified in Figure 1. Three relative speed differences between the objects were used to vary trial difficulty. Participants completed one block with a total of 108 trials. For the Interception task, the goal is to hit a moving target as it passes across the top of the screen with a 'missile' fired from a fixed location along the bottom of the screen. The target appeared in four different locations and traveled at four different speeds. Participants completed a total of 64 trials. The intent of the task was to measure how accurately the participants can judge the amount of time it will take for the 'missile' to intercept the target.

During the second session, participants played an hour of a first-person shooter action video game called Unreal Tournament 2004 (UT) as well as 45-50 minutes of the puzzle game Tetris. Which game was played first was counterbalanced between sets of participants.

During the 1 hour action video game session, game play was separated into three 20 minutes intervals. During the first two 20 minute game intervals participants played at the lowest level of difficulty (novice). For the last 20 minute game interval, the difficulty level was raised to the second lowest difficult level (average). The difficulty level determine how effective the 16 enemy

Figure 1: Sample trial from Race task adapted from D'Oliveira (2009)

“bots” controlled by the game were at firing and tracking down the player. In order to be successful the players must be able to avoid enemy fire while aiming and returning fire. The game keeps track of how many times the player kills an enemy as well as how many times the player is killed.

Tetris is a puzzle game in which players use 7 different block shapes in order to create lines. Every time a complete line is created the line disappears and the player is awarded points. The more lines that the player completes at a time the higher the point value awarded. If incomplete lines fill the given area the game ends. Participants are given one block shape at a time and have to place it somewhere at the bottom of the play area. As the player's score increases, the falling rate of the blocks increase making the game harder. The 7 block shapes can be rotated in increments of 90 degrees. Five of the block shapes are asymmetrical allowing for 4 different possible configurations that can be used to complete lines.

After finishing playing each game, participants were asked questions relating to their game satisfaction including how much they enjoyed the game, how likely they would play the game again, and how difficult they found playing the game. To measure performance on UT, total number of kills across all three games was used. For Tetris, performance was assessed by recording the highest score achieved while playing the game.

## Results

To first examine whether the order in which the participants played the game affected their performance independent sample t-tests were conducted. No significant differences were found between participants who played UT first or second for either UT performance,  $t(63) = .224, p = .823$ , or highest score on Tetris,  $t(64) = .906, p = .368$ . Looking at performance on just the first two games of Tetris, since all participants played at least 2 games, revealed that participants in the UT first group scored significantly higher than those that played Tetris

Table 1: Correlations between the game performance measures and performance on the four cognitive tasks.

Game performance	Mental rotation		Paper folding	Race RT Combined Easy	Intercept
	Total Errors	Mean RT	Score	Trials	Accuracy
Tetris (Top Score)	-.206	.002	.244*	-.196	.185
Unreal Tournament (Total Kills)	-0.267*	-0.334**	.271*	-.269*	.212

\*Designates a significance level of .05

\*\* Designates a significance of .01

first,  $t(64) = .2.087, p = .041$ , on their second game. This suggests that playing UT first may actually increase performance on Tetris playing. To examine whether performance on one video game related to performance on the other a Pearson correlation was conducted and revealed no significant correlation between UT kills and highest Tetris score,  $r(64) = -.007, p = .957$ .

**Static Spatial Tasks.** Table 1 shows the correlation between measures for mental rotation and paper-folding and UT and Tetris performance. For paper-folding, performance was assessed by combining the score for the two segments. Participants were penalized (-.2) for attempted items that they got wrong. As shown in the first column of Table 1, there was a modest, positive correlation between UT total kills and paper-folding score,  $r(63) = .271, p = .032$ , as well as a modest, positive correlation between high Tetris score and paper-folding score,  $r(64) = .244, p = .050$ . Next we examined whether response time (RT) performance on mental rotation correlated with performance on either UT or Tetris. As shown in the second column of Table 1, there was a moderate, negative correlation between UT total kills and mean response time across all mental rotation items,  $r(64) = -.334, p = .007$ . This indicates that participants who had higher scores on UT had faster response times for the mental rotation. There was no significant correlation between highest Tetris score and response time for mental rotation,  $r(66) = .002, p = .990$ . The same pattern was obtained for error rates on the mental rotation task: there was a significant negative correlation between total kills in UT and error rate for mental rotation,  $r(64) = -.267, p = .031$ , but no significant correlation between highest score in Tetris and error rate for mental rotation,  $r(66) = .002, p = .990$ .

**Dynamic Spatial Tasks.** For the race task we examined both accuracy (indicating the correct object would win the race) and response time (how quickly participants

determined which object would reach the goal first). Response times were only used for correct trials. In general there was a high accuracy across all participants, especially at the higher relative speed increases (easier trials). For Tetris, there was no significant correlation between Tetris score and race accuracy,  $r(67) = .144, p = .245$ , or race response times,  $r(67) = -.177, p = .152$ . For UT, there was no significant correlation between total kills and race accuracy,  $r(67) = .148, p = .239$ . When looking at response times, analysis revealed a weak, negative correlation between total kills and average response times for the higher speed difference ratios,  $r(65) = -.269, p = .030$ , but not the smallest speed increase,  $r(65) = -.178, p = .157$ , or overall average response times,  $r(65) = -.242, p = .052$ . This indicates that at the easier levels, when the relative speed between the two objects was greater, participants that had higher scores on UT made faster responses on the race task.

Finally, for the intercept/missile task, performance was measured by looking at the participant's accuracy at hitting the target over the 64 trials. No significant correlation was found between missile accuracy and game performance for either total kills in UT,  $r(64) = .212, p = .091$ , or highest score in Tetris,  $r(64) = .185, p = .135$ .

## Discussion

The results from the present study suggest that individuals who already possess certain spatial skills, such as indicated by faster response times for dynamic spatial skills, mental rotation, and paper-folding, are more likely to do better at playing an action video game such as Unreal Tournament, whereas the connection between spatial skills and early Tetris appears to be less pronounced.

Unlike prior research by Terlecki et al. (2008) this study found no connection between Tetris playing and mental rotation. This is similar to results found by Sims and Mayer (2002) in which there were no significant differences between high-skill and low-skill Tetris players

on any spatial tasks except for those that involved Tetris shapes or Tetris like shapes. In a separate study they also found that after 12 hours of training Tetris, participants did not significantly differ on mental rotation tests from those who had not practiced except for using different strategies when rotating Tetris shapes. Research by Kirsh and Maglio (1994) suggests that Tetris may not be the best environment to increase mental rotation performance. Tetris players often offload the mental rotation effort by using the game mechanics to rotate the figures instead of mentally doing the rotation. According to their model, the player should first compute the best place to put the Tetris piece before planning any rotation or movement to place it. The data shows that participants actually begin rotating the shape very early, before a possible placement could be decided upon. Rotating a shape in the external world is classified as an epistemic action, which are actions that are designed to change the input to the information-processing system and a way that an individual can alter the external environment to provide information needed to complete the task. In Tetris, if the game can complete the rotations faster than it takes the individual to do the rotations mentally, then it make sense from a limit cognitive resources standpoint for the individual to rely on the external rotation that only requires a simple motor action to complete (Kirsh & Maglio, 1994). Therefore, if participants are not actually practicing mental rotation during Tetris, it may not be the best game to use to increase spatial cognition.

Our findings did show that Tetris performance correlated significantly with paper-folding. One possible reason for this is that while Tetris does not require skills in mental rotation, it does require other visualization skills. Good Tetris players may be better able to visualize all possible configurations of the Tetris pieces therefore being able make quicker decisions about where to place pieces.

Both Tetris and action video games have been used to successfully train spatial cognition skills such as mental rotation (Terlecki et. al. 2008, Feng et al., 2007). The results from this study lead to two questions that should be addressed in future research. First, would playing one type of game lead to higher, more transferable, or longer lasting spatial skills compared to playing another? Four measures from our static and dynamic spatial skills were related to performance in game playing for Unreal Tournament while only one was related to Tetris. Feng et al. (2007) theorize that improvements in spatial tasks depend on the skills required during the game. The action video game improves lower-level spatial attention capacities, which in turn improves MRT performance. Their control condition did use a 2D puzzle game but because the game did not sufficiently exercise spatial attention capacities there was no benefit from playing. This suggests that the best way to improve mental rotation is to improve spatial skills in a way that is more

generalizable. This could involve improving lower level cognition skills such as attention. Spence and Feng (2010) also proposed that along with improving spatial selective attention, one other key difference between puzzle games like Tetris and many action video games is the perspective. The majority of puzzle games are played from a more allocentric perspective making the visuomotor coordination in Tetris is less natural compared to the more egocentric perspectives used in most first person shooter action games. Playing an action video game may therefore be more likely to increase spatial ability. A comparison of two comparable training regimes using either Tetris or an action game like Unreal Tournament should be done to determine whether there is any benefit to using one game over the other.

Another possible question is if both games can increase spatial ability, as prior research has shown, could the required level of preexisting spatial ability to play affect whether it is a viable choice for training? As proposed by Spence and Feng (2010), a student with poor spatial skills may avoid tasks that require them. As mentioned previously, this suggests the potential for a Matthew effect with spatial cognition and video games. Those that already possess high spatial skills do better at playing action video games and are more likely to continue to playing. By continuing to play these individuals increase their spatial ability. Therefore, a game such as Tetris which appeared to require less preexisting spatial skill to be successful may encourage students to play more than one like Unreal Tournament.

## Abstract

Worked examples have been found to be effective tools in reducing cognitive load and supporting learning. Erroneous examples are worked examples that include incorrect steps and are intended to help students learn how to identify important principles and errors to avoid. The current study examines whether using erroneous examples in an online intelligent tutoring system can help middle-school children learn decimals beyond simple problem solving with feedback. Results showed that although students did not differ between the two conditions on an immediate posttest, students in the erroneous examples group performed better on a delayed posttest. This suggests that working with errors, and thus processing the decimal problems at a deeper level, helped students retain more about decimals and build upon that understanding over time.

**Keywords:** erroneous examples, math learning, computer-based tutors

## Worked Examples and Math Learning

One effective method that has been applied to mathematics education to increase learning is worked-out-examples (also called *worked examples*). Worked examples consist of a problem formation, the steps taken to reach the solution, and the final solution (Cooper and Sweller, 1987; McLaren, Lim, and Koedinger, 2008; Renkl, 2005, 2010; Renkl and Atkinson, 2010; Zhu and Simon, 1987). Worked examples may be effective because they facilitate learning by helping to manage intrinsic processing levels (i.e. cognitive processing required to learn the material presented in a lesson); decreasing extraneous processing (i.e., cognitive processing that does not support the instructional goal); and by encouraging generative processing (i.e., cognitive processing that enables deeper learning). According to the cognitive theory of multimedia learning (Mayer, 2009)

and cognitive load theory from which it is derived (Moreno and Park, 2010) learners have a limited processing capacity in working memory and every learning task has an intrinsic level of processing required to understand and learn the task. During problem solving such as mathematics, students use strategies such as means-ends analyses to solve problems, comparing the state of the problem to the goal state and trying to reduce the differences (Renkl and Atkinson, 2010). Over time they develop procedural and schematic knowledge that facilitates problem solving. Worked examples can decrease both intrinsic and extraneous cognitive processing during learning by showing the students the solution procedures to follow. The freed up cognitive resources can then be applied to understanding and eventually to automatizing the different steps in the problem's procedure.

A study by Cooper and Sweller (1987) compared learning by doing/traditional problem solving and learning from worked examples. The results showed that participants in the learning by examples group could answer transfer problems much faster than students who learned by doing although the later group actually had more practice in solving problems.

An important issue with worked examples is that although students may have freed up cognitive resources, this does not mean that the freed cognitive capacity will be used for generative processing (also called *germane processing*) which requires deeper processing of the material (Renkl and Atkinson, 2010). Students may need further assistance in fully absorbing and learning solution methods or principles. Self-explanation is one way to achieve this. Chi et al. (1989) found that good problem solvers are more likely to generate self-explanation statements while thinking out loud when reading a lesson on physics. In addition, other research has shown the importance of explicitly prompting for self-explanation

(Hausman and Chi, 2002). Explanations can therefore be used to encourage further processing of the material and increase learning.

### **Erroneous Examples and Learning**

One other proposed way to encourage deeper processing while using worked examples is to present students with incorrect (or erroneous) examples. Erroneous examples may encourage students to use more explanations since they must identify and explain to themselves why the solution is incorrect and how it can be corrected. Erroneous examples may also help students focus on each step of a solution method separately to identify where the error occurred. However erroneous examples could also place additional processing demands on learners, overloading working memory. The student may have to simultaneously represent both the correct and incorrect solution steps while searching for what is wrong in the worked example (Grosse and Renkl, 2007). Therefore, learners with low prior knowledge may be more likely to be adversely affected by incorrect examples because they would be unable to hold large chunks of new information in memory while also looking for an error. Grosse and Renkl (2007) suggest relieving this processing demand by highlighting the error. Reiss, Hellmich, and Thomas (2002) found that learners only had a .35 probability of identifying a math false argument as being false while correct arguments had a .67 probability of being identified as correct.

Yet research has shown that erroneous examples can facilitate learning of mathematics. In a study by Kawasaki (2010), 170 5<sup>th</sup> grade students were presented with either a correct or incorrect solution to a math problem by one of the participants. The teacher then explained the correct solution either contrasting the two procedures for the incorrect or displaying the correct. Students who had used similar incorrect solutions benefitted the most from the instruction with the incorrect example. Tsovaltzi et al. (2010) found mixed results for whether erroneous examples facilitated learning of fractions. For 6<sup>th</sup> graders they found that including erroneous example, especially with help, increased metacognitive skills such as answering conceptual questions. With 9<sup>th</sup> and 10 graders, on standard problem solving tests, students in the erroneous examples with help condition outperformed students in the erroneous examples without help and the no erroneous examples groups. They propose that this was due to the low prior knowledge level of the students.

Grosse and Renkl (2007) also found an effect of prior knowledge on the effectiveness of erroneous examples. College level students were taught a lesson on probability. In their first experiment half of the conditions were presented with correct solutions only while the other half were presented with both correct and incorrect solutions. For groups with both incorrect and correct solutions, half

of the participants had the error highlighted while the other half did not. The study found an interaction between the prior knowledge of the individual and the inclusion of incorrect solutions. High prior knowledge students benefitted from having both correct and incorrect solutions and scored higher on far transfer problems that did not have solution structures similar to the problems presented during the lesson. In contrast, low prior knowledge students did worse on a far transfer test when given both correct and incorrect solutions. For highlighting the error, high prior knowledge students did not benefit from having errors highlighted (presumably because they were already able to identify the error on their own). Low prior knowledge individuals did significantly better when the errors were highlighted than when they were not. Grosse and Renkl's (2007) second study replicated the prior knowledge incorrect solution interaction but also found that including errors changes the sort of self-explanation statements students made. Students made more elaborations that were error related such as identifying the error or the reasons for the error, however, students in this group also made less principle-based self-explanation. Principle-based explanations have been proven to foster learning outcomes (Renkl, 1997).

In a recent study by Isotani et al. (2011) an online tutoring system with erroneous examples was used to teach decimals to middle school students. Six commonly held misconceptions dealing with decimals were identified, such as decimals being treated as negative numbers or students treating the two sides of a decimal as separate numbers. Participants were separated into three conditions: problem solving, worked examples, and erroneous examples. During the problem solving condition students had to at least attempt to answer a problem once and were given feedback in the form of green or red lettering as to whether their answer was correct. If the student supplied an incorrect answer they could choose to have the correct answer displayed. In the worked example condition students were given a word problem in which the correct answer was given. The students were then asked to complete two sentences that described how the problem was solved and what knowledge about decimals was needed to answer the problem. Students would select responses for the two blanks in the sentence and then receive feedback from the tutor as to whether their created explanation was correct. The erroneous examples problems were similar to the worked examples except that an incorrect solution was presented. It was the job of the students to fill in the blank to generate two sentences: the first identifies the particular decimal misconception while the second sentence prompts the student to explain how the individual in the problem could correctly solve the problem.

The results uncovered no significant differences among the three groups for either immediate posttest or the delayed posttest and unlike Grosse and Renkl (2007) there

was no interaction between high and low prior knowledge and condition. One possible reason for no significant differences among the three groups is the amount of cognitive load that the sentence completion task required of the participants. Instead of focusing on the math, the students may have been devoting their cognitive processing to selecting the correct sentence portions and reading their completed sentence.

## Present Study

For the current study we have streamlined the materials from Isotani et al. (2011) to increase the focus on finding and fixing errors in erroneous examples. In particular, we simplified that design to compare problem solving to erroneous examples. This study focused on whether erroneous examples could encourage more generative processing than problem solving, even though both conditions encourage at least some problem solving (for erroneous examples: finding and fixing errors). The two groups were presented with isomorphic problems, but with different ways of interacting with those problems. The erroneous examples subjects were presented with an incorrect solution, were prompted to explain and correct the error and reflect on the correct answer, and received feedback on their responses. The problem solving subjects were asked to solve the same problems, reflect on the correct answers, and received feedback on their work. The additional steps in the erroneous examples condition of explaining and correcting the error/misconception made in each problem was intended to improve learning outcomes by encouraging learners to engage in generative processing concerning decimal principles. The problems were also simplified from Isotani et al. (2011) by

providing more complete explanations for the students to choose from. Previous research on self-explanation prompts by Johnson and Mayer (2010), demonstrated that providing the explanation statements, rather than having learners generate their own, facilitated learning from an educational game. By providing the students with possible complete explanations to choose from rather than parts of sentences, processing demands should decrease.

**Participants.** Participants consisted of 208 (Male = 101, Female = 107) middle-school students from Pittsburgh, PA. Of those students, 105 were in the 6<sup>th</sup> grade while 103 were in 7<sup>th</sup> grade. Ages ranged from 11 to 13 ( $M = 11.99$ ,  $SD = .722$ ).

**Materials.** The computer-based materials consisted of 6 components, three tests (pretest, posttest, and delayed posttest), two surveys (demographic/math experience and evaluation), and the intervention problems. For the pretest and two posttests, three separate but isomorphic tests were constructed. Question types including placing decimals on a number line, putting a group of three or four decimal numbers in order, providing the next two numbers in a sequence, and answering true/false statements. All three tests contained 46 problems with a total of 50 points possible. For the demographic survey, along with basic information about age and grade level, students were asked about their experience with decimals and computers. They were also asked a few self-efficacy questions such as, "I am good in math at school", with 5-point Likert answers, ranging from "Strongly Agree" to "Strongly Disagree." For the evaluation survey, students were

Figure 1: Side-by-side comparison of the isomorphic questions from the two intervention conditions. An erroneous example problem is on the left and the equivalent problem to solve is on the right.

asked how they felt about the intervention using a 5-point Likert scale ranging from 1 to 5. Questions included items such as, “I would like to do more lessons like this.”

During the intervention students completed a total of 36 problems, with interaction and feedback implemented by intelligent tutoring software (Aleven et al, 2009). The problems were arranged in four groups of three (with each group targeted at one of four misconception types) making a total of 12 groups. For the erroneous condition, students would first receive two problems dealing with a misconception such as “shorter decimals are smaller.” The third problem was then a problem to solve (with feedback) related to the misconception (i.e. putting decimals of different lengths in order from largest to smallest). The erroneous problems contained up to 5 components (not including the problem statement) for the students to interact with (see Figure 1 for a comparison between the two interventions). In the top left box students read the error made by the individual in the word problem. After pressing a “Next” button students were asked to identify what the subject had done wrong from a list of 3-4 options, one of which was the misconception exhibited by that student. In the left middle panel students were then asked to correct the mistake. This involved either placing the decimal correctly on a number line, changing a decimal addition, correctly ordering a list of decimals (largest to smallest or smallest to largest), or correctly completing a sequence of decimals. In the right middle panel participants explained why the new answer was correct. Finally, in the bottom left panel the students were asked to give advice to the fictional student that had gotten the answer incorrect. For every panel that required the student to make a selection feedback was provided (green = correct; red = incorrect). Students also received text feedback from a message window that was placed at the bottom right corner of the intervention. Messages include encouragement for students to try incorrect steps again or feedback for students to continue on to the next step or problem.

In the problem-solving version of the intervention, students were given the same problems as in the erroneous examples condition except they were asked to provide the solutions themselves. These problems were also arranged in groups of three with a simple correct / incorrect feedback for the third problem in each sequence. On the first two problems of the problem solving condition, after solving the problem students were asked how they would explain their solution to another student. These options included the correct procedure along with misconception distracters. Students in this group also received feedback from a message window in the bottom right panel as well as green / red feedback on their solution and multiple-choice selections.

**Procedure.** Students were randomly assigned to one of the two conditions (PS = 108; ErrEx = 100). Students in both conditions were given a total of five 43-minute sessions to complete the entire intervention. The students were randomly assigned to either the problem solving or the erroneous worked example condition. Students were also randomly assigned to receive one of the six possible pretest / posttest / delay-posttest orderings (ABC, ACB, BAC, BCA, CAB, CBA). On the second day the students answered the demographic and math/computer experience questionnaire before starting the intervention. The students were given two days to complete the problem solving/worked example problems. Upon completion they were given the intervention assessment questionnaire. The next day students were given the immediate posttest. Finally, during the following week, students were given the delayed posttest.

## Results

Due to an error in data recording for four of the problems, the data for those problems was removed from the pretest, posttest, and delayed posttest scores making the total possible score out of 46. To first examine whether the problem solving (PS) and erroneous examples (ErrEx) condition performed similarly on the pretest an independent sample t-test was conducted. It was found that the ErrEx group performed significantly better on the pretest than the PS group,  $t(206) = 3.045, p = .003$  (See Table 1 for means and standard deviations). An ANOVA revealed that there was no significant difference between the test orders,  $F(5,202) = 1.293, MSE = .057, p = .268$ .

In general students significantly improved their test performance after the intervention, regardless of condition,  $t(207) = -8.058, p < .001$ , with a mean increase of 9%. Students continued to significantly improve between the immediate and delayed posttest,  $t(207) = -8.230, p < .001$ , with a mean increase of 6%. Overall students increased their performance an average of 15% between the pretest and the delayed posttest, yielding a medium-to-large effect,  $d = .75$ .

To examine whether one condition increased learning more than the other gain scores were calculated between the pretest and posttest, pretest and delayed posttest, and posttest and delayed posttest. An ANCOVA with pretest as a covariate revealed that for the pretest-to-immediate-posttest gain did not differ significantly for the two groups,  $F(1,205) = .768, MSE = 34.97, p = .382$ . There were significant differences between the two conditions for pretest-to-delayed-posttest gains,  $F(1,205) = 9.896, MSE = 349.08, p = .002$ , and between immediate posttest and delayed posttest,  $F(1,205) = 7.027, MSE = 163.07, p = .009$ , with participants in the ErrEx condition having higher gain scores. That is, although participants

## Discussion

The results of this study show that although using erroneous examples did not facilitate learning gains for an immediate pretest, students in the erroneous group had significantly higher gains on the delayed posttest. These results suggest that students taught with erroneous examples may have had a deeper learning experience, one that helped them build upon their initial understanding of decimals to gain a deeper understanding by the time they took the delayed posttest.

Previous research by Grosse and Renkl's (2007) found that prior knowledge interacted with incorrect examples; higher prior knowledge students performed better when presented with incorrect solutions. For our study, however, no significant interaction was found between prior knowledge and condition. The data showed that both low and high prior knowledge individuals did better in the erroneous examples condition than the problem solving condition. This might have occurred because the erroneous example students, both low and high prior knowledge, were enticed to engage in more generative processing than the problem solving students, through the prompted explanation and correction of errors.

One limitation of our study is that we did not include a correct worked examples condition. The reasons for this were straightforward. First, in the present study we wanted to compare the most common ecological control condition – that of students solving problems – to the much less typical learning experience of working with erroneous examples. Second, as we revised the instructional materials from the Isotani et al (2011) study, we realized that erroneous examples and problem solving were more comparable from a cognitive load perspective. As designed, they both require active problem solving – in the case of erroneous examples, the correction step; in the case of problem solving, generating the solution from the given problem – something worked examples does not require. Renkl and Atkinson (2010) mention a reversal of the worked examples effect when students already have sufficient knowledge. Studying just the examples without any sort of active problem solving may become redundant for the students therefore decreasing the amount of mental effort they put into the lesson. Nevertheless, to compare other possible instructional approaches, in a future study we intend to include a worked examples condition.

Table 1: Test performance for the two conditions

Test score	Groups	
	Problem Solving	Erroneous Examples
	<i>M</i> <i>SD</i>	<i>M</i> <i>SD</i>
Pretest	24.68 (9.42)	28.69 (9.58)
Posttest	29.07 (9.48)	32.58 (8.95)
Delayed Posttest	31.06 (9.20)	36.23 (7.47)

in the ErrEx condition may not have scored higher on the immediate posttest, they showed superior gains when tested after the week delay.

To determine whether the intervention had a different effect for students with high prior knowledge versus those with low prior knowledge, similar to Grosse and Renkl's (2007), we conducted an additional analysis. Participants were first classified as high versus low by using a median split on the pretest scores (8-25 points for low and 26-45 points for high). This divided the groups so that there were 107 students classified as low prior knowledge and 101 as high prior knowledge. For high prior knowledge individuals an ANCOVA with pretest as a covariate revealed the participants did not differ for pretest to immediate posttest gains,  $F(1,98) = .122$ ,  $MSE = 3.76$ ,  $p = .728$ , or posttest test to delayed posttest gains,  $F(1,98) = 2.01$ ,  $MSE = 46.15$ ,  $p = .160$  (see Table 2 for means and standard deviations). There was a significant difference with ErrEx showing greater gains between the pretest and delayed posttest,  $F(1,98) = 4.75$ ,  $MSE = 76.27$ ,  $p = .032$ . For low prior knowledge individuals there was still not significant difference between pretest and posttest gains,  $F(1,104) = .489$ ,  $MSE = 28.49$ ,  $p = .486$ . However there the ErrEx condition did have significantly higher gains between the pretest and delayed posttest,  $F(1,104) = 5.21$ ,  $MSE = 265.73$ ,  $p = .025$ , and the posttest and delayed posttest,  $F(1,104) = 5.02$ ,  $MSE = 120.21$ ,  $p = .027$ . Thus, the pretest-to-delayed posttest gain was greater for the ErrEx condition for both low and high prior knowledge learners.

Table 2: Test performance for low/high prior knowledge individuals for the two conditions

Test Score	Low Prior Knowledge		High Prior Knowledge	
	PS <i>M</i> ( <i>SD</i> )	ErrEx <i>M</i> ( <i>SD</i> )	PS <i>M</i> ( <i>SD</i> )	ErrEx <i>M</i> ( <i>SD</i> )
Pretest	17.73 (3.89)	19.25 (4.01)	34.40 (5.36)	36.11 (5.03)
Posttest	24.24 (8.82)	26.80 (8.06)	35.84 (5.33)	37.13 (6.75)
Delayed Posttest	26.30 (8.55)	31.07 (7.47)	37.71 (5.96)	40.29 (4.34)

In summary, our study provides evidence that presenting students with errors that they are prompted to analyze, explain, and correct can facilitate learning decimals from a computer-based tutor.

## Abstract

People excel at attributing intentionality to other agents, whether in simple scenarios such as shapes moving in two dimensions or complex scenarios such as people interacting. We note that intentionality attributions seem to fall into two categories: low-level intentionality in which an observer has a theory of mind about an agent, and high-level intentionality in which an observer believes the agent has a theory of mind about something else. We introduce the terms *L-intentionality* and *H-intentionality* to refer to these attributions, respectively, and describe this division by using examples from previous research. Social robots provide a particularly good platform for evaluating the presence of different types of intentionality, and we discuss how robots can help distinguish the relationship between H- and L-intentionality, based on a number of possible models that we enumerate. We conclude by highlighting some interesting questions about intentionality in general and the interplay between H- and L-intentionality in particular.

**Keywords:** intention; animacy; computer model; human-robot interaction; robotics

## Introduction

Much research in psychology has focused on people's ability—and eagerness—to attribute intentions and animacy to simple shapes based on motion. From Michotte's (1963) and Heider and Simmel's (1944) experiments with animacy and intention to recent work decomposing intentional actions such as chasing (Gao, Newman, & Scholl, 2009), psychologists have found that intention attributions to moving shapes appear to be immediate and irresistible. Animacy is often observed in a display of simple shapes when the motion in the display cannot be explained as ordinary inanimate motion, for instance when speed and direction change without direct contact with other objects (Tremoulet & Feldman, 2000).

At the same time, evidence shows that people attribute intentions based on high-level behavioral evaluations, as well. For instance, 18-month-old toddlers can recognize and imitate intentional actions performed by adults, even if those actions are unsuccessful (Meltzoff, 1995). By pre-school age, children begin to represent others' beliefs, even when those beliefs are mistaken, in order to correctly predict a person's intentional action (Wellman, Cross, & Watson, 2001). As adults, neurological evidence indicates that a certain region of the brain is sensitive to whether peoples' motions are consistent or inconsistent with their purported intentions (Pelphrey, Morris, & McCarthy, 2004).

While abundant evidence demonstrates peoples' attributions of intentionality, the types of attributions they make seem to differ. Cues that prompt intention attributions come in two categories: low-level, perceptual cues, such as motion, and high-level cues that must be reasoned about, such as facial expression. To distinguish between intentions cued

in these different ways, we introduce two novel terms, referring to intention attributions made from low-level cues as *L-intentionality* and to attributions made from high-level cues as *H-intentionality*. To date, little work has explored such categorical differences of intentionality. In the Types of Intentionality section, we use examples from previously published research to define our hypothesis that L-intentionality and H-intentionality are separate kinds of intention attributions.

Robotics has provided a valuable experimental platform to test perceptions of intentionality. Because robots are extremely flexible (in terms of appearance, motions, sounds, and so on), researchers can manipulate specific variables of a human-robot interaction to test specific features of intentionality attributions. In the Social Robots as Experimental Platforms section, we describe past work with robots and other computational models of intentionality, and we discuss the benefits social robotics can offer intentionality research.

The next section, Models of Intentionality, enumerates possible models for the relationship between H-intentionality and L-intentionality based on the hypothesis that these are distinct observations. We describe what each model implies about real-world intentionality attributions, and we note how each model can be tested to confirm or deny our hypothesis.

We conclude this paper by discussing some likely starting points for research on the different categories of intention, and describing some interesting questions about intentionality that have yet to be addressed.

## Types of Intentionality

In this paper, we define an intentional action as a goal-directed action that is performed deliberately. Intentionality is the capacity to express or perform intentional actions. A theory of mind for other agents enables us to attribute intentionality to those agents (Leslie, 1987; Baron-Cohen, 1995), an ability that develops early in life (Meltzoff, 1995). Note that for our purposes, animacy and intentionality are strongly correlated, in that it is impossible to attribute animacy without the presence of intentional, goal-directed behavior (Tremoulet & Feldman, 2006).

In this section, we distinguish L-intentionality and H-intentionality as distinct but related categories. We can define each category by how an observer perceives and recognizes intentionality. To put the categorical difference simply, L-intentionality in an agent involves an observer having a theory of mind for that agent; H-intentionality involves an observer believing that the agent has a theory of mind for something else (Figure 1).

Figure 1: Low-level intentionality (left) is attributed when an agent has a theory of mind for another agent. High-level intentionality (right) is attributed when an agent believes another agent has a theory of mind for something else.

### L-Intentionality

To illustrate the different types of intentionality, picture a preschool boy named Billy. Billy is good at putting away his toys: he readily brings them to the toy chest whenever it is time to clean up. This kind of goal-directed behavior—carrying toys directly to the toy chest and depositing them—involves a series of coordinated actions and knowledge, but it can occur independently of theories of mind about others in the environment. Observing this, we might attribute L-intentionality to Billy. (Assume for the sake of the example that we cannot infer that Billy is H-intentional based solely on what we know about human beings.)

Actions that cue L-intentionality reveal goal-directed, deliberate behavior. L-intentionality is often elicited from low-level perceptions, such as those arising from visual displays of moving shapes. The perception of intentionality and animacy from simple moving shapes has been well-established in psychology literature (see (Scholl & Tremoulet, 2000) for a review); even when people do not know the type of intentional action they are looking for, they show high validity with the ground truth and high reliability with each other when evaluating the motion of animated shapes (Pantelis et al., 2011). Most often, these shapes exhibit basic actions such as chasing, fighting, or foraging.

For example, in Gao et al. (2009), an animated “wolf” chases after an animated “sheep” by moving toward the sheep within some degree of direct heat-seeking behavior. When the degree of chase is sufficiently small, participants identify chasing consistently. When the wolf deviates more strongly from direct heat seeking, however, the perception of intentionality disappears. In these L-intentionality experiments, goal-directed motion leads to an attribution of intentionality.

### H-Intentionality

Now imagine that we observe Billy hiding his shoes inside the toy chest. He watches his mother place his shoes in a cov-

ered cubby. While his mother looks away, Billy retrieves the shoes, walks to the chest, looks to make sure his mother is not watching and puts his shoes in the closed chest. The action of watching his mother put the shoes in one place, and then covertly moving them to another, suggests that Billy has a theory of mind for his mother, understanding that she has her own (mistaken) beliefs; Billy is displaying H-intentionality.

While L-intentionality is based on a theory of mind for the agent in question, H-intentionality is based on that agent’s theory of mind for others. Therefore, H-intentionality is seen in more complex visual scenes than the simple moving shapes of L-intentionality; it is often be cued by a combination of stimuli such as facial expression, vocal prosody, and physical motion. H-intentionality does not “pop out” in the same way as L-intentionality because attributions of H-intentionality require additional cognitive processing to account for the agent’s beliefs about its environment.

## Social Robots as Experimental Platforms

Experiments with human-robot interaction are a particularly rich source of intentionality attributions. In one experiment, a robot received greater attributions of animacy and intelligence when it cheated at a game of rock-paper-scissors than when it played the game correctly (Short, Hart, Vu, & Scassellati, 2010). In each round of the game, a human participant and the robot both selected an item (rock, paper or scissors) in secret, then simultaneously displayed their selection through hand signals. Each of the items loses to one other item and wins over one other item, so that one’s performance in the game depends on the opponent’s selection as well as one’s own. In conditions where the robot verbally cheated—declaring “I win!” when it had lost—participants tended to report that the robot was broken and less intelligent; in conditions where the robot physically cheated—changing its losing hand signal after viewing the participant’s selection—participants were significantly more likely to use active verbs when describing the robot. In other words, a small change in behavior (switching hand signals) led to a dramatic increase in intentionality attributions.

Social robots are a valuable platform for experiments involving intentionality. Robots are available in a huge variety of appearances (from anthropomorphic to simple shapes) and motion abilities (fully mobile to stationary; with a broad range of physical capabilities). Being programmable, robot behavior can be carefully manipulated to alter individual features (such as moving an arm at a particular speed) and to ignore subtle (and potentially subconscious) social cues from others, a feat that a human experimenter might find difficult. As machines, robots can perform exactly the same action again and again, but as social tools, robots appear socially neutral: while most participants in experiments from our laboratory have seen or heard about robots, most have no experience with actual robot capabilities, allowing robots to act a blank slate on which social characteristics (such as intentionality) can be drawn at will.

Animations or videos of people provide many of the same benefits as robots, but they lack an embodiment that may affect interactions. Research has shown that people follow commands more consistently from physically present robots than from virtual robots, even when the virtual robot looks and acts exactly like the embodied robot (Bainbridge, Hart, Kim, & Scassellati, 2011). This reflects the common wisdom of sales, which asserts that you should visit someone in person to close a deal. For intentionality research, in which subtle features may make a difference in intention attributions, having an embodied agent observed in real time allows for highly realistic experimental setup while maintaining strict control over experimental variables.

H-intentionality has been of particular interest to social robotics researchers, who are motivated to design human-robot interactions that are natural and communicative. One part of natural interaction is identifying and displaying a theory of mind for others through non-verbal intentional behavior, whether with gaze (Mutlu, Yamaoka, Kanda, Ishiguro, & Hagita, 2009), hand gestures (Nehaniv, Dautenhahn, Kubacki, Haegle, & Parlitz, 2005), or facial expression (Breazeal & Scassellati, 1999). Therefore, understanding intentionality is important for the design of robots that will interact with people, such as service or assistive robots.

### Models of Intentionality

In this section, we enumerate the possible relationships between H-intentionality and L-intentionality (Figure 2); in the following Discussion section, we explain which models we believe are most viable. To better describe the models, we will return to the previous example with Billy and his toys.

Researchers have attempted to computationally recognize intentions through Bayesian models (Baker, Tenenbaum, & Saxe, 2006; Schrempf, Albrecht, & Hanbeck, 2007), hidden Markov models (Aarno & Kragic, 2006), and algorithmic methods (Feldman & Tremoulet, 2008). As observed actions and possible intentions become more complex, specifying a reasonably-sized state space for intention-action mapping becomes increasingly challenging, which limits the power of current computational models of intention recognition. The models in this paper are intended to be abstract, high-level views of how intention attributions can be conceptually organized, not algorithmic specifications for functional programs.

The descriptions of the models in this section are based on *features of intentionality*—observations that can be empirically measured. For instance, goal-directed movement toward another agent in an approximately heat-seeking manner (as in Gao et al. (2009)) is one feature of chasing, an L-intentional action. Behavior based on anticipation of others' responses, as when Billy looked to see whether his mother was watching him hide his shoes, is a feature of H-intentional actions. Many features for each type of intention have yet to be identified, and are part of the novelty of this area of research.

Of all of the models for the relationship between H- and L-intentionality, the simplest option is that there is no cor-

Figure 2: Potential models of the interaction between H- and L-intentionality. Each labeled circle represents the set of features that cue that type of intentionality. Set notation below each image mathematically describes the relationship between  $H$ , the set of features that cue H-intentionality, and  $L$ , the set of features that cue L-intentionality.

relation between the two (Figure 2a). In this model, the two types of perceptions share no features. Seeing Billy put his toys in the chest (and subsequently attributing L-intentionality to Billy) would not affect later judgements about H-intentionality, and vice versa. In the disjoint case, recognizing a feature of one type of intentionality would immediately identify the type of intentionality present, because that feature could not correspond to the other type of intentionality. To falsify this model, researchers must show that both H- and L-intentionality are cued by some feature.

A second possibility is that the two types of intentions share some features, but do not overlap completely (Figure 2b). In this case, seeing shared features would cue both types of intentionality attributions, though not every feature would be a shared feature. Identification of shared features would not confirm which type of intention is being perceived, but identification of disjoint features would allow experimenters to pinpoint the type of intention present. To prove that this model is correct, researchers would have to identify one feature that is unique to each type of intentionality, and one feature that is shared by both types.

Another possibility is that the types of intention are nested, so that one is wholly contained in the other. In the first form of nesting, which we'll call bottom-up perception, H-intentionality features are a strict subset of L-intentionality features (Figure 2c). In this case, L-intentionality is cued whenever H-intentionality is perceived, though the former can be present without the latter. In our example with Billy, merely perceiving H-intentionality—from watching Billy hide his shoes—would be enough to perceive L-intentionality, even without watching Billy put away his toys. This model can be falsified by identifying a scenario in which H-intentionality but not L-intentionality is perceived.

The complementary model posits that L-intentionality features are a strict subset of H-intentionality features (Figure 2d). We call this top-down perception, because the more complex H-intentionality can be cued without L-intentionality. In this model, H-intentionality is automatic whenever L-intentionality is perceived. This model can be falsified by identifying a feature of L-intentionality that does not cue H-intentionality.

A final possibility is that the feature sets of H-intentionality and L-intentionality are equal; that is, there is no difference between the features involved in cueing each type of intentionality. In this model, H-intentionality arises whenever L-intentionality is cued, and vice versa. To falsify this model, researchers would need to identify at least one feature from one type of intentionality that does not cue the other. Failing to falsify this model would challenge the hypothesis that H-intentionality and L-intentionality are separate processes.

### **The Importance of Intentional Duality**

Researchers have long established that people attribute intentionality to other people and to simple moving shapes under some conditions. The existence of H- and L-intentionality as

distinct types of intention attributions, if proven, might indicate a categorical distinction that runs more deeply in peoples' cognitive systems. H-intentionality and L-intentionality may not only be perceived differently; they may be understood and processed in different ways as well. After all, if the perceptual pathways for the two types of intentionality are different, perhaps the cognitive pathways that process them are also different. Perhaps there are distinct brain regions or neural pathways that process L-intentional and H-intentional stimuli. Perhaps, even, there is a different developmental time course for each type of intentionality, and infants can perceive one type of intentionality before the other. This difference might even extend to the perception of one agent as more complete or more animate than another, based on the type of cues that were used to establish its intentionality. All of these possibilities are consequences of our two-intention hypothesis, and will need to be further explored.

Understanding intentionality is also important for designing human-robot interactions. For robots that must interact naturally with people, being able to both recognize and perform intentional behavior is essential. To date, most computational approaches for intention recognition rely on statistical or probabilistic methods that do not scale well with increasing actions and intentions. Our model is a first step toward comprehensive understanding of intentionality that may lead to more complete and flexible computational models.

If cognitive differences underlie the different kinds of intentional attributions, these differences can be manipulated in interesting ways for human-robot interactions. Because robots are programmable, they can be made to display only cues from one type of intention, leading an observer to cognitively categorize them in a particular way. For instance, suppose researchers establish that unfamiliar L-intentional agents do not invoke as much shyness or fear as H-intentional agents, by virtue of their apparently less complicated mental structure. Robots that interact with children can then be manipulated to display only L-intentionality cues, reducing the likelihood that children will be afraid of them by controlling how they are perceived. The ability to craft human-robot interactions in a completely unprecedented way becomes possible if the categorical difference between intention types extends to cognitive processing levels.

### **Discussion**

Based on our distinction between H- and L-intentionality, some models are more likely than others. Clearly, a model in which the feature sets for both intentionality types are identical is impossible if we are to maintain the distinction between the two. We previously defined attributing H-intentionality to an agent as believing that the agent has a theory of mind for some other target. Inherent in this definition is the idea that we also believe the agent in question has its own goals and is capable of intentional actions to achieve those goals; in other words, that we have a theory of mind for that agent. Therefore, L-intentionality seems to be inherent in attribu-

tions of H-intentionality. For this reason, the disjoint model and the overlapping model seem unlikely candidates for our purposes. If L-intentionality is inherent in H-intentionality, then it would be impossible for the latter to be perceived without the former, which rules out the top-down model. In fact, we believe that the bottom-up model (Figure 2c), in which all features of H-intentionality are also features that cue L-intentionality, has the most promise as a model of intention attributions. In this model, L-intentionality can be present on its own—as supported by the many intention-from-motion studies described in the Introduction—but the presence of H-intentionality presupposes the presence of L-intentionality. For completeness, we have listed all possible models in this paper, but only the bottom-up model really serves the distinction we draw between H- and L-intentionality.

Though we distinguish between H- and L-intentionality, we have not made any claims about how these types of intentionality might be treated differently once they are perceived. Because our distinction is novel, we do not yet have evidence to ascertain whether or not H-intentionality affects peoples' reasoning differently from L-intentionality. The characteristics of intentionality described here might vary based on the type of intentionality that is perceived.

One characteristic that has yet to be explored is whether intentionality is revokable. Though many experiments identify the presence of intentionality, very few explore conditions under which intentionality disappears. It is possible that once intentionality is perceived, it remains for the duration of the exposure; on the other hand, perception of intentionality might also fade or be removed through some mechanism, such as time since the last intentional action. Anecdotal evidence from our lab suggests that attributions of H-intentionality are hard to remove, while attributions of L-intentionality may not be. In the rock-paper-scissors experiment described earlier (Short et al., 2010), once participants made attributions of H-intentionality to the robot, those attributions persisted despite the absence of additional H-intentional behavior. On the other hand, in the chasing studies (Gao et al., 2009), it seems easy to imagine that an agent that no longer chases would stop appearing L-intentional after some time.

Philosophers have identified yet another interesting characteristic of intentionality attributions: actions with harmful side-effects seem to be perceived as more intentional than actions with beneficial side-effects. For instance, if a company owner institutes a new manufacturing process that increases profits but damages the environment, the owner is seen as intentionally harming the environment. On the other hand, if the owner institutes a process that increases profits and helps the environment, the owner is not seen as intentionally helping the environment (Knobe, 2005). Does this type of disparity hold for both types of intentionality? Would a side-effect from an L-intentional action be seen as equally harmful to the same side effect from an H-intentional action? Or does the complexity of reasoning perceived in H-intentional agents endow them with more responsibility for side effects?

Along the same vein, observing intentional actions from an outsider's perspective may be different from identifying intentionality based on actions that personally affect one's self. Are attributions of intentionality different based on whether the effect of the action is personally relevant? Does it matter if the personally relevant effect is positive or negative? Are there differences between H-intentionality and L-intentionality in these cases?

Animals, like robots, present an interesting boundary condition for intentionality. Animals are clearly sentient and are generally attributed beliefs and goals. Whether animals can be said to be intentional, however, is open to debate (Heyes & Dickinson, 1990). It would be interesting to determine whether animals fall into the L-intentional or H-intentional category, and whether this separation of intention types might make it easier to attribute intentionality to animals.

Descriptions of models in the previous section refer to features that cue intentionality, but the precise nature of these features is still to be determined. These features need not be exclusively visual; they might include auditory features like prosody or kinesthetic features like heat. Some features, such as “approaches a target with a velocity between  $x$  and  $y$ ” may be quite specific; these are often used in rule-based intention detectors, but lack flexibility to account for novel or stochastic situations. Other features might be more general, such as “orients eyes toward the target.” Enumerating and sorting these features into H- and L-intentionality cues is a significant task, but it has the potential to dramatically increase understanding about intention perception.

Identifying and evaluating features of intentionality will require carefully designed experiments, and robots as intentional actors may be useful in teasing apart attributions of intentionality. Establishing features of intentionality will also help those who design interactions between people and objects, such as those working with social robots. By understanding features of intentionality, roboticists will be able to design robots that detect and exhibit relevant intentional behaviors, which would strengthen non-verbal communication in human-robot interactions.

## Conclusions

This paper presents a new representation and vocabulary for classifying different types of intentionality. Using examples from the extensive psychology literature on intention recognition, we hypothesize that intention attributions can be categorized into two types, L-intentionality and H-intentionality, based on the kinds of perceptions that cue those attributions. We describe the benefit of social robotics as a platform for experimenting with intentionality perceptions, and we mention some past research from robotics that explores intention attributions under various conditions. We then outline possible models for the relationship between H- and L-intentionality based on the set of features that elicit the perception of each: completely disjoint, partially overlapping, nested with H-intentionality as a proper subset, nested with

L-intentionality as a proper subset, and identical. Along with each model description, we specify how that model could be falsified. We posit some important consequences of proving our intention duality hypothesis, and we discuss the potential validity of these models, identifying that bottom-up processing is the most likely model given our separation of H- and L-intentionality. We discuss characteristics of intentionality that might vary between H- and L-intentionality, and we pose questions for future exploration of this area of research.

## Abstract

This paper proposes a computational system of narrative discourse generation and its implementation. In the system, Genette's discourse theory is reconstructed as discourse techniques which transform the tree structure for a story into discourse structures. Also, we introduce Jauss's reception theory to construct the control mechanism, which continues discourse generation through generation cycles based on the interaction between both narrator and narratee mechanisms. Moreover, we attempt two kinds of performance checks and two types of evaluation experiments and confirmed that the system generates diverse discourse structures on the rough correspondence with generative parameters. And furthermore, this study shows that two different types of literary knowledge are organically integrated into a system's framework.

**Keywords:** Narrative generation system; narrative discourse; story; narratology; Genette; Jauss.

## Introduction

The research of narrative generation system is a challenging theme in artificial intelligence and cognitive science. It has a close relationship to various topics such as problem solving, planning, schema, story grammar, natural language generation, creativity, etc. Moreover, in recent years, interdisciplinary approaches with narratology and literary theories are also emerging. We have proceeded on a narrative generation system based on this kind of mixed approach since early 1990s. A common framework for the narrative generation system (Ogata, 1994; Ogata & Kanai, 2010; Akimoto & Ogata, 2011) consists of three stages: story, discourse, and surface representations (by language, animated movie, and music). Story is the content or a temporal sequence of events to be narrated, and discourse means how to organize a story or a narrated structure of events. They are generated as the conceptual representation forms or deep structures of narrative. Therefore, discourse phase does not equal natural language generation phase. The discourse in this paper especially means the internal structure of narrative representation. For example, many of the objectives treated by Callaway and Lester (2002) belong in natural language generation phase in the architecture of our narrative generation system. This paper deals with the part of discourse and proposes a computational model of structural narrative discourse processing and its implementation. As a fundamental standpoint, we use the discourse theory of Genette (1972). In addition, reception theory of Jauss (1970) is introduced into the system to control the generation and transformation of narrative discourse structure. First, this paper introduces the system architecture. And second, we present results of the system's evaluations, which focuses on the correctness of structure transformation and the control mechanism based on the interaction

between narrator and narratee inside the system. Last, the problems and future directions are discussed.

In the area of researches on narrative generation system, there is no attempt that utilizes Jauss's reception theory. Moreover, most of previous systems (e.g., TALE-SPIN by Meehan (1980), BRUTUS by Bringsjord and Ferrucci (2000), and so on) focused on the aspect of "story" generation mainly. However, recently, Montfort (2007) applied Genette's discourse theory to develop an interactive fiction system, and Lönneker-Rodman (2005) introduced the category of "voice" in Genette theory into the conceptual design of natural language generation system. As stated above, the computational application of Jauss provides an original design which can be not comparable in other narrative generation systems. And, the introduction of Genette has the character based on systematic and comprehensive design more than the other attempts. Such introduction of the knowledge in literary area contributes to narrative generation system and artificial intelligence regarding the providing of more precise and pragmatic domain specific knowledge and can guide the exploration for the developing computational techniques in creative areas. Especially, we show that two different and separate narratologies are organically integrated into one computational mechanism. This is a worthy contribution that the introduction of narratology into computational simulation has.

## Genette's Narrative Discourse Theory

Gérard Genette (1930-, France) is a representative literary theorist and narratologist mainly associated with structuralism. The discourse theory by Genette (1972) comparatively clearly categorizes various types of discourse techniques through the analysis of a novel. The theory consists of following three broad categories: "tense" relevant to the relationship between story's time and discourse's time, "mood" relevant to the modality for regulating narrative information, and "voice" relevant to the relationship among narrating, story and discourse. Each category is further divided into many subcategories. In the proposed system, discourse techniques are mainly relating to both categories for tense and mood.

## Jauss's Reception Theory

Reception theory is one standpoint in modern literary theories and narratology, which focuses on the reception or reading process of literary works. In this theory, readers contribute strongly to the production process of literary works as a whole. Hans Robert Jauss (1921-1997, German) is a representative theorist of this area by proposing an idea to characterize literary history based on the concept of "horizon of expectation", which means a kind of previous knowledge for positioning a new work on the context of readers' experiences of reading. Artistic character of a new work is grasped by the disparity between the

given horizon and the work, and the appearance of a new work may result in the change of an old horizon. We grasp this theory as a model which literary works are continuously changing through the interaction between authors and readers.

### Proposing a Narrative Discourse Mechanism

We propose a narrative discourse system using both ideas of Genette and Jauss. This system is intended to be positioned in the part of narrative discourse in the common framework for the narrative generation system (Ogata, 1994; Ogata & Kanai, 2010; Akimoto & Ogata, 2011). In the proposed discourse system, each category in Genette theory is elaborately formalized as a discourse technique for transforming a story structure or the part into a discourse structure, and Jauss theory is simply interpreted as a mechanism in which above discourse construction process is controlled through the interaction between narrator mechanism with generative parameters and narratee mechanism with expectation parameters.

These narrator and narratee do not mean real existences but virtual agents inside the system. In the current implementation, both narrator and narratee is individual model. However, reception theory covers both individual model and collective one, and we should consider other possibilities about the concepts in the future. For example, there are multiple models such as the narrator as an individual & the narratees as multiple individuals, and the narrators as multiple individuals & the narratee(s) as a collection. Our narrative generation research is an exploratory approach through the incremental revision of a variety of elements or modules and the integration and a flexible framework for the step-by-step expansion and conversion is prepared.

Following cycle continues according to the interaction of narrator and narratee. The narrator mechanism performs the processing of discourse generation and transformation using discourse techniques and a set of rules for controlling the application based on generative parameters. On the other hand, the narratee mechanism evaluates the result based on the comparison of expectation parameters and generative ones. In the next cycle, referencing the narratee's evaluation, the narrator tries to do the generation in an effort to come close to the narratee's expectation or higher degree of the satisfaction. However, the processing eventually comes at a point where the narratee's satisfaction turns to fall from rise or the narratee gets tired. In such timing, the narrator abandons a part of old generative parameters ("deviation") and moves to a new cycle of discourse generation according to a new strategy, and narratee's expectation is also altered.

As this process is a principled and elaborate computational application based on the idea and concept of reception theory, it is characterized as a comprehensive and general control mechanism for narrative generation system to be able to be expanded to other narrative generation stages such as story generation and natural language generation.

### Structural Representations for Story and Discourse

Both structures for a story and a discourse have a same tree form. In the story tree, each leaf node is corresponding to an event described with conceptual representation, which is really described by a case frame consisting of one verb concept and eight kinds of cases such as agent and object. Each internal node in the story tree is corresponding to a "relation" combining with the child nodes like "cause-effect" and "serial". On the

other hand, a discourse is described as a tree structure transformed from a story tree. And next seven kinds of relations are used for only the discourse tree: "recall", "present-backward", "prophecy", "present-feature", "episode", "description", and "repetition\_discourse".

### Discourse Techniques

In computational perspective, since each technique for discourse by Genette is respectively corresponding to a type of discourse structure outputted from an input story, the process is able to define with a kind of transformation procedure. For the procedural definition of techniques, we prepare next five kinds of procedural primitives for operating any intermediate or terminal node in the input structure: deletion, copy, conjunction, substitution, and creation. Current version of the system has 13 kinds of discourse techniques using the primitives as shown in Table 1. Although techniques for tense cover the main part, a few techniques for mood are also contained. Figure 1 shows the operation of "complementary analepsis\_ellipsis" as an example of transformation.

### Control Mechanism

By reference to the comparatively vague description about effects of discourse techniques by Genette (1972), we originally defined discourse parameters including  $p_1$ :supplement,  $p_2$ :complexity,  $p_3$ :suspense,  $p_4$ :length,  $p_5$ :hiding,  $p_6$ :descripttiveness,  $p_7$ :repetition,  $p_8$ :diffuseness,  $p_9$ :implication, and  $p_{10}$ :temporal-independency. These parameters are associated with the feature and the effect of constructed discourse structures, and are used for generative goals for narrator and expectations for narratee. Each parameter takes the value of 1 (small), 2 (medium), or 3 (large). Moreover, we defined quantitative criteria for measuring the degree of attainment of each parameter in a generated discourse. These criteria are not based on the cognitive effects for recipient, but structural features which can be calculated from the number and order of specific leaf/internal nodes in the tree structure of discourse. For example, "length" is measured by the total number of leaf nodes in a discourse structure. The quantitative criteria are used for the system's evaluation experiments in the following section. And also, as mentioned later, the narrator decides discourse techniques to be applied based on the rules for selecting techniques by values of the generative parameters. These rules are defined according to the correlation coefficient between each generative parameter and each measured value using the above criteria.

Figure 2 shows the overview of control mechanism. The list of Table 2 is the explanation of important terms used in the process. For the process, an input story is given by user or previous story phase. Other necessary data are the saturation point in the degree of satisfaction ( $n_p$ , 1 or more), the number of generation cycles (1 or more), and some kinds of initial values including generative parameters, expectation parameters, the degree of desire in narratee (0 or more), and the number of sufficiency in narratee (0 or more). According to the input data, system repeats following five steps.

**(1) Selection of Techniques** Narrator decides techniques to be applied according to generative parameters and rules for selecting techniques to be used. These rules define 0 or more techniques corresponding to each parameter's value, such as [If "supplement" is 1 then nothing, 2 then "external analepsis",

and 3 then “external analepsis” & “external prolepsis”]. When a same kind of technique is selected by more than one rule, the narrator takes the number of times of this technique to be used, from one rule which has the greatest number of the technique.

Table 1: 13 kinds of discourse techniques

<b>External analepsis:</b> Narrating past events which are positioned outside of story’s time range (i.e., not contained in the story).
<b>Complementary analepsis_ellipsis:</b> Narrating past events which are lacked of the original position.
<b>Complementary analepsis_paralipsis:</b> Narrating past events which are partially lacked of the original position.
<b>Repetitive analepsis:</b> Narrating past events once more.
<b>External prolepsis:</b> Narrating prospective events which are positioned outside of story’s time range (i.e., not contained in the story).
<b>Complementary prolepsis_ellipsis:</b> Narrating prospective events and these events are lacked of the original position.
<b>Complementary prolepsis_paralipsis:</b> Narrating prospective events and these events are partially lacked of the original position.
<b>Repetitive prolepsis:</b> Narrating prospective events and these events are narrated at the original position once more.
<b>Achronie:</b> Narrating events which have unidentified temporal relation with time of story.
<b>Pause:</b> Pausing temporal progress of the story by inserting descriptions.
<b>Implicit ellipsis:</b> Skipping one part of story.
<b>Repeating:</b> Narrating same events twice.
<b>Paralipsis:</b> Narrating less information than original sequence of the events.

Figure 1: The transformation process of “complementary analepsis\_ellipsis”

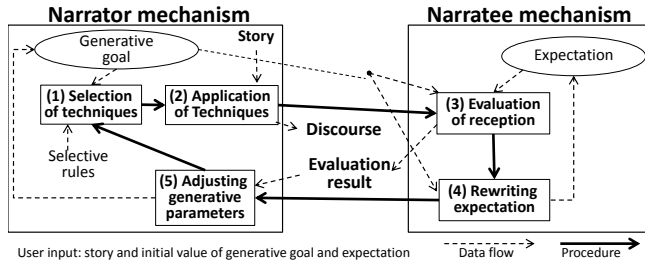

Figure 2: The overview of control mechanism

Table 2: Important terms in the control mechanism

Generative goal	Discourse parameters which represent the narrator’s direction of discourse generation.
Expectation	Discourse parameters which represent the expected discourse features by the narratee. Each parameter has two kinds of attributions which are “degree of desire” and “number of sufficiency”.
Degree of desire	This is numerical value and it represents the strength of expectation which is represented by the value of the parameter.
Number of sufficiency	This is number of time the parameter was sufficed. Suffice means the accordance of a value of generative parameter and a value of expectation parameter.
Degree of satisfaction	Degree of satisfaction in narratee’s each expectation parameter to narrator’s generative goal.
Indication	An annunciation to the narrator about the parameter which was the least “degree of satisfaction”.
Getting tired	The narratee is boring with the expected discourse, namely “degree of satisfaction” is decreased.
Deviation	The narrator intentionally sets a generative goal which counters the expectation of the narratee.

(2) **Application of Techniques** Narrator mechanism applies all selected techniques to the structure. The interference among techniques sometimes arises. For example, an inserted node by “repeating” is removed by “implicit ellipsis”. For avoiding such phenomena, we determined the order of priority that techniques are applied. Removal techniques like “implicit ellipsis” have higher priority than additional techniques like “pause”. The position for a technique to be applied is decided using some heuristic constraint rules relevant to the node’s size mainly. For instance, the large internal nodes containing more than 7 leafs can not be the position “implicit ellipsis” is applied.

(3) **Evaluation of Reception** First, the narratee calculates the degree of satisfaction in every expectation’s parameter. Here, higher satisfaction can be obtained when a more strongly desired parameter is satisfied. Next, narratee calculates and indicates one parameter with the lowest satisfaction. If two or more parameters have the lowest satisfaction, the parameter which has smaller subscript number will be selected. For example, when length ( $p_4$ ) and hiding ( $p_5$ ) were the lowest, the former is selected. The result is described as a pair of the name of parameter and the evaluation value.

(4) **Rewriting Expectation** The narratee rewrites the expectation parameters through following two processes. First process rewrites the number of sufficiency and the degree of desire. The former is increased when the narratee received the sufficed discourse in each time. And this change causes the rise and fall in the degree of satisfaction as shown in Figure 3. And,  $n_p$  in the figure sets a turning point of the degree of satisfaction. Smaller  $n_p$  means the narratee is get tired easily. Through the generation cycle, such change occurs in each of ten parameters independently and repeatedly. In another process, a parameter’s value caused by the reception of a deviated discourse is renewed. (5) **Adjusting Generative Parameters** The narrator rewrites one of generative parameter’s values according to the indication from the narratee. If there are no parameters to be changed, this process is skipped. “Deviation” is done in this step when narratee got tired in the expectation parameter. It randomly alters the value of parameter got tired with a value from 1 to 3 except for the current value. In the next cycle (step 4), narratee will rewrite the deviated parameter’s value.

## Implementation and Execution Example

We implemented the system with Common Lisp. It mainly consists of three main elements: discourse techniques, narrator mechanism, and narratee mechanism. The program contains about 60 kinds of defined functions. Story and discourse are described with the same form of list. Moreover, we preliminarily provide supplemental data for events and descriptive information to use in “external analepsis”, “external prolepsis”, “achronie”, and “pause”. The system finally outputs a list of generated discourse and a Japanese natural language text. The latter is generated by a simple natural language sentences generation program we have originally developed. Table 3 shows an execution example which contains an input story, generative parameters, and a generated discourse. Both input/output are also described in natural language. In the generated discourse, 13 kinds of discourse techniques are applying. In addition, the input story directly uses a generated result of a story generation system by (Ogata & Terano, 1991) which uses a story grammar based on Propp theory (Propp, 1969). This shows an actual case this proposed system can be combined with other components in the narrative generation system architecture.

Figure 3: Changing pattern of the degree of satisfaction

Table 3: An execution example

Input story
A snake abducted a princess. An older woman sang a grief-stricken song. Ivan resolved at searching the princess. Ivan departed from the town. Ivan battled with the snake. Ivan got arm wounded by the snake. Ivan won against the snake. Ivan abducted the princess. Ivan departed from the snake's country. The snake flew in the air to the snake's country. The snake followed Ivan. Ivan hid himself to a rock. The princess found Ivan's wound. Dwarfs built a palace. Ivan lived in the palace. Ivan married with the princess.
Generative goal
supplement:3, complexity:2, suspense:3, length:1, hiding:1, descriptive-ness:2, repetition:2, diffuseness:2, implication:3, temporal-independency:2
Generated discourse
An older woman sang a grief-stricken song. The woman was born. (And) the woman grew in a town. (Now,) Ivan battled with a snake in the snake's country. Ivan got arm wounded by the snake. (But) Ivan won against the snake. (And) Ivan departed from the snake's country. The snake followed Ivan. (A few years later,) the older woman will get weak and die. (By the way,) the snake prophesied that dwarfs will build a palace. Ivan hid himself to a rock. A princess found Ivan's wound. The snake's country is slightly dark. Ivan's wound is bleeding. The princess is beautiful. (Soon after,) Ivan lived in a palace. (A short time ago,) dwarfs built this palace. Dwarfs built this palace. Ivan married with the princess. (Go back to the time of beginning,) the snake abducted the princess. The older woman sang a grief-stricken song. Ivan abducted the princess. Ivan departed the snake's country. (At that time,) Ivan prophesied that dwarfs will build a palace, (and) dwarfs will build a palace. (By the way,) somewhere a bear went to farming village. The bear attacked a farmer.

## Operation Checks and Evaluations

We think that the evaluation of narrative generation system should be extremely done with a goal of narrative qualitative progress such as the improvement of creativity and interestingness. For example, Callaway and Lester (2002) proposed some evaluation items although the aspect of narrative comparatively surface language generation and Akimoto and Ogata (2009) organized evaluation criteria comprehensively. However, as the previous step, we attempt fundamental checks of the performance and simple evaluations. First two attempts are for the performance confirmation. In the first check, we analyze the aspect of logical structure in generated discourse representations. Next, an important purpose of the current system is the realization of no arbitrary diversity in the generation. First is a simple attempt for confirming whether changing generative goals results in the diversity of generated texts. And, second is an experiment for investigating narrative diversity through a generation cycle based on the interaction between narrator and narratee. In the last experiment, we quantitatively verify the correspondence relationship between used parameters and generated discourses. All experiments use the input story in preceding section.

## A Structural Analysis of Generated Discourse

First, as a confirmation of the system's performance, we explain the overall structure of the result shown in Table 3. The outline of input story is that "A snake abducts a princess, and then Ivan rescues the princess from the snake, and then Ivan married the princess". Whereas, the output discourse has some features: (a) some events relating to the princess are hidden at the early part of the discourse, and are revealed after the marriage, and, (b) the discourse is longer than the input obviously. Moreover, we confirmed although generated discourse is struc-

turally different from the story, both have a same semantic content. This coincides with the definition of the relationship between story and discourse. Next, we analyzed the transformation process of above result to check the logical correctness in the processing of used techniques and confirmed that each technique was correctly functioning as the individual level. However, we found out some matters at the level of combinatorial application of techniques. For example, a node inserted by "complementary analepsis\_paralipsis" was additionally moved by "complementary analepsis\_ellipsis", that is, the result of the former was negated by the latter. This topic is generalized that a part of tree constructed by previously applied discourse techniques is additionally transformed by the later techniques. Such phenomenon, i.e., the interference among techniques may bring logical errors in a discourse structure. For instance, under the "present-backward" relation, right side's child nodes may contain posterior events to left side's child nodes. To solve such problem, we prepared some heuristic constraints and priority order rules to apply techniques in step 2 in the control mechanism.

## Diverse Generation by Changing Parameters

Although it is no wonder in a sense, one of the merits in the proposed mechanism is that the diversity of generation brought by changing generative parameters. This characteristic is relating to a basic concept in the narrative generation system project of the flexible generation from fragmentary narrative elements and techniques. We confirmed generation diversity using "measured values" which means numerical numbers calculated based on the measurement criteria for each parameter. These values are automatically calculated from generated discourse using an embedded program routine. The various kinds of discourses are generated by different generative parameters such as very short one, longer and relatively complex ordered one, and so on. The obvious changes of measured values were caused by the change of values of the parameters. On the other hand, we confirmed that the system generates discourse structures in a certain range from same generative parameters. For example, 100 results generated from a same story (Table 3) and a set of generative parameters which generates very short discourse, the range of measured value "length" was 6 to 11. In summary, we could confirm that a certain degree of generative diversity is actualized from a generative goal and the change of parameters causes the change of the range of generation.

## Diverse Generation through Continuous Cycle

The objective of this experiment is to investigate the different changing patterns of a circulative discourse generation process based on the different values of  $n_p$ . We executed the program respectively 10000 cycles for two kinds of  $n_p$ , 20 and 200. Figure 4 shows the change of four measured values in generated discourses. However, although the only first 500 cycles are shown, a similar pattern of change was continued after that. Two types of changing patterns exist. First is a micro level changing pattern based on same generative parameters occurring in each cycle. However, in this figure, "supplement" has not such kind of change. Another type is a macro level changing pattern caused by different generative parameters. The frequency in this kind of change is influenced by the value of  $n_p$ , and more frequent changes occur with smaller value of  $n_p$ . This fact indicates that intentional or strategic control of the system's behavior may become possible by adjusting the value of

$n_p$ . For example, if we want to generate in a wide range of discourses, we can set smaller values of  $n_p$ . In contrast, if we want to generate in a narrow range of discourses, we can set larger values of  $n_p$ . Next, we focus on the range of generated discourses. In each measured value, there was a certain range as shown in Figure 4. On the other hand, as the combinations of measured values, 18765 patterns of discourse texts were generated from above 20000 discourses as the pattern which has completely similar measured values. In summary, the grasp of generative characteristics by parameters is connected to the development of a variety of control strategies. In addition, expansions of the existing control mechanism are also conceivable. The circulative generation process in the mechanism is thought of as a kind of closed-loop because same a changing pattern is repeating through a cycle. Regarding this, we programmed a simple mechanism which manipulates a specific parameter intentionally or randomly to create a part exceeding circulative loop. For example, by increasing a parameter's value incrementally, the corresponding aspect in discourse generation deviates from the closed-loop. Such a kind of breakdown or mutation may connect to narrative creativity or interestingness. These are implications for system implementation the experiments have. On the other hand, this kind of trial exploits a possibility of theoretical approach to creative genres like literature in terms of providing an experimental method to narratology, reception theory in this case.

### Correspondence between Generative Parameters and Generated Discourse

We programmed a function which generates discourse texts by all (59049) combinations of generative parameters to quantitatively confirm the correspondence between used parameters and generated texts. Table 4 shows all of the correlation coefficient between each generative parameter and each measured value. In this table, vertical line and horizontal line respectively shows generative parameters and measured values. Each intersection means their correlation coefficient. In each parameter,

higher value in the corresponding measured value's column (shaded one) and smaller values in other columns mean that the parameter is clearly reflected into the generated text. As a result, these are not complete correlations because the measured value by a parameter is sometimes influenced by the effect of other parameters. For example, the measured value by "length" is influenced by "descriptiveness" parameter. And, as correlations in "complexity", "suspense", "length", "repetition", and "diffuseness" were relatively weak, a reorganization of the correspondences between parameters and discourse techniques is required. As an idea, we are considering a method for hierarchically organizing parameters according to the abstraction level. For instance, parameters like "length" influenced by parameters such as "supplement" and "descriptiveness" may be positioned at the lower or more concrete layer in the hierarchy. In this hierarchical model, each technique is linked to one or more lower parameters which are influenced by the technique.

### Overall Discussion and Future Issues

This section shows more general discussions and future directions from several standpoints.

#### Toward the Expansion of Control Mechanism

Proposed system has the capacity to generate diverse discourses within a certain definite range based on the automatic change of both sets of parameters for generation (narrator) and evaluation (narrate). The changing pattern in discourse structures in a circulative process is based on variable  $n_p$ . In this mechanism, discourse generation is principally executed automatically. In contrast, as stated in previous section, we are considering a method with more intentional and conscious mechanism to control generation. We prepared an experimental program repeating discourse generation based on a direction which a real user directly gave. By increasing or decreasing the values of "length" and "complexity" intentionally, this program repeats the rises & falls or continues to extend the length. For instance, we confirmed that the program performed just as a given direction and very long outputs were generated. The measured value of "length" was 149 as maximum. Another idea is about "deviation" process in the narrator (Table 2). Although current system changes only one parameter's value randomly in deviation process, we experimentally modified the system to be able to adjust the number of changing parameters in deviation process. As a result, we confirmed more number of changing parameters causes more rapid change of outputs. These experiments show that proposed control mechanism is an expandable framework based on the strategic and flexible adjustment of parameters.

#### An Application for Narrative Creation Support

Although this research is directly aiming at automatic narrative generation, at the same time, we are involved in the planning of system for supporting user's narrative creation with the automatic generation function. For example, the system automatically generates diverse narrative texts and then the user selects one or more outputs to complete or expand by processing them as a kind of narrative material. In the case, narrative generation mechanism is corresponding to a function for stimulating user's thought and inspiration. To investigate the idea, next simple experiments is attempted. First, we selected two preferred texts from many outputs by the system (by the input information in Table 3). At this time, we can see graphs of measured values as

shown in Figure 4 to grasp parameters' characteristics in generated discourses. And then, we created a new story by the processing, expansion, and elaboration, moreover by combining two materials into one story. Human strong point is the creating of complex or complicated psychological narrative simulations and the processing of rhetorical techniques on surface text representation. On the other hand, machine's special skill is the generation of complex or complicated sequences in temporal progression and the logical processing of other discourse elements, and machine has the capacity to be able to generate superhuman texts, though, they may sometimes unnatural. Collaborative narrative creation or creation support by computer is one of the future directions in this research.

### Issues for Introducing Narratology

In this proposal of the application of Genette theory, we do not reach the comprehensive introduction. However, as we provided a common method for implementing discourse techniques, we can directly use it to extend the range of covering Genette based techniques and other categories. Previously, we have been developing several elemental systems for discourse techniques including order, distance, focalization, and other categories (Ogata et al. (2004) shows their overviews). However, these programs were not integrated as a whole system because of different data forms and processing methods. The first step for the integration at the level of discourse becomes the integration of existing functions into the proposed framework. On the other hand, the proposition of computational formation and implementation inspired by Jauss reception theory is also an original result in this paper. Although we stated the topic of individual narrator/narratee and collective ones, other various issues. For example, the narratee mechanism does not refer to generated discourse itself, and the narratee's reception pattern, which is the process of rise and fall in the degree of satisfaction, is preliminarily fixed. These issues will be solved through an exploratory approach in the future.

### The Integration with Narrative Generation System

Proposed system is positioned as a module of the narrative generation system. To integrate it into the system, first, it is necessary that the output data by the story generation phase becomes the input data of the discourse phase by unifying the form of knowledge representations. Regarding this, a tentative experimental version of integrated narrative generation system is already implemented by Akimoto and Ogata (2011). Next issue is the revision and expansion of discourse mechanism itself. Our immediate goal is to develop a systematic set of discourse techniques including all categories of Genette theory. At the same time, other types of techniques the theory does not describe are also required to be added into the comprehensive discourse mechanism. For example, Genette did not refer to the concrete way of "description" and "explanation" for character, object, and so on, at least systematically or formally. This sort of micro discourse techniques is a topic that has been discussing in the field of AI and natural language processing, and by the medium of this part, literary or narratological knowledge and AI-based knowledge will be blended in a narrative generation system. Moreover, we plan to expand the proposed narrative control method based on the interaction between narrator and narratee inside the system to an entire system including story phase and surface representation phases.

## Conclusions

This paper proposed a computational system of narrative discourse generation and its implementation. In the system, Genette's discourse theory is reconstructed as discourse techniques which transform the tree structure for a story into discourse structures. Also, we introduced Jauss's reception theory to construct the control mechanism, which continues discourse generation through generation cycles based on the interaction between both narrator and narratee mechanisms. Moreover, we did two kinds of performance checks and two types of evaluation experiments and confirmed that the system generates diverse discourse structures on the rough correspondence with generative parameters. And furthermore, this study showed that two different types of literary knowledge are organically integrated into a system's framework. At last, although this research does not directly treat the aspect of human cognition, as mentioned above, this indicates that advanced literary knowledge which is an important part at human cognition can be studied as a system, especially a computational system, more essentially beyond the traditional boundaries of fields of study. This is also a significance of cognitive science in a wide sense.

## Abstract

Research in visual cognition has demonstrated that scene understanding is influenced by the contextual properties of objects, and a number of computational models have been proposed that capture specific context effects. However, a general model that predicts the fit of an arbitrary object with the context established by the rest of the scene is until now lacking. In this paper, we explain the contextual fit of objects in visual scenes using Bayesian topic models, which we induce from a database of annotated images. We evaluate our models firstly on synthetic object intrusion data, and then on eye-tracking data from a spot-the-difference task and from an object naming experiment. For the synthetic data, we find that our models are able to detect object intrusions accurately. For the eye-tracking data, we show that context scores derived from our models are associated with fixation latencies on target objects.

**Keywords:** visual attention; object context; Bayesian modeling; eye-tracking data.

## Introduction

Real-world objects are often related to each other and typically form a coherent scene. For example, a toothbrush is likely to occur with a tube of toothpaste, a mirror, a sink; it is unlikely to occur with a sauce pan, a salt shaker, a cooker. For a given object, it is therefore possible to determine whether it is in context in a scene (toothbrush in bathroom), or out of context (toothbrush in kitchen). Experimental evidence shows that context information facilitates human object recognition (Bar, 2004). In visual search tasks, eye fixations are targeted towards contextually appropriate regions (Torralba et al., 2006), and out-of-context objects attract fixations earlier than in-context objects (Underwood et al., 2008).

In computer vision, being able to detect out of context objects is useful for object labeling. The local detectors standardly used for this task only consider the visual features of the pixels within the bounding box of the object of interest (Felzenszwalb et al., 2010). Local detectors are therefore prone to confusing objects that are visually similar (e.g., fork and toothbrush). This problem can be addressed by combining a local detectors with a model of object context, i.e., a model that determines which objects occur together. While this approach has been shown to increase object labeling performance (Choi et al., 2010; Galleguillos et al., 2008), the context models used are simple, typically relying on co-occurrence statistics over object labels. Furthermore, the context models used in computer vision are not designed to capture human performance (e.g., in visual search). Therefore, these models have not been evaluated on tasks such as detecting out-of-context objects.

In this paper, we present a new model of object context based on a more complex notion of object label co-occurrence that makes use of latent (i.e., unlabeled and unobserved) scene types: the Latent Scene Type model. This model allows us to exploit the common structure of scenes in order to estimate reliable parameters even for infrequently occurring objects. We investigate two model variants: the first is Latent Dirichlet Allocation (LDA, Blei et al. 2003), a standard model of word-topic co-occurrence, which we use to capture object-scene type co-occurrence. The second model variant is formulated as a Bayesian mixture of multinomials, which assumes one latent scene type per scene (rather than one per object, as in LDA).

We test both model variants on the task of producing context judgments for objects in scenes. We first use a synthetic data set for evaluation (in this data, context objects have been artificially inserted). In the second evaluation study, we use our model to mimic the data from an eye tracking experiment in which human participants had to spot out-of-context objects. Finally, we demonstrate that our model can predict fixation latencies in an object naming experiment which included out-of-context objects.

## Related Work

To our knowledge, ours is the first model to attempt to quantify the degree of fit between arbitrary objects in a scene, and to correlate the predictions of such a model with human behavior in scene viewing tasks. However, a number of models have been proposed to capture context effects on visual attention; a prominent example is the Contextual Guidance Model (CGM, Torralba et al. 2006), which combines bottom-up saliency with global scene information (scene gist, Oliva & Torralba 2006). The model is trained on a set of images in which the target objects are labeled; from this data a probability distribution of typical positions of objects is learned. This distribution is conditioned on the scene gist, essentially a coarse-grained representation of global image features. Gist is a latent variable in the model, comparable to scene type in our approach. The CGM has been evaluated on eye-tracking data from visual search experiments, and can successfully predict the scene-type-specific search behavior that participants exhibit. However, the model is not specifically designed to detect out-of-context objects, and has not been evaluated on tasks that require an estimate of the contextual fit of an object.

In the computer vision literature, the work closest to ours in spirit, if not in ultimate task, is that of Choi et al. (2010). The authors use a generative model of images features, scene gist, the set of objects in the image, and their locations, to re-rank the output of a local object detector to respect contextual interactions between objects, and show an improvement over the baseline detector. The co-occurrence model used by Choi et al. (2010) is a fairly simple binary tree of presence features whose principal purpose is to facilitate inference on other aspects of the image.

The model of object context proposed in this paper is formulated as a topic model. While topic models have been studied extensively in both the language and vision literature, they originate from applications to text, beginning with Latent Dirichlet Allocation. LDA assumes a document is sampled from a mixture of multinomials, where the multinomial from which words are drawn is sampled once per word, and the mixture co-efficients are sampled once per document. A corpus is then a distribution over mixture co-efficients. This approach can be adapted fairly straightforwardly for modeling objects instead of words, and scenes instead of documents. However, we note that instead of being used as descriptive tools to provide insight into collections, in this paper we are interested in the predictive aspects of a topic model and want to test how well they correlate with human scene viewing data. In this respect, while the models we used are standard, the purpose for which we use them is novel and we derive new metrics to correlate with human behavior.

Topic models have been applied to images in the computer vision literature (Wang et al., 2009; Li et al., 2009), but rather than describing the sampling of object labels, these models specify how discrete-valued image patches are sampled (by quantizing continuous image features), and the relation between these patches and the labels applied to the image.

## Models of Latent Scene Type

This paper presents a model of context, and by extension contextual fit, which rests solely on the set of object labels in the image. The method we employ has two components: a distribution over the set of labels in the scene, and the application of such a model to a continuous measure of how well any object fits with that scene. The observation of sets of objects is explained through latent scene types, which can be thought of as simple clusters of objects which are likely to co-occur. We then use the predictive distribution over new sets of objects, as derived from our latent scene type models, to determine the fit of target objects to the scenes.

### A Model Of the Probability of a Set of Object Labels

We experiment with two models of the probability of a set of object labels, both of which are topic models. Topic models comprise mixtures over multinomial distributions, where in this case the multinomial outcomes correspond to object labels. The first topic model, Latent Dirichlet Allocation, is fairly standard, while the second one, the mixture of multinomials model, is less commonly used. Each of the models

describes a distribution over a vector of counts, which we call  $o$ , such that  $o_i$  is the count of the  $i$ -th object in the current image (note that for most images, most of these elements will be zero).

**Latent Dirichlet Allocation** There has been much interest in the use of topic models as descriptive tools, able to infer structure in collections of documents, or other collections of discrete entities (Blei et al., 2003; Wang et al., 2009). For the LDA model, the predictive distribution over new sets of object labels is given by:

$$p_{LDA}(o|\alpha, \beta) = \int p(\theta|\alpha) \left( \prod_n \sum_{z_n} p(z_n|\theta) p(l_n|z_n, \beta) \right) d\theta \quad (1)$$

where  $l_n$  is the label for the  $n$ -th object in the image, and  $z_n$  is the (latent) topic assignment for this label—counting the  $l_n$  gives  $o$  as defined above. The  $z$ s are indicators explaining which latent scene type was used to generate the current label. As in the original paper,  $\alpha$  is the Dirichlet prior on  $\theta$ , and  $\beta$  is the topic–word probability matrix that gives the probability of each object label in each topic. The above is evaluated using a particle-filter-inspired Monte Carlo method described by Wallach et al. (2009).

**Mixture of Multinomials** The mixture of multinomials model is defined over the same count vector  $o$  as above, but for this model the scene type  $z$  is sampled only once per scene. The parameters to the model are  $\phi$  (the mixture coefficients) and  $\theta$  (the parameters for the component multinomials). The distribution over the observable variables,  $o$ , is:

$$p(o) = \sum_z \phi_z p(o|\theta_z) \quad (2)$$

where the distribution  $p(o|\theta_z)$  is a multinomial parametrized by the vector  $\theta_z$  (its components giving the probabilities of each possible label occurring within that component).

We explore two variants of this model—the first uses maximum a posteriori (MAP) estimation to fix the parameters to the (approximate) posterior mode—the single best estimate of model parameters. This can be done using EM, and we employ uniform priors on both sets of parameters. Conditioned on some observations (training data, which we label  $D$ ), the maximum likelihood method stipulates:

$$\hat{\phi}, \hat{\theta} = \arg \max_{\phi, \theta} p(D|\phi, \theta) \quad (3)$$

$$p_{ml}(o|D) = p(o|\hat{\phi}, \hat{\theta}) \quad (4)$$

This predictive distribution (4) is what we are interested in: exploring the probability of new scenes given our training data.

However, from a computational as well as cognitive perspective, given only limited samples from the process we should feel uneasy about saying with any certainty what the values of the parameters are. Instead, we suggest that given

our experience we have beliefs about what is likely to happen, but we retain uncertainty and factor this in to our predictions. In light of this, we also employ a Bayesian version of this model, which integrates over the full parameter space given our training data  $D$ :

$$p_{\text{bayes}}(o|D) = \int p(\phi, \theta|D) p(o|\phi, \theta) d\phi, d\theta \quad (5)$$

For the mixture of multinomials model we cannot evaluate this integral in closed form, so we sample mixture models from their posterior  $p(\phi, \theta|D)$ —i.e., we retain uncertainty about which model best explains our data, and average over this uncertainty in deriving our predictions. Assuming Dirichlet priors (in our case, uniform) on  $\phi$  and  $\theta$  leads to Dirichlet posteriors over these same parameters, conditioned on assignments of training observations to latent mixture components; it is these assignments that we sample. We then evaluate the  $p(o|\phi, \theta)$  at each of these sampled points; in practice we do not sample different mixture models for each new  $o$  we wish to evaluate, but run the sampler once in training and store all mixture models sampled. This allows us to simply average over the sampled components for the predictive distribution, leading to a deterministic evaluation of (5) as simply the mean of the probability  $p(o|\phi, \theta)$  under the sampled models.

As a final note for all these models, while inference techniques are approximate in all cases, and different between the MoM and LDA models, we are confident that the particular approximations do not overly sway the models' ultimate performance. While using heldout probability as the metric of concern show disparities between different approximations for the LDA model in Wallach et al. (2009), our uses of the models are different. Most of the problems we consider are decision problems where the exact probability is less of a concern than the relative probabilities of the scenes under two models, and in the final section we are interested in the correlation between the probabilities and some other continuous measure which is unlikely to be affected by (relatively) small changes due to approximation error.

### Detecting Out-of-context Objects with Scene Probability

The previous section presented models which have been used previously in other fields for describing the co-occurrence of entities. We turn in this section to the manipulation of these models to derive quantities which we will correlate with human performance.

There are two distinct tasks we explore in this paper: which of two objects is more probable given a scene, and whether a given object belongs to a scene or not. Here, we briefly describe the use of the models we defined in the previous section to achieve these tasks.

Firstly, the conditional probability of some object (label) in question  $o'$  given a set of object labels  $o$  (where  $o$  is the count vector as above) is:

$$p(o'|o) = \frac{p(o \cup o')}{\sum_{o_{\text{new}}} p(o_{\text{new}} \cup o)} \quad (6)$$

That is, the probability of the count vector which includes the new label  $o'$ , normalized by the probability of the context for all possible objects which could be added to the scene.

To determine which of  $o^1$  and  $o^2$  better fits some context  $o$  we can compare  $p(o^1|o)$  and  $p(o^2|o)$  computed as in (6)—we may simply interested in which of these is the larger, or perhaps in the ratio between these two quantities. Note that in either case, the normalizing constant can be dropped since it is common to both (this speeds up computation considerably).

Secondly, to determine whether  $o'$  is in context or not, we can compare  $p(o'|o)$  with the quantity obtained by marginalizing out the extra object, namely:

$$p(o^{\text{new}}|o) = \sum_{o^n} p(o^n) p(o^n|o) \quad (7)$$

where  $p(o^n)$  is the probability of  $o^n$  occurring in any scene, for which we use simply the fraction of all objects across all scenes which are  $o^n$ . For this paper, we explore both the decision problem (is  $p(o'|o) > p(o^{\text{new}}|o)$ , i.e., is the object in context or not) and the continuous scores derived as above.

### Evaluation on Synthetic Out-of-context Objects

We construct our first test set based on the Spatial Envelope data set (Oliva & Torralba, 2001). Here, the models will be used to determine whether an object is in context with respect to the rest of a scene, or not (Equation (7)). The images in the data set contain full object annotations, but also scene type labels. These allow us to construct test data for the scenario we are interested in. (Note, however, that this is the only use of overt scene type labels in this paper; the scene types in our model are latent.) The data set is annotated using LabelMe conventions, but does not overlap with the LabelMe data from which our models are estimated. In terms of objects per scene, there are on the order of ten objects in each image, and the number of images is reasonably balanced between scene types. We extract scenes which are either rural or urban (the two top level scene types). We produce frequency counts of objects within these two categories, and compute a  $\chi^2$  statistic for each to measure the distinctiveness of that object in that class. We then select the 25 most distinctive objects for each class which occur in at least ten scenes, and extract all scenes containing each of these objects. These distinctive objects are treated as the targets, and the other objects in the image form the contexts.

The original scenes form examples of in-context objects—to produce out-of-context ones, for each scene we replace the in-context target with a randomly selected member of the distinctive list for the other category. This produces a set of just over 26,000 scenes, equally balanced between in- and out-of-context objects, to use for further experimentation. We divide this into 6,000 scenes for development (model selection and parametrization), with the remainder being used for held-out testing. In all cases, the held-out data are unobserved until all model parameters are fixed. Table 1 shows examples of the data we produce.

Target	In/Out Context	Context
<b>stone</b>	<i>in</i>	stick:1 stone:1 tree_trunk_fallen:2 trees:1 ground:2 brushes:1
<b>buildings</b>	<i>in</i>	skyscraper:1 building_occluded:2 buildings:1 sky:1 skyscraper_occluded:1
<b>road</b>	<i>out</i>	tree:1 stone:3 river_water:1 trees:1 field:1 sky:1 stones:2 rocky_mountain:1
<b>sea_water</b>	<i>out</i>	window:11 car_occluded:2 pot_plant_occluded:1 sidewalk:1 person_occluded:1 arcade:1 palm_tree:1 car:1 window_occluded:1 person_walking:3 person_woman_walking:1 traffic_light:1 hall:1 building:1 road:1

Table 1: Some examples of the synthetic data—the context is depicted as a sparse vector over the outcomes in the form  $[label:count]$ , which is then reduced as appropriate for a trimmed vocabulary

	LDA		ML-MoM		B-MoM	
$ T $	500V	1000V	500V	1000V	500V	1000V
50	0.737	0.747	0.674	0.679	0.896	0.895
100	0.759	0.801	0.660	0.662	0.897	0.899

Table 2: Accuracy (proportion of decisions where the correct determination is made) on the synthetic data

**Results** Table 2 shows results on the synthetic dataset. The Bayesian Mixture of Multinomials is clearly superior to the other two models, and the larger vocabulary size and greater dimensionality improves this slightly. The LDA model shows greater sensitivity to parametrization than the other two, and the maximum likelihood model is considerably worse than the others across all parameter settings. Of particular note is the maximum likelihood model getting *worse* as the dimensionality increases; this is a classic result for non-Bayesian models, where as the parameter space expands it is less and less well summarized by a single point (the mode) and that mode becomes harder to find.

## Modeling Human Experimental Data

The evaluation study presented in the previous section used artificially generated data. It showed that the Latent Scene Type Model is highly accurate at detecting out-of-context objects which have been inserted into a scene. In the present study, we validate this result using a data set from an eye tracking experiment by Underwood et al. (2008). In this experiment, participants had to perform a search task (determine whether two scenes are the same or different); in the different-scene condition, the target object was either out of context or in context, with saliency being controlled. An example pair of scenes can be found in Figure 1. The results show that scenes with in-context objects are inspected for longer and received more fixations than scenes with out-of-context objects. Also the in-context objects themselves were detected later and required more fixations prior to detection than out-of-context objects.

We expect our Latent Scene Type Model to capture the behavioral effect of out-of-contextness demonstrated by Underwood et al.’s study: out-of-context objects should receive

lower probabilities than in-context objects in their data set.

Underwood et al.’s study contains 80 pairs of scenes. In one scene in the pair, the target object is in context (congruent, in the language of that paper) and in the other it is out of context. (Saliency was also manipulated in the study, but this is not of interest here.) We manually listed the objects in each scene (the contexts are identical between pairs, and two pairs are identical save for their targets). Checking the labels against our LabelMe training data revealed that 25% of target objects were observed in LabelMe, and just over 30% of all objects. LabelMe contains mainly outdoor scenes, while the experimental data set are all indoor scenes, predominantly kitchen, utility room or bathroom scenes, in which the objects have been carefully arranged.

We therefore iteratively relabeled the target objects to establish a closer match with the LabelMe database, choosing in some cases synonyms and in others (direct) hypernyms. This was a manual process which relied on linguistic resources such as WordNet. This produced a target coverage rate of just over 70%, making it possible to use 45 of the 80 scene pairs, with each scene having on average approximately 60% of its context object appear in the training data (note that this increase was incidental, as we optimized the coverage of the target objects and simply propagated corrections through to contexts as well so as to reduce the amount of manual engineering). The selected scenes contain an average of ten objects in total.

Given the small size of the test set, we were not able to split off a separate development set, and therefore retained the parameters as set in the previous section on the synthetic data set.

**Results** Table 3 shows results on the Underwood et al. data for the task of detecting which of two possible objects is out of context. As in previous sections, we note that the Bayesian version of the mixture of multinomials model performs better than the maximum likelihood version of the model, but given the small dataset it is not possible to compare the B-MoM and LDA models except to say that both are significantly different from a random (50%) baseline as established by a binomial test. Note that while seeming disappointing initially, the performance of the models here is limited because the Un-

Method	LDA	ML-MoM	B-MoM
Accuracy	31/45	24/45	29/45

Table 3: Proportion of scenes in the Underwood et al. (2008) data where the correct determination was made. The LDA and B-MoM models are significantly different from a random (50%) baseline, but not one another

Figure 1: A pair of example scenes from the eye tracking experiment of Underwood et al. (2008). The target object in the left hand image is the sock (in context), while in the right hand image it is the can of soup (out of context)

Underwood et al. scenes are staged indoor shots featuring many objects that occur infrequently, if at all, in our training data (only 60% of context objects appeared at all). The next section presents an evaluation where objects are more frequently observed.

## Modeling an Object Naming Dataset

The third evaluation of our models used eye-tracking data from an object naming experiment by Coco et al. (2012). In this study, 24 participants were presented with 28 photo-realistic scenes and asked to name the five most important objects in the scene. In each scene, an object of interest and two competitors were inserted using Photoshop. The Saliency (Salient, Non-Salient) and Contextual Fit (In-Context, Out-of-Context) of the object of interest was manipulated. In contrast to Underwood et al. (2008), this study shows that out-of-context objects are less likely to be named than in-context objects. Moreover, first fixation latency, i.e., the time to land on a target object for the first time from scene onset, is longer for out-of-context than for in-context objects. A naming task demands a joint evaluation of both linguistic and visual information, thus even if an out-of-context object might be visually more informative, it is linguistically less relevant.

We first evaluate our models on the task of determining which of two objects is in context, identical to that presented in the previous section. Then, we investigate whether the contextual scores calculated by the models are correlated with the visual responses observed on the associated objects. We employ linear mixed effects model (LME, Baayen et al. 2008)

(a) In context target

(b) Out of context

Figure 2: An example of a scene with an in-context target (cup) and the same scene with an out-of-context target (fish)

analysis to investigate how first fixation latency (the dependent measure) correlates with model score (our predictor). LME is more appropriate than simple correlation because there were many other factors considered in the experimental data which affect the dependent measure, including frequency and saliency of objects in the scene and size of the objects. Employing LME means we are able to control for these factors by including them as covariates in the analysis.

On the basis of the experimental data, we expect the model score to be negatively associated with first fixation latency, i.e., the more out-of-context an object is, the longer it takes to fixate it. Together with the Score, we include as predictors the Saliency of the object, and the type of Model. As a random effect, we include Scene. We residualize first fixation latency by the area of the object (in pixel square) to reduce the effect of area on the dependent measure. We select the final LME model by following a forward step-wise procedure, where nested models are compared on the basis of log-likelihood improvement. In the following, we report the coefficients of the predictors found significant after model selection.

Method	LDA	ML-MoM	B-MoM
Accuracy	46/56	33/56	50/56

Table 4: Proportion of scenes in the Underwood data where the correct determination was made. The LDA and B-MoM models are significantly different from a random (50%) baseline, but not one another

	LDA		ML-MoM		B-MoM	
	I	O	I	O	I	O
S	0.0106	0.0001	0.0010	0.0010	0.0071	0.0006
NS	0.0064	0.0002	0.0010	0.0010	0.0054	0.0012

Table 5: Average context scores across the conditions—I is in context, O out of context, S is the salient condition and NS is the non-salient condition. ML-MoM scores are in fact slightly different to one another, but both contexts are highly improbable under the model

**Results** We first present the results for the decision problem. There are fifty-six decisions to be made (28 pairs of scenes, each in the salient and non-salient condition), with the goal being to determine which of the pair is out of context. Table 4 shows the results on this task, where we once again see that the LDA and Bayesian models are significantly above chance, but given the limited sample size not significantly different from one another. Table 5 shows the mean context scores across the conditions for each of the three models, where we see that the effects of the models in the decision problem (Table 4) are equally visible on the continuous scale.

When using the LME to check whether model score is a predictor of first fixation latency, we find a significant effect with  $\beta_{Score} = -0.1309$ ;  $p < 0.0001$ : the more in-context an object is, the shorter the latency. We do not find an effect of Saliency and Model. This result also echoes the experimental finding obtained by Coco et al. (2012), and shows that the scores generated by our models can capture the patterns in the eye-movement responses.

## General Discussion

This paper introduced the Latent Scene Type models for describing the fit of objects to scenes. Our models quantify how well a target object fits an observed context (the other objects in the image). Sets of objects are generated by latent scene types, with scene types representing objects which tend to co-occur. We choose a Bayesian formulation for our models, as this is attractive from a cognitive point of view: a cognitive process operates with finite experience, which means that it has to estimate a model of the world based on a limited sample (in our case of context and objects). Committing to a single parameter setting based on a limited sample is difficult; it therefore seems more plausible to integrate over the full parameter space, which is the hallmark of Bayesian models. The Bayesian approach therefore captures the uncertainty

faced by a cognitive process with access to limited data.

We showed that the Latent Scene Type models perform well on the task of detecting out-of-context objects in a synthetic dataset. Furthermore, we successfully applied the models to two eye-tracking datasets, one involving a spot-the-difference task, the other involving object-naming. In both cases, the models were able to successfully detect out-of-context objects, and in the case of the naming data, we also showed that model scores are associated with first fixation latencies on a target object (either in or out of context).

## Abstract

The Theory of Visual Attention (TVA; Bundesen, 1990) is a comprehensive quantitative account of visual attention, which accounts for many empirical findings and has been extensively applied to clinical studies of attention. According to TVA, perceptual processing of objects occurs in parallel constrained by a limited processing capacity or rate, which is distributed among target and distractor objects with distractor objects receiving a smaller proportion of resources due to attentional filtering. Encoding into a limited visual short-term memory is implemented as a race model. Given its major influence it is surprising that few studies have compared TVA directly to alternative models. Here we insert an algebraically simpler model of encoding into TVA as an alternative to the race model and show that this provides a better fit to Shibuya and Bundesen's (1988) whole and partial report data, which have been a keystone test bed for TVA.

**Keywords:** Attention; working memory; Theory of Visual Attention; Vision; Psychophysics; Modeling

## Introduction

The Theory of Visual Attention (TVA; Bundesen, 1990) incorporates visual perceptual processing, attentional filtering and encoding into visual short-term memory (VSTM) in a unified quantitative model. The model has been extended to account for results from a wide variety of experimental paradigms (Logan, 1996; Logan & Gordon, 2001), and the neural implementation of TVA (NTVA) has been applied to results from single cell studies (Bundesen, Habekost, & Kyllingsbæk, 2005). Despite the extensiveness of the TVA based theoretical framework, we are aware of only a few recent studies (Dyrholm, Kyllingsbæk, Espeseth, & Bundesen, 2011; Kyllingsbæk, Markussen, & Bundesen, 2011; Petersen & Andersen, 2012) challenging the specific details of the model using standard model assessment methods. Of these studies we will include Petersen and Andersen's (2012) findings

that the log-logistic psychometric function inserted into TVA leads to improved performance in the current study.

Computational models of cognition such as TVA offer both theoretical and practical advantages. The theoretical advantages include the strict quantitative formulation of cognitive modules, the definition of which can otherwise prove to be elusive. Computational models can also be applied to a range of experimental paradigms and help arrive at a unified interpretation. This can be of practical use as the assessment of the function of cognitive modules is of great importance in clinical psychology and neuro-pharmacology. In this vein, TVA has been extensively applied to studies of clinical populations (Habekost & Starrfelt, 2009) and to the effect of psychoactive drugs (Finke, et al., 2010; Vangkilde, Bundesen, & Coull, 2011). Many of these studies base their assessment on estimates of the parameters in TVA and therefore rely on TVA precisely reflecting the actual computational mechanisms underlying visual attention. This makes it the more pressing to assure that this is indeed the case by comparing the specifics of TVA to competing models.

Whole and partial report tasks have been a keystone test bed for TVA. In whole report tasks, a number of objects, typically letters or digits, are presented to the observer. The task of the observer is to identify and report the objects presented. The exposure duration is typically brief (<200 ms) in order to avoid eye movements so that the information available can be assumed to be near constant across the stimuli and throughout the stimulus duration. Partial report tasks are like whole report except that in addition to the target

objects, a number of distractor objects are also presented. Some characteristic, like color, location or object category (e.g. letters vs. digits) distinguishes targets from distractors. The task of the observer is to report only the target objects and ignore the distractors.

Performance in whole report tasks is limited by perception and memory. In order for the target objects to be correctly reported, they must be perceived. This depends on stimulus attributes such as contrast, exposure duration, size, complexity and the number of stimulus categories (Pelli, Burns, Farell, & Moore-Page, 2006). Since these limitations exist also when only a single object is present the effect of these stimulus attributes can be studied in single letter identification experiments (Petersen & Andersen, 2012).

When multiple objects are presented the single letter psychometric functions cannot explain performance. Instead, the psychometric function needs to be adjusted. In TVA the adjustment is based on the assumption that the sum of processing resources, defined as the sum of hazard rates, is constant (Shibuya & Bundesen, 1988).

In partial report tasks, performance depends also on the ability to filter out the irrelevant distractor objects through selective attention in order to avoid their interference with perceptual processing and their taking up working memory capacity. If filtering is perfect, performance in partial report tasks should match that of whole report tasks with the same number of target objects. Shibuya and Bundesen (1988) showed that this is not the case and that the filtering process is imperfect. TVA models filtering as a smaller amount of processing resources being allocated to distractor objects.

Even when contrast and exposure duration are more than sufficient for all letters to be correctly identified according to the adjusted psychometric functions, observers fail to base their report on more than about four objects (Sperling, 1960). This seems to be due to limitations on VSTM rather than on perception *per se*. In TVA the mechanism of encoding is a race, so that objects are encoded into VSTM when they are

perceptually processed but only if VSTM capacity is still available, i.e. if it has not already been occupied by other objects.

TVA is thus able to describe performance in whole and partial report tasks with a given number of targets and distractors based on performance in single object identification in the form of the psychometric function. It does this based on assumptions of how multiple targets affect perceptual processing, the process of filtering and encoding into a limited VSTM. We find it difficult to envision a model that would not partition visual perception, attention and short-term memory into these components as does TVA but we find that there is room to examine the specific implementation of these stages.

In the following we shall examine the encoding stage of TVA, the race model. We will insert a different model of the encoding stage into TVA and compare the two encoding models' abilities to describe Shibuya and Bundesen's (1988) whole and partial report data. We will do this using either the exponential psychometric function conventionally used in TVA or the log-logistic function that Petersen and Andersen (2012) found to improve performance.

## Methods

### Modeling

#### The psychometric function and distributing resources

In TVA, perceptual processing of a single object is typically described by the exponential psychometric function

$$F(t) = 1 - \exp(-v_t(t - t_0)), t > t_0$$

$$F(t) = 0, t > t_0$$

where  $F$  is the probability of correctly identifying the object,  $v_t$  is the rate of processing for the target object,  $t$  is the exposure duration and  $t_0$  is a short time interval between stimulus onset and the beginning of perceptual processing. In terms of probability theory, the rate,  $v_t$ , is the hazard rate and  $v_t(t - t_0)$  is the cumulative hazard rate, the hazard rate integrated over time. When only a

single target is presented the sum of processing resources, or hazard rates,  $C$ , is allocated to that target so that  $v_t = C$ . In whole report, when multiple targets are presented, the objects are typically arranged at equal distances from the fixation point so that it is reasonable to assume that they receive equal shares of the processing resources, i.e.  $v_t = C/T$ , where  $T$  is the number of targets. In partial report, distractor objects are assumed to receive a proportionally smaller share of processing resources due to attentional filtering so that  $v_d = \alpha v_t$ . From this, we can deduce that  $v_t = C/(T + \alpha D)$  where  $D$  is the number of distractors (Bundesen, 1990).

In a recent study Petersen and Andersen (2012) showed that other psychometric functions can be inserted into TVA and that this, in general, improves the performance of the model. The log-logistic function gave the best fit of those functions having two free parameters like the exponential function. Therefore we will use it here. The log-logistic can be expressed as

$$F(t) = \frac{1}{1 + \left(\frac{t}{t_0}\right)^{-v_t}}$$

Although the parameters  $t_0$  and  $v_t$  describe the shift and the slope of the psychometric function respectively just as for the exponential function, their exact meaning is different than for the exponential function. The shift,  $t_0$ , is here the 50% correct threshold. Unlike the exponential function, the hazard rate is not explicit in the expression for the log-logistic function but the cumulative hazard rate,  $\Lambda_t$ , can be derived to be

$$\Lambda_t = -\log(1 - F) = \log\left(1 + \left(\frac{t}{t_0}\right)^{v_t}\right)$$

Distributing processing resources according to TVA with the log-logistic function becomes simpler if we notice that the assumption of a constant sum of hazard rates is equivalent to a constant sum of cumulative hazard rates. When

only a single object is presented the cumulative hazard rate is thus  $\Lambda_t = C_{cum}$ . From this the response probabilities in whole and partial report can be calculated by setting the cumulative hazard rate to  $C_{cum}/(T + \alpha D)$ .

### Encoding into a limited VSTM

The previous section outlined TVA applied to the case of whole and partial report when the total number of objects does not exceed the capacity of VSTM. In that case we can calculate the probability of the score,  $j$ , which is the number of correctly reported target objects, as

$$P(j) = \binom{T}{j} [F(t)]^j [1 - F(t)]^{T-j}$$

This expression is derived from the binomial distribution giving the probability of encoding  $j$  targets. The number of encoded target objects is termed the *score*.

When the number of objects exceeds VSTM capacity selection of the objects to encode is needed. According to TVA the selection happens as a race for free slots in VSTM; a race that ends when all slots are occupied or when perceptual processing ends. Inserting the race model into TVA is somewhat algebraically complex but allows calculating the score probability, i.e. the probability of correctly reporting a certain number of target objects. Detailed expressions and derivations are given in Petersen and Andersen (2012).

Here we introduce a different model of selection of objects to be encoded by conditioning on the total number of objects encoded being no greater than VSTM capacity, i.e.  $j + m \leq K$  where  $m$  is the number of distractor objects encoded. This probability is calculated by calculating the score probabilities for  $j = 1, \dots, T$  and  $m \leq \min(D, K - j)$

$$P(j) = \binom{T}{j} [F(t)]^j [1 - F(t)]^{T-j} \times \sum_{m=0}^{\min(D, K-j)} \binom{D}{m} [G(t)]^m [1 - G(t)]^{D-m}$$

Conditioning on  $j+m \leq K$  is then implemented by normalization of the probability mass function  $P(j)$ . Here, the psychometric function for distractor objects is denoted  $G(t)$ . Note that the number of encoded distractor objects,  $m$ , is considered an unobservable nuisance parameter, which is summed out.

For both encoding models, VSTM capacity,  $K$ , is allowed to take non-integer values, which are implemented as a mixture model where the VSTM capacity is the ceiling value of  $K$ ,  $\lceil K \rceil$ , with a probability of  $\text{mod}(K, \lfloor K \rfloor)$  where  $\lfloor K \rfloor$  is the floor value of  $K$  and  $\lfloor K \rfloor$  with a probability of  $1 - \text{mod}(K, \lfloor K \rfloor)$ .

### Model evaluation

As testing ground for comparing the two models of encoding we choose Shibuya and Bundesen's (1988) whole and partial report data that have been influential in the development of TVA (Bundesen, 1990). The data set consists of score counts for two observers each performing 6,480 trials with varying number of target and distractor elements and exposure durations. The observers were instructed to report the identity of targets only when they were reasonably confident in order to minimize the effect of guessing.

Only very rarely did the observers achieve scores greater than 4. Following the example of Bundesen (1990) we have registered these responses as scores of 4. The encoding models can be extended to account for these higher scores by allowing the VSTM capacity to vary between three integer values rather than just two but this requires an additional free parameter, which is difficult to justify by the ability to model only few of thousands of trials.

### Results

Table 1 displays the goodness of fits in terms of the negative logarithm of the likelihood for the two models of encoding and the two psychometric functions fitted to both observers in Shibuya and Bundesen's (1988) data. Note that the encoding

models and psychometric functions have the same number of free parameters.

The goodness of fits in Table 1 confirms that the log-logistic psychometric function provides a better fit than the exponential psychometric function as found by Petersen and Andersen (2012) and also that the conditioning model offers an additional, although slight, improvement in the goodness of fit.

Table 1: Goodness-of-fits

Psychometric function	Selection model	
	Race	Conditioning
Exponential	1579	1552
Log-logistic	1331	1273

To further examine the fits of the encoding models Figure 1 displays the cumulative score proportions, i.e. the proportion of responses to a given stimulus type with at least  $j$  correctly reported targets along with model fits for both encoding models with the log-logistic psychometric function for subject HV. As is evident from Figure 1, the model fits are very similar. It takes careful inspection to see that there are, in fact, systematic differences. The clearest difference is that when six targets are presented both encoding models tend to overestimate the cumulative score proportion but the conditioning model less so than the race model. Also, when the number of distractors is no greater than two, both models tend to underestimate the cumulative score proportion for exposure durations between 30–70 ms but the conditioning model less so.

For the briefest exposure durations of 10 ms observers rarely reported any targets. In Bundesen's (1990) analysis the few trials in which they did were discarded so that the score was assumed to be zero. This might favor the exponential psychometric function as it constrains the score to be zero for exposure durations shorter than  $t_0$ . We therefore fitted the models to the data with this data adjustment. The conditional model still fitted the data better but more so with the exponential psychometric function than with the log-logistic.

Table 2 lists the parameter values for the fits. Note that the VSTM capacity,  $K$ , and filter-parameter,  $\alpha$ , are comparable across both encoding model and psychometric function. They seem, however, to vary very little with these model variations within observers. The temporal threshold,  $t_0$ , and processing capacity,  $C$ , are not comparable across psychometric functions, only across encoding models. The temporal threshold seems also to vary very little with encoding model within observer and psychometric function. For the log-logistic function the processing capacity, i.e. the sum of hazard rates, varies over time and is therefore given for  $t = t_0$ . The processing capacity is slightly, but consistently, greater for the conditioning model than for the race model. This difference may seem slightly more pronounced for the log-logistic psychometric function ( $4 \text{ s}^{-1}$  averaged over the two observers) than for the exponential function ( $2 \text{ s}^{-1}$  averaged over the two observers) but this might be due to the difference in magnitude of  $C$  as the relative

differences were similar (7% for the log-logistic model and 5% for the exponential model averaged over the two observers).

Table 2: Estimated parameters for psychometric functions (Psy. F.), observer (Obs), and model.

Psy. F.	Obs.	Model	K	$\alpha$	C	$t_0$
Log-log.	MP	Race	3.8	0.40	57	0.036
		Cond.	3.9	0.41	61	0.036
	HV	Race	3.3	0.56	50	0.033
		Cond.	3.2	0.52	53	0.034
Exp.	MP	Race	3.9	0.39	37	0.010
		Cond.	4.0	0.38	38	0.010
	HV	Race	3.3	0.55	35	0.010
		Cond.	3.2	0.52	37	0.010

## Discussion

The differences that we found between the fits of the encoding models are consistent. They are, however, also small. This warrants care in model selection and this is, in fact, our main point. The

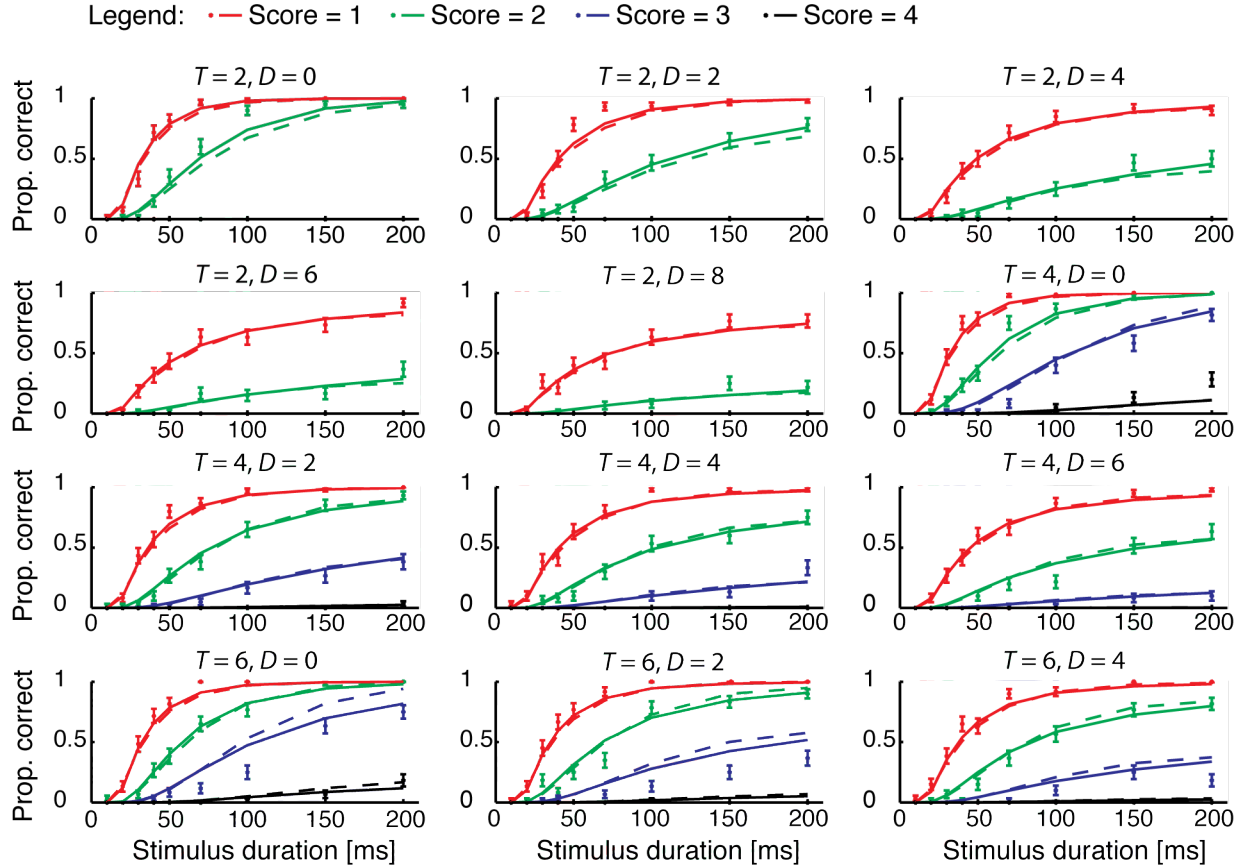

Figure 1: Cumulative score proportions for Shibuya and Bundesen's (1988) whole and partial report experiment with estimates from the conditional (solid line) and race (dashed line) encoding models using the log-logistic psychometric function.  $T$  and  $D$  at the top of each graph indicate the number of presented target and distractor objects respectively.

model fits do not provide strong evidence in favor of one model of selection over another. We find that this is a strong point as the race model has remained unchallenged as the model of selection for two decades of TVA based research.

Parameter estimates varied very little with the type of psychometric function and encoding model. The only consistent differences in parameter estimates between the two encoding models were in the processing capacity,  $C$ . This difference should however be compared to the variability within observers estimated by Finke et al. (2005) to be as high as 20% although variability between observers can also be as little as 10% (Vangkilde, et al., 2011), which is far less than the differences observed between clinic populations and normal controls (Starrfelt, Habekost, & Leff, 2009; Vangkilde, et al., 2011) yet greater than the differences between the models tested here. We therefore preliminarily conclude that parameter estimation is robust to variations in the type of psychometric function and encoding model with the caveat that studies of greater populations than the two observers studied may reveal greater variability.

Model comparison should be based on the models' ability to describe the data, here given by the goodness-of-fit; model flexibility, here given by the number of free parameters; but also on model interpretability. The interpretation of the race model is straightforward; it explicitly gives a mechanism for selection of objects to be encoded into VSTM. On this point the conditioning model is vague. We do not understand what mechanism, cognitive or neural, that could implement selection by conditioning but find that this is an interesting topic for future studies.

### Acknowledgments

The authors thank Claus Bundesen and Hitomi Shibuya for making the data from their whole and partial experiment (Shibuya & Bundesen, 1988) available.

## Abstract

In this study, the development of second-order social cognition and its possible relationship with language and memory were investigated. For this reason two second-order false belief tasks (FBT\_2), a short term memory task (WST), a complex working memory task (LST), a linguistic perspective-taking test (PTT) and a double-embedded relative clause task (REL\_2) were used with 21 Turkish kindergarten children (aged 4-5 years), 47 primary school children (aged 6-12 years) and 10 adults. A general developmental trend was found for all tasks. However, a multiple linear regression showed that once age was partialled out, none of the other tasks could predict FBT\_2 scores. Our findings are consistent with the modularity view that Theory of Mind (ToM) is a faculty of the human mind that does not share intrinsic content with other faculties such as language and memory (Leslie et al., 2004) and also with Apperly's (2011) 'two-systems' account of Theory of Mind. However, it develops together with those other faculties which may constrain the expression of children's false belief reasoning as a manifestation of their social cognitive abilities.

**Keywords:** Second-order Social Cognition; Cognitive Development; Theory of Mind; Language; Memory

## Introduction

In daily life, we are constantly in interaction with other agents, such as co-workers, friends and family members. As a result of this interaction, we form models pertaining to the different mental states of other agents. Social cognition of individuals is shaped based on these models. The ability to understand that different agents have different mental states, such as desires, beliefs, knowledge and intentions, which can be different from one's own, is called Theory of Mind (ToM) (Premack & Woodruff, 1978). Zero-order, first-order, second-order and higher-order reasoning are different levels of social cognition. The objects of zero-order reasoning are the rules of nature and our real-life environment. For instance, if David knows: "There is an apple on the table", he is applying zero-order reasoning. However, in daily life we are not just talking about world facts. Social interaction covers statements such as "David thinks Jessica knows that there is an apple on the table". In this situation David is applying first-order reasoning by attributing a mental state to Jessica. In addition to first-order reasoning, there are even more complex social situations

like "Jack thinks David knows that Jessica knows that there is an apple on the table". This time, Jack is applying second-order reasoning by attributing first-order reasoning to David who attributes a mental state to Jessica who reasons about an object in the real world; therefore we, in turn, are attributing third-order reasoning to Jack. In this study we follow Verbrugge (2009) in using the term 'second-order social cognition' in the same sense as 'second-order theory of mind'.

First-order ToM develops between the ages of three and five (Wimmer & Perner, 1983). Interestingly, second-order ToM develops much later, between the ages of six and nine (Perner, 1988). The reason for this gap is not entirely clear yet and attracts the curiosity of researchers who are working on ToM. In Verbrugge (2009), it is hypothesized that the developmental latency between first and second-order social reasoning is due to children's constraints on serial processing rather than limitations in simple working memory capacity. More explicitly, 6 year-old children may have the ability to represent another person's mental state about their own mental state. However, they cannot apply this ability because of the lack of efficiency in applying the related mental processes serially (cf. Hendriks, Van Rijn, & Valkenier, 2007).

One of the most widely applied verbal paradigms for studying ToM is the false-belief task (FBT), which has first been studied by Wimmer and Perner (1983). The main idea of the FBT is to examine whether children can attribute a false belief to another agent in a given story where they know the reality and the other agent has a false belief. Using language comprehension tasks is another verbal paradigm for studying the development of social cognition. These tasks generally test listeners' semantic and/or pragmatic inferential abilities. In these tasks, the listener has to take the speaker's linguistic alternatives and his/her choice into account to understand the correct meaning of the sentence. In the present study, a complex language comprehension task was used to test children's ability to meet a questioner's expectations of an appropriate answer to his / her questions in a given context, by taking the questioner's perspective.

The development of ToM has been intensely investigated and documented in the literature. However, one of the debatable issues is still if other factors contribute to ToM

understanding during development. There is one influential factor, namely language development (Astington & Baird, 2004; Flobbe, Verbrugge, Hendriks, & Krämer, 2008): Does language have an effect on acquiring ToM, or not? In order to elucidate the relationship between language and social reasoning during development, two language tasks were used in this study. The first one is a complex language comprehension task in which the morphological structure in particular zero- vs. accusative-marked nouns had to be mastered and the second one is a double-embedded relative clause task in which complex syntactic structure was required. Generally, complement clauses are studied in the literature in order to investigate the relationship between the syntactical component of language and ToM. Unlike complement clauses, relative clauses do not necessarily involve mental state predicates. Using relative clauses instead of complement clauses allows us to specifically focus on the structural format of 2-way embedding. This is a purely structural parallel between second-order embedding in the thought domain and second-order embedding in the language domain.

## Method

### Participants

A total of 68 (35 female, 33 male,  $M=7.53$  yrs,  $SD=2.53$ ) children and 10 (5 female, 5 male,  $M=33.48$  yrs,  $SD=10.00$ ) adults participated in the experiments. Children's grades varied from kindergarten to fifth-grade, and their age range varied from 4 to 12 years. There were 21 kindergarten children ( $M=4.43$  yrs,  $SE=.07$ ), 17 first graders ( $M=6.99$  yrs,  $SE=.09$ ), 15 third graders ( $M=9.01$  yrs,  $SE=.08$ ) and 15 fifth graders ( $M=11.00$  yrs,  $SE=.10$ ). A group of 10 adults served as a control group.

### Design

A cross-sectional study with the four above-mentioned age groups was conducted. All subjects participated in the following five tests: word span task, second-order false belief task, perspective-taking test, second-order relative clause task, and listening span task.

All of the tests were completed in one session, which varied from 25 minutes to 35 minutes. Children were tested in a quiet empty classroom at their school.

### Materials and Procedures

**Word Span Task (WST)** Children's short term memory was tested with Ünal's (2008) Turkish version of the WST. Mono-syllabic Turkish words such as "saç, tuz" and "yurt" (hair, salt and country) were selected considering their frequency in daily usage and easy pronunciation. There are a total of seven sets, which consist of 2 to 8 words. Each set comprised 3 sub-sets. An example of a set of 2 words is as follows: i) köşk muz (manor banana); ii) pil üst (battery upper); iii) buz dört (ice four).

The words from these sets were read to the participants starting from the 2-word set. After reading one set (i.e. köşk muz), the participant repeated the words in that order. If the participant made two errors, i.e., any error in two of the three sub-sets of that level, the experiment was terminated. If he/she made fewer than two errors, the subsequent, next higher, set was read (i.e. the 3-word set). The word span equals the correct number of words at the respective level at which the child makes fewer than two errors. Thus, in the analysis the word span range may vary between 1 and 8.

**Second-order False Belief Task (FBT\_2)** This task consists of two different second-order false belief stories, namely the 'Birthday Puppy' Story and the 'Chocolate Bar' Story. Both stories were adapted from English to Turkish from Flobbe et al. (2008) with the authors' permission. These stories were told to the subjects by presenting Flobbe et al.'s (2008) drawings. Second-order embedding structures such as "Mary thinks that John thinks the chocolate is in the drawer" were not used in the stories.

For both stories, the drawings were shown to the participants while the stories were being told. The order of stories in the false belief task was balanced. If a participant gave correct answers to the reality control (Where is the chocolate now?), first-order ignorance (Does John know that Mary has hidden the chocolate in the toy chest?), linguistic control (Does Mary know that John saw her hide the chocolate?), second-order false belief (Where does Mary think that John will look for the chocolate?) and justification (Why does she think that?) questions, the participant's score of the first story was 1. The total score for both of the false belief stories is therefore minimally 0 and maximally 2. Since the questions preceding the second-order false belief question are control questions, they need to be answered correctly in order for the false belief question to be possibly answered correctly.

**Perspective-taking Test (PTT)** The perspective-taking test is a complex language comprehension task including two close-ended questions with two options. In the story, Ali tells Ayşe that he is planning to go to the bookstore today. Ayşe wants Ali to buy a storybook. Ali goes to the bookstore and buys the book. While Ali is going back home, he sees his friend Mehmet on the road. Mehmet asks Ali what he did today. At this point, the experimenter asks the participant which of the following answers, (a) or (b), Ali gives to Mehmet:

- a) Kitab-ı al-dı-m. (I bought the book.)  
Book-ACC buy-PAST-1PSg
- b) Kitap al-dı-m. (I bought a book.)  
Book buy-PAST-1PSg

After that, the experimenter continues to tell the story. Ali goes back home. Ayşe opens the door and asks Ali what he did today. This time the experimenter asks the participant which of the following answers, (a) or (b), Ali gives to Ayşe: a) Kitabı aldım or b) Kitap aldım. The order of the answers to the close-ended questions provided to the

subjects was balanced across participants. Since Mehmet asks the question without having been introduced to the book before, the expected answer for the first question was the answer with zero-marking: “Kitap aldım” (referring to “a book”). The reasoning behind this answer is as follows: Ali knows that Mehmet does not know that Ali went to the bookstore to buy a storybook for Ayşe. However, the expected answer for the second question was “Kitabı aldım” (referring to “the book”) rather than “Kitap aldım”, since Ayşe had told Ali that she wanted him to buy a storybook. The reasoning behind this answer is as follows: Ali knows that Ayşe wants to know whether Ali bought the storybook or not.

If the participant gave the expected answer to the two questions, s/he received a score of 2 points.

**Double-embedded Relative Clause Task (REL\_2)** This task is related to the comprehension of relative clauses (RC) in Turkish. This task was adapted from Özge (2010) with the author’s permission. The questions and the drawings were modified to double-embedded RCs in order to analyze the participants’ second-order language embedding abilities, on a par with their second-order ToM abilities. One practice and 6 experimental items were used. Figure 1 demonstrates the drawings for one of the questions related to this task. The critical positions for finding the correct answers were equally distributed across the drawings (3 times in the first row and 3 times in the second row) and between right (2 times), left (2 times), and central position (2 times).

First, introductory pictures were shown to the participants in order to familiarize them with the animals in the action by telling the name of the animals and the actions (e.g., “this is a pushing sheep”). After that, the pictures representing the questions were shown one by one (see Figure 1).

Figure 1: Hangi resimde kuzuyu iten maymunu iten bir kuzu var? (“In which picture there is a sheep pushing a monkey that is pushing a sheep?”)

The first and second rows of the picture were pointed out in order to make it clear that there are two separate lines of pictures by saying, “This is the first picture and this is the second picture”. In the trial session, it was explained that the participants were required to point out the row with the animals related to their answer. If they could not answer correctly in the trial, the correct animals were pointed out by the first author with necessary explanations. The sentences

were repeated up to 4 times. Participants’ scores could range from 0-6.

**Listening Span Task (LST)** In order to measure complex working memory, Ünal’s (2008) English-to-Turkish adaptation of the original LST was used with the author’s permission. The task consists of sets of sentences read out to the participants one by one. There are a total of five collections, each of which consists of six sets of sentences. The first collection contains six sets of two sentences each, the second collection contains six sets of three sentences each, and so forth, until the fifth collection, which contains six sets of six sentences each. An example of a 3-sentence set of LST is as follows: i) Muzlar bisiklete biner. (Bananas ride bicycles); ii) Elimiz beş parmaklıdır. (Our hands have five fingers); iii) Soğan acıdır. (Onions are hot).

The participants were expected to first judge the truthfulness of the sentences by saying “Yes” or “No”. Secondly, they had to recall the last word of all the sentences of a set told to them, in reverse order. After they gave an answer to the first sentence, the next sentence was told to them. For example, for the 2-sentence set, if the first sentence is “Muzlar bisiklete biner.” (Bananas ride bicycles), the participants were required to say “Hayır<sup>1</sup>;biner”. After that, if the second sentence is “Elimiz beş parmaklıdır.” (Our hands have five fingers), they were required to say “Evet<sup>2</sup>;parmaklıdır, biner.”. If the participant made less than two mistakes in a sentence collection, the subsequent sentence set, which comprised one more sentence, was told to the participant. The score of the participants equaled the number of sentence collections in which they did not make more than one mistake. Participants’ scores could range from 0-6.

## Hypotheses

We hypothesized main effects of grade for all tasks. Children’s performance should increase with increasing grade. Furthermore, we hypothesized that FBT\_2 could be predicted by the remaining tasks, in particular by the complex language tasks, PTT and REL\_2, to the extent that those share variance with it.

## Results

First, the statistical analyses of children’s responses to the five tasks are presented. Later, the results of the fifth graders will be compared with the results of adults. The p values are two-tailed, unless stated otherwise (in which case they are one-tailed). In order to analyze the developmental trend in the tasks used in the experiment, the data was divided into four groups according to the children’s grades (kindergarten, 1st, 3rd, 5th grade). Since the data violates normality assumptions, non-parametric Kruskal-Wallis and Mann-Whitney tests were used. Since six Mann-Whitney Tests were used to test the difference across the grades, the

<sup>1</sup> ‘Hayır’ means ‘No’.

<sup>2</sup> ‘Evet’ means ‘Yes’.

alpha level for the Bonferroni correction was set to .008. Although the data was not normally distributed, linear regression analysis was used to investigate the relationship between the second-order false belief task and the other tasks. Error bars in Figures 2-6 represent standard errors.

### FBT\_2

There is a significant difference in performance between the grades ( $\chi^2(2) = 40.22, p = .000$ ). According to the Mann-Whitney Tests, while there is a steady increase in performance, there is no significant difference between the first and third grades and between the third and fifth grades. However, there is a significant difference between kindergarten and grade one ( $Z = -3.73, p = .000$ ), kindergarten and grade three ( $Z = -4.73, p = .000$ ), kindergarten and grade five ( $Z = -5.36, p = .000$ ), and grade one and five ( $Z = -2.99, p = .003$ ). Figure 2 shows the mean values of the FBT\_2 score according to the grades. Since all of the adults and all of the fifth graders answered all of the questions correctly, there is no significant difference between the adults' and fifth graders' FBT\_2 performance ( $\chi^2(2) = 0.00, p = 1.00$ ).

Figure 2: The development of FBT\_2

### WST

There is a significant difference between the grades ( $\chi^2(2) = 24.67, p = .000$ ). According to the Mann-Whitney Tests, there is no difference between the first, third and fifth grades, while there is a significant difference between kindergarten and grade one ( $Z = -3.06, p = .002$ ), kindergarten and grade three ( $Z = -4.14, p = .000$ ), and kindergarten and grade five ( $Z = -3.59, p = .000$ ). Figure 3 shows the mean values of the Word Span Task score according to the grades. The analysis showed that there is a significant difference between the adults' and fifth graders' performance ( $\chi^2(2) = 8.925, p = .003$ ).

Figure 3: The development of WST

### PTT

There is a significant difference between the grades ( $\chi^2(2) = 8.53, p = .036$ ). According to the Mann-Whitney Tests, there is no difference between the kindergarten and grade one, grade one and three, grade one and five, grade three and five, while there is a significant difference between the kindergarten and grade five ( $Z = -2.473, p = .006$ , one-tailed). Figure 4 shows the mean values of the perspective-taking test score according to the grades. The analysis showed that there is no significant difference between the adults' and fifth graders' performance ( $\chi^2(2) = 1.778, p = .182$ ).

Figure 4: The development of PTT

### REL\_2

There is a significant difference between the grades ( $\chi^2(2) = 27.37, p = .000$ ). In order to see which grades differ significantly from each other, Mann Whitney Tests were used. Figure 5 shows the mean values of the double-embedded relative clause score according to the grades. The analysis showed that there is a significant difference between the adults' and fifth graders' performance ( $\chi^2(2) = 6.096, p = .014$ ).

Figure 5: The development of REL\_2

### LST

There is a highly significant difference between the grades ( $\chi^2(2) = 30.87, p = .000$ ). According to the Mann-Whitney Tests, there is no difference between the kindergarten and first grade, nor between third and fifth grades, while there is a significant difference between the kindergarten and grade three ( $Z = -3.53, p = .000$ ), kindergarten and grade five ( $Z = -4.64, p = .000$ ), grades one and three ( $Z = -2.92, p = .003$ ), and grades one and five ( $Z = -4.08, p = .000$ ). Figure 6 shows the mean values of the Listening Span Task score according to the grades. The analysis showed that there is a significant difference between the adults' and fifth graders' performance ( $\chi^2(2) = 4.729, p = .030$ ).

Figure 6: The development of LST

### PTT Predicting FBT\_2

Since the data violates normality, the non-parametric Spearman's Rank Order Correlation was used to test the relationship between total FBT\_2 and PTT scores. This analysis showed that there is no significant relationship between total FBT\_2 and PTT ( $r_s = .19$ ,  $p = .126$ ). Partial correlation was also used in order to control the other variables. When age is controlled for, the previous correlation of  $r_s = .19$  between PTT and FBT\_2 drops to  $-.095$  ( $p = .444$ ); when WST is controlled for, the correlation drops to  $.12$  ( $p = .922$ ), when REL\_2 is controlled for, the correlation drops to  $.036$  ( $p = .772$ ) and when LST is controlled for, the correlation drops to  $-.22$  ( $p = .860$ ).

### REL\_2 Predicting FBT\_2

Since the data violates normality, the non-parametric Spearman's Rank Order Correlation was used to test the relationship between total FBT\_2 and REL\_2. This analysis showed that there is a significant relationship between total FBT\_2 and REL\_2 scores ( $r_s = .54$ ,  $p = .000$ ). Bivariate regression was also used in order to predict the model of REL\_2 score predicting the FBT\_2 score. Using the enter method, the FBT\_2 score could be predicted from the REL\_2 score by the following formula:  $0.24 \times \text{REL}_2 + 0.673$  ( $F_{66,1} = 26.196$ ,  $p = .000$ ,  $r = .533$ ,  $R^2 = .284$ ). Partial correlation was also used in order to control the other variables. When age is controlled for, the previous correlation of  $r = .533$  between REL\_2 and FBT\_2 drops to  $.10$  ( $p = .42$ ); when WST is controlled for, the correlation drops to  $.39$  ( $p = .001$ ); when PTT is controlled for, the correlation drops to  $.52$  ( $p = .000$ ) and when LST is controlled for, the correlation drops to  $.25$  ( $p = .041$ ).

In the light of the partial analyses, multiple linear regression was used with age and REL\_2 scores as independent variables and FBT\_2 as dependent variable. Using the enter method, the FBT\_2 score could be predicted from age and REL\_2 score by the following formula:  $\text{FBT}_2 = 0.039 \times \text{REL}_2 + 0.25 \times \text{age} - 0.751$  ( $F_{65,2} = 42.091$ ,  $p = .000$ ,  $r = .751$ ,  $R^2 = .564$ ). However, only the contribution of age is significant ( $\beta = .692$ ,  $t = 6.47$ ,  $p = .000$ ).

### Multiple Linear Regression for FBT\_2

Two models were constructed by using multiple linear regression to predict the FBT\_2 score: first just with age as predictor and second with age and all tasks. Table 2 shows the correlations of all tasks for FBT\_2. Using the enter

method, the FBT\_2 score could be predicted by age by the following formula:  $0.27 \times \text{age} - 0.814$  ( $F_{66,1} = 83.965$ ,  $p = .000$ ) and by age and all tasks by the following formula:  $0.236 \times \text{age} + 0.145 \times \text{WST} + 0.045 \times \text{REL}_2 - 0.034 \times \text{LST} - 0.130 \times \text{PTT} - 1.098$  ( $F_{62,5} = 17.519$ ,  $p = .000$ ,  $r = .765$ ,  $R^2 = .586$ ). However, only the contribution of age is significant ( $\beta = .655$ ,  $t = 5.45$ ,  $p = .000$ ). Collinearity diagnostics showed that age (94%) and WST (90%) each load highly on a different single dimension. This means that age and the WST do not share variance with each other. On the other hand, PTT, REL\_2 and LST share some variance with one another. Still they mainly load on their own distinctive dimension. This is because they are also related to different abilities. Moreover, the LST (60%) and the REL\_2 (75%) load highest on the same dimension which shows that both tasks tap into the same cognitive ability.

Table 2: Correlations of all tasks and age for FBT\_2

Variable	Correlation (r)	p
Age	.748	.000**
WST	.518	.000**
PTT	.160	.096 n.s.
REL_2	.533	.000**
LST	.503	.000**

### General Discussion and Conclusions

As can be seen clearly from Figure 2, a linear developmental trend was found for the second-order false belief task score from grade one (6- 7 years) to grade five (10- 12 years), preceded by a big step between kindergarten and grade 1. We can say that second-order false belief reasoning starts to develop around the age of 6, and reaches adult-like understanding at around the age of 9;5 (grade 5). These findings are compatible with Perner and Wimmer's (1985) study, which states that second-order false belief understanding occurs after the age of 6. Although kindergarten children failed in the second-order false belief task on average, there were three of them who succeeded in the 'Birthday Puppy' Story and one of them who succeeded in both the 'Birthday Puppy' Story and 'Chocolate Bar' Story. Since their Listening Span Task and double-embedded relative clause task scores were better than the others, this is compatible with the view that children before the age of 6 may indeed have second-order social cognition which may show itself if the respective cognitive resources have also developed.

The results of the Word Span Task showed a significant and clear developmental trend from kindergarten to third grade. Fifth graders' score was somewhat lower than that of the 3rd graders, but only insignificantly.

The results of the Perspective Taking Test showed that kindergarten children and first graders had scores around 1 which is the score expected by chance. The salient development occurs between 1st and 3rd grade. Making pragmatic inferences by picking up morpho-syntactic clues

like case-marking is a very advanced meta-linguistic skill. Giving correct answers to the questions requires a comparison between the two case forms and a decision which of them is better suited for the given context. Even adults' performance was not perfect and did not significantly differ from that of 5th graders. However, unlike children, some of the adults changed their first wrong answer and gave a correct answer after hearing the second question. This shows that some of the adults took the hearer's perspective and/or the experimenter's intention of asking those questions into account.

To the best of our knowledge this is the first time that a double-embedded relative clause task has been devised in a Turkish developmental study. Our result revealed a very strong developmental trend in the task. Also, adults outperformed fifth graders in this task.

In Listening Span Task, participants were expected to judge the semantic truth of the sentences, to report it, to remember the last word of that sentence, and then repeat the same steps again for the next sentence by also reporting the last word of the previous sentence, and so on. Since in Turkish the present form of the verb takes the suffixes –er, -ar, -ir, -ür, -ur for positive sentences and takes the suffixes –maz, -mez for the negative ones, the most challenging part of the task for children and even for some adults was to repeat the last word of the sentence when its semantic truth was false. So, they must inhibit the regular way of reporting, and have to report it in the instructed form. This inhibition in the Listening Span Task is thought to be similar to the inhibition necessary in false belief reasoning. The results showed a strong developmental trend, again particularly between first and third graders.

Even though second-order false belief scores could be significantly predicted by all other tasks (except for Perspective Taking Test), the regression analyses showed that only the contribution of age was significant. Once age was taken out, none of the other tasks could predict second-order false belief task anymore. In view of theoretical accounts of ToM, our findings are compatible with Leslie et al.'s (2004) modular account of ToM. He and his colleagues argue that ToM is a separate cognitive faculty as compared to language or memory. It is innate, i.e., in principle in place from early on, however, in order to manifest itself it may need to await the cognitive maturation of the child in those other domains. The “serial bottleneck” (Verbrugge 2009) might be one of those constraints that is overcome during development. Our findings are also compatible with Apperly's (2011) 'two-systems' account of ToM. Apperly posits that low-level efficient processing modules take care of simple ascriptions of perception, knowledge and belief, while high-level ToM makes use of less efficient and slower to develop general knowledge and inferential reasoning processes.

Since in our study we found concurrent development in all the cognitive abilities that we tested, that is, no delay between any of them, ToM may at any time have been supported just sufficiently enough to manifest itself at that

level. Indeed, it might be impossible to prove the relation between ToM and the other cognitive domains in a cross-sectional study like ours, but only in a longitudinal study where such delays may be observed within rather than across individuals.

# Learning of motor maps from perception: a dimensionality reduction approach

Ankit Awasthi, Sadbodh Sharma, Amitabha Mukerjee (aawasthi, sadbodh, amit@cse.iitk.ac.in)

Department of Computer Science and Engineering, IIT Kanpur

## Abstract

The role of perception in sighted infant motor development is well-established, but what are the processes by which an infant manages to handle the complex high-dimensional visual input? Clearly, the input has to be modeled in terms of low-dimensional codes so that plans may be made in a more abstract space. While a number of computational studies have investigated the question of motor control, the question of how the input dimensionality is reduced for motor control purposes remains unexplored. In this work we propose a mapping where starting from eye-centered input, we organize the perceptual images in a lower-dimensional space so that perceptually similar arm poses remain closer. In low-noise situations, we find that the dimensionality of this discovered lower-dimensional embedding matches the degrees-of-freedom of the motion. We further show how complex reaching and obstacle avoidance motions may be learned on this lower-dimensional motor space. The computational study suggests a possible mechanism for models in psychology that argue for high orders of dimensionality reduction in moving from task space to specific action.

**Keywords:** motor development, perception-action models, dimensionality reduction, reach learning

## Introduction

That the apparently random arm movements by neonates may have a role in terms of learning visuo-motor control is a position that has gained strength in recent years (A. Van der Meer, Weel, & Lee, 1995; Adolph & Berger, 2006). Visual control of arm movement is evident almost immediately after birth, when neonates appear to struggle with artificial handicaps to keep their arm in the field of view, such as when small weights are tied to their arms, or when they appear to be purposefully keeping their arms within a narrow beam of light (A. van der Meer, 1997).

The emphasis on motor development over the last few decades, arising from the linkage between perception and action that has driven new theories of dynamic cognition (Thelen, Smith, Lewkowicz, & Lickliter, 1994), has further highlighted this connection. Indeed, there is evidence to suggest that the very representation of action has some relation to mental imagery which may provides the prospective structure for organizing motions (Caeyenberghs, Wilson, Van Roon, Swinnen, & Smits-Engelsman, 2009). Studies on monkeys report that a large majority of neurons implicated in the reach planning area in the posterior parietal cortex, encode location in eye-centred coordinates (Batista, Buneo, Snyder, & Andersen, 1999). In addition, nearly half the neurons in the ventral premotor area - thought to be implicated in visual grasp planning - are responsive to eye-centered image data (Mushiake, Tanatsugu, & Tanji, 1997). It is thought that the eye-centric neural computations work together with other body-centric and arm-centric systems (Graziano, 2011) but much of the planning is thought to invoke eye-centered or visual images of the arm.

However, the exact mechanisms by which the complex high-dimensional visual stimulus is used for motor control of the arm, remain unclear. While there have been many computational studies of different aspects of motor development, several involving robots with embodied cameras (Beltrán-González, 2005; Hoffmann, Schenck, & Moller, 2005), such works usually address the question of managing the complexity and dimensionality reduction only peripherally (Jordan & Wolpert, 1999). A particularly interesting approach was the modeling of reaching and grasping via neural networks (Kuperstein, 1991), and a related attempt to map the workspace using self-organizing maps (Saxon & Mukerjee, 1990). However, these works do not deal directly with image models.

On the other hand, another body of work in robot motion planning attempts to construct paths through a workspace that are optimal in various senses of reducing path length, kinematic smoothness, dynamic smoothness, energy costs, etc. A class of efficient methods are based on sampling the motion space, which may also be rather high-dimensional, though of the order of tens, not thousands as in the image space. Such stochastic approaches include probabilistic roadmaps or branching trees of possible paths through the free space. However, these algorithms, some of which also have cognitive ramifications, work primarily with inputs defined directly in the workspace, and do not work on the image space as the input (Choset, 2005).

The objective of this work is then to try to develop a model that would reflect motor properties in an embedding derived purely from the visual space. Thus, we consider the mechanisms by which the system may observe certain similarities between perceived arm configurations to construct a local neighbourhood of visual configurations. These local neighbourhoods are presumed to lie on a low-dimensional surface in the very high-dimensional image space. In the ISOMAP algorithm being used here (Tenenbaum, Silva, & Langford, 2000), these local neighbourhoods are assumed to be linear in the dimensionality of the manifold, and they are then “composed” to construct the global relations between distant arm configurations. For the purposes of the demonstration we have used a simulated two degree of freedom arm.

## Reach planning and obstacle shifts

The input consists of a large number of images showing the arm in random poses in its workspace. These images are then mapped to a lower-dimensional manifold. We shall use the term *visuo-motor map* and *low-dimensional embedding* for this image to low-dimensional map. Note that the variables in the low-dimensional map are just mathematical abstractions that emerge from the computation and are not based on

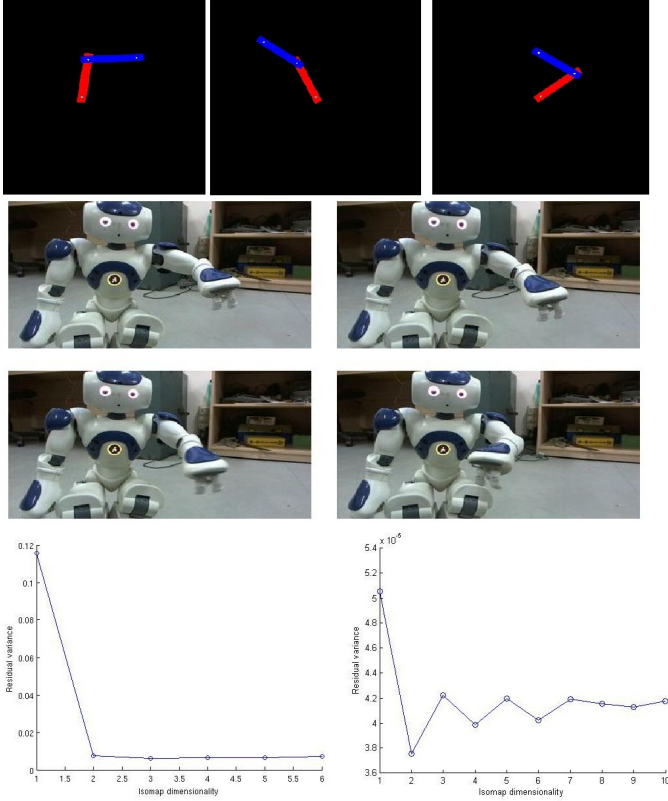

Figure 1: Image data from (a) two-degree of freedom planar arm, (b) humanoid robot nao moving one arm along a linear trajectory. The residual variance error in the lower-dimensional space after ISOMAP, versus the dimensionality of the embedding is shown below. Left: planar arm (2-DOF). Right: humanoid robot nao moving arm in straight line (1-DOF); errors are noisy,  $\sim 10^{-5}$ .

prior knowledge about any physical variable. Thus, we use no knowledge of the kinematics or geometry of the arm, except the initial image data. Despite this paucity of supervisory knowledge, we are able to identify the number of degrees of freedom (two) of the motion system, and also a set of (two) parameters that can be controlled to move the arm to different configurations within its workspace. We also show that these parameters can be easily mapped to physical variables such as joint angles.

The visuo-motor map is obtained as a graph embedded in the lower-dimensional space, each node is mapped to an image in the much higher-dimensional image space. The structure of the graph is shared between both the original image space as well as the lower-dimensional embedding space. In the following, we shall consider a) constructing such a map (with no prior knowledge about the physics of the arm), b) using it to map a path from a source to a target in the absence of obstacles, and c) map obstacles that may impinge on the path, and plan trajectories that may avoid it. A further aspect is that with increasingly dense samples in the image space,

the models become increasingly accurate.

We demonstrate the dimensionality reduction process - part (a) - on three domains - images of a simulated two-link planar arm moving to various positions in its workspace, a humanoid robot moving its arm along a straight line, and two coordinated planar arms moving a box. A two-dimensional interpolation is shown to work well for the first situation (two degree of freedom in the arm). For the other two situations, we find that one dimension is enough. For motion planning (part b), and obstacle avoidance (c), we restrict ourselves to only the first simulated arm - the two degree of freedom simulation of the upper and lower limbs.

For motion planning, both initial and desired configurations, as well as obstacles, if any, are known only in the visual space. The initial and target images are mapped to the manifold embedding using the out-of-sample mapping - i.e. they are interpolated based on the “nearest” images and the same interpolation is applied to the embedded points. Now, a mapping to the goal can be discovered in terms of edges in the graph, which actually constitute a roadmap, but in the visuomotor space and not in the usual configuration space of robot motion planning. The problem of having the visuomotor map represent obstacles is quite challenging, since some obstacles (such as the own body) may be permanent, but in most situations other constraints would arise in the workspace. As the obstacle positions shift with respect to the arm, must it relearn the visuo-motor embedding every time? This is indeed what happens to most robot-motion planning algorithms, and handling dynamic obstacles remains a considerable challenge in robotics. In our case, we assume that our map is a base map of the maximal free space, constructed in the absence of all movable obstacles. This results in an embedding from which nodes can be deleted if an obstacle is introduced to a region of the image space which was otherwise occupied by an arm in one of the data points. Such situations are handled by marking as *blocked* the non-free nodes of the graph in the lower-dimensional space. To start with therefore, we consider full rotations for each of the two joints of our simple 2-DOF arm, and images are randomly sampled across this entire  $360 \times 360$  degree rotation range.

As obstacles are introduced into the workspace, the system marks those nodes of the graph that visually overlap with the obstacle as *blocked*, and motions are restricted to the remaining “free” parts. Of course, this method assumes that if two nodes are in free space, the path between them is also free, which is not true for the non-linear mapping space. However, considering how densely sampled the image space of a limb in daily use is for an organism, we may argue that in real situations, the visuomotor map will have a dense mapping so that this assumption is far more likely to hold.

An additional characteristic of the learning process reflects increasing accuracy in the visuo-motor map. As the system encounters more and more motions in the visual space, the graph becomes more dense, and the accuracy of plans improves. This may also contribute to the observations of in-

creasing fluency in infant motions, though much of it is also due to development in the musculatory system.

## Dimensionality Reduction

We consider a computational system exposed to a large number of images reflecting different motor configurations of its arms. At the same time, it has muscle sensations of how the arm motion is executed. In this work, we focus primarily on the visual input space. We first observe that the data there, captured here in terms of a set of large images, constitute an extremely high dimensional image space. Every pixel may be considered to be independent, so that a  $800 \times 800$  image (figure. 1(a)), is a point in a  $64000$  dimensional space. That is each image is one point out of  $N^{64000}$ , where  $N$  is the number of values a pixel can take. Clearly, the system needs to reduce the complexity of this data drastically. In the biological system, this is achieved by a combination of neural data compaction processes starting in the retina, as well as a number of learned responses that eventually result in responses in the pre-motor areas, primarily in the posterior-parietal cortex (PPC) (Batista et al., 1999). Here we consider a computational model for constructing a lower-dimensional manifold from the image data.

Many approaches have been tried for dimensionality reduction. One class of approaches assume that the underlying manifold from which the observations are drawn is linear. Linear dimensionality reduction methods include linear methods such as Principal Component Analysis or Multi-dimensional Scaling (Bishop, 2006). On the other hand, non-linear dimensionality reduction assumes that the data is drawn from a manifold - a surface that is mappable everywhere to a disk in a euclidean space of much lower-dimension. Such NLDR algorithms include Isomap, Locally-Linear Embedding (LLE), Local Tangent Space Alignment, etc. (Lee & Verleysen, 2007). In this work, we have used the ISOMAP algorithm, which attempts to preserve geodesic distances in the lower-dimensional mapping.

### Isomap on the image space

To see how the ISOMAP algorithm is applied to our image space, we observe that a continuous motion will result in a sequence of images that lie along a one-dimensional curve in the image space. This is because images from successive instants in time are likely to be very similar, and extending this similarity locally would result in a 1-manifold. This applies to complex real images (figure. 1b) Now, let us consider a two-degree of freedom arm. For the two-degree of freedom, it turns out that all such one-dimensional trajectories in the image space are found to lie on a surface, which is everywhere mappable to a disk in the euclidean plane ( $R^2$ ). Thus, all these images lie on a curve 2-dimensional manifold in the image space (figure. 1). Distances between configurations can be thought of as distances between the shortest paths (geodesics) that lie on this manifold. The Isomap essentially solves an optimization problem where the lower-dimensional points are to

be chosen so as to minimize the error in these geodesic distances. This is the *residual error* which is reported in the graphs in figure 1c. If there is a sharp drop in the error at some value of the dimension used, then one assumes that this dimension is a good estimate for the dimensionality of the underlying manifold. In some cases (e.g. for the Nao robot images), all the errors are less than  $10^{-5}$  - this implies that the error is already very low at dimension one, so  $d=1$  is a good estimate for its dimensionality.

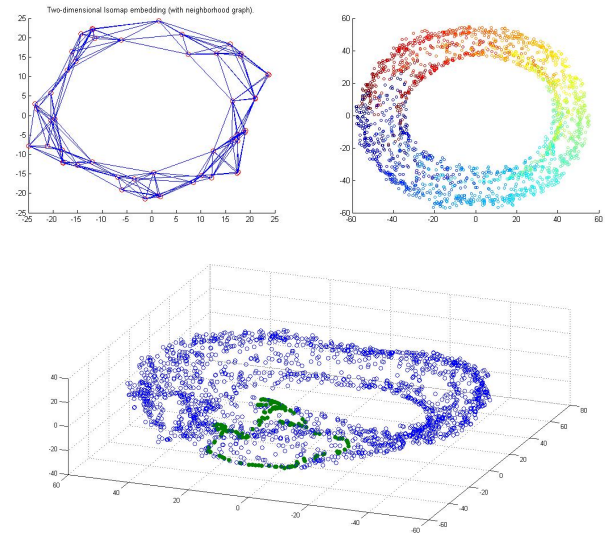

Figure 2: Two-dimensional embeddings generated by ISOMAP. Top Left: map from 50 robot images. Top Right: map from 2000 images showing variation of  $\theta_1$  along the manifold. Bottom: map in 3d showing a cross-section with  $\theta_1$  kept constant and  $\theta_2$  varying. Note that the topology of the embedding actually reflects the topology of the  $\theta_1, \theta_2$  space - in that the  $\theta_1$  variation occurs along the ring (top right figure), while the  $\theta_2$  variation is approximately radial (bottom). Note that the 50-case also captures the cyclic nature of  $\theta_1$ , though the resolution is poor. This suggests the torus topology of the  $\theta_1, \theta_2$  space.

### Out of sample points

A significant difficulty with non-linear dimensionality approaches is that these models are not very good for mapping novel (unseen) data points. In order to overcome this very significant difficulty, some approaches such as the Locality Preserving Projections (LPP) (Lee & Verleysen, 2007). Here a linear mapping is constructed based on a quadratic function that attempts to preserve some aspects of the non-linear data. However, the inverse mapping (from lower dimension to the original space) in such systems is poor, and we have restricted ourselves to true non-linear models.

In order to solve the out of sample interpolation problem, we have borrowed an idea from Locally-Linear Embedding, where a local approximation can be constructed for novel

points based on a weighted linear approximation in the image space. Now, the same weights are used in the lower-dimensional space to obtain a mapping for the point in that space. Indeed, in the LLE, the fact that these weights remain the same in the lower-dimensional space is the constraint that is the basis for its optimization. The underlying assumption is that locally, the nearest neighbours around the novel point may be approximated by a linear surface in both the image space and the target space. While the Isomap algorithm is premised on a somewhat different (global geodesic) constraint, the locally linear approximation is not too far off for the isomap, especially if the sampling is dense. Thus, this method is here adopted to our isomap data; though it is only approximate, the method appears to work well in practice.

Thus, the objective of this work is to use visual input that is as general as possible, but to show that for certain functional situations, it can lead to much reduced dimensionalities. Thus, here, the very fact that it reflects different configurations of the same physical arm restricts its variation in the image space. Although we have experimented with several other dimensionality reduction techniques, we report here only the results based on ISOMAP. The approach is to first reduce the dimensions of the visual input and then use this compact representation to do path planning in the presence of obstacles. Also, we show that a simple mapping can be learnt between the low dimensional embedding generated by ISOMAP and the motor signals and thus effectively eliminating the problem mentioned above.

## Visuo-Motor embedding

We conducted the following experiments on 100 x 100 images of a robot. For our experiments, we assumed that the robot is free to move all around - that is there are no restrictions on  $\theta_1$  and  $\theta_2$ , i.e.,  $0 \leq \theta_1 \leq 360$ ,  $0 \leq \theta_2 \leq 360$ . The lower dimensionality embedding generated by the Isomap, as shown in figure 3, is the visuo-motor embedding since it captures motor signals using visual data and both can be arrived at using the embedding.

### Mapping Visuo-Motor Embedding to Motor Signals

In this experiment, we illustrate that the ISOMAP not only reduces the number of dimensionality optimally, but this reduction is not arbitrary and geometry of the embedding captures important insights into parameterization of the data -  $\theta_1, \theta_2$  (figure 3). In order to further substantiate this point we show that there exists simple mapping from the embedding to motor signals -  $(\theta_1, \theta_2)$ . We used a 1-hidden layer (10 hidden units) feed forward neural network with linear output to learn the mapping with small errors. Moreover the parameters governing the data -  $\theta_1, \theta_2$ , can be seen as motor signals given to manipulate the robot. Note that, once a path is found in the embedding space, such a mapping is required to realize it in real i.e., generating the actual motor signals to traverse the path. While there exists a simple mapping from the embedding space to the motor signals, it is very hard to

Figure 3: ISOMAP embedding (torus) with points with a sampling of images. The base angle (what we call  $\theta_1$ ) changes along the circumference of the torus and  $\theta_2$  along the radius of the torus.

learn a mapping directly from the sensory input (image space) to motor signals ( $\theta$  space) (see figure 4)

Figure 4: Comparison of the performance of neural network when learnt from high dimensional images (left) and low dimensional embedding (right) to  $\theta_1, \theta_2$  for the two-link manipulator.

### Mapping Obstacles to Visuo-Motor Embedding

Given an obstacle, we mark all the points which are blocked by the obstacle as colliding and others as collision free configurations (this can be checked very easily in the image space) resulting a set of collision free points in which the path can be planned. An important advantage of this method is that it avoids recomputation of the embedding and obstacle mapping for each obstacle separately. The set of collision free points can be easily updated in the event of a moving obstacle (figure 5), new obstacles appearing in the workspace, and old obstacles going away. This also preserves the topology of the embedding.

Figure 5: Robot and obstacle configurations and corresponding mapping to embedding space. The set of collision free points can be easily updated for a moving obstacle as shown. Moreover, if a previously free path becomes obstructed due to movement of an obstacle or appearance of a new obstacle, a new path can be easily be planned with the updated set of collision free points. Blue points here are the set of collision free points and green points the set of colliding points. Red color shows the points along the path from the initial configuration to final configuration

### Path Planning in Visuo-Motor Embedding

Once we have the embedding points and a set of collision free points we can plan a path between any pair of start and end points, using any of the graph search algorithms. In case, the start or end point is not in the embedding, a nearby point is found in the embedding and then path planning is done between those points. One of the important observations is that a shortest path query in the graph, results in a path which avoids any redundant movements which is consistent with how a human would do if presented with same planning task. In other words, the shortest path in the embedding space corresponds to least changes to parameters -  $\theta_1, \theta_2$ . (see figure 6) Moreover, as an obstacle changes its position in the workspace, the obstructed points can be removed as visually perceived and a new path can be planned avoiding the obstacle.

### Learning a representation?

We have shown that this process, starting from a set of images and no other information, is able to discover a number of facts. We present these facts, which we call a *naive representation*, presenting in parentheses what a robotics text may call an analog for these.

- a two dimensional manifold obtains then best reduction in residual error. (Robotics: it has two degrees of freedom)
- the structure of the low-dimensional 2-D manifold is that of a torus, so it is cyclic in both dimensions, i.e. it is a  $S^1 \times S^1$  topology. (R: it is an  $S^1 \times S^1$  topology)
- if we associate two variables with these 2 DOFs, we may have one go around the torus in the main direction, and the

other along the thickness, then these capture some aspects of the variation (R:  $\theta_1, \theta_2$ )

- any node in the graph associated with two variables is mapped to the image space, and any image used in the original input is mapped to a node. (R: forward and inverse kinematics)
- the space of these variables is connected with edges that denote nearest neighbours. (R: there is a roadmap)
- given any images for the start and end positions, it is possible to find a path connecting them using these edges. (R: roadmap-based path planning)
- given an obstacle, the system can determine which configurations hit the obstacle in the image space. The corresponding nodes are removed in the manifold graph. (R: the C-space map of an obstacle).
- given an obstacle and a start and goal image, a path can be found via those edges not incident on any of the obstacle nodes. (R: C-space obstacle avoidance).

The above analogies are of course very coarse. Only the topology is really preserved; none of the metric properties are guaranteed to hold; thus the path obtained may not be very short. Nonetheless, considering that no prior knowledge of any kind was used in constructing this motor map, the above naive representation is surely an impressive analogy to present models of robotics.

Note however, that the system, in using these routines, need not be “conscious” that it is using such a representation - it just has to be able to use it effectively.

A final note on the precision of the process. We note that the space need not be sampled uniformly, as was done here. In many situations, certain configurations would be occurring more frequently, and there would higher accuracies would hold in these part of the space (as in the rough diagram of the 50-torus earlier). This is also true of animals and humans, where more frequently executed actions are much more precise.

## Conclusion

In this work, we have demonstrated that although visual input is extremely high-dimensional, the data lies on a nonlinear manifold that is much lower dimensional. The dimensionality of this manifold, and its structure, reveals much about the problem domain and may be called a *naïve representation*. We also propose an approximate mechanism for handling out-of-sample data in the NLDR algorithm - first, by constructing the manifold for the entire workspace and then deleting points, as opposed to trying to construct a new manifold for every workspace. This (figure ) also explains the fact that during the early stages of motor learning, the resolution of the map is poor, and this may also contribute to some aspects of the jerky movements demonstrated in early infancy. As the system populates the visual space with more data points, the resulting surface becomes smoother and permits fluent motions.

Is there cognitive evidence that such a method is actually implemented in the cortex? It is perhaps too early to comment on this. We can only point to a clear role for eye-centered coordinates in the reach planning process, and suggest that such a representation, involving “nearby” images from the image space, may constitute at least a plausible model for part of the computation involved in reach planning.

## Abstract

Contemporary visual environments bombard us with hundreds of face images every day, and this places a non-trivial demand on long-term memory. However, little is known about what makes certain faces remain in our memories, while others are quickly forgotten. To establish a basis for face memorability exploration, we assembled a database of 8,690 face photographs from online sources, spanning diverse face and image characteristics. Workers on Amazon's Mechanical Turk were asked to identify repetitions within a stream of these stimuli. Variations in image memorability (hit rates, false alarm rates, and their interactions) were reliable across participants, suggesting that face images may have different intrinsic levels of memorability. We discuss future directions in using this database to quantify face photograph memorability, as well as potential scientific and commercial applications.

**Keywords:** face recognition; image memorability; face photograph memory database

## Introduction

Every day, we encounter an overwhelming number of photographs and images of people's faces. Many interpersonal interactions are mediated by such images: we view people's Facebook profile pictures; memorize photographs of our students; browse personals on dating websites; skim through pictures attached to job applications; and encounter countless face images published on advertisements on billboards, in magazines, and online. As social creatures, we remember many of these faces.

Large-scale visual memory experiments have shown that people have a remarkable ability to remember which specific image they saw even after seeing thousands of pictures depicting objects, scenes or events (Konkle, Brady, Alvarez, & Oliva, 2010a; Standing, 1973). Importantly, these studies have shown that we do not just remember the gist of a picture, but we are able to recognize which precise image we saw and some of its visual details (Brady, Konkle, Alvarez, & Oliva, 2008; Konkle, Brady, Alvarez, & Oliva, 2010b). In addition to remembering particular images as icons, we also have the intuition that not all images are remembered equally. While the reasons why some images are remembered are varied, recent works have found that

Figure 1: An example set of 196 random images from the face photo database used for this study.

Figure 2: An illustration of the behavioral procedure. Participants were required to identify repeats amongst a stream of face photos.

images containing people with visible faces are highly memorable (Isola, Parikh, Torralba, & Oliva, 2011a; Isola, Xiao, Torralba, & Oliva, 2011b).

Despite the fact that the memorability of face photos is of both psychological and commercial significance, it is not clear how findings illuminating scene and object memorability will generalize to face images. First, memorability has been shown to be heavily influenced by the distinctiveness of stimuli (Konkle et al., 2010a, 2010b). Compared to scenes and objects, faces are a relatively homogeneous category and have low variation in visual features. However, faces could be coded with rich sub-categorical structure (e.g., gender, race, age, emotional expression, dominance level, attractiveness) that may render their representations more distinguishable in memory. Second, evidence suggest that faces are processed by specialized cognitive (Duchaine, Yovel, Butterworth, & Nakayama, 2006; Robbins & McKone, 2007) and neural (Kanwisher & Yovel, 2006) mechanisms (c.f., McKone, Crookes, & Kanwisher, 2009). For these reasons, face memorability deserves special attention.

In this study, we establish a large-scale face photograph database on which we have quantified performance on a repetition detection task. We examined inter-image variability, and its reliability, on this task. Specifically, we analyzed two memory-related behavioral measures – hit rate and false alarm rate – which we term “memorability scores”.

## Methodology

We conducted a large-scale experiment that used photos from a database of diverse faces, run on 337 participants on Amazon's Mechanical Turk. The following section describes the assembly of the database and the experiment run on Mechanical Turk.

### Face Photo Database Generation

We assembled a diverse database of 10,000 photos of faces. First, we generated a list of approximately 25,000 first and last name pairs from a database of names from the United States census (Kleimo, 2011), using parameters for a balance of both genders and names of high commonality. Use of the US census allowed us to collect names from a diverse range of ethnic backgrounds, representing the general gender, racial, and age distribution of the United States adult population. However, because the first and last

names were generated randomly, they did not necessarily represent specific people from the US population. Example names included “Wilma Reno,” “Phillip Robichaux,” “Lori Blank,” and “Arlene Olivarez”.

Each of the 25,000 names was used as a search query, and, for each query, approximately 10 photos were automatically downloaded from Google Images. Our Google Image Search parameters included that all photos be at least 400×300 pixels, full-color, and of faces. The experimenters went through the set of photos and deleted those that were low-quality, depicted children, were obscured by other objects, included accessories such as hats and glasses, or had unusual makeup. The database was filtered down to over 10,000 photos of faces that were diverse over a wide range of ages, genders, races, and attractiveness levels. Faces had both eyes visible and open and, in general, expressions tended to range from neutral to smiling. Five experimenters then went through the set and deleted recognizable celebrities for the purposes of this study, bringing the set used for this experiment to a final size of 8,690 photos. We expect that only a small percent of our database should be celebrity photos that were not identified through our initial screening. The stimuli for the experiment were then generated by placing ovals around the faces to frame them and to diminish the influence of irrelevant background features in the photo. All photos were resized to a standard of 256 pixels in height with variable width to preserve aspect ratio. Figure 1 shows a collection of example photos from the database.

### The Behavioral Experiment

Face memory performance was measured through a behavioral study called the “Face Memory Game” run on Amazon's Mechanical Turk. Mechanical Turk is a tool belonging to Amazon.com's Web Services that allows researchers to crowdsource tasks and experiments for monetary compensation to a large Internet population. Mechanical Turk served as an ideal environment for this study, allowing us to obtain memory scores for thousands of images.

The methodology for this game is based off the methodology from a previous image memorability study conducted with scenes (Isola et al., 2011b; see Figure 2). The task was structured into a series of 30 levels, each taking about 4.8 minutes and consisting of 120 photos. Although labeled “levels” to give a sense of progress to the participant, the levels did not differ from each other in

difficulty or stimulus type. For each level, the participant saw a constant stream of stimuli, each displayed for 1 second and then followed by a 1.4 second fixation point before the next stimulus was presented. Stimulus presentation order was different for each participant. Participants had to press the key ‘r’ (for “repeat”) whenever the current stimulus was the same photo as one they had seen before (sometimes across levels). When they responded correctly to a repeat, a green cross appeared as feedback. When participants missed a repeated photo or pressed ‘r’ for a novel photo, a gray X appeared to indicate an error. The game was first preceded by a short qualification and training round of 30 photos. Between levels, participants were given a brief break of up to five minutes and were presented with their correct response score for that level. After 30 levels of the game were over, the game ended. However, participants could choose to end the game at any time, and their data was used up to that point.

From the face stimulus database, 2222 photos were randomly selected as target photos, while the remaining 6468 photos were used as filler photos. Repetitions of photos in the task happened with both target and filler photos. The memory performance measures are based off the results from the target photos, where repetitions were spaced 91-109 photos apart. The repetition with the filler photos acted as a “vigilance task” to test the reliability of participants, with repetitions spaced 1-7 photos apart. The filler photos were also used as spacing between the target photos, and some had no repetitions. Neither target photos nor filler photos had more than one repetition across the entire study.

A total of 337 Mechanical Turk workers participated in the game, and 90% of the data came from 168 workers. The average worker played over 8 levels. We limited the game to only Mechanical Turk workers in the US, so that the workers’ demographics would approximately match the demographics of the faces used as stimuli. Workers were paid \$0.40 per level, or approximately \$5 an hour. Workers were screened in several ways throughout the study to ensure they were attentive to the task. First, only workers with at least a 95% Mechanical Turk approval rate were allowed to participate in the study. During the study, if a participant’s error rate for false alarms exceeded 50% for the last 30 photos, or if their hit rate for vigilance task repeats fell below 50% for the last 10 photos, then the data from that level were discarded and the participant received a flag. Rejection criteria were reset for each level. If the participant received three flags, they were blocked from continuing in the experiment. Otherwise, participants could restart the game as many times as they liked, until they had completed 30 levels. When restarting the game, unseen photos were always selected as stimuli.

## Results

We collected an average of 30.4 hit rate (HR) scores per photo and 35.4 false alarm rate (FAR) scores per photo. The

Figure 3: Hit rate and false alarm rate histograms over the target photos in our experiment.

average HR was 53.6% ( $SD=14.3\%$ ), and the average FAR was 14.5% ( $SD=9.9\%$ ). The distributions of these memorability scores followed simple unimodal forms (Figure 3).

## Is Memory Performance on Some Images Reliably Different than on Other Images?

To evaluate the reliability of our measurements, we split our participant pool into two independent halves, and quantified how well memorability scores measured on the first half of the participants matched memorability scores measured on the second half of the participants. Averaging over 25 random split-half trials, we calculated a Spearman's rank correlation  $\rho$  of 0.44 between HRs on the two halves and a  $\rho$  of 0.48 on FARs. The strength of these correlations demonstrates that we have characterized real differences between photos.

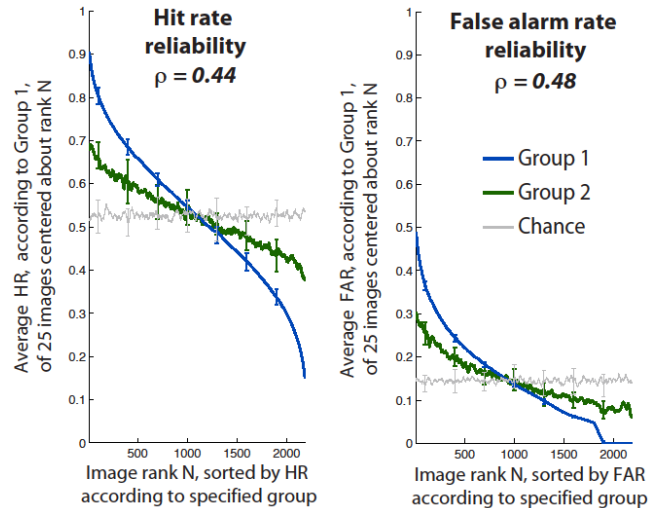

Figure 4: Data split-half reliability. Photos are ordered on the x-axis by the HR (left) and FAR (right) of a random half of the participants, and are plotted against these measures on the same half (blue line) or the remaining half (green line) of participants. Chance reliability is shown by randomly ordering the photos on the x-axis (gray line). Plots are averaged across 25 such random splits of the participant pool.

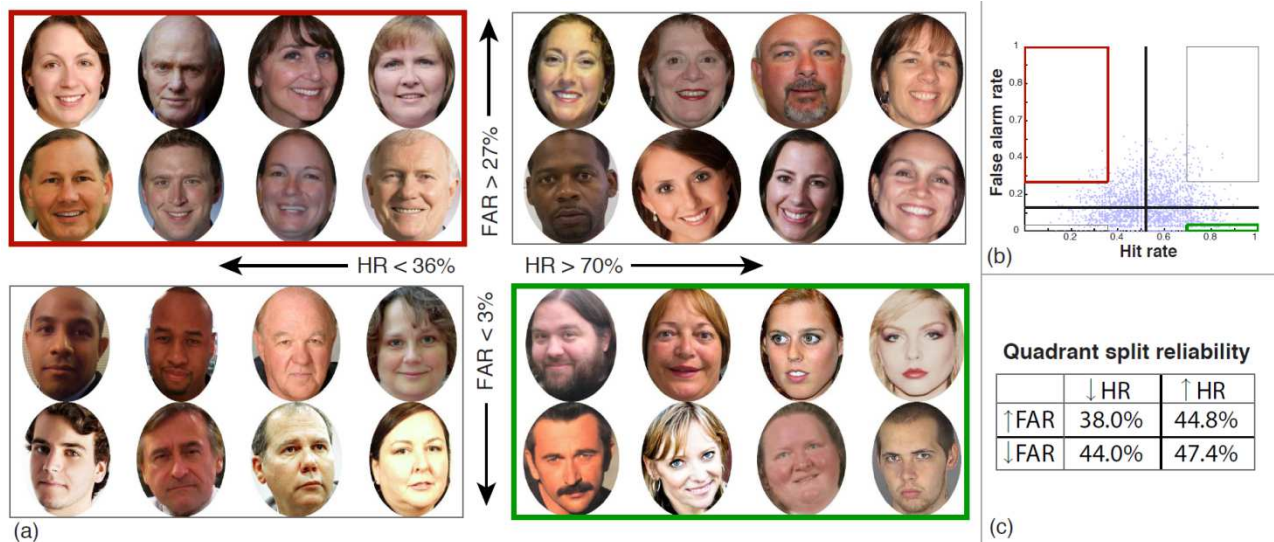

Figure 5: (a) Sample images of four performance profiles. The image set was broken into a  $5 \times 5$  grid of HR quintiles crossed with FAR quintiles. Each quadrant shows a random sample of the photos at each of the four corners of this distribution (highest/lowest HR/FAR). The set outlined in green can be characterized as more memorable than the set outlined in red since the green set has both a higher HR and a lower FAR than the red set. (b) A scatterplot showing HR versus FAR. Rectangles indicate the same corners of the quintile grid as in (a). The black lines split the distribution along the median HR and FAR creating four performance profiles. (c) Reliability computed as percent overlap of HR/FAR profile assignments of photos between two halves of the participants (averaged across 25 random splits of the participant pool). Profiles correspond to the quadrants defined by the black lines in (b).

Are these differences large enough to be interesting? We examined the reliability of the size of the memorability differences as follows. We sorted photos by their scores given by the first half of the participants and plotted this against memorability scores according to the second half of the participants (Figure 4). For clarity, we convolve the resulting function with a length-25 box filter. This shows that, for example, if a repeat is correctly detected 80% of the time by one half of the participants, we can expect the other half of the participants to correctly detect this repeat around 66% of the time, corroborating that this photo is truly memorable. At the other end of the spectrum, if a repeat is only detected 30% of the time by one half of the participants, the other half will tend to detect it only 42% of the time – this photo is consistently forgotten. It thus appears that there really is sizable variation in face photo memorability.

Thus, our data show enough variation and enough reliability that it should be possible to use these data to model detailed aspects of photo memorability in later work (c.f., Isola et al., 2011a, 2011b). Individual differences and random variability in the sequence of photos each participant viewed add noise to these estimations; nonetheless, this level of reliability suggests that information intrinsic to the photos plays a key role in determining which photos are remembered.

## False Memories versus True Memories

Our data allow us to look at both false memories and true memories. False memories may arise in response to highly typical faces, because they resemble many other faces (Vokey & Read, 1992). True memories should relate to specific encodings of the photos seen in our experiment. Can we separate these two signals in our data? If a photo receives both a high hit rate and a high false alarm rate, it may be highly memorable, but it also may just be a face that always feels familiar, regardless of whether or not it has been previously seen. A stronger case for high memorability can be made when we find photos that have high hit rates and low false alarm rates – what is termed a "mirror effect" (Glanzer & Adams, 1985, 1990). If one photo consistently has both a higher hit rate and a lower false alarm rate than another photo, then we can confidently say that the first photo evoked a stronger true memory than the second.

To isolate truly memorable photos, we split our photo set about the median HR and then again about the median FAR, producing four performance profiles (high/low HR/FAR) (see Figure 5). Are some photos consistently assigned to the high-HR/low-FAR profile, whereas others are consistently assigned to the low-HR/high-FAR profile? If so, we can say the former photos are more memorable than the latter. We tested this level of consistency by splitting our photos into profiles according to one random half of the participants and comparing these assignments to those given by the other half of the participants. Averaging over 25 such trials, the

two halves of the subjects agree 47% of the time on assignments to the high-HR/low-FAR profile (chance level would be 25%). Interestingly, we see similar levels of agreement in each of the remaining quadrants, as reported in Figure 5c.

These quadrants may reflect different types of photos with respect to memory: some photos may be distinctive and strongly remembered; some may be prototypical and produce both strong memories and many false alarms; others may evoke many false memories while, interestingly, generating relatively few true memories (low-HR/high-FAR); and still others may simply be ignored all together (low-HR/low-FAR).

## Discussion

This study has established a database for the exploration of face photograph memory, and shows that memorability of face photographs can be reliably measured. We found an average hit rate of 53.6% across the target face photos, compared to a false alarm rate of only 14.5%. In contrast, Isola et al. (2011b) used the same experimental protocol and found an average hit rate of 67.5% and false alarm rate of 10.7% for scene photo memory capacity. Do these numbers for face photos indicate that we are worse at remembering faces than scenes? Or, is the face photo performance high, considering that faces vary at the exemplar level (i.e., all belong to the same basic-level category), while the scenes used by Isola, et al. (2011b) vary at the categorical level (Rosch, Mervis, Gray, Johnson, & Boyes-Braem, 1976)? It is difficult to compare across separate studies and participant pools – for example, Isola et al. (2011b) recruited international participants, while the current study limited participants to the United States. It will also be essential to find a way to quantify the differences between face and scene photos in order to meaningfully compare memorability between the two different groups of stimuli.

A second interesting question to explore is what attributes lead to the separation of photos into the four performance profiles we identified based on hit rate and false alarm rate (Figure 5). Previous research has suggested that more distinct faces have high hit rates and low false-alarm rates in an old/new task (Deffenbacher, Johanson, Vetter, & O'Toole, 2000; Light, Kayra-Stuart, & Hollander, 1979). In contrast, both hit and false-alarm rates are high for typical faces, due to the effect of "context-free familiarity", a sense of familiarity not related to a specific previous encounter with a face (Vokey & Read, 1992). The other two profiles we explored may also have interesting qualifying characteristics to examine that were not explicitly addressed in the past literature.

Beyond distinctiveness and typicality, we advocate the exploration of several other attributes and their correlations with memorability. Previous research has noted that memorability of a face, both perceived and actual, may differ based on viewer characteristics, such as race (Chiroro & Valentine, 1995; Meissner, Brigham, & Butz, 2005) or recent experience with other face images (Lewis &

Johnston, 1997); however, the current study shows surprising reliability across subjects of diverse backgrounds, viewing a widespread distribution of photos. This suggests there are similarities across participants in how they represent different photos in memory. One next important step will be to examine how the demographic characteristics of the participant (e.g., race, gender, and age) may or may not predict the memorability of face photos with matching or non-matching characteristics. Other properties to examine in the context of memorability include perceived memorability (do people actually remember what they think they will remember?), attractiveness, and eye contact. While the current work focuses on memory for photos of faces, future work will also explore memory for face identity across different photos of the same person.

The future possibility of quantifying "memorability" of a face lends itself to many useful applications in both the field of psychology and mainstream society. For instance, Todorov (2011) identified features in faces linked to different subjective judgments of those faces, such as attractiveness and trustworthiness. These were used to build computer models that generated faces varying along these featural dimensions. A score of memorability could similarly be added to the feature set of a face, and thus be used to rate, manipulate, and generate face images. For animated films, animators could create cartoon characters with different levels of memorability (c.f., Gooch, Reinhard, & Gooch, 2004), such as a highly memorable protagonist surrounded by forgettable extras. Makeup artists could use software that would identify where to apply makeup to make celebrities memorable for a photoshoot. Algorithms could automatically identify the most memorable face photographs out of an album to use in textbooks, magazines, or even social network profiles.

## Conclusion

This study serves as an initial, empirical look at a new large, diverse database of face photos and the average rate and reliability of memorability measurements across this database. When viewing a stream of hundreds, sometimes thousands, of novel face photos, participants in our experiment were able to accurately identify repeats about half the time they appeared, while making relatively few false alarms. This suggests that participants were holding in memory detailed representations of hundreds of face photos even though each photo was presented with just a single one-second view. In addition, we found that photos of faces vary substantially in memorability; these reliable differences indicate the importance of memorability for understanding how we process face images. This research opens the door to future investigation in various fields, from cognitive psychology to cognitive neuroscience to computer vision, as to what makes some face images or facial features more memorable than others.

## Acknowledgments

We would like to thank Marc Howard for helpful discussions and advice. This work is partly funded by a NSF grant (1016862) and a Google research award to A.O. W.A.B. is funded by the Leventhal Graduate Fellowship, P.I is funded by an NSF graduate research fellowship, and I.A.B. is funded by the Henry E. Singleton Fund.

The face photograph database will be publicly available on the author's website.

# The Representation and Processing of Tense, Aspect & Voice across Verbal Elements in English

Jerry T. Ball (Jerry.Ball@wpafb.af.mil)

711<sup>th</sup> Human Performance Wing, Air Force Research Laboratory,  
Wright-Patterson Air Force Base, OH 45431

## Abstract

We consider the representation and processing of the English verb features tense, aspect and voice, within a computational cognitive model of human language processing. We assume that a collection of features is associated with each verbal element and that these features may project to the clauses in which they occur. When multiple verbal elements occur, it is possible for the features to conflict, necessitating mechanisms of feature blocking and overriding to determine feature projection. The alternative of having multiple entries in the mental lexicon for each verbal element with different feature sets is avoided due to the ambiguity that would be introduced, and the weak grammatical motivation for doing so. However, we do assume an ambiguity in the case of most v-ed and v-base verb forms, with the past tense v-ed form being distinct from the past participle v-ed form and the present tense v-base form being distinct from the non-finite v-base form. We assume that every finite clause expresses a tense and voice feature and many finite clauses express an aspect feature as well. We consider the case of transitive and intransitive verbs in combination with the auxiliary verbs “be” and “have” in finite clauses. For intransitive verbs, we introduce an active/inactive voice feature distinction which aligns with the transitive distinction between active and passive voice.

**Keywords:** grammatical feature, tense, aspect, voice

## Introduction

We consider the representation and processing of the English verb features tense, aspect and voice, within the context of a *pseudo-deterministic* model of human language processing (Ball, 2011a) implemented in the ACT-R cognitive architecture (Anderson, 2007). The pseudo-deterministic model reflects the integration of a highly parallel, probabilistic, and context dependent, activation and selection mechanism and non-monotonic *context accommodation* mechanism (with limited parallelism) with what is otherwise an incremental processor which pursues the best analysis. The overall effect is a human language processor (HLP) which presents the appearance and efficiency of deterministic processing, despite the rampant ambiguity which makes truly deterministic processing impossible. Our non-monotonic context accommodation mechanism replaces the monotonic *look-ahead* mechanism of Marcus’s deterministic parser (Marcus, 1980) and is argued to be more cognitively plausible (Ball, 2011a).

We assume that a collection of verb features is associated with each verbal element (cf. Gazdar et al., 1985) and that

these features may project to the clauses in which they occur. We consider the composition of verb features across verbal elements within a clause. When multiple verbal elements occur, it is possible for the verb features to conflict. The context accommodation mechanism, which has been independently motivated (Ball, 2010a), is crucial for handling conflicts. In particular, we propose specialized mechanisms of *feature blocking* (i.e. a feature of a preceding verbal element precludes projection of a conflicting feature of a subsequent verbal element) and *feature overriding* (i.e. a feature of a subsequent verbal element overrides a conflicting feature of a preceding verbal element) to handle conflicts. Feature overriding is non-monotonic in that it changes the incrementally evolving representation.

Our non-monotonic approach can be contrasted with approaches which rely on monotonic unification of non-conflicting features (Gazdar et al., 1985; Sag et al., 1986; Sag, Wasow & Bender, 2003). To avoid feature conflicts, such approaches tend to posit alternative entries in the mental lexicon which are structurally ambiguous, often linguistically unmotivated and sometimes grammatically inadequate. For example, “a few books” is grammatical in English despite the fact that “a” is singular and “few” and “books” are plural. In a monotonic unification-based approach, the number feature of “a” must somehow unify with the number feature of “few” and “books”. To handle this, one could posit a plural or number lacking version of “a”. But this introduces ambiguity and lacks linguistic motivation. In our non-monotonic approach, the plural feature of “few” and “books” is allowed to override the singular feature of “a” (Ball, 2010b). Feature blocking and overriding are concerned with the composition of features across lexical items within constructions and differ from non-monotonic *default constraint inheritance* (cf. Sag, Wasow & Bender, 2003, 229ff.) which is concerned with defeasible inheritance of features within individual lexical items—which we also use (Ball, 2011b).

English has a highly restricted number of distinct verb forms which include the following:

- V-base (or V-plain) form (e.g. “give”, “go”)
- V-s form (e.g. “gives”, “goes”)
- V-ed form (e.g. “gave”, “went”, “kicked”)
- V-en form (e.g. “given”, “gone”)
- V-ing form (e.g. “giving”, “going”)

“Goes” is a slightly irregular v-s form, “gave” and “went” are irregular v-ed forms, and “gone” is an irregular v-en form. We also treat the combination of the infinitive marker “to” and the base verb form as a distinct verb form, abbreviated as to+v-base (e.g., “to give”). Having a distinct infinitive form allows the model to unambiguously recognize infinitives as multi-word units and reduces overall ambiguity. In total, we claim the existence of six distinct verb forms. By comparison, Quirk et al. (1985, p. 96) claim only five regular verb forms

- Base form (v-base)
- -s form (v-s)
- -ing participle (v-ing)
- Past form (v-ed)
- -ed participle (v-ed or v-en)

not recognizing to+v-base as a distinct form, treating v-en as an irregular -ed participle, and calling v-ed the past form (distinct from the -ed participle). Huddleston & Pullum (2002, p. 74) recognize six verb forms, three primary forms and three secondary forms:

- Primary
  - preterite (v-ed)
  - 3<sup>rd</sup> singular present tense (v-s)
  - plain present tense (v-base)
- Secondary
  - plain form (v-base)
  - gerund-participle (v-ing)
  - past participle (v-ed or v-en)

We follow Quirk et al. and Huddleston & Pullum in allowing the v-ed form to map to two distinct tenses: *past* tense and *non-finite* or untensed. We follow Huddleston & Pullum in allowing the v-base form to map to two different tenses: *present* tense and *non-finite*. Quirk et al. and Huddleston & Pullum treat the v-ed (*non-finite*) and v-en forms as alternative forms of the past participle. We keep them distinct since the v-en form is unambiguous. Huddleston & Pullum, like Quirk et al., do not recognize to+v-base as a distinct form.

In terms of the mapping from different verb forms to the tense feature, we propose the following ontology:

There are eight tense differentiated verb categories corresponding to the six different verb forms. The v-base (*present* tense and *non-finite*) and v-ed (*past* tense and *non-finite*) forms are ambiguous with respect to tense.

For aspect, we propose the following ontology:

We categorize *perfect* as a type of aspect in agreement with Quirk et al. (1985), but contrary to Huddleston & Pullum (2002) who treat *perfect* as a type of tense. Grammatically, there is a clear contrast in form between *progressive* and *perfect* aspect in English with the v-ing verb form corresponding to the *progressive* and the v-en or v-ed (*non-finite*) verb form corresponding to the *perfect*. *Perfect* aspect encodes the completion of an action in contrast to *progressive* aspect which encodes its continuation. However, *perfect* aspect is also closely associated with *past* tense since completed actions typically occur in the past, although the completion may be co-intensive with the present.

For voice, we propose the following ontology:

We assume that voice is a grammatical feature of intransitive as well as transitive verbs. *Active* voice indicates that the subject is actively involved in the action of the verb. *Passive* voice indicates that the subject of the transitive verb corresponds to one of the affected objects (object, indirect object) of the active equivalent. *Inactive* voice indicates that the subject is an inactive participant of an intransitive verb.

Combining features across the six forms and distinguishing transitive and intransitive verbs, the following feature combinations exist:

- V-base (fin): *present* tense, *active* voice
- V-s (fin): *present* tense, *active* voice
- V-ed (fin): *past* tense, *active* voice
- V-base (non-fin): *non-finite*, *active* voice
- To+v-base (non-fin): *non-finite*, *active* voice
- V-ed (non-fin, trans-verb): *non-finite*, *perfect* aspect, *passive* voice
- V-ed (non-fin, intrans-verb): *non-finite*, *perfect* aspect, *inactive* voice

- V-en (non-fin, trans-verb): *non-finite, perfect* aspect, *passive* voice
- V-en (non-fin, intrans-verb): *non-finite, perfect* aspect, *inactive* voice
- V-ing (non-fin): *non-finite, progressive* aspect, *active* voice

Any verbal entry in the mental lexicon will contain the features associated with one of these combinations. All forms of the auxiliary verb “be” encode *inactive* voice. All forms of the auxiliary verb “have” encode *active* voice. When used as a transitive verb, “have” follows the transitive verb pattern. Modal auxiliaries (e.g. “He *can* go”) encode a modal feature in addition to *present* tense and *active* voice. V-base (*present* tense, *active* voice) is the combination associated with imperative (e.g. “*give* me it”) and subjunctive uses (e.g. “I desire that he *give* me it”).

We consider the combining of tense, aspect and voice across the verbal elements in a clause, restricting the discussion to main verbs and the auxiliary verbs “be” and “have” in finite clauses. A key assumption is that the features of verbal elements may conflict, necessitating mechanisms for feature *blocking* and *overriding*, and prohibiting unification as the primary integration mechanism (i.e., conflicting features cannot unify).

With respect to feature blocking, we assume that the grammatical features of the first of two immediately adjacent verbal elements normally suppress expression of conflicting grammatical features of the second. A preceding verbal element expressing *active* voice is incompatible with an immediately following verbal element expressing *passive* or *inactive* voice. For example, in “he has kicked the ball” expression of *active* voice by “has” suppresses expression of *passive* voice by “kicked” (i.e. “he” is actively involved in kicking), and in “he has gone” expression of *active* voice by “has” suppresses expression of *inactive* voice by “gone” (i.e. “he” is actively involved in going). However, the combination of “have” with “been” is special in that the *inactive* voice of “been” overrides the *active* voice of “have”. In addition, the *inactive* voice of “been” is compatible with either the *inactive* voice of a main intransitive verb or the *passive* voice of a main transitive verb. For example, in “the ball has been kicked”, the *passive* voice of “kicked” can project to the clause since the *inactive* voice of “been” overrides the *active* voice of “has”, and the *passive* voice of “kicked” is compatible with the *inactive* voice of “been”. Likewise in “he has been gone”, the *inactive* voice of “gone” can project to the clause (i.e. “he” is not actively involved in going). Feature blocking and overriding are the most distinctive elements of the approach presented in this paper. Both are incompatible with monotonic unification of features.

## Feature Projection for Transitive Verbs

We start by considering the encoding and projection of features in clauses containing the transitive verb “give” as

the main verb. First, we consider clauses with a single main verb, starting with *present* and *past* tense “give”.

1. He gives (**pres+act**) me the ball
2. He gave (**past+act**) me the ball

In 1, “gives” encodes and projects the *present* tense and the *active* voice features. In 2, “gave” encodes and projects the *past* tense and *active* voice features.

If we add the auxiliary verb “be” to “give”, things start to get more interesting:

3. He is (**pres+inaet**) giving (**prog+act**) me the ball
4. He was (**past+inaet**) giving (**prog+act**) me the ball

In 3, “is” encodes and projects *present* tense and *inactive* voice and “giving” encodes and projects *active* voice—overriding the *inactive* voice of “is”—and *progressive* aspect. The overriding of the *inactive* voice of “is” by the *active* voice of “giving” is an exception to the rule that the competing features of the preceding verbal element block projection of the features of the following verbal element (specific to “be”+verb). Example 4 only differs in that “was” encodes and projects *past* tense.

5. He is (**pres+inaet**) given (**perf+pass**) the ball
6. He was (**past+inaet**) given (**perf+pass**) the ball

In 5, “is” encodes and projects *present* tense and *inactive* voice, allowing “given” to project *passive* voice to the clause. Allowing “be” to encode *inactive* voice which can be overridden by an immediately following verbal element, allows “giving” to project *active* voice and “given” to project *passive* voice. In addition to projecting *passive* voice, “given” also encodes and projects *perfect* aspect. There is a clear sense in which “He is given the ball” implies completion of the act of giving, which comes from the *perfect* aspect of “given”. Example 6 only differs in that “was” encodes and projects *past* tense. One might think that completion of the act of giving comes from “was” and not “given” in this example. However, note that “he was giving me the ball” does not imply completion even though “was” is *past* tense.

7. He is (**pres+inaet**) to give (**nonfin+act**) me the ball
8. He was (**past+inaet**) to give (**nonfin+act**) me the ball

In 7, “is” encodes and projects *present* tense and *inactive* voice and “to give” encodes *non-finite* tense (i.e. the absence of tense) and *active* voice, but only projects *active* voice since *present* tense is projected by “is” and blocks the *non-finite* feature of “to give”. The overall effect is that the clause is *present* tense and *active* voice similar to “he gives me the ball”. However, “He is to give me the ball” also implies a modal obligation which is not captured by the current analysis. Example 8 only differs in that “was” is *past* tense.

Adding the auxiliary verb “have” to “give” also has interesting effects.

9. He has (**pres+act**) given (**perf+pass**) me the ball  
 10. He had (**past+act**) given (**perf+pass**) me the ball

In 9, “has” encodes and projects *present* tense and *active* voice. Projection of *active* voice by “has” blocks the possibility of “given” projecting *passive* voice. This leaves only *perfect* aspect to project from “given”. In contrast with the more usual treatment in which “have” combines with a v-en or v-ed (non-finite) form verb to project *perfect* aspect, we propose that “have” instead has the effect of suppressing projection of *passive* voice from the immediately following v-en or v-ed (non-finite) verb form, by projecting *active* voice. Example 10 only differs in that “had” projects *past* tense. If there were separate entries for the passive and perfect variants of “given”, then “have” could bias selection of the perfect entry, whereas “be” could bias selection of the passive entry and this ambiguity is manageable. However, with separate entries, it would not be possible to project both *perfect* aspect and *passive* voice from a single verbal element. Under our current approach, “have” suppresses *passive* voice, but allows *perfect* aspect to project, whereas “be” allows both *passive* voice and *perfect* aspect to project.

11. He has (**pres+act**) to give (**nonfin+act**) me the ball

In 11, “has” encodes and projects *present* tense and *active* voice. “To give” also encodes and can express *active* voice, but this is redundant (but not incompatible) with “has”. Like “be”, “have” combines with an infinitive to express a modal obligation to complete the act. In both cases, this effect appears to derive from the construction (e.g. “is” + “to give”, “have” + “to give”) rather than the individual lexical items. Constructional effects can become encoded in complex lexical items and it is likely that “have to” is encoded in the mental lexicon as a multi-word unit (in spoken language as the reduced form “hafta”) and expresses an obligation as part of its idiomatic meaning as shown in example 12.

12. He has to (**pres+act+must**) give (**nonfin+act**) me it  
 13. He had to (**past+act+must**) give (**nonfin+act**) me it

Example 13 with *past* tense “had” expresses a past obligation rather than a present obligation.

The combination of *perfect* aspect and *passive* voice may also be realized across verbal elements. Consider

14. He has (**pres+act**) been (**perf+inact**) given (**perf+pass**) the ball

As an exception, the *inactive* voice of “been” overrides the *active* voice of “has” allowing the *passive* voice of “given” to project. Note that both “been” and “given” encode and may express *perfect* aspect. At the clausal level, we have *perfect* aspect whether it comes from one or more verbal elements.

As the preceding example shows, it is possible to combine verb features across verbal elements in ways that are not allowed within a single verb (e.g. present perfect), although one would like to assume that conflicting features cannot be simultaneously expressed, even across verbal elements.

However, besides the combining of *present* tense and *perfect* aspect—which represent different dimensions of meaning that do not conflict—surprisingly, *perfect* aspect and *progressive* aspect can also be combined across verbal elements.

15. He has (**pres+act**) been (**perf+inaet**) giving (**prog+act**) me the ball

In this example, “has” expresses *present* tense and *active* voice, “been” expresses *perfect* aspect, with *inactive* voice overriding the *active* voice of “has”, and “giving” expresses *progressive* aspect and *active* voice which overrides the *inactive* voice of “been”. It may be that the combination results in an iterative interpretation that is at once *progressive* in iterating and *perfect* in the completion of each iteration (e.g. “He has been giving me the ball over and over”). It is an open research question how to represent the projection of two aspectual features (i.e. *perfect* and *progressive*) in a single clause. The computational model currently supports projection of a single aspectual feature.

*Progressive* aspect can be combined with *passive* voice across verbal elements.

16. He is (**pres+inact**) being (**prog+inact**) given (**perf+pass**) the ball

In 16, “is” projects *present* tense, “being” projects *progressive* aspect, and “given” projects *passive* voice. It is unclear if “given” projects *perfect* aspect in this example—it appears not to (the gray font for **perf** indicates this).

*Perfect* aspect can combine with *progressive* aspect and *passive* voice across verbal elements.

17. He has (**pres+act**) been (**perf+inact**) being (**prog+inact**) given (**perf+pass**) the ball

In 17, “has” projects *present* tense and *active* voice, but *active* voice is subsequently overridden by the *inactive* voice of “been”. “Been” projects *perfect* aspect, “being” projects *progressive* aspect (perhaps overriding the *perfect* aspect of “been”), and “given” projects *passive* voice, with *perfect* aspect questionable. This clause expresses a complex collection of tense, aspect and voice features across four verbal elements.

## Feature Projection for Intransitive Verbs

When we consider intransitive verbs like “go”, the introduction of the *inactive* voice feature becomes especially important. The intransitive v-en form is particularly revealing. Consider the verb “gone”.

18. He has (**pres+act**) gone (**perf+inaet**)

Like typical v-en forms of transitive verbs, “gone” expresses *perfect* aspect when preceded by “has”. But why do we need *inactive* voice for intransitive verbs? Because intransitive verbs can occur with “be” just like transitive verbs:

19. He is (**pres+inact**) gone (**perf+inact**)

There is clearly an expression of completion in this example, reflected in the projection of *perfect* aspect from “gone”, but the active involvement of the referent of “he” is de-emphasized. This de-emphasis is the intransitive verb equivalent of passivization in transitive verbs. In the intransitive verb case, there is no object available to be promoted to the subject function. Instead, the subject of the intransitive verb is demoted from active participant to inactive participant, but remains the subject.

Now consider a set of even more revealing examples:

- 20. He has (**pres+act**) tired (**perf+inact**)
- 21. He is (**pres+inact**) tired (**perf+inact**)
- 22. He is (**pres+inact**) very tired (**perf+inact**)

In “he has tired”, “tired” is the v-ed (non-finite) verb form. Since “has” projects *active* voice, the *inactive* voice of “tired” is blocked, but *perfect* aspect projects. In “he is tired (all of a sudden)”, it is unclear if *perfect* aspect projects. If it doesn’t, then the clause is *present* tense and *inactive* voice. Since “tired” is an intransitive verb, *inactive* voice demotes the subject making it an inactive participant. We are left with an expression that has essentially the same force as an adjectival expression—a single subject argument that is an inactive participant, and an auxiliary + verb combination that lacks any aspectual feature. If we view *stative* force as the lack of any aspect (either perfect or progressive), then the expression is effectively *stative*. Many researchers, including Huddleston & Pullum (2002) and Quirk et al. (1985) treat “tired” in 21 and 22 as an adjective. Huddleston & Pullum (2002, p. 1436) claim that the ability of a word like “tired” to combine with the adverb “very” is a definitive test for an adjective. Quirk et al. (1985, p. 167) make a similar claim. However, it is hard to see how this test is definitive given that “tired” has the form of a v-ed verb. The assumption that “tired” is an adjective when combined with “be” and a verb when combined with “have” necessitates two entries in the mental lexicon to represent “tired”. The approach advocated here requires a single verb entry, but allows the context to control the projection of grammatical features such that an intransitive verb can function very much like an adjective. As a challenge to the claim that “very” definitively identifies an adjective, consider

- 23. He is (**pres+inact**) very worn out (**perf+inact**)

It is atypical of adjectives, and typical of verbs to combine with prepositions to form verb-particle constructions. “Worn out” appears to be a typical verb-particle construction, except that it can occur with “very”. There is also a sense in which “worn out” implies completion of the process of wearing out as encoded by *perfect* aspect.

In general, we argue against the dual treatment of inflected verbs, including stative verbs, as adjectives since this introduces an ambiguity that does not facilitate processing. However, this does not mean that there is never an ambiguity between verbs and adjectives. Consider

- 24. The door is (**pres+inact**) open

“Open” appears to be a genuine adjective in that it does not have any verb inflection and it occurs after “is” where v-base verb forms do not occur. (Note that “\*He is tire” is not grammatical.) If “open” is genuinely ambiguous, how does the incremental, pseudo-deterministic processor deal with it? If we restrict “is” to setting a bias for non-finite inflected verb forms (e.g. v-ing, v-en or v-ed (non-finite)), adjectives and prepositions, then “open” will be biased to the adjective, rather than the v-base verb form, in the context of “is”. Note that this bias will not be sufficient if “gone” is both a v-en verb form and adjective, or “tired” is both a v-ed (non-finite) verb form and adjective.

Huddleston & Pullum (2002, p. 1436) note that expressions like “they were married” are ambiguous between an adjectival and a verbal interpretation. In “they were married last week” the verbal interpretation dominates, and in “they were married for ten years” the adjectival interpretation dominates. Is it possible to handle this ambiguity without positing distinct entries in the mental lexicon?

- 25. They were (**past+inact**) married (**perf+pass**)
- 26. They were (**past+inact**) married (**perf+pass**)

If the verbal interpretation corresponds to the projection of *perfect* aspect and *passive* voice, and the adjectival interpretation corresponds to suppression of *perfect* aspect and *passive* voice, then we can represent the distinction without positing separate entries in the mental lexicon. One immediate advantage of this approach is an ability to handle post verbal modification via feature overriding:

- 27. They were (**past+inact**) married (**perf+pass**) last week
- 28. They were (**past+inact**) married (**perf+pass**) for ten years

In the first example, the relatively punctual nature of “last week” encourages the expression of *perfect* aspect, whereas in the second example, the durative nature of “for ten years” discourages and perhaps overrides the expression of *perfect* aspect—although there still appears to be an implication that they are no longer married. The “adjectival” use also lacks *passive* voice. In the case of transitive verbs like “marry”, *passive* voice applies to the event reading in which the agent of the event (e.g. the priest) is demoted from subject to optional oblique argument. In the case of “they were married for ten years”, we have a durative event that is stative-like and lacking an agent. Note that at the processing of the word “married” we do not know what affect post verbal modifiers will have or even if there will be any. In an approach which has separate verb and adjective entries for “married”, an incremental, pseudo-deterministic processor will run into problems. It is not possible to decide at “married” which entry is needed. Either both entries will need to be carried forward in parallel, or the processor must have some mechanism for backing up and trying the alternative. From an incremental processing perspective, neither of these is

attractive. The human language processor does not have sufficient resources to carry forward multiple options in parallel—at least not across multiple choice points where additional parallelism might be required. Backtracking is equally problematic. Resources are needed to store the alternatives to be considered on backtracking, and knowing when to backtrack is indeterminate. Our pseudo-deterministic processor eschews backtracking and constrains parallel propagation of alternatives, relying instead primarily on non-monotonic adjustment of the evolving representation via feature overriding and feature blocking to deal with many forms of ambiguity without positing multiple entries in the mental lexicon.

As a final example with “married”, consider

29. They are (**pres+inact**) being (**prog+inact**) married (**perf+pass**) by a priest

In this example, “are” expresses *present* tense and “being” expresses *progressive* aspect. Since “are” and “being” are forms of “be”, they express *inactive* voice. This allows “married” to express *passive* voice, but the *perfect* aspect of “married” is blocked by the *progressive* aspect of “being”. The result is a clause that is *present progressive* and *passive*. There is an ambiguity here: are they in the act of being married by a priest or is the event just planned for the future? Since the *present* tense ranges over future events in English, this ambiguity may not be resolvable in terms of feature projection or suppression.

There is a related ambiguity in the meaning of expressions with *progressive* verb forms. According to Huddleston & Pullum (2002, p. 80)

30. Her parents are entertaining

is ambiguous between “entertaining” as a progressive verb form and “entertaining” as a stative adjective. If we allow the *active* voice feature of “entertaining” to be suppressed then these two uses can result from a single verb entry:

31. Her parents are (**pres+inaet**) entertaining (**prog+ act**)  
 32. Her parents are (**pres+inact**) entertaining (**prog+ aet**)

In 31, the parents are actively involved in entertaining, whereas, in 32, the parents are not actively involved. It does not seem necessary to suppress *progressive* aspect in this example since *progressive* aspect is already stative-like compared to *perfect* aspect. Note that this allows us to handle “her parents are entertaining tomorrow” and “her parents are entertaining to be around” via feature projection or suppression without multiple entries in the lexicon.

## Summary

We described the representation and processing of the inflectional verb features tense, aspect and voice within the context of an incremental, pseudo-deterministic human language processor (Ball, 2011a). Diagrammatic trees generated during the execution of the processor which show

verb feature projection on a broad range of different inputs are available at <http://www.doublertheory.com/compiler/compiler-grammar.htm>.

Verbs, including auxiliary and modal verbs, are encoded with tense, aspect and voice features in the mental lexicon and these features can project to, or be expressed by, the clauses in which they occur. When the verb group contains multiple elements, the grammatical features of the verbal elements must be reconciled. Monotonic unification of grammatical features is not possible when the grammatical features conflict. Mechanisms of feature blocking and overriding are needed to handle the reconciling of incompatible features and to minimize the amount of ambiguity in the mental lexicon—at least when localist representations (cf. Sag, Boas & Kay 2012) in which all verbal features compete for expression at the clausal level are assumed. A non-localist alternative of using hierarchically organized features (as suggested by a reviewer) such that in “He has been kicked”, “has” takes “been” as a complement with “has” expressing *present* tense and “been” expressing *perfect* aspect on a second level, and “been” takes “kicked” as a complement which expresses *perfect* aspect on a third level, may handle the case of feature blocking, but doesn’t explain how the overall expression is *passive*, which requires overriding the higher level *active* feature of “have” at the clausal level—if verbs express a voice feature as is assumed.

## Abstract

The term cognitive reserve (CR) is used to describe the lack of direct relationship between the severity of brain damage, or pathology and subsequent levels of observed impairments. It has been suggested by Stern (2009), that CR may reflect differences in (a) pre-existing levels of some reserve capacity of the brain (the *passive* form); or, (b) differences in the underlying functional architectures supporting cognitive processes (the *active* form). In this paper, we explore two implementations of cognitive reserve that seek to target both these forms, extending recent work using dynamical systems framework (Baughman & Thomas, 2008; van der Maas et al., 2006). We examine how variability in cognitive reserve may modulate the effects of damage, at different levels of intelligence. The resulting simulations showed that level of intelligence does not differentially modulate the pattern of cognitive change following complete destruction of a single cognitive process, but that the effects of damage are proportionate across each level of intelligence. Following the two implementations of cognitive reserve that we tested, we found: (1) higher levels of connectivity within a given architecture resulted in greater spread of damage and lower endstate performance; and, (2) functional architectures that are characterized by greater specialization of function, rather than distributed function, differentially protected against the effects of damage, with these models also exhibiting better recovery.

**Keywords:** Cognitive reserve; intelligence; ageing; damage; recovery; dynamical systems; functional architecture.

## Introduction

The term *cognitive reserve* (CR) is often used in relation to the pattern of general cognitive decline found in normally ageing adults, and to the more extreme forms of cognitive breakdown seen following brain damage (e.g., stroke), or disease (e.g., dementia and Alzheimer's). In healthy ageing adults, the term is used to refer to the variability observed between individuals of the same age. In clinical samples, the term refers to the observation that levels of brain damage, or pathology have no clear relationship to the severity of subsequent impairments. This is to say, two individuals with similar levels of brain damage may exhibit different cognitive profiles (e.g., the impairments for one individual may be subtle, while for the other they may be much more pronounced). The lack of direct relationship between the degree of pathology, or brain damage and clinical manifestation, has led to the suggestion that individuals differ with respect to their pre-existing levels of cognitive reserve (Stern, 2002; Stern, 2009).

A number of studies have reported mixed findings concerning the extent to which factors such as ones levels of intelligence, educational attainment, occupation and activity are associated with reduced risk of dementia, stroke, and lower levels of general decline (Kaplan et al., 2009; Koenen et al., 2009; Nithianantharajah & Hannan, 2009; Tucker-Drob, Johnson, & Jones, 2009; Whalley, Deary, Appleton, & Starr, 2004; Zahodne et al., 2011). However, these studies have not yielded causal accounts detailing how variability in CR may directly influence cognitive performance. Theoretical accounts of CR have however distinguished two broad forms (Stern, 2009). The *passive model* posits that CR may be delivered through differences in pre-existing reserve levels of some capacity of the brain (e.g., this might be number of neurons, or number of connections). Under this view, damage to a cognitive system with lower pre-existing levels of capacity, will lead to poorer outcomes, compared to cognitive systems where these levels are higher. The *active model* describes that differences in CR may be explained by differences in functional architectures underlying cognition. Under this view, it is hypothesized that some functional architectures are more efficient, and thus more resilient to the effects of damage, than others (Stern, 2009). Computational approaches provide an ideal platform from which to examine these issues because they provide an explicit framework for testing how various neurocomputational properties may directly lead to changes in a cognitive system. Here, we describe one approach using dynamical systems theory which aims to capture a broad pattern of development across a range of cognitive profiles and which allows for the consequences of damage to be assessed at the level of the whole cognitive system and across time.

## Computational approaches to the study of ageing and damage

Computational studies to ageing, and to damage in ageing systems, have mostly focused on the effects of variation to three main parameter manipulations: (1) reducing the slope of gradients in activation functions (Li, Von Oertzen, & Lindenberger, 2006); (2) reducing the connectivity between processes (Alstott, Breakspear, Hagmann, Cammoun, & Sporns, 2009); and, (3) removal, or deletion of processing units to simulate neuronal death (Rubinov, McIntosh, Valenzuela, & Breakspear, 2009). The effects of these parameter manipulations can be subtle and varied. However,

their effects are generally that they show reduced levels of performance, require that networks need more time to learn (akin to older adults needing more time to learn, compared to younger adults) and result in a more protracted process of recovery, following damage. Individual differences in ageing and damage within a cognitive system with more CR might thus be explained by: (a) steeper gradients in the activation functions; (b) a greater number of pre-existing levels of connections (or, weights) between processing units; or, (c) lower rates of cell death.

Thomas (2008) recently examined issues concerning ageing and cognitive reserve within a connectionist model of English past tense learning. In these simulations, aging was implemented separately via: (1) a reduction of gradient in processing units; and, (2) a reduction (loss) of connections. CR was implemented via manipulating the number of hidden units within the model. Specifically, low cognitive reserve models were assigned 50 hidden units (a level just sufficient to allow the model to learn) and high cognitive reserve models were assigned 100 hidden units. Damage, applied at various different timepoints, was implemented by probabilistically removing 50% of the connection weights in the network. This work is notable in that it provides an explicit test of one role of CR in modulating the effects of damage within a cognitive domain. There are relatively few studies that have sought to develop on this approach. Furthermore, most computational approaches to date appear to have targeted the capacity reserve (passive) form of CR proposed by Stern. We argue that a better understanding is needed for how the use of different functional architectures may modulate the effects of damage.

In this paper we examine the effects of damage within ageing dynamical systems models. Our central goal is to test two implementations of CR. We implement passive and active forms of CR proposed by Stern (2009). In the first instance, we assess the effects of varying the degree of connectivity between processes in a given architecture. In the second instance, we examine how the use of different functional architectures may modulate the effects of damage. Our target architectures are the Fully distributed, Hemispheric, Central processor, Bi-directional and Uni-directional architectures, represented in Figure 1. We further aim to examine how intelligence levels may modulate the patterns of damage, given the different implementations of CR.

### Dynamical systems theory

Dynamical systems theory (DST) provides one way of addressing these questions as it offers a framework for exploring the interaction between multiple component processes in a cognitive system. This then allows the possibility of tracing the consequence of changes to a given system over time. By specifying the relationship between component processes, we may stipulate exactly what the functional architecture is, and then test how the effects of ageing and damage unfold in a particular architecture. We base our approach, on the ‘mutualism model’ of intelligence

first proposed by van der Maas and colleagues (2006) and which was subsequently extended by Baughman and Thomas (2008) to explore the effects of early focal impairments to a process within a range of different functional architectures.

Figure 1: Five alternative model architectures. Note, this figure is illustrative of the architectural design. The actual models contained 16 processes each, and 17 in the case of the Central processor model.

### The mutualism model

van der Maas et al. (2006) offered a fully connected dynamical systems model of the development of intelligence that simulates cognitive development for a number of components (depicted by Model 1, of Figure 1). The model provides a number of parameters that influence development for each individual processes, but where development of the model, as a whole, is influenced dynamically by all processes within the model. A key feature of their model, is that the processes which are connected to each other within a system interact with one another and influence each other, in a mutually beneficial way throughout development. Hence, the model is called the ‘mutualism’ model. Equation 1 gives the dynamics of the mutualism model.

$$\frac{dx_i}{dt} = a_i x_i \left( \frac{1 - x_i}{K_i} \right) + a_i \sum_{\substack{j=1 \\ j \neq i}}^w M_{ij} x_j x_i / K_i$$

Equation 1. The mutualism model (van der Maas (2006))

The mutualism equation is derived from population dynamics and the Lotka-Volterra equation. Briefly, the equation states that at each point in time ( $t$ ) the change in the performance level  $x$  of a given process  $i$  ( $dx_i$ ) is a

product of the sum of the interaction weights of each process  $j$  to which it is functionally connected ( $M_{ij}x_j$ ), multiplied by the rate of growth of process  $i$  ( $a_i$ ), multiplied by the current level of performance of process  $x_i$ , divided by the asymptote level for that process ( $K_i$ ). Changes in  $x_i$  at each time step are thereby constrained by the performance (and thus the individual properties) of all other processes to which it is connected.

Extending the mutualism model, Baughman and Thomas (2008) showed that following impairments to a single process, early on in development, architectures characterized by greater connectivity between processes offered greater *compensation* and showed reduced levels of *spread* of damage. Additionally, they showed that compensation and spread were further modulated by where in the cognitive system impairments were applied. Baughman and Thomas distinguished *peripheral* processes from those that occupied *key* positions within a given architecture. For example, while in the Fully distributed model all processes are equal (and so impairment to one process is equivalent to damage to any other process), this is not the same for the Hemispheric and Central processor architectures. Both these models contain peripheral processes (e.g., processes in one hemisphere which do not directly influence processes in the other hemisphere) and key processes (e.g., processes within one hemisphere share a direct connection to processes in the other hemisphere). Figure 1 illustrates the distinction between peripheral and key processes. The effects of damage to peripheral versus key processes within different functional architectures remains largely untested. As such, it is not obvious whether the same architectures that offer advantages following damage to processes early in development, will also offer advantages to damage later in development.

## Simulations

In both the Normal and Damaged models, Ageing and IQ were implemented by manipulating values of the capacity for each process ( $K$ ).

**Ageing:** General cognitive decline was simulated by applying a fixed level of decay (0.075%) to the capacity ( $K$ ) of each process from 400 timesteps onwards. For the present simulations, we did not examine the consequences of variability in the rate, or the onset of decay.

**IQ:** To create Low IQ, Average IQ and High IQ models, models were calibrated to begin with different starting values of  $K$  (Low IQ=2, Average IQ=3, and High IQ=4).

**Cognitive Reserve:** For the passive form of CR, we tested three levels of Connection strength between processes ( $M$ ). However, because the boundaries of values that this parameter accepts without exhibiting catastrophic effects are limited, the range we implemented was small. We used  $M=0.049$ ,  $M=0.050$ , and  $M=0.051$ , to simulate Low, Average and High Connectivity, respectively. For the active form of CR, we compared the effects of damage in Fully distributed, Hemispheric, Central processor, Bi-directional, and Uni-directional architectures (see Figure 1).

**Damage:** In the damaged models, a single process was removed from the cognitive system to simulate total destruction of that process. Damage was applied separately to a peripheral process in each architecture, then to the key processes in the Hemispheric and Central Processor architectures. We held constant the level of damage (one process was damaged in under all architectures) and the onset of damage. Damage was applied to either a peripheral or a key process at timepoint 550, just over half-way through the models 'lifetime'. The damaged process was thus removed from the network and the relevant connections to and from it, also removed. All other parameters specified in the mutualism model, namely those relating to the growth rates of processes ( $a$ ), and the initial starting states of each process ( $x$ ) were also held constant and did not vary in these simulations ( $x=0.05$ ,  $a=6.0$ ). Finally, because one of our primary concerns was examining specific levels of IQ, we were not concerned with population variability. Thus, we did not require the models to be run for many pseudosubjects and only a single model was run for each architecture in Figure 1 for 1000 time steps. The full set of models that we tested totaled 108. These were comprised of: (i) Normal ageing models at 3 levels of IQ (Low, Average and High) within 3 levels of Connectivity (Low, Average and High) and 5 Architectures (Fully distributed, Hemispheric, Central processor, Bi-directional, and Uni-directional); (ii) Peripherally-damaged ageing models (as Normal, but with one process damaged); and, (iii) Key-damage ageing models (IQ: Low, Average and High x Connectivity (Low, Average and High) x 2 Architectures (Hemispheric, Central processor). Figure 2 shows the trajectories for Normal and Damaged models for the Fully distributed, Central processor and Uni-directional architectures, at Average IQ, Average Connectivity levels.

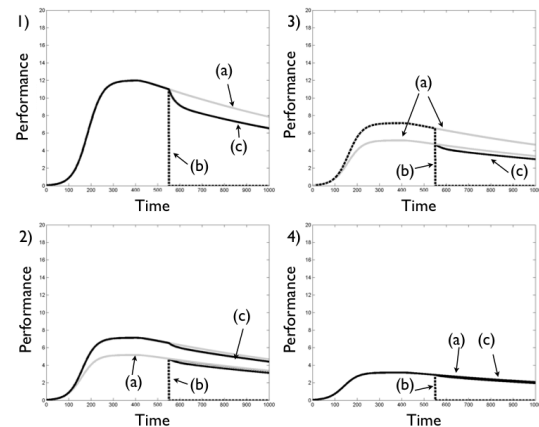

Figure 2: Trajectories of Normal and Damaged models for the Fully distributed (Tile 1), Central Processor (Tile 2: damage to peripheral process; Tile 3: damage to key process), and Uni-directional (Tile 4) architectures at Average Connectivity ( $M=0.05$ ) and Average IQ ( $K=3$ ) levels. Tiles depict processes in the Normal models (a) with a grey line, and the damaged (b) and affected processes (c) in the Damaged models, with dashed and solid black lines, respectively.

## Measures

Asymptote levels in the architectures differ as a consequence of the number of processes that are connected within it. As such, comparisons between the absolute levels reached by two architectures would be misleading. Instead, we use each Normal model as the benchmark for which to compare the performance of its damaged counterpart. This allows for relative comparisons across the different architectures. The two key metrics we use to assess the effects of damage are: (1) Area - the extent to which the trajectories of processes in the Damaged model resembles those in the Normal model (we compute the area under the curve, for each Damaged processes, and this is turned into a proportion of the area of the processes in the Normal model); and, (2) Endstate level - the extent to which the endstate levels of the Damage model reaches the functional endstate of the Normal model. Thus, area gives a measure of models attempt to compensate for damage, and endstate provides a measure of the models ability to recover.

## Results

Table 1 provides the Area data for Normal and Damaged models, at each level of intelligence and each level of Connectivity. The table shows effects of manipulations to IQ and Connectivity, across each of the architectures tested. The uppermost part of the table provides the data for comparisons for Normal versus Peripherally-Damaged models, the lowermost part of the table shows these comparisons for Normal versus Key-Damaged processes, in the Hemispheric and Central Processor models.

### Intelligence

As expected, varying the level of intelligence (IQ) in a model had direct effects on the overall level of performances reached. Table 1 shows that for each architecture higher IQ models performed better compared to lower IQ models (e.g., the level of performances reached in the Uni-dimensional architecture at each level of IQ, under Low Connectivity, are 11769.8, 17654.6 and 23539.5, respectively). However, the results of the simulations showed that IQ level did not modulate the effects of damage within architecture, at the various levels of CR. That is, within a given level of Connectivity, the effect of damage was proportionate at each level of IQ. For example, in the Low Connectivity Fully distributed model, the proportion of area reached by the Damaged models in Low IQ, Average IQ and High IQ models were all 80.2% of Normal levels.

### Cognitive reserve as differences in connectivity

Varying CR, when implemented as level of Connectivity, showed small, but consistent effects on level of performance reached (e.g., the levels reached in the Normal Hemispheric model at each level of Connectivity, under High IQ, are 35425.8, 35852.7 and 362900.0. However, greater levels of CR did not protect models from the effects of damage. In

fact, the reverse was found to be the case. Increased connectivity between processes resulted in higher proportion of spread of damage and poorer endstate recovery. This outcome was true for all architectures, but most apparent in the Fully distributed model. Figure 3 shows the proportion of area and endstate levels reached for each architecture, at each level of Connectivity, following peripheral damage.

Figure 3: Proportion of Area and Endstate obtained in peripherally-damaged models by level of Connectivity.

Figure 4 shows that these effects are further exaggerated by damage to the key processes, in the Hemispheric and Central processor models. This figure shows that following damage to the key process, the Hemispheric model reached levels of recovery that were similar to the peripherally-damaged model (the greatest difference between key and peripherally-damaged process endstate was 1%). In the Central processor model, endstates differed by approximately 9%. The figure also shows that in the Central Processor model, key damage resulted in both lower recovery (Endstate) and more protracted form of recovery (Area).

Figure 4: Proportion of Area and Endstate obtained in key-damaged models by level of Connectivity.

## Cognitive reserve as differences in functional architecture

Implementing CR, as different functional architectures, did modulate the effects of damage. However, it was not those architectures characterized by more connectivity between processes that proved most resilient to damage. Indeed, it was those architectures comprised of more limited connectivity where the effects of damage were minimized and the endstate levels of recovery most complete. In the architectures tested here, this was the Uni-directional architecture. Damage to any process in this architecture had effects on processes downstream of the damaged process. But these effects became increasingly small, over the remainder of the models lifetime. Figure 5 shows Area (left) and Endstate levels (right), respectively, for each of the architectures tested.

Figure 5: Comparisons of functional architectures by proportion of Area (left) and Endstate (right) obtained in peripherally-damaged and key-damaged models.

## Conclusions

Previous simulation studies have showed that following early forms of focal impairment, architectures characterized by greater levels of connectivity offer superior levels of protection compared to those with more limited connectivity (see Baughman & Thomas, 2008). However, in the simulations reported here, where permanent damage occurred to a system late on in its development, it was those models characterized by less connectivity (i.e., more specialized in function) that offered greatest resilience to damage. Examples of those offering the greatest protection are the Bi-directional and Uni-directional models, with the Fully distributed architecture offering the least protection following damage. These results indicate that throughout the process of development, similar events that impair just a limited number of processes to a system may have very different consequences for its outcome. These results are consistent with the notion that different functional architectures may underlie different stages of development (Fransson, Aden, Blennow, & Lagercrantz, 2011), possibly through a process of emergent specialization (Karmiloff-Smith, 2009). Future work is needed to investigate how the parameters we held constant (such as rate of decline, cognitive growth, and the severity and onset of damage) might provide a more complete account of the factors that contribute to real-world variability in ageing.

## Abstract

We investigate the mechanisms that allow people to successfully understand language given noise in the world and in their own perceptual inputs. We address two parts of this question. First, what knowledge do people use to make sense of language inputs that may have been corrupted? Second, how much of this knowledge is used while people are processing sentences? We conduct a sentence production experiment and an on-line reading experiment in order to answer these questions. Both experiments provide evidence that syntactic knowledge can drive top-down reinterpretations of word identities, as well as syntactic reanalyses that are incompatible with people's language input. In addition, Experiment 2 provides evidence that this knowledge is deployed on-line, as people process sentences.

**Keywords:** Language Understanding; Sentence Production; Rational Analysis

## Introduction

People typically understand language effortlessly and successfully despite the fact that the language input can be corrupted in many ways between the speaker's planning of an utterance and the listener's comprehension of it. This suggests that the language comprehension mechanism has developed methods for correcting noise added to the input, in order to recover the speaker's true intent. We will be viewing this problem from the perspective of rational Bayesian inference. According to this position, people identify the intended language input by rationally integrating their prior linguistic expectations with the possibility of noise. The claim that people are at least somewhat rational when correcting for noise seems obviously true – if someone hears “The teacher write”, they are unlikely to perceive this as a totally different phrase, but are instead likely to interpret it as the very similar “The teachers write” or “The teacher writes.” A more interesting question therefore is: how thoroughly do rational noisy-channel effects permeate real-time comprehension at different levels and detail of linguistic representation?

This question can be broken into two parts:

1. What kinds of knowledge are deployed during processing in order to determine if an error has occurred in the input?
2. What kinds of reanalyses due to noise does the sentence processing mechanism pursue? Is it restricted to the reanalysis of single words, or will it pursue more radical reanalyses of the syntactic structure?

In order to address these questions, we will first discuss what is entailed by an ideal-observer perspective on sentence processing in the presence of noise. We will then survey some open questions about the extent to which the sentence processing mechanism is adapted to noise. Finally, we will present the results of a sentence production and a sentence comprehension experiment that each bear on these questions.

## Noisy channel models

According to a noisy channel model of sentence comprehension, a rational comprehender uses their perceptual input, which may have been corrupted, to identify the language input intended by the speaker. There are two sides to the comprehender's inference problem. First, prior linguistic knowledge should constrain people's inferences about what the speaker actually meant. If a particular phrase is very unlikely *a priori*, then it is even more unlikely that it was intended by the speaker but later corrupted by noise. For example, people's syntactic knowledge will inform how they interpret an ungrammatical sentence like “The voter hope there will be a recount.” There is a conflict between the two parts of this sentence: the phrase “The voter hope” is a noun-noun compound, but the phrase “there will be a recount” is the argument of a verb. This conflict can be resolved by a simple syntactic reanalysis of the first phrase. If the first phrase is reanalyzed as a noun-verb construction, then the second phrase will have its required verb, and the sentence will be grammatical. As a result, it seems very compelling to reanalyze the first phrase as “The voter hopes” or “The voters hope.”

While people's linguistic knowledge constrains their inferences about the intended input on one side, their knowledge about the process that generated the noise constrains them on the other. People do not usually intend to say one thing and then accidentally say something completely unrelated. Consequently, the noise process makes certain hypotheses about how the input was corrupted very unlikely. Similarly, our perception does not usually introduce massive errors into the input we receive. Hence in the example above, people only consider similar sentences when they are trying to figure out the intended meaning of “The voter hope.”

The problem of inferring the true intended input can be posed in terms of optimal Bayesian inference. The comprehender's prior linguistic information can be represented by a probability distribution  $P_L$ , which is defined over phrases or sentences. The model of the noise process is given by the distribution  $P_N$ . This distribution specifies how likely a particular noise event is to occur, e.g. the deletion of a letter in the perception of the input, or the accidental insertion of a morpheme by the speaker. By Bayes' Theorem, the probability that a sentence or phrase  $s$  was intended given the perceived sentence or phrase  $s'$  is equal to:

$$P(s|s') = \frac{P_L(s)P_N(s \rightarrow s')}{P(s')} \quad (1)$$

where  $P_N(s \rightarrow s')$  is the probability that  $s'$  will be perceived when  $s$  is intended by the speaker.

In general, having perceived the input  $s'$ , we can measure the comprehender's evidence for phrase  $s_1$  relative to  $s_2$  by

looking at the ratio

$$\frac{P(s_1|s')}{P(s_2|s')} = \frac{P_L(s_1)P_N(s_1 \rightarrow s')}{P_L(s_2)P_N(s_2 \rightarrow s')}. \quad (2)$$

The higher this value, the more evidence that  $s_1$  and not  $s_2$  was intended. We can apply this formula to the case that  $s_2 = s'$ . The resulting ratio

$$\frac{P(s|s')}{P(s'|s')} = \frac{P_L(s)P_N(s \rightarrow s')}{P_L(s')P_N(s' \rightarrow s')}. \quad (3)$$

can be interpreted as the probability that an error occurred and  $s$  was intended relative to the probability that no error occurred and  $s'$  was in fact intended.

These formulas capture some important intuitions about how people should infer the intended input, and also have some interesting consequences. Only sentences  $s$  that have a relatively high probability of causing the perceptual input  $s'$  will be plausible candidates for the intended meaning of the speaker. If this probability  $P_N(s \rightarrow s')$  is low, then by equation 1, the probability  $P(s|s')$  that  $s$  was intended must also be low. For example, if sentence  $s$  is very different than  $s'$ , then it would require a large number of specific errors to transform  $s$  into  $s'$ . As a result,  $P_N(s \rightarrow s')$  would be low, and there would be low probability that  $s$  was actually intended.

The model also captures an interesting tradeoff between the comprehender's linguistic knowledge and the noise model. It will always be the case that the easiest way to generate a perceptual input is for that perceptual input to have been intended: it is not necessary to posit any errors in this case in order to explain the perceptual input. However, the comprehender may infer the presence of noise when there is an alternative sentence  $s$  that is sufficiently similar to  $s'$  and has higher probability according to the language model  $P_L$ . Formula 3 states that as the ratio  $\frac{P_L(s)}{P_L(s')}$  of the probability of  $s$  relative to  $s'$  increases, the comprehender will be more likely to infer that  $s$  was intended. One simple consequence of this is that spelling mistakes will be corrected by the comprehender: misspelled words will receive low probability under the model  $P_L$  relative to nearby, correctly spelled words.

A more interesting consequence is that under certain conditions, the comprehender should infer that noise was added to the input even when the actual sentence has a legitimate analysis. This can happen when the perceived sentence is well-formed but highly unlikely because of semantic implausibility or because it contains low-frequency syntactic constructions. If there is a sufficiently similar sentence  $s$  that has higher probability under the language model, then the ratio in formula 3 may be high enough for the comprehender to infer that  $s$  was actually intended.

Finally, the noisy channel model should lead us to predict that comprehenders will treat the presence of a language-unit (e.g. a letter, morpheme, or word) differently from its absence. In particular, comprehenders should be more likely to infer that a perceived language unit was intended by the speaker than that the absence of a language unit was intended.

The Bayesian size principle of (Xu & Tenenbaum, 2007) explains this asymmetry. This principle states that when a hypothesis allows for many possibilities to occur, it must place a small amount of probability on each of these possibilities. More formally, the principle states that

$$P(h|H) = \frac{1}{|H|} \quad (4)$$

where  $H$  is a hypothesis containing  $h$ , and  $|H|$  is the number of possibilities contained in  $H$ . In the present setting, this implies that there is a lower chance of any specific language unit being accidentally inserted into a perceived sentence than there is of a specific language unit being accidentally deleted. To see this, imagine that because of perceptual noise, a random letter is either deleted from or inserted into part of the sentence. While there are 26 English letters that could be inserted at a given location, there is only one way to delete a specific letter. It follows that there is a higher probability that a particular sentence  $s_1$  was intended, but a letter was deleted from it, than that another sentence  $s_2$  was intended, but a letter was inserted into it. The same reasoning applies to noise generated from speech errors, or insertions and deletions that occur on larger language units such as morphemes and words.

## Previous work

While these types of comprehension behavior are predicted by an ideal-observer model, it is unclear if they are borne out in human comprehension. Previous work has addressed parts of this question. A number of studies have shown the influence of non-syntactic factors on how people determine word identity. In the speech perception literature, researchers have demonstrated context effects in word recognition (Marslen-Wilson, 1975, 1987; Dahan & Tanenhaus, 2004). However, our understanding of two aspects of word recognition remains more limited: (i) the role of syntactic ambiguity as a contextual factor for word recognition; (ii) the consequences of misrecognizing a word, or remaining uncertain as to its identity, for downstream comprehension of the sentence. Event plausibility has also been shown to induce word misrecognition and subsequent processing difficulty, but such processing difficulty has not yet been demonstrated when different syntactic analyses are involved (Slattery, 2009).

Other modeling and experimental studies have provided evidence for the effect of syntax on the correction of noise. Levy (2008) proposed a Bayesian model of noisy-channel sentence comprehension similar to the present one, and suggested that such models might shed light on a number of syntactic-comprehension phenomena difficult to reconcile with traditional sentence-processing models. Gibson and Bergen (2012) provided evidence suggesting that comprehenders can come to global misinterpretations of complete sentences that are incompatible with the true string on the basis of both semantic and syntactic information, but this work does not show how these misinterpretations unfold in real time, and only considers cases in which a word is inserted or

swapped, and not those in which a word is substituted. There is also evidence that comprehenders can be induced to disregard orthographic material (commas) in reading on the basis of strongly biased grammatical expectations, and to adopt a garden-path syntactic analysis that should be incompatible with the actual orthographic material (Levy, 2011), but this has not been shown to happen when actual word identities are at stake. Finally, there is evidence that comprehenders can entertain the possibility that a previous word was misrecognized on the basis of alternative syntactic analyses of an input prefix (Levy, Bicknell, Slattery, & Rayner, 2009). However, this does not show that comprehenders will actually pursue these alternative syntactic analyses further in the sentence.

The present studies aim to fill several gaps in this literature. We will provide evidence that the misrecognition of words can be driven by the comprehender considering grammatical analyses that are incompatible with the true input and taking into account fine-grained (word-word-collocation-dependent) preferences for syntactic analysis. Our evidence will suggest that comprehenders pursue these alternative analyses downstream in the sentence. Finally, we will provide evidence that comprehenders' inferences about noise are rationally sensitive to the asymmetry between insertions and deletions.

### Experiment 1: Verb omission errors

We discussed two distinctive claims of the noisy channel model in the previous section:

1. Comprehenders should infer that a perceived phrase contains an error when there exists a nearby syntactic construction with a much higher base-rate of occurrence. This is true even when the phrase appears well-formed.
2. Comprehenders should be more likely to infer that part of the intended phrase was deleted than that part was inserted. As a result, they should be more likely to believe that a phrase was intended when the only nearby alternatives could have only produced the phrase via insertion.

We test these claims using a timed sentence completion task, with participants asked to complete short sentence preambles. Participants were briefly shown a sentence preamble. This preamble then disappeared, and they were asked to type a complete sentence beginning with this preamble.

Participants were shown preambles that were unambiguously noun-verb ("NV"), unambiguously noun-noun ("NN"), or NN/NV ambiguous constructions (Frazier & Rayner, 1987; MacDonald, 1993). Crucially, each NV preamble differed by only a single morpheme ("-ed") from an NN preamble, and similarly for all of the NN preambles. For example, "The immigrant feared" was used as an unambiguous NV construction, because "feared" must be interpreted as the main verb of the resulting sentence, while "The immigrant fear" was used as an unambiguous NN construction, because "fear" must be interpreted as a noun in the resulting sentence. In addition, the preambles varied in their degree of bias towards the NV or NN constructions. A summary of these con-

ditions is provided in Table 1. The purpose of the ambiguous-preamble continuations was to validate the categorization of each item as NN-biased or NV-biased (see Results below).<sup>1</sup>

Table 1: Experiment 1 conditions

Condition	Example
NV-biased/NN preamble	The immigrant fear
NV-biased/NV preamble	The immigrant feared
NV-biased/ambiguous preamble	The immigrant fears
NN-biased/NN preamble	The almond roll
NN-biased/NV preamble	The almond rolled
NN-biased/ambiguous preamble	The almond rolls

Our noisy channel model predicts a specific pattern of *rational misidentification* of the unambiguous sentence preambles. Participants should primarily misidentify less likely constructions in favor of more likely constructions, and should primarily infer that a morpheme was dropped from a construction, not that it was added. Under the model, therefore, there are two criteria both of which must hold for misidentifications to be most frequent. The first is that the preamble be NN, since NV can be converted to NN by deletion of a single letter or past-tense morpheme, whereas NN-to-NV conversion requires an insertion. The second is that the preamble be NV-biased, since the NV construction is *a priori* more likely in this case. We thus predict that NV-biased NN preambles should be the most likely to be misidentified; in each of the other conditions at least one of the two above criteria fails to hold, and we therefore expect fewer misidentifications of the preambles in these cases.

There are several ways that such a pattern of rational misidentification could manifest itself in our sentence completion paradigm. First, if participants misidentify the preamble, then we expect *repetition errors* in which they retype the preamble incorrectly. For example, if they misidentify an NN preamble as an NV preamble, then we expect them to retype a preamble containing a verb with a past-tense morpheme.

We may also find a more interesting effect which results from participants' rational *uncertainty* about the identity of the sentence preamble. The evidence that participants receive from an NV-biased NN preamble may lead them to be rationally uncertain about whether an NN or NV preamble was intended, as there is still a tradeoff between positing noise and moving to a more probable construction. An optimal sentence processing mechanism would maintain representations of both of these possibilities after encountering the preamble.

We may find evidence of these multiple representations in the form of *verb omission errors*. In such sentences, participants would correctly reproduce the NN preamble, but complete the sentence as though they had already introduced a

<sup>1</sup> Some of our unambiguous preambles do have alternate syntactically permissible readings, e.g. "The almond rolled ice cream was good," but these are low-frequency constructions, and participants never used them in their completions.

main verb. The following sentence provides an example:

- (1) The immigrant fear being deported.

The word “fear” is a noun here, though it would need to be a verb for the sentence to be grammatical. If participants produce such sentences, then this would be evidence that they are maintaining uncertainty about the identity of the preamble, and are repeating the preamble according to one representation, but completing it according to the other.

Figure 1: Experiment 1 results. The left panel shows the error rates in the NN condition, depending on the syntactic bias of the construction, while the right panel shows the error rates in the NV condition. Error bars are 95% confidence intervals. Note that, according to the coding criteria, verb omission errors occurred only in the NN-preamble condition, while verb insertion errors occurred only in the NV-preamble condition.

## Methods:

**Participants:** Sixty native English speakers from the United States were recruited from Amazon Mechanical Turk. They were paid a small amount of money for participation.

**Materials and Procedure:** Participants were shown each sentence preamble for 1.5 seconds. After this, the preamble disappeared from the screen, and participants were given 13 seconds to retype the preamble exactly and complete the sentence. During the instructions, participants were shown several instances of incorrect completions; for example, they were told that if they were asked to complete “The dog in the park”, then they could not add anything to the preamble as in “The dog in the parks.”

Items consisted of 12 NN-biased and 12 NV-biased preambles that were selected for their bias. These preambles were presented in one of three conditions: NN, NV, or an ambiguous condition. These items were presented in a within-subjects design. The ambiguous condition consisted of plural or present-tense items of the form “The immigrant fears”, which is consistent with either an NN or NV reading. This condition was used for norming the items: higher rates of NV completions indicated NV-bias, and similarly for NN completions. Finally, 12 unambiguous NN and 12 unambiguous NV items were used as fillers; these were distinct from the test items in not being in the morphological neighborhood of an alternative construction.

**Coding:** Completed sentences were coded as correct if the sentence preamble was repeated correctly and the sentence was grammatically well-formed. A sentence was coded as a repetition error if its preamble was repeated with a morphological error that switched its grammatical role (e.g. if an NN preamble was repeated with past-tense morphology) and the rest of the sentence was grammatically consistent with the repeated preamble. In the NN conditions, a sentence was coded as a verb omission error if the preamble was repeated correctly but the rest of the sentence grammatically required a main verb to appear in the preamble. In the NV conditions, a sentence was coded as a verb insertion error if the preamble was repeated correctly but the rest of the sentence grammatically required the preamble to be a noun phrase.

Of the total responses, 7% contained miscellaneous errors, which did not fall under the other criteria. For 74% of these errors, the sentence did not contain a complete independent clause; most of the remainder contained word substitutions in the preamble, or number or tense agreement errors.

## Results and discussion

We first analyzed whether the NN and NV-biased items were biased in the correct direction. This was determined using the completions for the ambiguous condition. All 12 of the NN-biased items received NN completions most frequently; 11 of the 12 NV-biased items received NV completions most frequently, and 1 was equi-biased. Of the 229 NN-biased items in the ambiguous condition completed correctly, 197 (86%) were given NN completions. Of the 228 NV-biased items completed correctly, 184 (81%) were given NV completions.

We next looked at whether repetition errors and verb omission errors occurred more frequently for the NN preambles. We tested this using repeated measures ANOVAs; Figure 1 shows the frequencies of each type of error for each experimental condition.<sup>2</sup> There were significantly more repetition errors in the NN preambles than in the NV preambles (12 vs. 2;  $p < 0.05$ ). In addition, there were significantly more verb omission errors in the NN preambles than noun omission errors in the NV preambles (27 vs. 0;  $p < 0.001$ ). We note that for the NN preambles, the repetition errors were approx-

<sup>2</sup>We did not use mixed logit models because of convergence issues with random slopes.

imately evenly distributed among errors to the plural marking of the first noun, past-tense errors on the second noun, and present-tense errors on the second noun.

Our final question was whether the error rate for the NN items was higher for the NV-biased items (we did not analyze this for the NV items, because these contained so few errors). Because the bias was manipulated between-items, we tested this using ANOVAs with subjects as random factors. All of the repetition errors for the NN items occurred on NV-biased items (12 vs. 0;  $p < 0.01$ ). All but one of the verb omission errors occurred on NV-biased items (26 vs. 1;  $p < 0.001$ ).

These results provide evidence for both predictions of the noisy channel model. First, we observed the predicted asymmetry between insertions and deletions: nearly all of the observed errors were consistent with the participants inferring that a morpheme had been dropped from the preamble they observed. Second, we observed that nearly all errors were made in the direction of the more probable construction.

We also found evidence for a more tentative prediction of the model, which is that participants would maintain uncertainty about the identity of the preamble. Verb omission errors patterned in the same manner as the repetition errors; moreover, they occurred at twice the rate of the repetition errors. This suggests that participants were maintaining multiple representations of the sentence preamble; verb omission errors occurred when more than one representation was deployed in the completion of the sentence.

## Experiment 2

In Experiment 2, we used a different method to evaluate the predictions of the noisy channel model. The model predicts that people will adopt incorrect syntactic analyses if there exist similar phrases that could have easily generated them. In such cases, we should be able to observe the effects of misidentification downstream in sentence comprehension: specifically, comprehenders should have difficulty if the later parts of a sentence are inconsistent with their interpretation.

We used NN and NV preambles like those in Experiment 1 to probe such garden-path effects. If people misidentify an NN preamble as an NV preamble, then they should be surprised when a main verb is used later in the sentence; conversely, if they misidentify an NV preamble as an NN preamble, then they should be surprised when the clause ends without a main verb. For example, in the Dense-neighborhood/NN condition in Table 2 – which is so named because there are other grammatical phrases in the morphological neighborhood of its preamble – people should sometimes infer that the past tense “chauffeured” was intended instead of “chauffeur”, and therefore they should be surprised when they arrive at the main verb “hoped.” On the other hand, if they infer that “chauffeur” was intended instead of “chauffeured” in the Dense-neighborhood/NV condition, then we would expect difficulty at “but”, which indicates the end of the first clause. Such effects have been shown for truly ambiguous NN/NV preambles such as “The voter hopes” (Frazier &

Rayner, 1987), and have also been shown to be affected by the collocation’s lexical bias (MacDonald, 1993), but have never been demonstrated when the preamble is unambiguous.

We used self-paced reading to evaluate whether people had difficulty at these “disambiguating” regions (note, however, that these items are only ambiguous given the possibility of noise). People’s performance at these regions was evaluated against two control conditions, Sparse-neighborhood/NN and Sparse-neighborhood/NV, which were given this name because their preambles were not in the morphological neighborhood of alternative syntactic constructions. These conditions were identical to the Dense-neighborhood conditions, except for this difference in the density of the morphological neighborhood. For the Sparse-neighborhood/NN condition, this was done by using an adjective before the head noun, and for the NV condition, this was done by using the quantifier “some” and a plural morpheme before the main verb.

The noisy channel model predicts an interaction between the density of the morphological neighborhood and grammatical structure at the disambiguating region. In particular, because of the asymmetry between morpheme insertion and deletion, people misidentify the preamble most frequently in the Dense-neighborhood/NN condition. We should expect less difficulty at the disambiguating region of the Dense-neighborhood/NV condition because the syntactic alternative of the preamble would require an insertion to produce the perceived wordform. We should similarly expect less difficulty in both Sparse-neighborhood conditions, because these preambles are far from alternative syntactic constructions.

Table 2: Experiment 2 conditions

Condition	Example
Dense-neighborhood/NN	The intern chauffeur for the governor hoped for more interesting work.
Dense-neighborhood/NV	The intern chauffeured for the governor but hoped for more interesting work.
Sparse-neighborhood/NN	The inexperienced chauffeur for the governor hoped for more interesting work.
Sparse-neighborhood/NV	Some interns chauffeured for the governor but hoped for more interesting work.

## Methods:

**Participants:** We recruited 120 native English speakers from the United States from Amazon Mechanical Turk. They were paid a small amount of money for participation.

**Materials and Procedure:** We tested participants using a self-paced reading program that ran in participants’ web browsers. Words were presented one at a time. After each sentence, participants were asked a comprehension question.

We constructed 16 items in the conditions shown in Table 2. These conditions varied in a within-subjects design. We also included 32 filler sentences during testing.

Figure 2: Reading-times from Experiment 2. Region 6 is the critical disambiguating region.

## Results and discussion

Before analyzing the data, we excluded participants that answered fewer than 80% of the comprehension questions correctly, and excluded trials on which reading times were farther than 2 standard deviations from the mean. Accuracies on comprehension questions were above 90% on all conditions. The results are shown in Figure 2. For the analysis, words were aligned relative to the disambiguating word, which is labelled as region 6 and is the first place we can expect to find any critical effects of disambiguation.

Our first question was whether there was an effect of neighborhood density for the NN items, for which we expected difficulty at the disambiguating region. We performed our analysis with a linear mixed-effects model with random slopes and interactions for participants and items. We found a significant increase in RTs at the disambiguating region for the Dense-neighborhood items ( $\beta=33.08$  ms,  $t=2.49$ ,  $p < 0.05$ ). We next looked at whether this effect was strongest for the NN items. There was a significant interaction between neighborhood density and syntactic structure ( $\beta=35.06$  ms,  $t=2.21$ ,  $p < 0.05$ ), indicating a superadditive effect of density and structure on RTs. No interactions were significant ( $p>0.05$ ) at any region prior to the critical region.

These results provide evidence that participants misidentified the sentence preambles, and that this misidentification was rational. Specifically, we found evidence that participants were most likely to misidentify preambles that could have been produced by an alternative phrase via a deletion. This is consistent with the asymmetry between insertions and deletions implied by the Bayesian size principle.

## Discussion

We have investigated the knowledge that people use to correct noise in their language input, as well as the on-line process-

ing mechanisms that support this error correction. Regarding the first topic, our experiments provide evidence that comprehenders entertain and even adopt syntactic reanalyses of their language input to account for the possibility of noise, even when these reanalyses are inconsistent with the true input. Moreover, we found evidence that these reanalyses are driven by the rational integration of grammatical expectations and expectations about the noise process. The results of Experiment 1 suggest that people prefer alternative explanations for their input that involve higher probability syntactic constructions, and noise consisting deletions rather than insertions.

We have also found evidence that people employ these alternative syntactic analyses during on-line sentence processing. In Experiment 2, we found downstream effects of noise-driven reinterpretations at the point when they contradicted the input sentence. This suggests that the sentence processing mechanism is not delayed in positing or making use of syntactic reanalyses during the course of comprehension. This is the first result demonstrating that comprehenders will pursue garden-path syntactic analyses differing from the true sentence preamble by a word substitution, and that garden-path disambiguation in these cases incurs measurable costs; this result is directly predicted by our noisy-channel model. Together with other recent work, these results raise new questions regarding the full breadth of sentence-processing phenomena that may be best understood as the consequence of rational, noisy-channel probabilistic inference.

## Abstract

A well-known phenomenon in natural interaction is that speakers adapt their linguistic and nonverbal behaviors. Research on *gestural* alignment is, however, still in its early stages based on evidence from experimental settings. This paper provides a first systematic study of gesture form convergence based on a large sample of naturalistic dialogue data. We found evidence for gestural alignment, but not all form features of co-speech gestures are subject to this effect. In a detailed analysis of those sensitive features we further address questions of how gestural alignment depends on the temporal distance between gestures, and whether *intra*-speaker or *inter*-speaker influences on gesture form are stronger.

**Keywords:** Alignment, co-speech gestures, natural interaction

## Introduction

Co-speech gesturing is an integral part of human communication, but it is not well understood why and how gestures take on their particular physical form. This holds especially for iconic gestures that apparently communicate by virtue of iconicity, i.e., through a correspondence between their form and geometrical or spatial properties of what they refer to. Empirical studies, however, revealed that similarity with the referent cannot fully account for all occurrences of iconic gesture use (Kopp, Tepper, Ferriman, Striegnitz, & Cassell, 2007). Findings also indicate that a gesture's form is influenced by other contextual constraints such as discourse (Holler & Stevens, 2007) or the linguistic context (Kita & Özyürek, 2003). In addition there are considerable differences in how speakers gesture, partly assumed to be due to different cognitive abilities (Hostetter & Alibali, 2007).

In addition to intra-speaker sensitivities, co-speech gesturing in dialogue may also be influenced by the gestures of the interlocutor. A large body of work has demonstrated inter-personal sensitivities in verbal and nonverbal behavior in natural social interaction, leading often to coordination and alignment between interlocutors (cf. (Kopp, 2010)). For example, linguistic coordination has been reported with respect to words, phrase structures, speech rate, tones of voice, speech rhythms, etc. (cf. Chartrand, Maddux, and Lakin (2005); Branigan, Pickering, Pearson, and McLean (2010)). Pickering and Garrod (2004) ascribed this linguistic alignment largely to an automatic priming of interlocutors lexical, syntactic, or semantic representations and a percolation of activation between adjacent representational levels. Others, e.g. (Brennan & Clark, 1996), suggested that speakers strategically design utterances for an addressee and thereby prefer previously used (grounded) constructions. Regarding nonverbal behavior, interactants can likewise be found to mimic each

other, e.g., in posture, body movements like foot shaking, mannerism, or facial expressions (cf. Chartrand and Bargh (1999); Lakin and Chartrand (2003)). This kind of mimicry is assumed to be largely non-conscious and automatic, being mediated by perception-action links that involve the own motor system in the perception of others actions (Dijksterhuis & Bargh, 2001). Only recently, researchers have started to look at whether speakers also align in their *co-speech* gestures, i.e., the spontaneous and meaningful hand movements that accompany speech. Such gestures stand out as they are very closely linked to the speech they accompany, in both content and timing (McNeill, 1992). Investigating whether speakers align in and via their gestures can thus help, first, to understand what shapes these gestures and, second, to shed light on the role of interpersonal coordination in dialogical communication.

Figure 1: Example of alignment of two successive gestures (left: router's assertion; right: follower's acknowledgement).

In this paper we present results from the first large-scale investigation of gestural alignment in natural dialogue. Fig. 1 shows an example, in which some properties of the first gesture (left) are being mimicked (e.g., handshape, trajectory) while others are not (e.g. relative movement direction). This suggests a feature-based, multi-level analysis of gestural alignment. We will thereby focus on the *form-based aspects* of gestural alignment here. In the next section we review the few existing studies that have looked at occurrences of form convergence in co-speech gestures, so far. Then we present the corpus data and the approach taken to investigate the phenomenon of gestural alignment in it, and present results of three analyses meant to answer the following questions: (1) Is there gestural alignment, compared against a baseline, and are there differences between different form features of a gesture? (2) What is stronger, the influence of the interlocutor's gestures or of one's own previous gesturing? (3) How does gestural alignment depend on (temporal) distance between the gestures? Finally, we discuss our findings in light of these questions and draw conclusions.

## Related Work

Based on initial evidence by Kimbara (2006), who reported a couple of examples of gesture form convergence among interlocutors, some recent studies addressed the phenomena of gestural alignment (in this context often termed ‘mimicry’) more deeply. Parrill and Kimbara (2006) investigated the question to what extent observing mimicry affects people’s behavior. They found that participants who observed mimicry in a video-recorded interaction were subsequently more likely to reproduce the mimicked behavior in their own descriptions, whereby a gesture was assessed as a reproduction if it corresponded with the stimulus gesture in handshape, motion and location.

In a similar setting, Mol, Krahmer, Maes, and Swerts (2012) provided evidence for the alignment of handshapes in co-speech gestures: Participants who saw a speaker in a video stimulus using gestures with a particular handshape were more likely to produce gestures with these handshapes later on, while retelling the story. This evidence is, however, limited to a particular kind of gestures (‘path gestures’ in directions), distinguishing between two different handshape classes (index finger extended vs. more than one finger extended). Mol et al. further addressed the role of meaning in this context. They found that gesture forms were only repeated across speakers if they had occurred in a meaningful context as expressed in concurrent speech. It is concluded that gesture form adaptation resembles adaptation in speech, rather than it being an instance of automated motor mimicry.

Kimbara (2008) studied triadic interaction with two co-narrators providing a joint narration to a third person, while manipulating the mutual visibility between co-narrators. Greater convergence in one gesture form feature (handshape) was found when participants could see each other. However, in this setting the two narrators were required to provide a coherent description for the recipient which might enhance the likability for gesture form convergence. Holler and Wilkin (2011) showed that gesture mimicry also occurs in face-to-face dialogue. In repeated references to the same figure-like stimuli, participants were found to be more likely to use similar gestures when they could see each other (vs. a non-visible condition). Holler & Wilkin concluded that gestures seem to play an active role in the process of grounding, because the vast majority of mimicked gestures occurred in phrases devoted to the presentation or acceptance of information.

In sum, existing studies lend considerable evidence that a speaker’s gesture use is influenced by others’ gestures. However, this quantitative empirical evidence is limited to experimental settings with video-based stimuli or elicited repeated references—an caveat often put forward against studies in linguistic alignment (cf. Howes, Healey, and Purver (2010)). To date, there is no analysis of gestural alignment based on a large sample of naturalistic dialogue data. The present study aims to close this gap.

## Present Study

We have conducted statistical analyses on a large data corpus of spontaneous speech and gesture in dialogue (SaGA corpus (Lücking, Bergmann, Hahn, Kopp, & Rieser, 2010)). With these analyses we aimed for a systematic investigation of gesture form convergence going beyond previous studies in several respects. First of all, our corpus provides a detailed coding of the gestures’ physical form including handshapes, palm and finger orientation, wrist movement, and position. This allows for addressing the degree to which *single* gesture form features are sensitive to influences of an interlocutor’s gestures, instead of considering the “same overall form” (Holler & Wilkin, 2011), one particular form feature only (Kimbara, 2008), or the sum of several form features (Parrill & Kimbara, 2006). Second, some of the above mentioned experimental studies manipulated the visibility between interactants to create a baseline for gestural alignment occurring by chance. Investigating natural dialogues allows for an alternative baseline by creating artificial dialogues, as previously done in corpus analyses of linguistic alignment (Howes et al., 2010); for details see sect. ‘Control Data’. Third, a characterizing feature for alignment in speech corpora is that the repetition probability is increased immediately after the prime and decreases toward the global mean with greater distances between prime and target (Reitter, 2008). A corpus analysis on extended dialogue allows to address this issue for gestural alignment, too. Fourth, we are able to investigate the *contingencies* involved in gestural alignment. Pickering and Garrod (2004) suggested to treat alignment not only as an *inter*-subjective phenomenon (‘other-alignment’), but also *intra*-subjectively (‘self-alignment’). Given the fact that the use of co-speech gestures is subject to major inter-individual differences (Hostetter & Alibali, 2007), the relationship between self- and other-alignment is important to assess the strength of inter-speaker gesture form convergence. Finally, the above mentioned studies have in common that they are limited to gestural alignment in repeated references to the same referent. Analyzing a large data sample allows to study the degree of gesture adaptation on a level of gesture form beyond the connection to specific referent objects, allowing to delineate grounding and mere motor resonances. In the following, we will briefly describe the corpus and explain how we framed the problem of detecting and measuring alignment between gestures occurring in dialogue.

**Data Corpus** The SaGA corpus consists of 25 dyads (21 female, 29 male participants) engaged in a spatial communication task combining direction-giving and sight description. This task required participants to convey the shape of objects and the spatial relations between them. The stimulus was an artificial town presented in a Virtual Reality environment, affording experimental control for the content of speaker messages. After taking a “bus ride” through the town, a router explained the route to an unknown and naïve follower. In total, the SaGA corpus consists of 280 minutes of

video material containing 4449 iconic/deictic gestures. All dialogues are completely and systematically annotated based on an annotation grid, tested and refined using multi-coder agreement tests; for details see Lücking et al. (2010). Each gesture is demarcated by the beginning and end of the expressive, so-called ‘stroke’ phase. The gesture’s form during the stroke phase, as far as relevant here, is annotated in terms of the following distinct form features: (1) **HANDEDNESS**: one-handed (either left- or right-handed), or two-handed gestures; (2) **HANDSHAPE**: ASL-based coding of hand configurations like ASL-B, ASL-C, etc. + modifiers (e.g. bent, loose); (3) **PALM- AND FINGER ORIENTATION**: up, down, sideways, towards body, away + combinations and sequences; and (4) **WRIST MOVEMENT TYPE**: static, linear, or curved + sequences. A further important and characterizing feature of an iconic gesture is the more general **REPRESENTATION TECHNIQUE** (e.g. Kendon (2004)). For the spatial domain of the SaGA dialogues, the following set of techniques proved to be adequate: indexing, placing (as if putting a virtual object somewhere), shaping (as if sculpting a 3D shape), drawing (as if sketching a 2D outline), and posturing (using the hand/arm as a model for something).

**Prime-target Pairs** From 4449 iconic/deictic gestures in the SaGA corpus, a total of 17130 prime-target pairs<sup>1</sup> were extracted. Figure 2 exemplifies the possible alignment-relevant influences between different prime-target pairs that can occur in dialogue. Each of these pairs is characterized by a distance **DIST** between prime and target gesture, taken to be the number of other gesture occurrences in-between plus 1. Each prime-target pair is further characterized by a **CONTINGENCY TYPE**: whether prime and target gestures are produced by the *same* speaker (‘self-pair’) or by *different* speakers (‘other-pair’), respectively. In the SaGA corpus there are 17362 self-pairs and 3993 other-pairs.

Figure 2: Possible alignment influences between gestures: Speaker A produces two gestures (G1, G4), while speaker B makes two gestures (G2, G3) in-between. Gestures are characterized by features ( $F_1 \dots F_n$ ) and can influence each other both within a speaker (‘self’) and across speakers (‘other’), where the relation’s distance (DIST) is determined by the occurrences of gestures in-between.

<sup>1</sup>We employ the term ‘prime-target pair’ in lack of a better one. This is not to imply that alignment is due to *priming*.

**Control Data** A common problem in studies on behavioral coordination is to lay down a baseline of how much coordination can occur simply by chance, regardless of any contingencies between primes and targets. Adopting the approach of Howes et al. (2010) in their corpus analyses of lexical and syntactic alignment in speech, we created ‘fake’ dialogues by re-combining the gestures of two speakers from originally different dialogues. This is done in an interleaved fashion, i.e., the whole sequence of gestures produced by one particular direction-giver is kept, but merged with the complete gesture sequence produced by a different direction-follower. This way we created 25 control dialogues with randomly chosen participants while respectively maintaining the participants’ role (direction giver vs. direction follower). As a matter of course, although the total number of gestures remains the same, this results in a different number of prime-target pairs in the control data set with regard to **CONTINGENCY TYPE**: 16523 self-pairs and 2407 other-pairs.

**Metric** Considering gestural alignment necessitates to define a metric estimating the similarity between prime and target gesture. Since we want to be able to assess alignment even at the level of single features of a gesture, we define a metric for each particular gesture feature. To make results comparable with each other, we employ a binary metric for all variables: it scores 1 if prime and target gesture are identical in a particular gesture feature, and 0 otherwise. For some features this definition can be applied straightforwardly (e.g. **HANDEDNESS**: one-handed vs. two-handed), for others it is reasonable to allow some minor variation between prime and target gesture. Palm and finger orientation, for instance, are coded as combinations of five basic values (up, down, sideways, towards, away). That is, a palm orientation of ‘down’ and an orientation of ‘down/away’ would count as a mismatch although the actual difference in palm orientation is 45° which can be regarded a slight deviation given the natural fuzziness of human gesture use. Accordingly, the binary metric is applied to the gesture features as follows, whereby for features which allow sequential coding the final segment of the prime’s value and the first segment of the target’s value are considered:

- **REPRESENTATION TECHNIQUE** and **HANDEDNESS**: A score of 1 is given only if the values for prime and target gesture are identical, 0 otherwise.
- **HANDSHAPE**: Any modifiers of ASL handshapes like ‘spread’ or ‘loose’ are omitted, i.e. ‘ASL-B-spread’ and ‘ASL-B-loose-spread’ both fall into the basic category ‘ASL-B’. A score of 1 is given only if prime and target are identical in this basic category for both hands, 0 otherwise.
- **PALM AND FINGER ORIENTATION**: A score of 1 is given if prime and target match in at least one part of the annotation value for both hands, 0 otherwise.

- **WRIST MOVEMENT TYPE:** A score of 1 is given if prime and target are identical or – in case of a two-handed gesture with different movement types – if the value for one hand is identical with the other gesture’s value, 0 otherwise.

## Results

**Is there gestural alignment in dialogue?** This analysis aims to show whether gesture use in real dialogues shows reliably more other-alignment than would occur by chance. To this end, we compare similarity scores in real vs. control dialogues for each gesture feature with a one-way analysis of variance for each of the gesture features. We only consider prime-target pairs with DIST=1 here, since it is more likely that alignment occurs in consecutive gestures than in more distant pairs. With regard to Figure 2 this means that we take prime-target pairs like (G1,G2) or (G3,G4) into account ( $N=950$  pairs; 579 from the original data, and 371 from control dialogues). Exact means and standard deviations are given in Table 1.

For REPRESENTATION TECHNIQUE ( $F_{(1,948)} = 24.61, p < .001$ ), HANDSHAPE ( $F_{(1,948)} = 17.92, p < .001$ ), and PALM ORIENTATION ( $F_{(1,948)} = 6.65, p = .01$ ), there is a reliable difference between the two groups such that the mean similarity in control dialogues is significantly lower than in real dialogues. For HANDEDNESS ( $F_{(1,948)} = 3.47, p = .063$ ) the analysis marginally fails to reach significance, but by trend the mean similarity in control dialogues is significantly lower than in real dialogues. For FINGER ORIENTATION ( $F_{(1,948)} = .16, p = .69$ ) and WRIST MOVEMENT TYPE ( $F_{(1,948)} = .06, p = .94$ ) the analysis shows no significant main effect between real and control data.

This means that there exists other-alignment in gesture use, but not all gesture features are subject to this effect. Only for the features REPRESENTATION TECHNIQUE, HANDSHAPE, PALM ORIENTATION, and HANDEDNESS the mean similarity of prime and target is higher as to be expected by chance. We continue with these features to a finer analysis.

Table 1: Mean similarity of gesture features for real and control dialogues (standard deviations in parentheses).

	Real	Control
Representation Technique	.31 (.37)	.16 (.46)
Handedness	.68 (.47)	.62 (.49)
Handshape	.37 (.48)	.24 (.43)
Palm Orientation	.49 (.50)	.41 (.50)
Finger Orientation	.61 (.49)	.60 (.49)
Wrist Movement Type	.40 (.49)	.40 (.49)

**Self- vs. Other-Alignment?** To compare the effects of self- and other-alignment, we now investigate the difference between prime-target pairs in the same speaker (CONTINGENCY TYPE = ‘self’) vs. prime-target pairs with different speakers (CONTINGENCY TYPE = ‘other’). We only consider adjacent prime-target pairs with DIST=1 (for instance, in Figure 2 self-pairs like (G2,G3) with other-pairs

like (G1,G2). The total number of pairs amounts to  $N=4317$  (3738 self-pairs, and 579 other-pairs). Again we employ a one-way analysis of variance, exact means and standard deviations are given in Table 2.

For all variables under consideration the analysis reveals significant main effects: REPRESENTATION TECHNIQUE ( $F_{(1,4315)} = 25.05, p < .001$ ), HANDSHAPE ( $F_{(1,4315)} = 51.86, p < .001$ ), HANDEDNESS ( $F_{(1,4315)} = 39.38, p < .001$ ), PALM ORIENTATION ( $F_{(1,4315)} = 67.95, p < .001$ ). These effects are due to the fact that mean similarity of prime and target are higher for self-pairs than in other-pairs. That is, the alignment between gestures is reliably stronger *within* speakers than it is *across* speakers.

Table 2: Mean similarity of gesture features for self- and other-speaker pairs (standard deviations in parentheses).

	Self	Other
Representation Technique	.41 (.49)	.31 (.46)
Handedness	.79 (.40)	.68 (.46)
Handshape	.53 (.50)	.37 (.48)
Palm Orientation	.67 (.47)	.49 (.50)

**Effect of temporal distance on other-alignment?** To elucidate how gestural alignment is affected by temporal distance, we analyze how the similarity score depends on the distance between prime and target gestures. For this analysis we consider other-pairs of distance 1-4. In Figure 2 examples of other-pairs with DIST=1 would be (G1,G2) or (G3,G4), examples of an other-pair with DIST=2 are (1,3) or (2,4). We employ a one-way analysis of variance for the dependent variable SIMILARITY and the independent variable DIST. A total of 3081 primed-target pairs is analyzed ( $N(\text{DIST}=1)=579$ ,  $N(\text{DIST}=2)=758$ ,  $N(\text{DIST}=3)=843$ ,  $N(\text{DIST}=4)=901$ ).

For REPRESENTATION TECHNIQUE there is a main effect of DIST and similarity score  $F_{(3,3077)} = 6.22, p < .001$ : the similarity score is smaller the greater the distance between prime and target. This is due to significant differences between prime-target pairs with DIST=1 and others (DIST=2:  $t_{(1335)} = 1.96, p = .05$ ; DIST=3:  $t_{(1420)} = 2.51, p = .012$ ; DIST=4:  $t_{(1478)} = 4.30, p < .001$ ), as well as between distances 2 and 4 ( $t_{(1657)} = 2.40, p = .017$ ). Likewise, for HANDSHAPE the similarity scores decrease significantly with increasing distance between prime and target DIST ( $F_{(3,3077)} = 7.10, p < .001$ ). This is due to the fact that the similarity of prime-target pairs with DIST=1 is higher than for prime-target pairs with higher distances (DIST=2:  $t_{(1335)} = 2.63, p = .09$ ; DIST=3:  $t_{(1420)} = 3.37, p = .001$ ; DIST=4:  $t_{(1478)} = 4.51, p < .001$ ). In contrast, for HANDEDNESS ( $F_{(3,3077)} = .045, p = .99$ ), and PALM ORIENTATION ( $F_{(3,3077)} = .41, p = .75$ ) there is no main effect of distance between prime and target gesture.

That is, the more gestures occur between prime and target, the smaller is their similarity with respect to REPRESENTATION TECHNIQUE and HANDSHAPE, which is corroborated when checking the actual temporal distances in milliseconds.

By contrast, the similarity score remains more or less constant for the features HANDEDNESS and PALM ORIENTATION.

Table 3: Mean similarity for varying distances between prime and target gesture (standard deviations in parentheses).

	DIST=1	DIST=2	DIST=3	DIST=4
Representation Technique	.31 (.46)	.26 (.44)	.25 (.43)	.21 (.41)
Handedness	.68 (.47)	.67 (.47)	.68 (.47)	.67 (.47)
Handshape	.37 (.48)	.30 (.46)	.29 (.45)	.26 (.44)
Palm Orientation	.49 (.50)	.49 (.50)	.48 (.50)	.47 (.50)

Together with results from the first analysis that revealed highest  $F$ -scores for the former two features in comparison with control data, this provides the following picture: For REPRESENTATION TECHNIQUE and HANDSHAPE there is a strong other-alignment effect which decreases with greater distances from the prime gesture. For HANDEDNESS and PALM ORIENTATION there is a rather weak difference when comparing original and control data and the effect is more or less constant. In other words, there seems to be a general (weak) tendency to produce gestures with a certain amount of similarity in these two features, but this is not biased by the other's directly preceding gesture use.

## Discussion

In this paper we reported results from the first fine-grained and systematic analysis of alignment in co-speech (iconic) gesturing in natural direction-giving dyads. What did we find? First, there is significant gestural alignment in dialogue. That is, a speaker's use of co-speech gestures is affected by the other's gestures in the dialogue. Remarkably, not all gesture features seem to be equally sensitive, with WRIST MOVEMENT and FINGER ORIENTATION being most resistant. Second, alignment effects are significantly stronger *within* speakers than *across* speakers. That is, a speaker's gestures influence each other more than the gestures the interlocutor performs, albeit the effectiveness of other-alignment. Third, regarding the relation between the strength of other-alignment and the prime-target distance, a multi-faceted picture emerges: alignment in handshape or representation technique becomes weaker with greater distances, while alignment in handedness and palm orientation remain constant.

These findings can shed new light on iconic co-speech gestures, as well as the cognitive processes underlying their production in dialogue. To start with, how can we make sense of the heterogeneity of feature-based gestural alignment? A closer look at the role of gestural representation techniques might be informative. Each of these techniques is characterized by a specific pattern of how meaning is depicted. For example, in drawing gestures as in Figure 1 it is the *wrist trajectory* that conveys most of the intended meaning, while in indexing or placing gestures the *position* of the hands is of major importance to convey meaning. That is, some features can be considered more communicatively significant than others. Indeed, variation within the less significant features has also been reported to reflect individual gesturing style (Bergmann,

2012). Our results here suggest that those features, like handshape, are also more amenable to inter-personal coordination, while the communicatively more significant features tend to be more resistant. This suggests a notion of gestural alignment as adaptation within the degrees of freedom available under given communicative constraints.

Existing cognitive models of speech and gesture production lack an account of other-alignment. However, our findings suggest a row of implications for such models. At first it is important to note that our analysis of gestural alignment at the level of different features supports a view that a gesture is not produced as a whole, but in different steps that can exert influences over the constitution of different features of a gesture. We thus hypothesize that different gesture form features are determined at different points in time with other-alignment arising potentially from high-level mechanisms in terms of full grounding, i.e. signaling established links between form and meaning, as well as low-level mechanisms of priming or motor resonance (Montgomery, Isenberg, & Haxby, 2007). That is, such a model provides (at least) two routes than could mediate alignment. However, our finding that communicatively significant features are less affected by alignment may be a consequence of a hypothesized more "ego-centric" nature of early, high-level stages of the production process, which may be more concerned with the necessary, communicatively intended functions and less with corrective or audience-design functions (Keysar & Henly, 2002). Lower-level processes, on the other hand, involve connected sensory and motor processes which have been shown to be effective also in gesture (Montgomery et al., 2007) and have often been assumed to mediate interpersonal coordination. Our empirical findings suggest that the sensorimotor route is particularly effective. To further distinguish between the two routes, we are concerned with measuring the degree of form similarity in relation to referent similarity in ongoing work.

Our observation of strong self-alignment effects may be explained by a strong role of internal priming or caching in the cognitive speech-gesture production process. This conforms hypotheses of self-routinization or *expert performance* effects, which state that over repeated encounters with a particular problem, memory traces build up that directly map a problem stimulus to a solution (e.g., Logan (1988)). It is important to note, however, that gesture use also seems to be subject to adaptations taking place in extended dialogue with repeated references. Such processes have been found, e.g., to lead to considerable *reduction* of the complexity of speech and gestures (Hoetjes, Koolen, Goudbeek, Krahmer, & Swerts, 2011). That is, gestures can become simpler or less precise over repeated uses when referring to the same entity. Further research is needed to elucidate how different mechanisms and driving forces (e.g., alignment through repetition vs. simplification through reduction) compete and interact with each other.

With all these raised questions, we think that computational simulation can provide a valuable tool to test whether

different kinds of cognitive mechanisms result in the effects we observe empirically. We have developed a computational model for speech and gesture production in previous work (Kopp, Bergmann, & Wachsmuth, 2008). Opening this to the effects of dialogical interaction, e.g. endowing it with perceptive abilities, will enable us to complement this empirical work with computational studies.

## Abstract

The paper argues for a new view on and an approach to rationality as a concept of study and modeling paradigm of human behavior. After critically reviewing classical (normative) approaches to rationality, decision-making, and rational behavior, we present cornerstones of a positive, integrative, and holistic conception of these cognitive capacities. A discussion of key elements of this new view is given, and possible consequences and implications are considered.

**Keywords:** Rationality; Human-level intelligence; Subject-centered model; Cognitive capabilities; Integrative model.

## Introduction

With Aristotle's famous characterization of man as a rational animal ("zoon logikon") in his *Metaphysics* (Tredennick, 1933-35), and the ascription of a rational principle to the human being in his *Nicomachean Ethics* (Broadie & Rowe, 2002), the idea of seeing rationality and rational behavior as indispensable parts of our humanity has been introduced into human self-conception, starting centuries of inquiry into the nature and properties of this alleged *conditio sine qua non*. Still millennia after Aristotle, Descartes is only one amongst many famous scholars explicitly mentioning the question in his writings: "*But what is a man? Shall I say 'a rational animal'? No; for then I should have to inquire what an animal is, what rationality is, and in this one question would lead me down the slope to other harder ones (...)*" (Cottingham, Stoothoff, & Murdoch, 1984).

Nowadays, with the background of modern sciences, and especially with the advent of cognitive science, new questions and perspectives have been added to the question for the nature of rationality. Instead of merely studying properties and features of its manifestation in humans and their behavior, and measuring those against standards for rationality derived from normative theories, prediction and modeling aspects of theories of rationality are gaining more and more importance. These efforts can take various forms, ranging from formal studies of customer preferences and behavior, over cognitive modeling of decision-making and choice processes, to rational agency projects within AI.

Nonetheless, although this shift of emphasis within the study of rationality is clearly happening, it is a change of priorities within the existing overall setting, but not a revolutionary process overthrowing existing paradigms, or creating new approaches and ideas. In the following, we want to argue that the latter is what would be needed, on the one hand for real progress with respect to the aforementioned modeling and prediction tasks, but on the other hand also for the sake

of a deeper understanding and progress within rationality research itself.

The paper is structured as follows: The next section gives an overview of classical accounts and paradigms within rationality research, together with well-known objections and caveats to these standard frameworks. Then, a review of recent empirical and theoretical findings is presented, indicating a way to a new understanding and modeling of rationality and rational behavior. This new conception, for the time being called "subject-centered rationality", is sketched and elaborated on in a dedicated section. The penultimate section discusses basic features of this new stance in a juxtaposition of (expected) standard objections and reservations with solutions and answers to the former. Concludingly, the paper is put into a bigger context within the respective fields.

## Standards in Rationality

In the following, when talking about rationality, we mostly want to refer to the manner in which people derive conclusions when considering things deliberately in the domain of individual problem-solving, also including the conformity of one's beliefs with one's reasons for those beliefs or of one's actions with one's reasons for those actions. In consequence, at least for our considerations, beliefs and knowledge (which are also seen as presuppositions for respective actions), that is the epistemic aspects of rationality, are our main concerns. Within this context, rationality is intrinsically connected to an optimality principle, making a decision rational if it is not just reasoned, but if it is also in certain ways optimal for achieving a goal or solving a problem.

Several centuries of thought and investigation in relation to rationality and its manifestations in humans and their behavior resulted in the formation of mainly four abstract general models (most of which also bring along corresponding normative theories, and even definitions, of rationality):

- Logic-based systems (cf. e.g. (Evans, 2002)): A belief is rational, if there is a logically valid reasoning process to reach this belief relative to available/given background knowledge.
- Probability-based frameworks (cf. e.g. (Griffiths, Kemp, & Tenenbaum, 2008)): A belief is rational, if the expectation value of this belief is maximized relative to given probability distributions of background beliefs.
- Game theory-based models (cf. e.g. (Osborne & Rubinstein, 1994)): A belief is rational, if the expected payoff of

maintaining the belief is maximized relative to other possible beliefs.

- Accounts based on the use of heuristics (cf. e.g. (Gigerenzer, Hertwig, & Pachur, 2011)).

Unfortunately, when comparing the different conceptions, it shows that the frameworks (and also the resulting definitions of rationality) are in many cases almost orthogonal to each other, making them in the best case incommensurable, if not inconsistent or even partly contradictory in their modeling assumptions. Also, in many cases the predictive power of these classical theories of rationality turns out to be rather limited (at least when applied to real-world examples instead of artificially simplified and constructed scenarios), as they have more normative or postdictive-explanatory character.

Even more, although each of the listed accounts has gained merit in modeling certain aspects of human rationality, the generality of each such class of frameworks has at the same time been challenged by psychological experiments or theoretical objections. On the one hand, studies by Byrne on human reasoning with conditionals (Byrne, 1989) indicated severe deviations from classical logic (see below), a finding also supported by human subjects failing at a seemingly simple logical task in the famous Wason-selection task (Wason, 1966). Similarly, Tversky and Kahneman's Linda problem (Tversky & Kahneman, 1983) illustrates a striking violation of the rules of probability theory. On the other hand, game-based frameworks are questionable due to the lack of a unique concept of optimality in game-theory which could possibly support different "rational behaviors" for one and the same situation (just think of the plethora of different equilibrium concepts which have been derived from the original Nash equilibrium, cf. e.g. (Halpern, 2008)). Finally, heuristic approaches to judgment and reasoning (Gigerenzer, 2008) are often seen as approximations to a rational ideal and in some cases could work in practice, but mostly lack formal transparency and explanatory power. Also, from a methodological or philosophical point of view, severe reservations can be put forward: Due to the open nature of the collection of heuristics (the "heuristic toolbox") propagated in most current accounts, the possibility of falsification and refutation of modeling assumptions and theories is not guaranteed (as always another heuristics could be introduced, covering cases previously not accounted for), and a (reasonable) completion of the model can neither be checked for, nor guaranteed at any point.

### A More Cognitive Perspective

Already starting out with Simon's seminal work on "*A Behavioral Model of Rational Choice*" (Simon, 1955) more than half a century ago, conceptually different takes on rationality and rational behavior have been introduced into the discussion. Where logic-based, probability-based, and game-based accounts normally do not take into account limitations and cognitive properties of the reasoner (i.e., in our case, the human agent), the last decades have seen a growth of awareness for the importance and indispensability of these factors

in models of (human) rationality. Nonetheless, from our point of view, understanding the full meaning and implications of the commitment to a more "cognitively adequate" theory of rationality still is in an early stage, with researchers in different disciplines, both on the more theoretical and the empirical side, only starting to fully integrate these concepts into their accounts of rationality and rational behavior. In the following, we want to sketch some important developments and insights, preparing the ground for the subsequent presentation of our account of "subject-centered rationality".

### Theoretical Considerations

In (Simon, 1955), Simon articulates a simple but groundbreaking insight: (Human) agents are bounded in their resources and computational power. Once accepted, this proposition has far reaching consequences for the entire conceptual endeavor of formalizing and modeling rationality. All of a sudden, internal limitations of the reasoner, like limitations on working memory and computational power, but also external constraints, like limited time for decision-making, or incomplete and possibly also false information, have to be accounted for when creating a framework for rationality. Where this might not necessarily be a problem at first sight, it casts more than just a slight shadow of doubt on some of the fundamental assumptions underlying many "classical" accounts of rationality: It might be the case that reaching a conclusion via *modus ponens* in a logic-based model, once the preconditions are fulfilled, can computationally be realized rather simple - but what if the reasoner has to deal with incomplete information? If expectations have to be maximized in a probability-based model, where actually do the priors come from, once their existence cannot just be imported as given by the modeling assumptions? For many game-theoretic settings, even modern computers have a hard time finding equilibria or optimal solutions to not overly complex problems - how then can a mere human take the corresponding decision within a split second?

Although these issues clearly were identified as urgent questions, subsequent attempts at solutions mostly tried to solve the appearing problems within the original models, instead of putting the foundations to the proof and (possibly) having to construct entirely new models of rationality. Nonetheless, this has changed over the course of the last years. In a reply to Colman's article "*Cooperation, psychological game theory, and limitations of rationality in social interaction*" (Colman, 2003), Kokinov challenges traditional views on rationality (Kokinov, 2003). Taking an initial stance similar to Colman's, that is agreeing that rationality fails as both, descriptive theory of human decision-making and normative theory for good decision-making, Kokinov reaches a different, more radical conclusion than Colman did before. Instead of trying to fix the concept of rationality by redefining it, adding formerly unconsidered criteria for optimization of some kind, he proposes to replace the concept of rationality as a theory in its own right by a multilevel theory based on cognitive processes involved in decision-making. Where

Colman proposes a collection of ad-hoc strategies for explaining the deviations from rationality which people exhibit in their behavior, Kokinov proposes analogy as means of unifying the different, formerly unconnected parts of Colman's attempt at describing the mechanisms of decision-making. In Kokinov's view, the classical concept of utility making has to be rendered as an emergent property, which will emerge in most, but not all, cases, converting rationality itself into an emergent phenomenon, assigning rational rules the status of approximate explanations of human behavior.

Of course, this also defines a rather extreme position. But also scholars in "more standard" disciplines of rationality research, as for example decision theory, have become aware of fundamental problems with the traditional conception of rationality. In (Gilboa, 2010), Gilboa (in accordance with an earlier definition in (Gilboa & Schmeidler, 2001)) defines rationality as a subjective concept: "(...) *a mode of behavior is rational for a given decision maker if, when confronted with the analysis of her behavior, the decision maker does not wish to change it.*". This of course has far-reaching consequences. First of all, rationality becomes subject-centered, in that what is rational might vary with the population in question. But probably the most important implication is the dependence on the individual subject's abilities and limitations. If the decision maker does not understand the analysis, or why her behavior is not judged as rational, she cannot be judged irrational for not complying with the alleged norm of rationality. If limited cognitive capacities do not allow the reasoner to understand the rules he should follow in his reasoning (e.g. the Neumann-Morgenstern theory (von Neumann & Morgenstern, 1944)), but would always take the same decision again, he has to be called rational.

### Experimental Evidence

But also on the more empirical side, there is evidence galore that cognitive capacities and limitations have a clear influence on behavior and decision-making. Evidence for a crucial role of analogy as cognitive ability in decision-making can be found in psychological studies on decision-making and choice processes. An overview by Markman and Moreau (2001), based on experiments and observations from psychological studies (amongst others on consumer behavior and political decision-making), reaches the conclusion that there are at least two central ways how analogy-making influences choice processes. Analogies to other domains can provide means of representation for a choice situation, as generally speaking the making of a decision relies on a certain degree of familiarity with the choice setting. In many cases of this kind, analogy plays a crucial role in structuring the representation of the choice situation, and thus may strongly influence the outcome of a decision. Also, structural alignment (a key process of analogy-making) plays a role when comparing the different possible options offered by a decision situation, with new options being learned by comparison to already known ones. An experimental study by Kokinov (2005) demonstrated that people actually do use analogies in the process

of decision-making, with significant benefit already if only one case is found to be analogous to the choice situation under consideration. Furthermore, evidence has been found that there is no significant difference between close and remote analogies in this process, and that people are not limited to rely only on analogous cases from their own experience, but that also cases which were only witnessed passively (e.g., by being a bystander, or learning about a situation from reports in the media) may have beneficial influence.

Another example can be given in form of well-known studies on human decision-making under time pressure, which show a change in the applied inference procedure. In (Rieskamp & Hoffrage, 2008), the authors report that, whilst the best predicting model of human inference for decision making in an unstressed condition was a weighted linear model integrating all available information, when time pressure was induced, best predictions were obtained by using a simple lexicographic heuristic (Fishburn, 1974). When speculating about the precise way in which the induced pressure influences the reasoning process, the presumed change from a more complex strategy using complex relational structures to a simple single-attribute-based procedure, one possible explanation can again be found in research on analogy-making: In (Tohill & Holyoak, 2000), it is reported that anxiety made participants of an analogical-reasoning experiment switch from a preference for complex relational mappings to simple attribute-based mappings. So presupposing that analogy to already familiar situations serves as a basis for the decision-making, this reduction of the complexity of the mapping would be in line with the observed change in strategies.

### Cornerstones of "Subject-Centered Rationality"

Continuing and expanding thoughts already started for example in (Besold et al., 2011) and (Besold et al., 2012), in this section, we want to present some key features and cornerstones of a new account and understanding of rationality which we call "subject-centered rationality". What shall be presented is not yet another model of rationality and rational behavior, but an overall view and meta-conception of rationality, defining a supporting and limiting background and context for the construction of new models:

1. Rationality in a human context clearly has to be considered as a subject-centered notion, demanding for the integration of subject-related properties and constraints. This goes in line with Simon's and Gilboa's already discussed positions in that there is no use establishing models and norms which can never be implemented or fulfilled by human reasoners due to limitations of the agent or of its environment. Going back to the very beginnings, taking Aristotle's characterization of humans as rational animals as defining statement, a framework of rationality which cannot be applied at any moment by a human in everyday life has to be considered as limited in its usefulness and adequacy. This means that especially limiting constraints of human cognition, as for

example the computational boundedness of human agents and thus also the computational complexity of the rationality theory at hand, have to be accounted for.

2. The main aspect of theories and models of rationality has to be their use and applicability as positive theories, and not as mere normative or postdictive explanatory accounts. A valuable and adequate account of rationality has to provide a feasible prediction of human rational behavior and decision-making when being provided with the information the human reasoner can access at the moment of reasoning, that is, when possibly only having access to incomplete knowledge, when having to deal with ambiguities and possible false assessments of situations, etc.
3. A feasible theory of rationality does not have to be committed to one single formal modeling paradigm, but instead of being monolithic should pursue a holistic approach. Different formalisms and approaches to modeling should be unified and integrated into one account, providing the amalgamation of the different approaches with the union of their respective advantages and particular strengths, whilst mitigating each others deficiencies and weaknesses. Logic-based formalisms can be used alongside probability-based techniques alongside heuristic elements alongside models of cognitive core capacities alongside game-theoretic means for utility maximization. This integration of means and paradigms is governed by two guiding principles, the appropriateness with respect to the boundedness and the limited resources of the human reasoner, and the respect for and reproduction of human particularities in rational behavior and decision-making.

As should have become obvious from the above listing, we clearly consider rationality as a concept which is not connected to a particular formalism or theoretical modeling paradigm, but instead see it as possibly a plethora of different mechanisms competing, interacting and contributing to what we externally observe as a single capacity. Of course, this brings along challenges and questions, but from our point of view at the same time offers even more chances and opportunities. In the following, we want to give two examples where incorporating different (formal) paradigms into (distinct) traditional contexts has shown to be highly profitable:

With “algorithmic rationality”, Halpern and Pass (2011) proposed a framework including computational costs in otherwise game-theoretical notions of rationality, allowing to directly take into account the complexity dimension of agents’ boundedness when modeling rationality with game-theoretical means.

“Probabilistic dynamic epistemic logic” by Kooi (2003) presents an attempt at amalgamation between probabilistic and logical views of rationality, which can for example be used when treating with aspects of rationality at the intersection between epistemic logic and game theory.

Also, we strongly advocate the integration of factors and mechanisms describing the influence of cognitive capacities

and abilities into models of rationality, possibly offering entirely new perspectives and explanations for classical paradoxes of human rationality, as illustrated by the following examples:

Well-known empirical studies by Byrne (1989) question whether human reasoning can be covered by a classical logic-based framework. Presented with the information given in Table 1 and asked for what can be concluded from this, from 1. 46% of subjects conclude that Marian will not study late in the library, erring with respect to classical logic (as denial of the antecedent does not validate a negation of the consequent). Also, from 2. 96% of subjects conclude that Marian will study late in the library, whilst only 38% of subjects reach the same conclusion from 3.. Thus an introduction of another antecedent (without any indication that the antecedent should not hold) dramatically reduced the number of subjects applying a simple modus ponens in their process of forming a conclusion. Giving the task and the find-

Table 1: Inferences and Conditionals (Byrne, 1989)

- |   |
|---|
| <ol style="list-style-type: none"> <li>1. If Marian has an essay to write, she will study late in the library. She does not have an essay to write.</li> <li>2. If Marian has an essay to write, she will study late in the library. She has an essay to write.</li> <li>3. If Marian has an essay to write, she will study late in the library. She has an essay to write. If the library stays open, she will study late in the library.</li> </ol> |
|---|

ings a more cognitive capacities-oriented view than supported by the logic-based framework, the results concerning conclusions drawn by the subjects can for example be explained through analogy. People faced with the information given in 1. will recall similar conversations they had before, using these known situations as basis for their decision on what to conclude. According to Grice (Grice, 1975), in conversations, speakers are supposed to provide the hearer with as much information as is needed for exchanging the necessary information, a rule which also goes in accordance with our everyday observation. Thus, when being given the additional information that “Marian does not have to write an essay.”, the set of candidate situations for establishing an analogy to the present one will be biased towards situations in which this information had an impact on the outcome, resulting in the conclusion that Marian would not study late in the library either. Regarding 2. and 3., a similar conjecture seems likely to hold: By additionally mentioning the library, similar situations in which the library might actually have played a crucial role (e.g., by being closed) will be taken into account as possible base domains of the analogy, causing the change in conclusions made.

Already more than a decade ago, in the field of decision theory and economics Gilboa and Schmeidler (1995) devel-

oped an (at least partly) case-based theory and model for decision-making under uncertainty. In their model, cases are primitive and provide a simple axiomatization of a decision rule that selects an act to be performed based on the act's past performance in similar cases. Each act is evaluated by the sum of the utility levels that resulted from using this act in past cases, where the degree of (dis)similarity between the past cases and the problem at hand is accounted for by weighting the respective utility by the value of a similarity measure between both situations. Remarkably, this formal approach in a natural way gives rise to (amongst others) the notions of satisficing decisions and aspiration levels (cf. also (Gilboa & Schmeidler, 2001) for a detailed account).

### **Solutions for Problems of a Subject-Centered Notion of Rationality**

Of course, a positive subject-centered approach to rationality brings along quite some ground for reservations and skepticism. In the following, we want to address some of the most probable objections.

Doesn't your account collapse into pure subjectivity, making it not usable as basis for a general theory and framework anymore? No, it does not. The idea to overcome the problem of pure subjectivity is to identify central cognitive mechanisms, limitations and properties, common to all humans, and use those as basis for building up the theory. This is not a commitment to any particular modeling paradigm, but rather a strong statement assigning the positive aspects of the model (i.e. the adequate reflection of actual human properties) a higher priority than detail decisions for how to model a particular capacity, or overall methodological modeling consistency.

But then, how do you want to (theoretically) explain and (practically) preserve the individual aspects of your subject-centered modeling notion? In real life, each human comes equipped with different gifts and talents. Distinct cognitive capacities, although present in (almost) every human, are developed to a different extent. This also gives a cognitively-based model of rationality the possibility to account for different individual behaviors and decisions. Although there is an overall unified framework on a general human level, once reliable predictions shall be made on an individual scale, the weights and levels of developments between these different capacities will have to be assessed and adapted.

Your account does not provide any normative power, a key feature one would expect from a theory of rationality? To the contrary, normativity can be introduced on two levels, allowing for a distinction between a more general form of rationality, and a subjective one. Even more, contrary to some of the classical approaches, it is even possible to provide a quantitative account of performance on a normative scale. On a higher level, normativity can be introduced via the question "Given the general cognitive mechanisms and model, how well does the individual perform compared to the general optimal case?", that is, by assessing whether, tak-

ing into account goal-oriented behavior, the chosen way of acting resulted in the best outcome possible for an ideal representative of the species. If this is the case, the respective behavior or decision has to be considered as generally rational. If this is not the case, comparing the quality of the outcome to the performance of other individuals of the species can provide a quantification of the quality of the decision or behavior on a normative scale (e.g. "the subject performed at least as rational as 80% of his species"). On the individual level, normativity can be introduced via the question "Given the individual distribution of properties and limitations of the individual, how well does the subject perform compared to the individually optimal case?", that is, by assessing whether, taking into account goal-oriented behavior, the chosen way of acting resulted in the best outcome possible for the individual (a notion reminiscent of Gilboa's already aforementioned idea of rationality (Gilboa, 2010)). Also here, similar to the more general case, a quantitative aspect can be introduced to judging a behavior or decision rational: Provided that the model has accurately been fitted to the individual, reflecting its cognitive capacities, properties and limitations to a sufficient degree, it can be assessed to what extent the subject made use of its theoretical capacities.

### **Conclusion**

In the present paper, we give an account of basic principles and cornerstones of our positive conception of a theory and framework for rationality and rational behavior, envisioning a modeling paradigm which integrates different perspectives and approaches into a holistic system, giving rise to an integrated multiverse of rationality, replacing the multiple (mostly) mutually exclusive competing universes which there currently are.

From our point of view, our perspective on rationality offers several advantages not only within the field of cognitive science, but also for neighboring disciplines. A positive, predictively usable theory and framework for rationality (moreover if equipped with a quantitatively accessible notion of normativity) would allow for manifold applications, for example within decision theory and psychology (serving as an initial test bed for conjectures and research hypotheses), but also in more technical fields such as human-computer interaction (allowing for more natural and better adapting interfaces between man and machine) or artificial intelligence (greatly contributing to an overall model of human intelligence; cf. e.g. (Besold, 2011) for an AI-centric perspective).

Of course, there still are numerous open questions left for future investigation: How can the given cornerstones, characterizations and properties of "subject-centered rationality" be developed into a completely worked out meta-theory? Which are the key particularities, properties and limitations of human cognition that have to be integrated and accounted for by a subject-centered theory of rationality? How compatible are the already existing "classical" frameworks for rationality with our proposed view? How do our meta-level considera-

tions relate to conceptual work done in other relevant fields modeling (and possibly predicting) human behavior, and thus most likely dealing with similar questions? What would be a promising paradigm for an implementation: a highly modular bottom-up approach starting out by modeling one facet of rationality, consecutively adding more modules later, an entirely hybrid top-down approach, applying an amalgamated broad mixture of formalisms and a very general modeling paradigm from the very beginning, addressing different forms and facets of rationality by specialization within the overall framework, or something in between?

Although these are challenging and demanding questions, and a complete answer to any of those still is far from being visible, we are convinced that each single one of them is worth scientific effort and attention already by itself, in their totality moreover promising key insights into a core concept of human intelligence and cognition.

## Abstract

Verb-particle constructions (phrasal verbs) are a notoriously difficult aspect of English to acquire for second-language (L2) learners. This study was conducted to assess whether L2 English speakers would show sensitivity to the subtle semantic properties of these constructions, namely the gradations in semantic transparency of different verb-particle constructions (e.g., *finish up* vs. *chew out*). L1 French, L2 English bilingual participants completed an off-line (explicit) survey of similarity ratings, as well as an on-line (implicit) masked priming task. Bilinguals showed less agreement in their off-line ratings of semantic similarity, but their ratings were generally similar to those of monolinguals. On the masked priming task, the more proficient bilinguals showed a pattern of effects parallel to monolinguals, indicating similar sensitivity to semantic similarity at an implicit level. These findings suggest that the properties of verb-particle constructions can be both implicitly and explicitly grasped by L2 speakers whose L1 lacks phrasal verbs.

**Keywords:** Verb-particle constructions; bilingualism; semantic ratings; second language; masked priming.

## Introduction

Verb-particle constructions, also known as phrasal verbs<sup>1</sup>, are semantic units composed of a verb and a particle, which may be superficially similar to either a preposition (e.g., *turn out of the house*) or an adverb (e.g., *break the question down*). Common examples in English include *THROW OUT*, *LOOK UP*, *CHEW OUT*, *FINISH UP*, *PULL OVER*, and hundreds of others. These expressions are extremely common in some languages (e.g., English, German), though notably absent in others (e.g., French, Spanish, Italian). The language-specific properties of this phenomenon make it of interest to research in both monolingual and bilingual psycholinguistics. Current bilingualism research has demonstrated that non-native speakers have particular difficulty using these constructions, but has not yet identified the source of this difficulty. The present study was thus designed to investigate one aspect of verb-particle constructions that has been shown to affect monolinguals' processing: semantic transparency of the construction, which ranges from transparent (e.g., *finish up*) to opaque (e.g., *chew out*).

<sup>1</sup>While some authors prefer one or the other for various reasons, in this text the terms "phrasal verb" and "verb-particle construction" will be used interchangeably.

Semantic transparency was investigated using both an explicit and an implicit measure, to determine the level of processing where monolinguals and bilinguals differ.

## The Nature and Processing of Phrasal Verbs

Semantically, phrasal verbs are generally assumed to be stored as units in the lexicon, similarly to words or idioms (e.g., Jackendoff, 1995). That is, the meanings of such expressions are memorized holistically, separately from the meanings of the component words. There is much less consensus, however, as to whether these units are processed lexically in the same way as any other word, or whether syntactic processing is also necessary. Arguments based on traditional linguistic analysis have shed some light on this issue, but have been ultimately inconclusive. For example, phrasal verbs are amenable to processes of derivational morphology, changing from verbs into nouns in expressions such as "a show-off," "a fixer-upper" or "a passer-by" (e.g., Farrell, 2005). On the other hand, the verb and particle are clearly distinct units in the sentence that can be separated both by a noun phrase (e.g., *throw it out*) and by an adverb (e.g., *fixed it right up*). This type of insertion should not be possible within a single word, according to the so-called Lexical Integrity Principle (Chomsky, 1970); thus, in this sense verb-particle constructions behave similarly to syntactic phrases.

More recently, researchers have approached this question of whether verb-particle constructions are more phrase-like or word-like, using psycholinguistic and neuroimaging techniques. For example, Konopka and Bock (2009) showed that word order preferences for verb particles can be structurally primed; participants were more likely to remember a sentence as having an adjacent (or non-adjacent) verb and particle if they had just seen a different sentence with the same structure. This finding, which held regardless of the idiomaticity of the construction, was taken as evidence for more structurally-based accounts of phrasal verb processing. A different conclusion was drawn by Cappelle, Shtyrov and Pulvermuller (2010), who used magnetoencephalography (MEG) to record neural responses to verb-particle pairs that were congruent (e.g., *heat up*) or incongruent (e.g., *heat down*). The mismatch negativity responses to these pairs were comparable to responses patterns typically elicited by words, rather than sentences.

The authors concluded that at a neural level, phrasal verbs are processed lexically rather than syntactically. Thus, both linguistic and neuro-cognitive methods have yielded mixed results with regard to the nature of phrasal verb processing.

An alternative perspective holds that this strictly modular view of the lexicon versus the syntax creates a false dichotomy that fails to account for the behavior of verb-particles. For example, in an effort to conform them to these designations, many researchers have categorized phrasal verbs as either “transparent,” that is, interpretable based on knowledge of the component words, or “idiomatic,” having an opaque meaning that can only be memorized (e.g., Dagut & Laufer, 1985). However, it has recently been recognized that an entire spectrum exists between these two extremes. Gonnerman and Hayes (2005) asked native English speakers to rate, on a scale of 1-9, the degree of similarity between a verb-particle construction and its component verb alone (e.g., “How similar is *carry off* to *carry*?”). Their participants gave highly consistent ratings that were distributed through the entire range of the scale. For example, the pair *finish up/finish* was considered to be very similar while *chew out/chew* was rated as highly dissimilar. Other items, such as *look up/look* were generally rated around the middle of the scale.

In the same study, the authors tested participants’ implicit sensitivity to dependency using masked priming, an on-line task. Participants were asked to make a lexical decision to target words presented visually on a computer screen. Before each target, a prime consisting of another word or word combination was presented for 35ms, long enough to be processed subliminally but too short to be recognized consciously. Lexical decisions were facilitated when a target verb (e.g., *finish*) was primed by a low-dependency verb particle construction (e.g., *finish up*), but not when the target (e.g., *chew*) was primed by a high-dependency construction (e.g., *chew out*). Thus, these participants were shown to recognize dependency variations in both offline and on-line semantic processing.

### Processing in Second-language (L2) Learners

Phrasal verbs have long been recognized as among the most difficult aspects of English to acquire for second-language (L2) learners, and are also therefore of interest to those in the English as a Second Language (ESL) teaching profession (Neagu, 2007). Several researchers have investigated this phenomenon in bilinguals, though most of this work has focused on the avoidance of verb-particles in production. For example, Dagut and Laufer (1985) found that in written English tasks, native Hebrew speakers tended to avoid phrasal verbs (e.g., *let down*) in favor of single-verb synonyms (e.g., *disappoint*). While the authors attributed this effect to the lack of verb-particle constructions in Hebrew, subsequent studies have shown that similar difficulties are experienced by learners whose native languages include phrasal verbs, such as Dutch (Hulstijn & Marchena, 1989) and Swedish (Laufer & Eliasson, 1992). For these speakers, however, phrasal verbs seem to be more

easily acquired as a function of proficiency; advanced Dutch and Swedish learners display more native-like behaviour than either intermediates with the same L1s or advanced learners with L1 Hebrew. Thus, the difficulty of L2 English phrasal verbs appears to result from a compounding of factors that are both syntactic (inter-language differences) and semantic (inherent difficulty of acquiring idiomatic vocabulary). Later research (e.g., Liao & Fukuya, 2005; Gonzalez, 2010) has strengthened the hypothesis that avoidance of phrasal verbs decreases as English proficiency increases for all speakers, but that it does so more quickly for speakers with verb-particle constructions in their L1s.

Thus far, most investigations of verb-particles in L2 speakers have focused on production, particularly on the phenomenon of avoidance. However, it is equally important to investigate these structures at the level of receptive language processing. Comprehension of various linguistic structures precedes their production, both in first language (e.g., Benedict, 1977) and second language (e.g., Ringbom, 1992) acquisition, making this an important aspect of determining bilinguals’ competence with phrasal verbs.

In one of the few studies of phrasal verbs in on-line L2 comprehension, Matlock and Heredia (2002) measured the time it took for non-native speakers with various L1s to read English sentences involving the same phrase in either a verb+preposition context (e.g., *John ate up the street*) or a verb+particle context (e.g., *John ate up the pizza*). While native English speakers and early bilinguals (i.e., having acquired English before age 12) reacted more quickly to verb-particle constructions, late bilinguals seemed to process phrases involving a literal preposition most easily. This was taken as evidence that in processing figurative language, native speakers and early bilinguals can activate a figurative meaning instantly while late bilinguals must first retrieve the literal meaning before seeking alternate interpretations. While promising, however, this study had several limitations. First, the authors’ “on-line” measure was response time to an entire sentence, a relatively crude method which was unable to isolate the processing of the verb-particle construction itself. Moreover, first language and current proficiency level were not carefully controlled in this experiment.

A different, though related line of research is the study of idioms in second language comprehension. Like phrasal verbs, idioms consist of words that appear in other contexts but which take on a new meaning in a particular combination and a particular context. Given this similarity, it is not surprising that both types of constructions are difficult for second language learners. Models of monolingual idiom comprehension differ in the role they attribute to compositional versus non-compositional processes (see Titone & Connine, 1999, for a review); however, most current theories agree that native speakers may access either the literal or non-literal meaning of an idiom first depending on the construction itself as well as contextual and discourse factors (Giora, 2002; Titone & Connine, 1999). There is somewhat less consensus about

whether non-native speakers take full advantage of this complex processing strategy. One proposal (Cieslicka, 2006; Cieslicka & Heredia, 2011) is that the literal meanings of idioms enjoy universal salience for non-native speakers; that is, these speakers will always activate a literal interpretation before seeking an alternative reading. This “Literal Salience Hypothesis” is proposed to hold regardless of the context, familiarity, or decomposability of an idiom. However, not all researchers agree with this account (e.g., Bulut and Çelik-Yazici, 2004).

Thus, psycholinguistic studies suggest that both phrasal verbs and other types of non-literal language are processed in fundamentally different ways by native versus non-native speakers. However, there remains a significant need for more work describing the comprehension of L2 phrasal verbs. First, while work on idiom processing has made valuable contributions to this line of research, it must be recognized that full idioms, such as *kick the bucket* and *let the cat out of the bag*, differ from phrasal verbs in several important respects. While idioms constitute a large class of expressions with a great deal of variation in their syntax and flexibility, verb-particles pattern fairly regularly and behave much like literal verb-preposition combinations syntactically (Dixon, 1982). Some particles also behave more like morphemes in the sense that they can be applied productively; for example, the perfective UP can be applied to any verb that can be thought of as completive, yielding FINISH UP, WASH UP, GROW UP, ROLL UP, WRITE UP and many more. Thus, it might be expected that in interpreting verb-particles, as opposed to idioms, second-language learners would have additional sources of information (from regularities in the language) and may not rely so heavily on an initial literal interpretation.

Second, research on second language learning in general must distinguish between explicit and implicit language processes. The importance of dissociating these aspects of comprehension has been recognized at least as far back as Bialystok (1979), who found that while learners acquired both explicit and implicit knowledge of a new language, it was largely the explicit component that improved with increased instruction. This study also found that learners employed either their implicit or explicit knowledge depending on the processing demands of the task. More recently, Ellis (2005) emphasized the difference between these types of knowledge, which he defined using a variety of criteria including awareness, time available, attention, systematicity, certainty, metalinguistic knowledge, and learnability. This study found that explicit language ability was more strongly related to years of instruction, while implicit competence was correlated with age of acquisition.

Taken together, these results support the need to measure acquisition of a particular structure both implicitly and explicitly, an approach we have taken in the present study. The following experiments were conducted to test whether native speakers of French, a language that lacks verb-particle constructions, are sensitive to the same semantic variations recognized by native speakers.

## Verb-particle Similarity Ratings

To measure bilinguals’ sensitivity to the semantic transparency of verb-particle constructions, we used an explicit, off-line, similarity rating task. Past research (Gonnerman & Hayes, 2005) has shown that when asked to rate the similarity between verbs and their corresponding verb-particle constructions, native English speakers provide consistent ratings across a spectrum ranging from low (*chew out/chew*) to mid (*look up/look*) to high (*chew out/chew*) similarity. To determine whether L2 speakers are sensitive to this variability, we administered a similar survey to French dominant English bilinguals. This metalinguistic task was designed to measure participants’ explicit knowledge of verb-particle semantics, which we predicted would be similar to, but less accurate than that of monolinguals.

### Participants

34 adult (age 18-40) native speakers of Canadian French were recruited through web-based advertisements on a university research mailing list, and participated voluntarily. English proficiency was self-rated as either Beginner (n=1), Intermediate (n=9), Advanced (n=20) or Near-native (n=4). Participants also reported their age of first exposure to English, which ranged from 1 to 20 years, with a mean of 8.21 years.

### Materials

78 verb-particle pairs were presented in an internet-based survey. Stimuli were selected from a larger set of 212 verb-particle constructions that were rated by monolinguals in Gonnerman & Hayes’ (2005) study, and contained an even distribution of low (mean rating < 4), medium (4-6) and high (>6) similarity items as rated by the monolinguals. Particles (e.g., *up*, *on*, *off*) were evenly distributed among high, medium and low similarity items. In addition, items in each group were matched for the frequency (Kucera & Francis, 1967) of the verbs (e.g., *throw*), as well as for the frequency of verb-particle constructions in their entirety (e.g., *throw up*).

### Procedure

Each participant rated all 78 items. Participants were asked to rate the similarity in meaning of verb particle/verb pairs on a scale from 1 (very dissimilar) to 9 (very similar). Instructions for this task included examples of highly similar as well as dissimilar pairs with corresponding ratings. Ratings were compiled electronically and analyzed for comparison with the ratings obtained from monolinguals by Gonnerman & Hayes (2005).

### Results & Discussion

Similarity ratings of the 78 items from monolinguals and bilinguals are shown in Figure 1. Results are arranged in ascending order of the monolinguals’ ratings. Monolingual and bilingual ratings are positively correlated with

correlation coefficient 0.707 ( $p < .01$ ), indicating that bilinguals can make similar judgments of semantic similarity to native English speakers. Ratings from the bilinguals were fairly evenly distributed across the range of the scale; on average, participants chose each point on the scale between 6 and 10 times. Interestingly, ratings of the two groups agreed more consistently in the middle of the scale than at either end, with those of the lowest-similarity items being most discrepant.

Figure 1: Mean semantic similarity ratings obtained from French-English bilinguals and English monolinguals from Gonnerman & Hayes' (2005). Verb/verb-particle pairs are arranged in ascending order of the monolinguals' mean ratings.

In other respects, bilinguals' ratings differed from those of the monolinguals. Bilingual speakers' ratings were significantly less consistent than monolinguals, with an average standard deviation of 2.33, as opposed to 1.96 for the monolinguals ( $F(1,77)=56.16$ ,  $p < .001$ ). Bilinguals' ratings also showed a reduced range (5.94), as compared to the monolinguals' range of 6.82. These results indicate that while second language speakers do recognize a range of semantic transparency across verb-particle constructions, they are generally more variable in their responses.

### Masked Priming

As an on-line measure of semantic processing, participants completed a masked priming task in which a target verb (e.g., LOOK) was primed by its corresponding verb-particle construction (e.g., *look up*). In past research (Gonnerman & Hayes, 2005), priming has been found to be strongest for verb-particle constructions rated as highly similar in meaning to their isolated verbs. This task was designed to determine whether bilinguals' implicit processing of verb-particle constructions would be predicted by the degree of semantic transparency, as has been shown for monolinguals. In addition, the task serves as an implicit comparison to the explicit data obtained from the ratings task. If applicable to verb-particle constructions, the Literal Salience Hypothesis (Cieslicka, 2006; Cieslicka & Heredia, 2011), would predict poor performance on the priming task; Literal Salience holds that non-literal language is always first interpreted literally and only then re-analyzed, a

process which would not have time to occur in a masked priming paradigm.

### Participants

30 native speakers of French, aged 18 to 35, participated for monetary compensation. Inclusion criteria were identical to those of the similarity rating experiment: participants were required to consider themselves non-native speakers of English but to have functional proficiency in English. Age of first exposure to English ranged from 1 to 15 years, with a mean of 7.79 years. English proficiency was self-reported as Intermediate ( $n=7$ ), Advanced ( $n=16$ ) or Near-native ( $n=5$ ).

### Materials

The same 78 verb-particle constructions were used as related primes for their corresponding verbs (e.g., *cover up/cover*). For each construction, an unrelated control prime was created to match in frequency and number of letters (e.g., *show off/cover*). Control primes did not overlap with test primes in meaning or orthography. Finally, identity primes (e.g., *cover/cover*) were included for each item. Stimuli were divided into three lists, with one of these conditions in each list so that no participant responded to any verb more than once. In order to reduce the proportion of related prime-target pairs, 78 real word prime-target filler items were added to each list. In addition, 156 non-word filler items were included, matching the real words in frequency and orthography as closely as possible. Of these, half employed verb particle primes with non-words that were either "related" (e.g., *keep out/keem*) or "unrelated" (e.g., *live down/bool*), while the other half used single words as primes. Thus, each participant responded to 312 items, of which 39 were related prime-target pairs containing verb particle constructions.

### Procedure

Participants were tested individually in a quiet room with dim, natural lighting. Stimuli were presented using PsyScope (Cohen, MacWhinney, Flatt, & Provost, 1993) software on CRT monitors running at 85 HZ. Each trial consisted of a fixation point (\*) displayed for 1000ms, after which a mask (%#@!&^\$) was displayed for 500ms; subsequently, the prime appeared briefly for 35ms followed immediately by the target, which remained on the screen for 200ms. Participants made a lexical decision to the target by pressing the yes/no buttons on a button box, from which reaction times were recorded. After the participant's response, a 500ms delay occurred before presentation of the next trial. Stimuli appeared in white on a black background, with primes in lower case letters and targets in upper case letters.

### Results & Discussion

Four participants, who made errors on more than 40% of the items, were excluded from the analyses. For all other participants, only correct responses were included in the

analyses. Data were trimmed to exclude outliers; that is, response times slower than 300ms or faster than 1000ms. A 3 (Prime Type: Related vs. Unrelated vs. Identity) by 3 (Prime-target similarity: Low vs. Mid vs. High) repeated measures ANOVA was conducted to determine whether priming effects were modulated by semantic similarity. Because we were interested in priming effects specifically, we also planned comparisons between the unrelated and related response times. Priming effect for the monolinguals (from Gonnerman & Hayes, 2005) and bilinguals are shown in Tables 1 and 2 below. An identity condition was also included for the bilinguals to rule out the possibility that bilinguals are only reading the first word in the verb-particle primes, that is, reading only the first element (*e.g.*, *throw*) and ignoring the particle separated by a space (*e.g.* *up*). Including the identity condition therefore allowed us to determine whether priming for related targets reflects the whole prime, since otherwise *throw off/throw* would simply elicit the same identity priming as *throw/throw*).

Results showed a significant main effect of Prime Type ( $F(2, 50)=7.96, p<.01$ ) and a significant main effect of Similarity ( $F(2, 50)=7.19, p<.01$ ). The interaction of these factors was non-significant. Planned comparisons revealed significant ( $p<.05$ ) differences between the unrelated and identity primes across all conditions, and significant differences between the unrelated and related primes in the mid and high-similarity conditions (see Table 2 below).

Table 1: Monolinguals' response latencies for target words by prime type and similarity (from Gonnerman & Hayes, 2005).

Monolinguals	Prime-target Similarity		
	Low	Mid	High
Prime Type			
Unrelated ( <i>cast off/throw</i> )	550	553	557
Related ( <i>throw up/throw</i> )	543	532	537
<b>Unrelated-Related</b>	<b>7</b>	<b>21*</b>	<b>20*</b>

Table 2: Bilinguals' response latencies for target words by prime type and similarity.

Bilinguals	Prime-target Similarity		
	Low	Mid	High
Prime Type			
Unrelated ( <i>cast off/throw</i> )	605	619	605
Related ( <i>throw up/throw</i> )	592	599	576
Identity ( <i>throw/throw</i> )	583	595	569
Unrelated-Identity	22*	24*	36*
<b>Unrelated-Related</b>	<b>13</b>	<b>20*</b>	<b>24*</b>

Tables 1 and 2 show the response latencies from monolingual and bilingual participants to unrelated, related and (for the bilinguals) identity primes. Responses from the bilinguals were slower overall, consistent with the increased processing cost of responding in one's second language. In

all other respects, however, results from the two groups are strikingly similar. In addition, for the bilinguals identity priming across all three conditions was higher than Unrelated-Related priming, indicating that the bilinguals did in fact respond differently to the verb-particle constructions than to the verbs alone. As did the monolinguals, the bilingual speakers showed no priming effect for low similarity items, but significant facilitation from verb-particles rated as having mid or high similarity to the target verbs. These results suggest that, contrary to our expectations, at an implicit level L2 speakers are sensitive to the same gradations in semantic transparency that are reflected in monolingual priming effects.

## General Discussion

The present study was designed to investigate the performance of non-native English speakers on implicit and explicit measures of phrasal verb comprehension. Based on past research, we hypothesized that the bilinguals would have difficulty with both tasks, showing decreased sensitivity to the variations in verb/verb-particle similarity that are easily recognized by monolinguals.

Somewhat surprisingly, responses of the L2 speakers approximated those of monolinguals on both the explicit and implicit semantic tasks. This native-like behaviour supports the findings of past research (*e.g.*, Laufer & Eliason, 1992; Liao & Fukuya, 2005) demonstrating that non-native speakers can improve their competence with verb-particle constructions regardless of L1. Importantly, it also extends this literature from production to comprehension, suggesting that use of these constructions reflects their mastery even at a subconscious level. Nevertheless, it should be noted that bilingual responses were not identical to those of monolinguals, especially in the variability between participants on the similarity rating task. More research is needed to determine whether this reflects a fundamental difference between monolinguals and bilinguals, or whether even this effect might disappear in high-proficiency L2 speakers.

The results from the masked priming experiment do not support an extension of the Literal Salience Hypothesis (Cieslicka, 2006; Cieslicka & Heredia, 2011) to verb-particle construction processing in L2. Being below the consciousness threshold, the presentation length of the primes in this experiment was considered brief enough to measure initial, automatic interpretation. Thus, if bilingual speakers universally activated the literal meaning of a verb without considering it in conjunction with a particle, then identical priming would be expected for verb-particle constructions and identity primes across conditions. In contrast, our participants showed consistently higher priming for identity primes than for related verb-particle primes. Additionally, the difference between high and low/mid similarity items can only be explained if participants were responding to the construction as a unit and not simply to the literal combination of words. These data suggest that the literal salience account of idiom

processing in bilinguals does not apply to processing of verb-particle constructions.

When comparing the present study to past research, it should be noted that the bilingual participants in this study had a somewhat different language experience than those in most previous studies of phrasal verb acquisition (e.g., Dagut & Laufer, 1985; Hulstijn & Marchena, 1989; Laufer & Eliason, 1992). While past research has largely focused on speakers learning English in a formal or foreign-language setting, our participants were inhabitants of Montreal, where both French and English are regularly used in formal/educational as well as informal contexts. Thus, although context of exposure was not explicitly controlled in our study, it is reasonable to expect that most of our participants had (either currently or at some point in the past) some degree of contact with and use of English in everyday speaking situations. The present study therefore offers an important extension of work on L2 phrasal verbs to a bilingual population more apt to use English in informal as well as formal contexts.

Several possible directions for future research are suggested by the present study. Gonnerman & Hayes (2005), have noted that variations in verb-particle similarity can influence speakers' word-order preferences, for instance, deciding whether a verb and particle should appear in an adjacent (e.g., *throw out the garbage*) or shifted (e.g., *throw the garbage out*) construction. A logical extension of this experiment would be to investigate whether bilinguals use semantic similarity to influence their word-order preferences. In addition, past work on avoidance of verb-particle constructions in bilinguals suggests a need for more careful comparison of bilinguals with different proficiency levels and ages of acquisition. Finally, evidence from both bilingual and monolingual processing must ultimately be integrated with theoretical models of cognitive/linguistic function, addressing such issues as the interface between the lexical and semantic systems.

# Perception of Ambiguous Drawings and the Construction and Inhibition of its Alternative Interpretation – Reflections on Consciousness

Svetoslav Bliznashki (valsotevs@gmail.com)

Mariya Popova (popova.mariya@gmail.com)

## Abstract

Based on some of our previous experimental findings concerning the negative priming which occasionally occurs during perception of ambiguous drawings we propose a simple mathematical model which we believe may account for important aspects of our data. We tested some (but not all) of the crucial predictions of our model using a newly developed set of asymmetric ambiguous drawings. The results further supported the phenomenon of negative priming taking place during perception of ambiguous drawings and were consistent with the predictions of the model.

**Keywords:** ambiguous drawings; negative priming; vector reflection.

## Introduction

Early gestalt psychologists pointed out that human beings are incapable of perceiving two interpretations of an ambiguous drawing simultaneously. Only one of the interpretations seems to be consciously available at any given moment. Numerous studies show that the conscious experience of a particular interpretation of an ambiguous drawing is subject to context effects (e.g. Balceits & Dunning, 2006; Fisher, 1968; Long & Olszweski, 1999, 2004; Rock & Mitchener, 1992; Kokinov et al., 2007, 2009), i.e. depending on the context we can experience either of the two interpretations. These context effects raise the question whether both interpretations are built in parallel but only the stronger is experienced, or depending on the context only the relevant interpretation is built. This question is analogous to the question asked by Swinney (1979) whether both meanings of a homophone are accessed when the word is encountered or only the meaning relevant to the context. The answer provided by Swinney is that both meanings are accessed. His explanation is in terms of an autonomous lexical access device that does not interact with the context. However, in the case of perception of a picture it is impossible to think in terms of access to pre-stored meanings of the picture, it is clear that the interpretations have to be constructed on the fly. Thus if it turns out that the alternative interpretation is also primed, that would mean that both interpretations are constructed in parallel. Such results would potentially cause a re-interpretation of Swinney's results since that would mean that this is not a specific linguistic phenomenon that could be explained by the specific organization of the language system and more general explanations should be sought for.

Kokinov, Biznashki, Kosev, and Hristova (2007) were interested in how analogy could cause re-representation and re-interpretation of an ambiguous picture. In a further extension of Experiment 1, Bliznashki and Kokinov decided to use additionally Swinney's methodology (a post-test Lexical Decision Task, called LDT for short) in order to evaluate whether the unseen interpretation will be primed. If this was the case, that would be evidence in favor of the idea that parallel processes are constructing both interpretations. The results of this experiment confirmed the hypothesis of parallel representation building of both interpretations, however, they were rather surprising since we obtained negative priming, i.e. we obtained evidence that the unseen interpretation was inhibited (Kokinov, Vankov, Bliznashki, 2009). This was in accordance with some simulation data with the AMBR model which also exhibited inhibition of the corresponding concepts.

We were happy with these results, but there was a puzzle that remained unresolved and which we found very challenging. In this experiment we used an asymmetric drawing with one interpretation being easy to perceive and the other one being hard to notice. We also varied the context in which the drawing was provided by pushing the participants in the study to perceive either the easy or the hard interpretation in order to solve a complex analogical task. We were happy to prove that the relational structure of the task exerted strong influence upon subjects' perception (which was the main goal of our studies) but we were puzzled to find out that the negative priming was not always present. More specifically the negative priming occurred *if and only if* subjects were contextually prompted to perceive the weak (hard-to-see) interpretation of the drawing. In that case the strong (easy-to-see) interpretation showed pronounced negative priming during a Lexical Decision Task which followed immediately after the presentation of the ambiguous drawing, while if the participants saw the easy to see interpretation, there was no negative priming of the alternative interpretation. In our current study we try to explain that finding in formal terms as well as to replicate the results in an experiment specifically designed to detect priming of an unperceived interpretation of ambiguous drawings (which was not the case with our previous studies which focused primarily on exploring the parallel nature of different processes which took place during analogical reasoning).

## Mathematical Model and Predictions

Modeling our results was a challenging enterprise. To see why consider the simple competitive learning network (e.g. Knight 1990) shown in figure 1.

Figure 1. A standard competitive learning network; the two output units are inhibiting each other; all other connections are positive; the node “c” represents external context.

Let’s suppose such a network is trained to classify two sets of drawings – one set consisting of drawings of rabbits and another consisting of drawings of dogs. Now suppose that after a successful learning phase the network is presented with a linear combination of two exemplars with the weights of the combination reflecting the degree to which the elements of the input vector retain their similarity to the original exemplars. In most cases the network will “see” the easier interpretation and (given a relevant activation function) will inhibit the harder interpretation. How can we make the network “see” the harder interpretation? One way we might achieve that is by allowing a context node to pour activation towards the relevant output node. This would be analogous to our previous experiments during which we pressed subjects to see the harder interpretation of an ambiguous drawing by placing the drawing in a particular context. As long as the inhibitory connection/s between the output nodes remain constant and uninfluenced by the inputs to the network, however, all our manipulations will result in the more relevant interpretation winning the competition and the inhibition of the alternative. This contradicts with our data since as already explained negative priming seemed to be present only for the strong interpretation when the weak one was supported by context. Because of that we tried to explain our data by a model which will not rely on constraint satisfaction.

### Simple Vector Reflection Achieving Conscious Appraisal (SVRACA): conceptual description.

In SVRACA we regard concepts as orthogonal vectors residing in a high dimensional space. Each newly perceived entity is represented as a linear combination of the already existing concepts in memory. The vectors representing concepts are considered analogous to Long Term Memory (LTM) while vectors representing newly perceived entities are supposed to be analogous to the content of Working Memory (WM). SVRACA makes a clear distinction

between conscious and subliminal perception. Subliminal perception is modeled by simply constructing a vector in WM as a linear combination of concepts/percepts in LTM. Conscious perception is modeled by the categorization of the constructed vector as an example of one of the existing concepts in LTM. The vector from LTM which shows the highest positive correlation with the vector in WM is supposed to represent its designated category. In cases of ambiguity the newly constructed vector in WM exhibits non negligible positive correlation with more than one vectors residing in LTM. In such cases SVRACA *reflects* the WM vector along all axes (LTM vectors) which the WM vector correlates positively with except for one. The one exception is the single axis which the WM vector still correlates positively with after the reflection operation. All other axes correlate negatively or negligibly with the WM vector. In that state the system is said to have resolved the ambiguity. In other words *conscious perception of an entity is said to occur when a WM vector is fully constructed and when it is roughly orthogonal or negatively correlated with all vectors in LTM except for one with which it exhibits a relatively high correlation*. Thus in SVRACA vector reflection is considered a metaphor for consciously perceiving only one interpretation of an ambiguous stimulus at any given time. In SVRACA the main operation – reflection is executed in a probabilistic fashion (i.e. a stochastic process decides around which axes the WM vector is reflected and which axis remains constant) and in determining the probabilities of reflection both the internal and external context play crucial role. Internal context (or perceptual context) is represented by the weights of the linear combination which constitutes the WM vector. The larger a weight the more probable the WM vector will *not* be reflected along the axis the weight is associated with. External context is represented by a vector of probabilities with each probability reflecting the relative strength with which environment pushes towards a particular interpretation. The interaction between internal and external context probabilistically determines which interpretation of an ambiguous stimulus is perceived. Figure 2 illustrates how SVRACA works and some of its predictions:

Figure 2. LTM vectors are X and Y, WM vector is A. A is ambiguous since it correlates positively (makes sharp angles) with both X and Y.

SVRACA will reflect A either around the X axis (this reflection is indicated as r1 in the figure) or around the Y axis (r2). In the first case the result is A' – a vector unambiguously perceived as X while in the second the result is A'' – a vector unambiguously perceived as Y. Which reflection takes place – r1 or r2 is determined by taking into account both perceptual and external context. Ignoring external context for the moment we see that A is much closer to X and consequently it will be much more probable that r1 occurs. If that is the case A' will result and X but not Y will be considered to have been consciously perceived. A' now is practically orthogonal to Y (a very small and possibly undetectable negative correlation exists between A' and Y). Thus the system has perceived the strong interpretation (X) of the ambiguous stimulus (A) and the alternative interpretation (Y) is neither primed nor suppressed. In the other scenario r2 occurs (because of external context or by pure chance) and A'' is perceived unambiguously as Y. Here however the unperceived interpretation (X) correlates very strongly and negatively with A'', i.e. SVRACA predicts that in this case (perceiving the weak interpretation for whatever reason) the unperceived interpretation will be negatively primed. That is exactly what we have observed in our previous studies. It may seem quite arbitrary that we chose vector reflection as the main operation which deals with ambiguity so let's state our reasons at the very beginning. First of all reflection is a computationally cheap operation. Second it makes a direct use of a meaningful representation of ambiguous stimuli. If an ambiguous stimulus is represented as a linear combination of unambiguous stimuli then reflection is probably the cheapest way to attain an unambiguous representation while maintaining the base representational scheme. Third, reflection allows us to model our stimuli as vectors in a high dimensional space which in turn opens the door for exploiting many of the advantages of using highly distributed representations. Fourth, vector reflection may serve as a useful and mathematically sound metaphor for conscious experience. Another such metaphor is reaching a stable state in a recurrent neural network but as we already saw at least some neural architectures don't provide a straightforward way of explaining the selective negative priming which is the topic of our study. Moreover it is not at all inconceivable representing SVRACA as a complex recurrent neural net in the future. Last but not least a model based on vector reflection not only makes sense of currently available data but also makes useful and testable predictions which will be discussed later.

### SVRACA: semi formal description.

Currently SVRACA supports 10 LTM vectors residing in a 10000 dimensional space. LTM vectors are orthogonal to each other and can be said to form a basis of a 10 dimensional space. Each vector is standardized to have a mean of 0 and a standard deviation of 1. Thus all vectors can be conceived as being of unit length. Here we will discuss the simplest case of ambiguity where a WM vector

is a linear combination of only two LTM vectors (e.g. an ambiguous drawing which can be interpreted as a rabbit or as a dog). A simulation begins with the system being supplied with a vector of coefficients  $\mathbf{w}$  which serve as weights for the linear combination. In the simplest case the system is supplied with two coefficients. The sums of squares of the coefficients must be equal to 1 ( $\|\mathbf{w}\|=1$ ) and thus the length of the linear combination is also equal to 1. The system proceeds by forming a linear combination of as many vectors from LTM as there are coefficients in  $\mathbf{w}$ . This construction stage reflects encoding a stimulus by the perceptual system and it requires a certain amount of time. Our simulations involve applying  $\mathbf{w}$  to randomly chosen vectors from LTM since the next stage involves SVRACA determining the relationship of the WM vector to each of the LTM vectors. SVRACA performs a linear regression on WM and collects all coefficients larger than some threshold value (e.g. 0.01). The vectors in LTM corresponding to these coefficients are those which make a significant contribution to the linear combination in WM. The larger a coefficient the closer the WM vector to the LTM vector associated with that coefficient. If all coefficients in  $\mathbf{w}$  are close to 0 (i.e. below a threshold of 0.1) or negative, SVRACA identifies the WM vector as a previously inexperienced entity and the simulation stops (see the lower left quadrant in figure 2). If all entries in  $\mathbf{w}$  are close to 0 or negative except for one than SVRACA identifies the WM vector as belonging to the category in LTM associated with the only positive coefficient (see the lower right and the upper left quadrants in figure 2). If more than one entry in  $\mathbf{w}$  is positive SVRACA interprets the situation as ambiguous and tries to resolve the ambiguity by reflection (see the upper right quadrant in figure 2). In the absence of any external context SVRACA reflects the WM vector around all axes associated with positive coefficients except for one. The probability of any axis remaining unaffected by the reflection operation is proportional to its squared coefficient. For example the probability of WM being reflected around all axes but the third is equal to  $w(3)^2$ . External context is represented by a set of weights each ranging from 0 to infinity. The elements of the vector of context weights, denoted  $\mathbf{c}$ , are subject to only one constraint namely that each of them should be 0 or positive. When external context is present the probability  $\mathbf{p}$  of each axis being the only one unaffected by reflection is equal to:

$$\mathbf{p} = ((\mathbf{w} * \mathbf{c} + \mathbf{w})^2) / \text{sum}((\mathbf{w} * \mathbf{c} + \mathbf{w})^2) \quad (1)$$

where “.” designates element-wise operations,  $\mathbf{p}$  is the vector of probabilities that each axis is the only one unaffected by reflection,  $\mathbf{w}$  is the vector containing the weights determining the WM vector and  $\mathbf{c}$  is the vector containing the weights representing the strength of external context towards each LTM axis. After a single axis is chosen to be unaffected by reflection SVRACA reflects the WM vector around all other axis with positive weights. This is achieved by setting to 0 all elements in  $\mathbf{w}$  which were initially negative as well as the element corresponding to the unaffected axis. This newly formed vector is called

reflection vector and is denoted by  $\mathbf{wr}$ . Now all positive elements in  $\mathbf{wr}$  refer to axes WM is to be reflected around and all other elements are 0. If we denote the collection of vectors in LTM which are involved in the linear combination WM as  $\mathbf{V}$  ( $\mathbf{V}$  is now a matrix with dimensions  $10000 \times \text{length}(\mathbf{w})$ ) the reflection WMr is achieved by:

$$\mathbf{WMr} = \mathbf{WM} + \mathbf{V} * (-2 * \mathbf{wr}) \quad (2)$$

where WMr is the reflected version of WM,  $\mathbf{V}$  is the collection of all vectors in LTM originally participating in the formation of WM and  $\mathbf{wr}$  is the reflection vector. The final step in a SVRACA simulation is to examine the relationship of WMr to the vectors in LTM in order to decide which LTM concept is the only positively related one to WMr (i.e. which concept WMr is perceived as). The relationship between any two concepts in SVRACA (LTM, WM, WMr) is defined as the cosine of the angle between the vectors in question. Since all vectors are defined as being of unit length the cosine of the angle between two vectors is also equal to the product moment correlation between them. Thus after reflection WMr will in most cases be positively correlated with only a single vector in LTM, negatively correlated with all other vectors in LTM which participated in the formation of WM and orthogonal to all vectors in LTM which were not involved in the construction of WM in the first place. The signs and magnitudes of these correlation coefficients are supposed to predict priming (positive or negative) in real world situations.

**A Typical Simulation** is described next. We supply SVRACA with a highly asymmetrical concept which is a linear combination of two LTM vectors with coefficients  $\mathbf{w} = [0.95 \ 0.3122]$ . We see that the WM vector is much closer to the LTM1 vector than to LTM2 vector. The context vector, however reflects the opposite picture:  $\mathbf{c} = [0 \ 5]$ , i.e., the LTM1 vector is absolutely irrelevant to the situation while the LTM2 would be very useful. Since both numbers in  $\mathbf{w}$  are positive SVRACA recognizes the ambiguity (i.e. identifies the LTM vectors correlating positively with WM) and calculates the probabilities  $\mathbf{p}$  of consciously perceiving each of the two possible interpretations according to (1):  $\mathbf{p} = [0.2045 \ 0.7955]$ . We see that the contextual influence radically changes the odds towards a conscious perception of LTM2. Next SVRACA stochastically determines around which axis to reflect WM based on the just obtained probabilities. Among 100 simulations with the same input parameters SVRACA interpreted the ambiguous WM as LTM1 16 times, and as LTM2 84 times. The reflection operation (2) resulted in WMr correlating -0.3122 with LTM2 and 0.95 with LTM1 in the 16 cases (conscious perception of LTM1) and 0.3122 with LTM2 and -0.95 with LTM1 in the 84 cases (conscious perception of LTM2). If we take the square of these correlation coefficients while keeping in mind their signs we see that when LTM1 is consciously perceived LTM2 remains practically unprimed – its overlap with WMr is equal to -0.0975. In the second case however when LTM2 is consciously perceived LTM1 exhibits pronounced negative priming – the magnitude of

the negative overlap (i.e. the signed coefficient of determination) between WMr and LTM1 is -0.9025. In other words SVRACA predicts practically no priming of the unperceived interpretation when the system perceives the strong interpretation and strong negative priming of the unperceived interpretation when the weak interpretation is perceived due to external context. We proceed with an empirical study testing these predictions.

## Experiment

### Design and Stimuli

We attempted to test our current predictions and further verify our previous findings by developing a new set of ambiguous drawings. We developed 3 pairs of asymmetrical drawings. Each pair contained an easy-to-see and a hard-to-see version of a particular picture. The first pair of ambiguous drawings can be seen as either a rabbit or a dog (figure 3). The two variants of this drawing included an easy-to-see rabbit (hence a hard-to-see dog) and an easy-to-see dog (hence a hard-to-see rabbit). The second ambiguous drawing can be seen as either a duck or a goat. The third drawing embodied a mouse and a frog and its two variants depicted an easy-to-see mouse (a hard-to-see frog) and an easy-to-see frog (a hard-to-see mouse).

Easy rabbit/hard dog

Easy dog/hard rabbit

Figure 3. The two variants of the first ambiguous drawing.

Table 1: Percentages of people who saw each interpretation

Version:	% who saw the strong interpretation	% who saw the weak interpretation
Strong rabbit (weak dog):	95	5
Strong dog (weak rabbit):	78	22
Strong duck (weak goat):	71	29
Strong goat (weak duck):	95	5
Strong mouse (weak frog):	84	16
Strong frog (weak mouse):	88	12

The variants of each drawing were validated in a simple picture naming task in which each variant of each drawing was presented on a computer screen (among many fillers

depicting unambiguous drawings) and subjects were simply required to name what they saw. Each subject saw only one version of an ambiguous drawing (to avoid priming effects) and each version was seen by 100 subjects. Thus 200 subjects participated in the standardization procedure. Table 1 shows the percentages of people who interpreted each version in each way.

For each variant of a picture we compared statistically (chi squared tests) the percentages of people seeing the strong and the weak interpretation of a drawing and all comparisons yielded highly significant results. Thus our stimuli indeed represented asymmetrical ambiguity. In the study we used the drawings as follows: each subject was presented with a single version of each ambiguous drawing only. The drawing was placed in a context which favored either the easy or the hard interpretation. There were three conditions in a repeated measures design: in the first condition subjects were contextually prompted to see the easy version of a drawing; in the second condition subjects were prompted to perceive the hard version; in the control condition subjects saw an unambiguous version of a drawing.

## Procedure

Each subject saw three drawings in three conditions in three target trials. Each target drawing appeared as a possible solution to a simple analogical task of the type A:B::C:? with two possible answers. The ambiguous drawing was one of the possible answers and the only way to solve the task correctly was to perceive the ambiguous drawing in its intended interpretation. The analogical task served as a context which prompted participants to perceive consciously only one of the possible interpretations in each drawing. In the first condition (called Easy Condition or EC from now on) subjects were required to perceive the easy interpretation of a drawing in order to solve the task correctly. In the second condition (called Hard Condition or HC) subjects were required to perceive consciously only the hard interpretation of a drawing. In the third condition (Control Condition or CC) subjects were presented with an unambiguous version of the drawing which was obviously the correct response to the analogical task. Each subjects saw only one version of an ambiguous drawing in order to avoid priming effects. Subjects were required to respond with the solution to each analogical task verbally in front of a microphone by naming the option they felt best fitted the analogy. After the response the microphone triggered the start of a LDT. A word appeared at the center of the computer screen and subjects were required to indicate whether it was a meaningful word in Bulgarian or a random sequence of letters by pressing a button. After each target trial a meaningful word appeared which referred to the supposedly unperceived interpretation of the just presented ambiguous drawing. In the CC where an unambiguous version of one of the ambiguous drawings was presented the word in the LDT referred to the other interpretation of the corresponding ambiguous drawing. The timing of the study

was as follows: an analogical task remained on the screen until the subject responded to it in front of the microphone. Immediately after the response a white screen with a fixation cross at the center appeared and remained for 350ms. After that a string of letters appeared at the center of the screen and remained there until subjects indicated by pressing one of two buttons whether the letters comprised a meaningful word or not. After the response a blank screen lasted 7sec. before the beginning of the next trial. The experiment contained three target trials and seventeen filler trials (the filler trials were the same as the target ones with the exception that the analogical tasks didn't contain ambiguous drawings and the LDT following them could contain both words or non-words after each analogical task; in contrast only words followed the target trials). The order of presentation of the three conditions as well as the order of presentation of the three drawings and the variants of each drawing were counterbalanced between participants resulting in 24 different lists. Each subject participated in only one list. We give examples of the first two lists in order to clarify the procedure: A subject in the first list was firstly supposed to see an easy duck (i.e. the easy-to-see duck variant of the duck/goat drawing was presented in a task that required the subject to see a duck in order to solve the task correctly) – EC, then she was supposed to see a hard frog (i.e. a hard-to-see frog variant of the frog/mouse drawing was presented in a task that required the subject to see a frog in order to solve the task correctly) – HC and finally she saw an unambiguous dog in a task that required her to see a dog in order to solve the task correctly – CC. In the EC condition she responded to the word “goat” during the LDT, in the HC she responded to the word “mouse”, and in the CC she responded to the word “rabbit”. A participant in the second list was firstly supposed to see a hard dog (respond to the word “rabbit” during LDT) – HC, then she was supposed to perceive an unambiguous goat (respond to “duck”) – CC and finally she was supposed to see an easy frog (respond to “mouse”) –EC. The remaining 22 lists exhausted all other possible combinations of variants of pictures to be perceived (and hence words to react to during LDT) and orders of presentation of conditions. In total we collected Reaction Times (RT) to six words all appearing in each of the three conditions. Those RTs constituted our dependent measure.

## Participants

Sixty eight undergraduate students (45 females and 23 males) from New Bulgarian University participated in the study for obtaining credits.

## Results and Discussion

Fifteen subjects failed to perceive the hard-to-see interpretation in the HC condition and were replaced. Five subjects were replaced because some of their RTs to target words during the LDT exceeded our threshold of 1500ms. After replacement of those subjects we were left with 48 participants – exactly two participants per list. The decision

to have two valid participants per list was made prior to the beginning of the study. The average RTs for each condition are presented in table 2.

Table 2: Average RTs for the LDT in each condition. Standard deviations are presented in parentheses.

Condition:	RT
Control Condition (CC)	774ms. (134)
Easy Condition (EC)	777ms. (130)
Hard Condition (HC)	824ms. (146)

We analyzed our data with a linear mixed model (e.g. Hoffman, 2007; Brysbaert, 2007) in which we entered subjects and items (i.e. words in the LDT) as random factors simultaneously. Our design allowed only for the inclusion of random intercepts for each random factor. The fixed factor was “Condition” with three levels for each subject (EC, HC, CC). The analysis showed a highly significant overall result for our independent variable –  $F(2, 89.301)=5.718, p=0.005$ . Multiple comparisons (performed via the SIDAK method) revealed a significant difference between CC and HC ( $p=0.01$ ), EC and HC ( $p=0.017$ ) and virtually no difference between CC and EC ( $p=0.997$ ). We see that the results corroborate our previous findings and are perfectly consistent with the predictions of SVRACA: when subjects perceived consciously the hard-to-see interpretation words referring to the easy-to-see interpretation become negatively primed compared to a control condition involving no ambiguity but not vice versa (i.e. no priming is detected when subjects perceive consciously only the easy-to-see interpretations). It is important however not to overgeneralize these findings. Fifteen subjects in our study (22%) failed to perceive the hard-to-see interpretation in the HC (i.e. perceived only the easy interpretation or reported perceiving both interpretations) even in the presence of strong context. This wasn’t unexpected since our study involved a condition in which subjects were required to perceive consciously only a very hard interpretation of an ambiguous figure. No contextual influence exists which can assure that this happens 100% of the time. Nevertheless we feel compelled to point out that given these circumstances our findings extend only to subjects which were “context sensitive” enough to comply with our experimental manipulation. The future directions of our work include testing other explicit predictions of SVRACA. Such predictions include: priming positively only the strong interpretation of an ambiguous drawing when the figure is presented subliminally; smaller effects compared to the just presented when symmetric ambiguous drawings are involved (i.e. when dealing with drawings with two equally easy to perceive interpretations SVRACA predicts that negative priming will again occur due to reflection but the amount of priming will be considerably smaller since reflection of a bisecting angle vector will result in a smaller negative correlation with the unperceived concept in LTM);

generally smaller effects of positive priming during subliminal presentation of ambiguous stimuli.

The obtained results are coherent with analogous results obtained by Nievas and Mari-Beffa (2002) who discovered negative priming of the non-selected meaning of a homograph, but only if the non-selected meaning is the dominating one. The combination of their and our data shows that the phenomenon of negative priming of the alternative representation is broader and holds both for linguistic and perceptual task and thus should be interpreted as unconsciously building a representation of both alternatives and inhibiting the stronger one if for contextual reasons we are pressed to use the weaker interpretation.

## Abstract

Foreign language professionals invest considerable time and effort in acquiring foreign language skills. Of key interest is how these skills change over time, and which sustenance, or language training activities, are efficacious in maintaining or improving proficiency. This paper discusses the results of mining more than 800 test/re-test records of foreign language professionals. Analyses investigated the extent to which lag time between test occasions and formal language training impacted changes in listening and reading proficiency ratings. Results indicate that certain factors, such as initial proficiency level, affect both patterns of change and the rate at which foreign language skills manifest evidence of loss.

**Keywords:** foreign language attrition, foreign language assessment, language training

## Introduction

The study of how foreign language proficiency changes over time is a relatively new area of research, often noted as receiving its first major impetus from a conference at the University of Pennsylvania in May 1980 (e.g., Clark & Jorden, 1984; De Bot & Weltens, 1995; Lambert & Freed, 1982; Weltens, 1987). In the few decades during which research on this topic has been active, a variety of papers have been published, though many of these studies have focused on which aspects of the foreign language are lost, and in what order (e.g., syntax vs. lexical knowledge first; Jordens, De Bot, & Trapman, 1989). Although this approach is valuable for describing the language aspects most vulnerable to loss, it does not target the question of what factors (e.g., conversing informally with friends in the L2) increase or decrease the rate of loss or how quickly general language abilities, such as reading comprehension, begin to show loss. Studies which have investigated factors influencing the loss of foreign language skills have examined the duration of the period of reduced input (i.e., time elapsed since peak language ability was attained), achieved proficiency level prior to the period of reduced input, and target language use during the period of reduced input, as well as other factors. The current study expands on previous research by examining the language skills of adults with foreign language proficiency in a variety of languages at multiple points of time to determine the rate at which loss

occurs, and how change in proficiency over time is affected both by formal language training and starting proficiency level.

## Period of reduced input and change in language skills

Duration of the period of reduced input has been defined as time since the end of formal training (e.g., Bahrck, 1984) or time since the end of intensive language exposure, such as an immersion experience (e.g., Snow, Padilla, & Campbell, 1988). More generally, this factor has been conceptualized as the amount of time since learners achieved their peak proficiency (Bardovi-Harlig & Stringer, 2010), though this characterization can be problematic when learners' abilities actually improve during the period (Gardner, Lalonde, Moorcroft, & Evers, 1987; Murtagh & van der Slik, 2004). The amount of time the learner has had to lose language skills is a particularly intuitive factor in explaining degree of foreign language loss, with the common sense prediction being that loss increases with elapsed time. Several studies have found evidence for such a relationship (e.g., Murtagh & van der Slik, 2004; Nagasawa, 1999; Reetz-Kurashige, 1999), though there are some findings suggesting the rate of loss over time may not be linear (Bahrck, 1984). However, it is important to take into consideration other factors, such as the target language-specific activities the learner has engaged in during the period of reduced input, rather than just the time elapsed since some benchmark of language learning was attained.

One issue with research on the duration of the period of reduced input is that these studies explore duration as a discrete factor, investigating language skills at a few specific points in time (often at only one or two time points after the period of reduced input has begun). In general, there is a tradeoff in the literature between sample size and the number of time points at which the language skills of the participants are measured: those studies with sizable *n* (e.g., Clark & Jorden, 1984; Gardner et al., 1987; Murtagh & van der Slik, 2004) tend to measure language skills only twice, once at the beginning of the period of reduced input (i.e., the baseline) and again a set amount of time later. Cross-sectional studies, like Bahrck (1984) and Snow et al. (1988), take only one measure of language skills for each participant and compare across groups that have

experienced different durations of reduced input (note that this method does not take into account potential differences in initial proficiency levels). By contrast, some studies compare language skills for the same individual at a number of time points, but tend to involve only very small groups of participants, generally children (but see Russell, 1999, for an exception), and to focus on the specific aspects of the language that are lost rather than loss of general language ability (e.g., Hansen-Strain, 1990; Reetz-Kurashige, 1999; Yoshitomi, 1999). The reason for the small number of studies exploring multiple time points with adult foreign language learners is likely attributable to practical constraints: it is difficult to longitudinally track and maintain contact with the same group of language learners over a long period of time. Yet, to explore how foreign language skills change over time, it is desirable to examine the skills of the same set of individuals repeatedly during the period of reduced input.

### Language use during the period of reduced input

The extent to which foreign language is used during the period of reduced input is likely to be an important determiner of the amount of knowledge lost at the end of this period because it determines just how “reduced” the input during this period is for the learner. Clark and Jorden (1984) found that the learners of Japanese who did not show loss months after formal language training ended reported using the language more regularly than those who did show loss. In a similar study, Murtagh and van der Slik (2004) demonstrated that use of the target language after leaving formal language training predicted strength of language skills for learners of Irish eighteen months after leaving school. In a study with employees of the Canadian government, French-dominant bilinguals reported more opportunities to use their less dominant language (English) and also showed less loss of skills in their weaker language than did English-dominant bilinguals (Edwards, 1977, discussed in Oxford, 1982). Snow (1982) found that, at the group level, the lowest amount of loss was exhibited by Spanish immersion student groups that had the highest proportion of learners who continued to study the target language after the immersion ended (reported in Snow et al., 1988).

### Achieved proficiency and change in language skills

Achieved proficiency in the L2 is important for assessing change in foreign language skills because it provides the baseline against which to compare current ability. This factor has also been considered in its own right as a potential predictor for foreign language loss. Having higher target language proficiency may lead to decreased loss over time (for reviews, see Bardovi-Harlig & Stringer, 2010; Weltens, 1987). One potential reason for this is that having greater foreign language proficiency may provide a learner with more available strategies to compensate for loss of specific foreign language knowledge. For example, a learner could use target language morphological knowledge to

uncover the meaning of a forgotten lexical item in the same way children use this type of information to comprehend unfamiliar words (Carr & Johnston, 2001). In addition, some theories of foreign language acquisition suggest that language knowledge, once it reaches a critical threshold, simply becomes resistant to loss (Bardovi-Harlig & Stringer, 2010). However, there are somewhat mixed results for the relationship between achieved proficiency and change in language skills over time, with several studies suggesting that higher proficiency learners do indeed experience less loss over time than do lower proficiency learners (Clark & Jorden, 1984; Gardner et al., 1987; Kaufman, 1995; Nagasawa, 1999) and others suggesting there is no difference in rate of language loss between higher and lower proficiency learners (Bahrick, 1984; Weltens & Grendel, 1993).

## The Current Study

The current study explored change in general foreign language skills (reading and listening comprehension) for a large number of foreign language professionals who were tested multiple times (2-7 test occasions, with the majority having 3 or more) over a period as long as 6 years. The dataset included test histories for nearly 50 different languages; because of the small number of people testing in any one language, all analyses were completed in aggregate across the tested languages. Most people in the dataset were tested annually, but there was considerable variation in the frequency of testing. In addition to test records, information on participation in official language training was available for individuals in the dataset.

### Method

The dataset included 1084 test histories for listening and 1085 for reading.<sup>1</sup> Each test event was associated with a rating of proficiency based on the raw score from the test; the raw score was not included in the dataset. Ratings are based on the Interagency Language Roundtable (ILR) scale for that particular skill: possible scores can range from 0 to 5, with 0 = *No Proficiency* and 5 = *Functionally Native Proficiency*; between each pair of adjacent levels is a “plus level” (e.g., 0+, 2+), *assigned when proficiency substantially exceeds one skill level and does not fully meet the criteria for the next level* (Interagency Language Roundtable, 2011).<sup>2</sup> For the purpose of analyses, all ILR ratings were recoded into numeric values.<sup>3</sup> All scores were associated with a test date, so it was possible to calculate the amount of time, in days, from the first test administration to each subsequent test. Whether or not a person received language training, dummy coded as 0 = *no training* and 1 = *training*, was included in all analyses. Only a small subset

<sup>1</sup> A minority of individuals tested in more than one language; analyses treat each test history as a separate case.

<sup>2</sup> For more information on the ILR proficiency scales, see <http://www.govtirl.org/Skills/ILRscale1.htm>.

<sup>3</sup> For example, 1 = 10, 1+ = 16, 2 = 20, 2+ = 26, etc.

Initial target language proficiency was defined as the first ILR rating on record for any given language in the relevant skill (i.e., reading or listening). Due to the sparseness of individuals at some levels of proficiency, each person's first rating was coded as either *high*/2 = a rating of 2+ or greater or *low*/1 = a rating of 2 or lower. This recoded variable was used in analyses of skill loss. In addition, information about whether or not the test version changed during the testing history was available for the dataset. This factor is likely to be important when examining change in ratings, as the introduction of a new, unfamiliar test may decrease ratings even in the absence of loss of language skills. This factor was coded as 1 = *version change* and 0 = *no version change*.

**Overall patterns of change** To explore the pattern of change across test administrations, a latent growth analysis (Bollen & Curran, 2006) was used to examine the direction and trajectory of change over time. In these latent growth analyses, the first score or intercept (*ICEPT*) and the growth over time (*SLOPE*) were dependent variables, while participation in formal language training (*Training*) and the occurrence of a test version change (*verdif*) were included as independent variables (see Figure 1). Because few test histories contained more than four tests, only the first four tests in the dataset were included in the latent growth analyses.

the slope was also significant for listening scores ( $r = -0.37$ ,  $p < .001$ ), indicating that people who started with lower initial ILR ratings had a faster rate of improvement over time than did those who started with higher ILR ratings. The *training* variable had a significant negative relation ( $-0.15$ ) to the intercept for listening scores ( $t = -4.27$ ,  $p < .001$ ), indicating the people who participated in formal training had lower initial ILR ratings, perhaps indicating that these individuals self-selected for training. In addition, training had a significant positive relationship ( $0.20$ ) with slope ( $t = 3.09$ ,  $p < .01$ ), indicating that the trajectories of improvement for professionals who had some kind of language training were higher than for those who had not participated in a training activity. The version change variable also had a significant relationship with slope, but this relationship was negative ( $-0.19$ ;  $t = -2.88$ ,  $p < .01$ ). The direction of this relationship is intuitive: the introduction of a new test version decreases the rate of improvement. What is less intuitive, however, is the significant positive relationship ( $0.09$ ) between the version change variable and the intercept ( $t = 2.76$ ,  $p < .01$ ). This relationship indicates that people who experienced a version change at some time in their testing history also tended to have higher initial ILR ratings. A new test version was introduced for only a subset of languages during the time covered by the test history data, so whether a version change occurred was partially dependent on the language tested. It may be that initial proficiency in this dataset was higher in those languages that experienced a version change, leading to the relationship between version change and the intercept. In fact, chi-square tests revealed that significantly more people with starting proficiency of 2+ or above experienced a version change for both listening and reading ( $\chi^2(1) = 8.08$  and  $\chi^2(1) = 8.32$ , respectively; both  $ps < .01$ ).

As for listening, the *training* variable has a significant negative relationship ( $-0.20$ ) with the intercept for reading ( $t = -5.71, p < .001$ ), indicating that people who participated in training tended to have lower initial reading ILR ratings, and has a significant positive relationship ( $0.16$ ) to the slope ( $t = 2.67, p < .01$ ), suggesting that improvement was faster for those individuals who have received some type of language training. The version difference variable has a significant negative relationship ( $-0.19$ ) to slope ( $t = -2.88, p < 0.01$ ); as for listening, the introduction of a new test version leads to a slower rate of growth in reading ratings

over time. The same non-intuitive positive relationship between version change and the intercept was also present for reading scores (0.12;  $t = 3.42$ ,  $p < .001$ ). Again, the most likely explanation is that those languages for which a new test version has been introduced also tend to be languages where the individuals have a higher initial rating.

Ratings improved over time for both reading and listening, as indicated by the significant positive slopes in the latent growth analyses. Version change negatively impacted this trend, leading to a slower rate of improvement over time for listening scores but did not affect change over time for reading scores. Training, on the other hand, positively affected this trend, indicating that the formal language training resulted in faster improvement in ILR ratings for both listening and reading. While people with lower initial ratings showed a faster rate of improvement in listening, this pattern was reversed for reading. It may be that attaining higher proficiency levels in reading becomes easier as proficiency increases, while attaining higher levels for listening becomes more difficult as proficiency increases. This is a topic for future research.

**Loss in ILR ratings** To examine how the amount of time between test occasions affected the incidence of loss in ratings, event history analyses were conducted separately for reading and listening. A test history was coded as showing a loss if any subsequent test occasion produced a lower ILR rating than the first test occasion. In an event history analysis, the time between the first test and the test that yielded a lower score (i.e., lag time) is modeled to capture the amount of lag time for cases coded as losses compared to the lag time for cases where scores are sustained or increased from the first to the most recent test (i.e., non-loss cases).<sup>4</sup> The goal of the event history analysis is an estimation of the average time lag associated with increasing incidences (events) of proficiency loss and the effect of any covariates on the rate of loss.

The version change factor was revised somewhat for the event history analyses. The factor captured whether a person who experienced a loss experienced a version change *prior to that loss*, rather than at another point in their test history. For individuals who did not show loss, this factor continued to indicate whether they had experienced a version change at any time in their test history.

Across all sets of listening test records, 17.7% of the cases were coded as showing a loss (i.e., at least one rating was lower than the first ILR rating on record). The event history analysis estimates the time lag associated with survival (i.e., not showing a loss) as a function of time beginning with 100% of the cohort surviving. The event history model assesses whether loss is a possible function of time between test occasions. For an event phenomenon

impervious to time, the rate of loss would be expected to remain close to zero across all observed time lags. However, the prediction based on previous studies (e.g., Nagasawa, 1999; Reetz-Kurashige, 1999) would be for the rate of loss to increase as time lag increases, which was in fact found for listening ratings. Event history analysis revealed that the projected survival rate for listening was fairly long, with over 80% of cases found to maintain or improve listening ratings with three years' lag between test occasions (see Figure 2).

Figure 2. Loss in listening ratings over time

Version change was a marginally significant covariate in the event history analysis ( $B = 0.32$ ,  $p < 0.07$ ), with the predictable impact of increasing the rate of loss for listening: the odds of showing loss were projected to be roughly 1.37 times higher for people experiencing a version change than those who did not experience a version change. In addition, whether or not the person engaged in formal language training was entered as a covariate into the analysis. Participation in training did not significantly affect rate of loss for listening ILR ratings ( $B = -0.15$ ,  $p = 0.51$ ). However, the initial proficiency of the individual, coded as *low* for those with an initial ILR rating of 2 or lower and as *high* for those with first ILR rating of 2+ or higher, was a significant covariate ( $B = 0.71$ ,  $p < 0.01$ , see Figure 3).

Figure 3. Initial proficiency and loss in listening ratings

<sup>4</sup> Cases where the first rating on record was 0 (providing no opportunity to see a pattern of loss over time) and those where two test ratings were listed for the same date (suggesting the person was tested twice in one day) were excluded from event history analyses.

Surprisingly, however, those with higher scores exhibited a faster rate of loss, with the odds of this group showing loss projected as roughly 1.99 times higher than the odds for those with lower initial ratings. This finding is contrary to what has been found in previous studies (Clark & Jorden, 1984; Gardner et al., 1987; Kaufman, 1995; Nagasawa, 1999), and will be discussed in the Summary below.

Across all sets of reading test records, 17.6% of the cases were coded as showing a loss compared with the first score. As for listening, the incidence of loss increased with the amount of time between test occasions for reading tests scores (see Figure 4). Event history analysis projected the survival rate for reading to be comparable to that seen for listening: about 80% of cases were found to maintain or improve listening scores with three years' lag between test occasions.

Consistent with the analyses completed for listening scores, test version change was entered as a covariate into the event history analysis for reading scores. This factor failed to approach significance for reading scores, however ( $B = 0.13, p = 0.48$ ). Whether or not the individual engaged in formal language training also failed to approach significance as a covariate for loss of reading ratings ( $B = 0.12, p = 0.56$ ). However, as for listening ILR ratings, the first rating on record, coded as *high* = 2+ or higher and *low* = 2 or lower, was again a significant covariate ( $B = 0.55, p < .05$ ; see Figure 5). The difference between the high and low proficiency groups was similar to that seen for listening scores, with the higher proficiency group showing a faster rate of loss than the lower proficiency group.

The results of the event history analyses reveal that the proportion of test cases in the dataset showing loss increased as the amount of time since the first test increased. However, training did not have a significant effect on the rate of loss for listening or reading. Because only a small portion (~14%) of the individuals included in the current analyses had formal language training on record, and only a subset of this group experienced a loss in ratings, it is possible that there was not enough power in these analyses to detect an impact of training on the rate of skill loss. Further, experiencing a test version change was a marginally significant covariate for the rate of loss of listening scores, but not for reading scores.

## Summary and Conclusion

The findings from the current study are in line with previous results from studies examining change in foreign language skills in several ways. Consistent with previous research investigating the duration of the period of reduced input (e.g., Murtagh & van der Slik, 2004; Nagasawa, 1999; Reetz-Kurashige, 1999), the probability of loss increased as the amount of time since the first test increased for both reading and listening. These results indicate that, all other factors being equal (amount of foreign language use, motivation, etc.), ILR ratings for these individuals will tend to decrease as the amount of time between test administrations increases.

Figure 4. Loss in reading ratings over time

In contrast, the investigation of achieved proficiency (the degree of proficiency achieved in the language) and its effects on the rate of loss were not consistent with previous research findings. In the event history analyses, initial proficiency was a significant covariate for the rate of loss for all three skills, with higher proficiency individuals projected to have *faster* loss rates than lower proficiency individuals. This result is in the opposite direction from what is typically found when there is a difference in change for higher and lower proficiency learners (e.g., Clark & Jorden, 1984; Gardner et al., 1987). The current dataset contained many more individuals with *high* proficiency (a first score of 2+ or higher) than with *low* proficiency (a first score of 2 or lower), so it is possible that there was something unique about the individuals with lower initial ILR ratings that led to the relationship between initial proficiency and rate of loss. It is also possible that maintaining a higher rating is simply more difficult, with a smaller margin for error, leading to a faster rate of loss for this group. Further, there may be differences in motivation between the two groups, with the lower proficiency individuals more motivated to work to improve their language skills, and so slower to show loss over time. These possibilities will be investigated in future studies.

Figure 5. Initial proficiency and reading attrition

The current study also found no effect of whether an individual engaged in formal language training on the rate of loss for either listening or reading, though engaging in training did lead to a faster rate of improvement over time. This result runs counter to previous findings showing that the extent of target language use and exposure during the period of reduced input predicts retention (e.g., Clark & Jorden, 1984; Edwards, 1977; Murtagh & van der Slik, 2004). However, it is important to note that the information on formal language training was available for only a small subset of all people (14%), and that it is unclear why this subset of the sample participated in language training. It may be that these individuals were selected for training specifically because they struggled to maintain their foreign language skills. Further, the records of formal language training were the only information available about what the people included in the dataset might have been doing with their foreign language skills since the first language test in the dataset. It is very possible that large individual differences exist in the sample in terms of informal language training and other types of use and exposure (e.g., watching TV in the target language) during the period of time since the first test.

In conclusion, the current study introduced a method for investigating factors affecting change in adult foreign language skills in a longitudinal design, and described the results of an analysis of change in proficiency ratings for one group of foreign language professionals. Although this dataset was limited in several ways, including providing little information about use of the foreign language between proficiency tests, it did offer two or more data points for most individuals that were spread across a number of years. Further, the first ILR rating in the dataset offered a proxy for achieved language proficiency, so a given individual's current performance could be compared against his or her own previous abilities. A survey is currently being distributed to collect additional information about language learning history and current language use for professionals in this population to provide a more complete picture of the factors that affect change in foreign language skills.

## Abstract

Investigating people's representations of categories of complicated objects is a difficult challenge, not least because of the large number of ways in which such objects can vary. To make progress we need to take advantage of the structure of object categories – one compelling regularity is that object categories can be described by a small number of dimensions. We present Look-Ahead Monte Carlo with People, a method for exploring people's representations of a category where there are many irrelevant dimensions. This method combines ideas from Markov chain Monte Carlo with People, an experimental paradigm derived from an algorithm for sampling complicated distributions, with hybrid Monte Carlo, a technique that uses directional information to construct efficient statistical sampling algorithms. We show that even in a simple example, our approach takes advantage of the structure of object categories to make experiments shorter and increase our ability to accurately estimate category representations.

**Keywords:** category representation; Markov chain Monte Carlo; directional judgements

## Introduction

Categories are an essential component of how people reason about the world, allowing us to act intelligently when we encounter new objects, new people, or new situations. Natural stimuli, such as images or text, tend to be very complicated. In contrast, much of our understanding of categorisation behaviour has been built on experiments using well-controlled stimuli that vary along only one or two dimensions (e.g., Nosofsky, 1986). A major driver of the disconnect between experimental investigations and real-world behaviour is that standard experimental methods do not allow the experimenter to adaptively focus on informative stimuli. Attempting to map out a complicated category with standard methods would require participants to complete an unendurable number of trials.

Identifying connections between cognitive science and statistics can help us develop new methods to extend our experimental reach. Many of the computational models of categorisation developed from carefully-controlled laboratory studies can be interpreted as representing categories as probability distributions over their constituent stimuli (Ashby & Alfonso-Reese, 1995). Statisticians have developed sophisticated methods to sample from high-dimensional distributions and Sanborn and Griffiths (2008) identified how to use one of these methods, Markov Chain Monte Carlo (MCMC), to draw samples from categories that were represented in the mind. This method, termed Markov Chain Monte Carlo with

People (MCMCP), focused trials on informative regions of stimuli – greatly reducing the number of trials a participant needs to perform.

While MCMCP exploited the local nature of categories, it could not exploit the way that many categories lie on manifolds. Many seemingly complex stimulus representations possess a simpler embedded representation. For example, images, when represented as a grid of pixel values, inhabit a high-dimensional space, typically hundreds to hundreds of thousands of dimensions. Yet modifications to these images, such as changing a facial expression or moving a limb, require simultaneously modifying only some of the dimensions. Thus often stimuli possess many irrelevant dimensions and many “linked” dimensions, where changing one implies proportionally changing many other connected dimensions. Since such relationships are often smooth among dimensions, suggesting a manifold structure.

In this paper, we present an extension to MCMCP that is able to take advantage of the manifold structure of continuous-valued stimuli and apply it to a low-dimensional stimulus. We take inspiration from the large literature in statistical computing that has explored how MCMC algorithms can be modified to increase their efficiency in solving specific problems. For example, Hybrid Monte Carlo (Neal, 1996) is a successful method for sampling in high-dimensional spaces that incorporates directional information into MCMC methods. We adapt MCMCP to include directional information, allowing participants to “look ahead” at the consequences of their decisions so they can guide stimulus generation, increasing the efficiency with which we can investigate categories.

The remainder of this paper is organised as follows. We first introduce the MCMC and explain how it was adapted to people. Next we introduce Look-Ahead Monte Carlo with People (LAMCP), first motivating it intuitively and then presenting the technical justification of our method. We compare LAMCP to MCMCP empirically in an experiment exploring the golden ratio in rectangles—a simple example of a low-dimensional manifold in a higher-dimensional space. We then conclude with a brief discussion how our method relates to hybrid Monte Carlo and other sampling techniques.

## Background: MCMC with People

Using the connection between computational models of categorisation and probability distributions (Ashby & Alfonso-

Reese, 1995), let  $p(x|c)$  denote the probability of stimulus  $x$  under the distribution associated with category  $c$ . We could attempt to elicit people's category representation by asking them to rate the typicality of item  $x$  in category  $c$ , but that would require us to present participants with every stimulus of interest. Instead we would like to draw samples from  $p(x|c)$ .

The Metropolis sampling scheme (Metropolis, Rosenbluth, Rosenbluth, Teller, & Teller, 1953) is a commonly used algorithm for generating a sequence of samples from a designer-supplied probability distribution. It constructs a Markov chain whose stationary distribution is the provided probability distribution and then uses this Markov chain to, eventually, generate a sequence of samples from the stationary distribution. The algorithm has two parts that are provided by the designer: a proposal distribution  $q(x^*|x)$ , and an acceptance function  $A(x^*, x)$ . The proposal distribution is typically a simple distribution (such as a Gaussian or uniform distribution) and is used to propose possible samples,  $x^*$ , given the current sample,  $x$ . The acceptance function tests how similar samples from this proposal distribution are to the desired stationary distribution, guiding the algorithm towards this distribution. Both the proposal distribution and acceptance function must be carefully selected to ensure the Markov chain converges correctly (see Neal, 1993). At each step  $t$  of the algorithm, a new state of the chain is proposed,  $x_t^*$ , by sampling it from the proposal distribution,  $q(x_t^*|x_{t-1})$ . With probability  $A(x_t^*, x_{t-1})$ , the state of the Markov chain at step  $t$  is the proposal  $x_t^*$ , otherwise it is the previous state, i.e.,  $x_t = x_{t-1}$ . The initial state  $x_0$  of the Markov chain is picked at random. It can be shown that if this procedure is repeated for long enough, the Markov chain it defines will eventually converge on the desired stationary distribution.

MCMCP (Sanborn & Griffiths, 2008; Sanborn, Griffiths, & Shiffrin, 2010) transformed the Metropolis sampling scheme into an experimental method for cognitive science. MCMCP is a sequential paradigm in which participants construct the stimuli themselves, in small, manageable steps. The equilibrium distribution of interest is the distribution over stimuli belonging to a single category  $p(x|c)$ , which we shall write as  $\pi(x)$  for short-hand, the particular category being implicit.

On each trial of the MCMCP procedure, a new stimulus sample  $x_t^*$  is generated by a computer from an experimenter-provided proposal distribution, such as a Gaussian or uniform distribution. Participants are presented with a choice of two possible samples; the current state,  $x_{t-1}$ , or the proposed new state,  $x_t^*$ . Their selection becomes the new state of the Markov chain,  $x_{t+1}$ . The next trial has the same form, and the procedure repeats until the Markov chain is deemed to have equilibrated.

If participants choose  $x_t^*$  according to a valid acceptance function, then one can show that, just like Metropolis sampling, this scheme forms a Markov chain whose stationary distribution is the distribution over stimuli in a particular category  $\pi(x)$ . Fortunately there is an exact correspondence be-

tween the ratio rule of human decision making (Luce, 1963) and a valid acceptance function for use with Metropolis sampling, namely the Barker acceptance function (Barker, 1965):

$$A(x_t^*, x_{t-1}) = \frac{\pi(x_t^*)}{\pi(x_t^*) + \pi(x_{t-1})} \quad (1)$$

Assuming participants' choices are Markov, the paradigm forms a Metropolis sampling scheme whose states are samples from people's distribution of objects in a particular category at the equilibration of the Markov chain.

The proposal distribution used by MCMCP is fixed and provided by the experimenter; typically it is an isotropic Gaussian distribution. This induces a random-walk Markov kernel, which, as Neal (1993) notes for general MCMC, and as Martin, Griffiths, and Sanborn (2012) note for MCMCP, can be inefficient for exploring large, correlated spaces. Gains in efficacy are to be had by removing this random walk, whilst maintaining the properties that allow it to converge to the category distribution.

## An Intuitive View of MCMCP and LAMCP

Before presenting our novel Look-Ahead Monte Carlo with People (LAMCP) method, we will provide some intuitions as to how it differs from MCMCP. Intuitively, we can think about exploring a probability distribution by following a Markov chain in terms of a hiker attempting to travel along a ridge path. The ridge represents an interesting low-dimensional manifold embedded in a largely irrelevant higher-dimensional space, and we wish participants to explore this manifold efficiently.

Suppose our hiker is standing upon a bumpy ridge in an otherwise large flat landscape. He wishes to explore the ridge, whilst only descending into the lower parts of the landscape fleetingly. Suppose also that he cannot see anything, and must be told about the terrain by MCMCP or LAMCP.

MCMCP allows our hiker to know about the terrain where he currently stands and also at another location, picked at random by MCMCP. He must then choose whether he wishes to step to this new location or stay where he is. MCMCP does not know of our hiker's intention to follow the ridge, and so when MCMCP proposes locations far away from him, the new location is likely to be in the flat and so he will often elect not to move. Proposed locations very close to our hiker are likely to be on the ridge so he will be willing to make a step. Walking along the ridge in this random fashion will take a great many small steps.

LAMCP gives our hiker a guide. This guide walks away from the hiker along a randomly oriented straight line. The guide then returns to the hiker and tells him on average, how much of the ridge she saw on her travels. If the hiker feels that the guide saw a lot of the ridge, then LAMCP randomly picks a location along this straight line. The hiker can then either stay where he is, or walk to this new location offered by LAMCP. With LAMCP, the hiker can take advantage of a longer view. In addition, our guide will propose the same

direction in which our hiker just travelled, which will be advantageous in following a straight ridge path. Both aspects allow our hiker to travel more quickly.

### Look-Ahead Monte Carlo with People

Look-Ahead Monte Carlo with People (LAMCP) is a sequential paradigm that, like MCMCP, samples from a participant's distribution over stimuli for a particular category. Unlike MCMCP, LAMCP has two kinds of trials. The first kind are just like the trials of MCMCP; participants are asked to choose between a generated stimulus and the previous stimulus as the next state of a Markov chain. In the second kind of trial, however, participants are asked to choose a direction in the stimulus space to explore. This directional information is then used to generate a stimulus to be presented to the participant in the first kind of trial. Thus LAMCP produces two kinds of samples; stimuli, which we shall denote  $x$ , and also directions, which we shall denote with  $d$ .

LAMCP alternates between proposing stimuli using the current direction and previous stimulus and proposing directions using the current stimulus and previous direction. In this way, LAMCP is able to capture and to some extent remember local manifold structure when generating stimuli.

Recalling the analogy of the hiker trying to follow a ridge; new stimuli are generated from directions by starting at the current stimulus and advancing some distance according to the current direction. The distance advanced is sampled at random. More precisely, the two kinds of trials of LAMCP operate as follows:

**Stimulus trial:** Suppose that a direction  $d_t$  has been sampled already. The direction has an additive effect upon the current stimulus and so the proposal for the new stimulus,  $x_t^*$ , is:

$$x_t^* = x_{t-1} + \epsilon_t d_t$$

where  $\epsilon_t$  is a random value, sampled once for each stimulus trial, with distribution which we shall denote  $q_\epsilon(\epsilon_t)$ , determining for how far the direction  $d_t$  should be followed. The variable  $\epsilon_t$  is the distance travelled, in direction  $d_t$  to obtain the new stimulus.

Participants are then presented with the previous stimulus  $x_{t-1}$  and the proposal  $x_t^*$  and asked which of these stimuli looked like they belonged more to the category of interest  $\pi(x)$ . As in MCMCP, we assume this choice is made by participants according to the ratio rule and thus corresponds to the Barker acceptance function (Equation 1).

**Direction trial:** In this step, participants pick a suitable direction for advancing the current stimulus  $x$ . A direction proposal is sampled from the direction proposal distribution  $q_d(d_t^* | d_{t-1}, x_{t-1})$ . Direction values are presented to participants as animations, showing how the proposed stimuli will be derived from the direction. This is the look-ahead part of our paradigm: this animation provides participants with insight into how selecting a direction would

affect the proposal of stimuli during future stimulus trials. Participants can decide to continue along a single direction for multiple stimulus trials by continuing to select the current direction during a direction trial.

Suppose  $N$  frames are to be generated for a proposed direction  $d_t^*$ . First  $N$  values of  $\epsilon_t$  are selected, typically uniformly spaced within some task-specific interval:  $\epsilon_t^1, \epsilon_t^2, \dots, \epsilon_t^N$ . Then frame  $n \in \{1, \dots, N\}$  is the stimulus produced by  $x_t + \epsilon_t^n d_t^*$ . The animation loops, first increasing the frame number  $n$  from 1 to  $N$ , then decreasing the frame number from  $N$  to 1.

Participants are presented with two animations: one corresponding to the proposed direction  $d_t^*$  and another for the previous direction  $d_{t-1}$ . Participants are asked to select the animation in which the stimuli look most like they belongs to the category of interest. By doing so, participants are picking the direction that is most likely to offer a stimulus belonging to the category during the next stimulus trial.

Again, as in MCMCP, we assume this choice is made by participants according to the ratio rule and thus corresponds to the Barker acceptance function (Equation 1).

In summary, the LAMCP paradigm is as follows:

1. Generate new direction proposal from direction proposal distribution  $q_d$ :

$$d_t^* \sim q_d(d_t^* | d_{t-1}) \quad (2)$$

The experimenter provides  $q_d$ : the distribution is required by the Barker acceptance function to be symmetric,  $q_d(d^* | d) = q_d(d | d^*)$ .

2. Generate an  $N$ -frame animation of the resulting samples:  $x_t^* = x_{t-1} + \epsilon_n d_t^*$  for each  $n \in \{1, 2, \dots, N\}$ .
3. Participants asked to choose between  $d_t^*$  and  $d_{t-1}$  for the new direction  $d_t$ , based upon the animated stimuli. In particular they select the new direction with probability:

$$\frac{\pi(d_t^* | x_{t-1})}{\pi(d_t^* | x_{t-1}) + \pi(d_{t-1} | x_{t-1})}$$

4. Generate new stimulus proposal from direction  $d_t$  and previous stimulus  $x_{t-1}$ :

$$\epsilon_t \sim q_\epsilon(\epsilon_t) \quad (3)$$

$$x_t^* = x_{t-1} + \epsilon_t d_t \quad (4)$$

The experimenter provides  $q_\epsilon$ . Typically it will be a Gaussian distribution or a scale mixture of Gaussian distributions.

5. Participants are asked to choose between  $x_t^*$  and  $x_{t-1}$  as the new stimulus  $x_t$ , choosing  $x_t^*$  with probability:

$$\frac{\pi(x_t^*)}{\pi(x_t^*) + \pi(x_{t-1})}$$

In terms of Markov chains, LAMCP is a Metropolis sampler, where each kind of trial can be understood to be updates to either the stimulus or the direction. The overall stationary distribution is  $\pi(x, d) = \pi(x)\pi(d|x)$ . Participants are asked to pick directions whose animation show a high probability stimulus for the longest. Stated more formally, the stationary distribution for directions is:

$$\pi(d|x) \propto \int \pi(x^*) \delta(x^* = x + \epsilon d) dx^* d\epsilon \quad (5)$$

where  $x^*$  are the look-ahead points and  $\pi(x^*)$  is the stimulus distribution evaluated at these look-ahead points, whilst  $\epsilon$  is their distance along the direction  $d$  from the original stimulus  $x$ .

### Extending LAMCP to Many Choices

As originally developed, MCMCP and LAMCP consisted of two alternative forced choice (2AFC) trials. This follows naturally from the Barker acceptance function (Equation 1). However, a larger number of alternatives could provide even more informative judgements.

At the start of each trial, instead of generating one proposal  $x_t^*$ , a set of  $n$  proposals is generated  $\{x_t^p : p \in \{1, \dots, n\}\}$ . Let  $c$  denote the index of the selected choice; instead of the Barker acceptance function in Equation 1, we use:

$$A(x_t^c, x_{t-1}) = \frac{\pi(x_t^c)}{\pi(x_{t-1}) + \sum_{p=1}^n \pi(x_t^p)} \quad (6)$$

Just as the Barker acceptance function (Equation 1) naturally arises in people's decision making from the Luce's choice axiom (Luce, 1963), so too does Equation 6.

It is not obvious, however, whether such an acceptance function leads to a valid Markov chain Monte Carlo sampler. By considering the multiple choice Markov transition kernel, one can show that the condition of *detailed balance* is satisfied by this acceptance function, and hence the above acceptance function maintains the equilibrium distribution  $\pi(x)$ . In particular, the Markov transition kernel is:

$$T(x \rightarrow x') = \sum_{p=1}^n \delta(x', x^p) A(x^p, x) S(x, x^p) + \delta(x', x) \left[ 1 - \sum_{p=1}^n \int A(x^p, x) S(x, x^p) dx^p \right] \quad (7)$$

where  $S$  is the symmetric proposal distribution for generating new proposals. Detailed balance requires one to show that  $\pi(x)T(x \rightarrow x') = \pi(x')T(x' \rightarrow x)$  holds for all  $x$  and  $x'$ , which is easily achieved by substitution of definitions and algebra.

Though we have shown that the connection between the ratio rule and a valid acceptance function holds for more than two choices, there is evidence that people do not follow the ratio rule in this case (Wills, Reimers, Stewart, Suret, & McLaren, 2000). Rouder (2004) suggests that behaviour is better explained by raising the choice probabilities to a power

that varies from trial to trial. In our experiment, we shall only use this new regime for direction trials, where we do not need to sample from a stable distribution. In future, however, it would be interesting to explore how robust MCMCP is to the deviations from the ratio rule that people display.

### Experiment: Testing LAMCP

We evaluated whether LAMCP is able to produce proposals that are more commonly accepted than MCMCP, generated higher quality samples than MCMCP, and use fewer trials to achieve the same quality of estimates as MCMCP. Each trial shall correspond to one decision made by a participant. For LAMCP, this means it will take two trials to produce one stimulus.

We applied LAMCP and MCMCP to a simple task where stimuli are parameterized by two dimensions—rectangles with width and height. Our aim is to elicit from participants samples from the category of golden rectangles, where the height is equal to the golden ratio (1.618) times the width. This scenario is a manifestation the ridge example that we motivated our approach with earlier. The golden ratio lies along a ridge in the two dimensional space form by all widths and heights.

Participants were asked to select the rectangle that looked most like a golden ratio rectangle on stimulus trials, or in the case of direction trials, to pick the animation that looked most like a golden ratio rectangle for the longest amount of time. We evaluated how their output deviated from ideal golden ratio rectangles.

**Participants.** A total of 43 participants were recruited from Amazon Mechanical Turk: each having at least a 95% task approval rate, and had at least 100 approved tasks. Each participant was required to contribute at least 100 decisions to the task to be paid \$0.05. To check for consistency among participants, approximately 10% of participants' decisions were repeats of their own or other participants' decisions. These repeats were not used in the analysis. Participants' decisions were incorporated in real-time, and so some participants discontinued the experiment before 100 decisions but their results were still included (five participants for LAMCP, six for MCMCP24, and two for MCMCP).

**Stimuli.** Stimuli were black rectangles rendered in the participant's web browser. Each stimulus was drawn in a 232 pixel by 232 pixel light grey box, with an internal border of 5 pixels. The light grey box had a border of 5 pixels surrounding it, and was on a white background. For animated stimuli, 25 frames were generated, and the frame was advanced, in a loop, changed approximately every 100 ms. For 2AFC trials, stimuli were shown side by side. For 4AFC trials, stimuli were shown in a grid of two rows and two columns. The stimuli parameters (width and height) were generated by either MCMCP or LAMCP, using truncated Gaussians for the

initial stimulus and proposal distributions to ensure the parameters remained within the range 0 to 1. For MCMCP, the variance of the truncated Gaussians was randomly chosen at each trial to either be 0.01 or 0.25. For LAMCP, the variance of the truncated Gaussians was randomly chosen at each trial to either be 0.1 or 0.5. Variance parameters for LAMCP were higher than those for MCMCP.

**Procedure.** Participants were asked to study 24 examples of rectangles, six of which were golden ratio rectangles and 18 non-golden ratio rectangles. Six of the counter-examples were the six examples rotated by 90 degrees, with explicit instructions highlighting that golden ratio rectangles are tall and thin, not short and wide.

We ran three regimes—MCMCP with just 2AFC trials, MCMCP with alternating 2AFC and 4AFC trials (to account for the effects of including alternating 2AFC/4AFC trials, which we shall call MCMCP24), and LAMCP with 2AFC for stimulus trials and 4AFC for direction trials. For each regime, we ran 10 chains, each chain being 100 trials long. Each trial consisted of choosing between either the stimulus selected by the previous trial and one or three new stimuli.

**Results.** The median acceptance rates of MCMCP and MCMCP24 were 38% ( $\pm 2\%$ ; semi-interquartile range) and 37% ( $\pm 4\%$ ), respectively, whilst the median acceptance rate of stimulus for LAMCP was 46% ( $\pm 2\%$ ), suggesting that the proposals generated by LAMCP were typically more representative than those generated by MCMCP.

The median absolute difference between the estimated golden ratio and the true golden ratio was 0.72 ( $\pm 0.44$  semi-interquartile range) and 0.92 ( $\pm 2.73$ ) for MCMCP and MCMCP24, respectively. The median absolute difference of LAMCP, 0.52 ( $\pm 0.38$ ) is closer to the golden ratio than both MCMCP methods. The absolute differences of MCMCP and MCMCP24 are significantly ( $p < 0.001$ ) different to the absolute differences of LAMCP under the Wilcoxon rank-sum test.

Effective sample size is a heuristic for determining the number of independent samples yielded by an MCMC procedure. We compared effective sample size estimates of LAMCP, MCMCP and MCMCP24 using R-CODA (Plummer, Best, Cowles, & Vines, 2006). We found that the median effective sample size for LAMCP was 5 ( $\pm 1$ ) whilst it was 11 ( $\pm 4$ ) and 19 ( $\pm 15$ ) for MCMCP and MCMCP24, respectively. This suggests that whilst LAMCP produces more favourable samples, the samples are more correlated with one another than those produced by MCMCP. This could be a consequence a linear correlation introduced by the generative process of the stimuli used by LAMCP. Interestingly the effective sample size for directional samples was  $15 \pm 3$  with an acceptance rate of  $75\% \pm 2\%$ .

Figure 1 shows the estimated golden ratio and distance of samples to the golden ratio produced by MCMCP and LAMCP. The top row of Figure 1 shows that participants us-

ing LAMCP quickly find the golden ratio and are easily able to explore and follow this correlation in the stimulus parameters, compared to MCMCP participants. The bottom row of Figure 1 shows that throughout the evolution of both Markov chains, LAMCP participants generate samples that are closer to the golden ratio than MCMCP participants.

We recorded the time between trials for each participant, and for LAMCP, compared the difference between these times for stimulus and direction trials. We could find no significant difference in these times under a variety of two-sample tests (Wilcoxon rank-sum, t-, and Kolmogorov-Smirnov tests;  $p > 0.05$ ,  $n = 500$ ). A likely explanation for this is that network transmission time dominates participants decision time: the median time between trials was 2.8 seconds ( $\pm 1$  second semi-interquartile range). Thus for Mechanical Turk experiments, using directional trials do not appear to take more of a participants' time than stimulus trials.

## Discussion

Look-Ahead Monte Carlo with People is an extension to MCMCP that exploits local manifold structure found in continuous valued stimuli by soliciting direction judgements from participants. This method will allow us to more efficiently explore and understand complicated categories in higher dimensions than previously attempted, by extracting more useful information per trial from participants. Whilst our simple experiment demonstrated the efficacy of our techniques in even the simplest case, for tasks such as images of faces, similar local structure likely exists in stimuli and so we can hope for similar gains.

Compared to other procedures for eliciting distributions from people, LAMCP's two kind of trial paradigm is also similar to iterated learning (Kirby, 1998; Griffiths & Kalish, 2007) where people either sample an internal representation or a physical manifestation of that representation. Directions are akin to an internal representation of what lies ahead, whilst the stimuli are the manifestations of the directions. The analogy is particularly apt if different people participate in each pair of LAMCP trials.

LAMCP not only produces samples from people's stimulus distribution, but also samples from their distribution over directions in stimulus space. Whilst our motivation for sampling from this distribution is purely incidental—we wish to obtain directions in some principled fashion so as to inform the stimulus generation process—the directions give a direct hint as to what people estimate to be the shape of the manifold in which samples lie. This extra piece of statistical information may be useful in gaining a better estimate of structure of stimuli, as well as aiding the estimation process.

**Acknowledgements:** We wish to thank Peter Dayan and Charles Sutton for several useful discussions.

Figure 1: Estimates of the golden ratio (top) and distance of samples to the golden ratio manifold (bottom) under three regimes: MCMCP (left), MCMCP24 (middle), and LAMCP (right). Heavy solid lines correspond to the median over 10 chains, whilst lighter solid lines are the interquartile range. Dashed straight lines in the top plots correspond to the golden ratio (top) and its reciprocal (bottom).

# A Study of Loan Color Terms Collocation in Modern Japanese

Graduate School of Humanities, Kobe University, 1-1 Rokkodai-machi,  
Nada-ku, Kobe 657-8501 JAPAN

## Abstract

The Japanese lexicon consists of Japanese-origin words (WAGO), Chinese-origin words (KANGO) and words borrowed from English and other European languages (GAIRAIGO). The acquisition of words from three sources results in the abundance of near synonyms without any clear rules when a particular synonym should be used. Loveday has hypothesized that WAGO/KANGO and GAIRAIGO concrete nouns are used to address similar phenomena of Japanese and Western origins, respectively. This is referred as Hypothesis of Foreign vs. Native Dichotomy (HFND). However, the matter of abstract nouns, adjectivals and their collocations remains unstudied. In contrast to the previous studies, based on questionnaires, our approach stems from statistical analysis of corpus data. Our results illuminate a distinguishable bias in the structure of collocations – nouns and adjectivals of the same origin tend to appear together more often than the ones of the different origins. Our finding implies extension of HFND to the level of collocations.

**Keywords:** cognitive linguistics, Modern Japanese, loanwords, corpus study

## Introduction

The structure of the Japanese lexicon is a very complex and rapidly developing system. It consists of Japanese-origin words (WAGO), Sino-(Chinese)origin words (KANGO) and words borrowed from English and other European languages (GAIRAIGO). The adoption of words from Chinese has a long history, while borrowing of GAIRAIGO loanwords intensified starting from Meiji period (1868 - 1912).

However, GAIRAIGO increased in number notably and became widely used only in the second half of the 20th century: “English words have become especially important since WWII, and these loanwords have become genuine parts of the Japanese lexicon, found in daily conversation and the world of letters.” (Daulton, 2008).

The acquisition of words from three sources (WAGO, KANGO and GAIRAIGO) results in the abundance of near synonyms. The differentiation between such synonyms in some cases is clear-cut. For example, there is a historically developed stylistic constraint for Sino-origin synonyms to be used mainly in written speech as opposing to Japanese-origin words, which are widely used in oral speech.

However, the differentiation between WAGO/KANGO and GAIRAIGO near synonyms in Modern Japanese is a more complicated issue.

English loanwords in Japanese have been a topic of various studies by both native and foreign linguists for about 100 years.

Some researchers are more interested in the assimilation processes of loanwords (Kay, 1995; Irwin, 2011), other linguists focus on semantic changes (Daulton, 2008), third mainly study sociolinguistic background and functions (Loveday, 1986, 1996).

At present, the number of GAIRAIGO is increasing rapidly and loanwords penetrate into different spheres of life. Dictionaries (Katakanago Jiten Consaizu (The Concise Dictionary of Katakana Words), etc.) in most cases do not state any clear differences in the meaning and usage for the abovementioned near synonyms.

On the other hand, the experience of studying and communicating in Japanese shows that it is not possible to substitute WAGO/KANGO and GAIRAIGO near synonyms freely.

Many of GAIRAIGO words are concrete nouns borrowed from Western culture that came to be used abundantly with the modernization of life in Japan. Along with concrete nouns, numerous abstract nouns and adjectives were also borrowed into the basic vocabulary. Loanwords integrated into the Japanese language had passed through difficult assimilation processes: orthographical, phonetic, grammatical changes etc.

The issue of loanwords increase and native words substitution has always been a topic not only of semantic but also of sociolinguistic research. The comprehensive results on this topic are presented by Loveday (1996). In this work, Loveday gives a historical overview starting with the contact of Japanese with the Chinese language and finishing by describing the role, types and functioning of English loans in Japanese mass media, etc.

According to Loveday (1996), GAIRAIGO words comprise about 10 per cent of the Modern Japanese lexicon. Although, the ratio of GAIRAIGO depends on the sphere of usage. GAIRAIGO are rarely used in official documents, political, religious, law lexicon. On the other hand, the percentage of English loanwords is higher in daily routine, fashion, mass media language: GAIRAIGO words “are particularly high in the areas of fashion, cosmetics, food, audio technology, sport, housing, music, art, business management, and engineering.” (Loveday, 1996).

Loveday (1996) considers that the occurrence of the synonymic WAGO-GAIRAIGO pairs is the result of the “Westernization of Japanese culture”. Such pairs exist “in semantic opposition where a word referring to a Western phenomenon is English-based and ‘complementary’ with a

word deriving from (Sino-) Japanese and referring to a related version of the phenomenon belonging to native culture".

Therefore, Loveday (1996) has hypothesized Foreign vs. Native Dichotomy: GAIRAIGO is "a word referring to a Western phenomenon", while WAGO/KANGO is "referring to a related version of the phenomenon belonging to native culture."

Thus, Modern Japanese has a clear-cut opposition between WAGO/KANGO and GAIRAIGO near synonyms for concrete nouns, i.e., GAIRAIGO concrete nouns are used to name foreign-originated phenomena, while (Sino-) Japanese words are used to name native-originated phenomena. Loveday provides the following examples: *tō/shōji* (= sliding door) – *doa* ('door'); *futon* (= quilted bedding) – *beddo* ('bed'), etc.

On the other hand, Loveday's study does not consider any abstract nouns and adjective-derived (adjectivals) loanwords. However, GAIRAIGO abstract nouns and adjectivals are also of extreme importance.

One of the central places among the adjectivals is occupied by the color terms. Japanese color nomenclature is not a new object for studying. There was some research on loan color terms in Modern Japanese as well.

Stanlaw (1997) stated that "the Japanese colour lexicon actually consists of two sets of mutually exclusive terms, one of native origin, the other borrowed from English". His research demonstrates that some of Japanese native color terms (such as MOMO-IRO (pink), DAIDAI-IRO (orange)) are replaced by English loanwords (PINKU and ORENJI respectively). He also suggested that the replacement took place "in reverse order to the Berlin and Kay evolutionary sequence"<sup>1</sup> (Stanlaw, 1997).

The major finding by Stanlaw is that in Modern Japanese some of the loan color terms are more salient in the minds of the Japanese than native color terms, where the substitution of native color terms for loanwords develops in a certain order.

The shortcoming of Stanlaw's study is that neither the semantic and stylistic differences between native and loan words nor constraints on color terms usage are discussed.

The layer of loan color terms in modern Japanese has been poorly investigated. At present the correct application of loan color terms for non-native speakers, who do not possess any implicit rules or so-called native speakers' linguistic sense of intuition, is a difficult task.

Considering the importance of color terms and absence of any explicit roles of application, we focus our study on illuminating the regularities which can provide a hint for such explicit rules.

### Extended Hypothesis

Loveday's hypothesis is easily applicable to concrete nouns. However, Loveday's research does not cover the

differences between GAIRAIGO derived from adjectives describing existing cultural phenomena and their WAGO/KANGO counterparts. For example, a phenomenon of 'white' color has already existed before borrowing GAIRAIGO adjectival HOWAITO, which is used to address the same color. The same is true for phenomena other than basic color terms. For instance, YANGU and WAKAI, which both refer to 'young' attribute.

In present study we focus on the descriptive role of adjectivals, therefore we consider the collocation of nouns and adjectivals in attributive positions. Consequently, in our study we focus not on the single words (nouns), but on collocations: pairs of nouns and adjectivals.

Our hypothesis is the extension of Loveday's Foreign vs. Native Dichotomy for collocations of nouns and adjectives/adjectivals. We assume that GAIRAIGO adjectivals are used for the description of foreign-originated phenomena and, thus, are more likely to collocate with GAIRAIGO nouns in attributive position. Similarly, WAGO/KANGO adjectives are used to describe the native-originated phenomena, that is, we expect WAGO/KANGO adjectives to be more inclined to collocate with WAGO/KANGO nouns rather than with GAIRAIGO nouns.

We call this hypothesis to be Extended Hypothesis of Foreign vs. Native Dichotomy (EHFND).

The important difference between Loveday's original hypothesis and our *extended hypothesis* is that the former one refers to the difference in usage of single words (concrete nouns), while the later one considers collocations. Therefore, our extended hypothesis deals with a more general linguistic level of collocation.

Thus, the problem is to differentiate the usage of collocations between GAIRAIGO and WAGO/KANGO near synonyms in Modern Japanese. To our knowledge, this matter has not been previously addressed.

## Methodology

### Objectives

Our primary objective is to test Extended hypothesis for the color terms in Modern Japanese. The secondary objective is to examine the matter of substitution of native color terms for the GAIRAIGO ones.

### Materials: Corpus-based analysis

The objective of the given research is to define the tendency of collocation of English adjectives borrowed and assimilated to Modern Japanese.

The number of WAGO/KANGO vs. GAIRAIGO near synonymic pairs is considerably numerous. Since we are interested in the presence of correlation between attributes and words they modify the object of research is GAIRAIGO adjectivals derived from English adjectives and Japanese words corresponding to them, we focus on basic color terms. For the purpose of the present study, we have selected eight loan basic color terms, which are frequently used in attributive position: HOWAITO, BURAKKU,

<sup>1</sup> Berlin and Kay (1991) speculate that as languages evolve, they develop new basic color terms in a strict chronological sequence.

REDDO, IERO:, BURAUN, PA:PURU, PINKU, GURE:/GUREI. They correspond to (Sino-) Japanese color terms SHIROI (white), KUROI (black), AKAI (red), KIIRO (yellow), CHAIRO (brown), MURASAKIIRO (purple), MOMOIRO (pink), HAIIRO (grey), respectively.

The reasons for choosing these color terms are

- all of the abovementioned GAIRAIGO color terms have long-term assimilation to the Japanese language (since Meiji period, more than 100 years);
- these GAIRAIGO color terms have a clear-cut correspondence to WAGO/KANGO near synonyms, that is why GURI:N (green) and BURU: (blue) were excluded from the study as their correspondence to native color terms (AOI and MIDORIIRO) is ambiguous;
- selected loanwords belong to one semantic category ‘basic color terms’, that is why they give a wider outlook of the Modern Japanese vocabulary.

## Method

The corpus-based analysis of GAIRAIGO collocation patterns is the main method of the analysis in the present study. The corpus used for data collection is KOTONOHA corpus (Balanced Corpus of Contemporary Written Japanese) available on-line<sup>2</sup>. This corpus was selected because it is considered to be a well-balanced corpus of Modern Japanese, including not only printed sources (such as newspapers, magazines and literature), but also web resources (such as Yahoo blogs and Yahoo answers).

KOTONOHA corpus was searched to compare the frequencies for four following collocation patterns: 1) attributive GAIRAIGO + NO + GAIRAIGO noun; 2) attributive GAIRAIGO + NO + WAGO/KANGO noun; 3) attributive WAGO/KANGO + (NO)<sup>3</sup> + GAIRAIGO noun; and 4) attributive WAGO/KANGO + (NO) + WAGO/KANGO noun.

The cases when selected GAIRAIGO were referring to a person’s name (like HOWAITO NO IKEN - ‘the opinion of Mr. White’), were eliminated from the search results. The idiomatic expressions like ‘blue blood’, ‘White House’, ‘black funds’, etc. have been excluded from the study as well.

## Results and Data Analysis

**Collocation Frequency Data.** The collocation frequency data for each color term are presented in Tables 1 through 8. The main means for statistic analysis are Chi-square test of independence of categorical data and Binomial test. However, if the conditions of Chi-square application were violated, Fisher’s exact test was used instead.

**HOWAITO vs. SHIROI pair.** The results on HOWAITO and SHIROI collocations are presented in Table 1.

Table 1: HOWAITO vs. SHIROI collocation.

	Gairaigo nouns (%)	Wago/kango nouns (%)	Total
Howaito	23 (77%)	7 (23%)	30 (100%)
Shiroi	47 (30%)	109 (70%)	156 (100%)
Total	70	116	186

The Chi-square test of independence of categorical data has been applied to the data in Table 1. The Chi-square test revealed statistically significant dependence between origin of adjective/adjectival and origin of noun ( $\chi^2(1, 186) = 23.218, p < 0.001$ ). On the other hand, the Binomial test for pairs (HOWAITO + GAIRAIGO nouns) vs. (HOWAITO + WAGO/KANGO nouns) reveals significant difference in frequencies ( $p < 0.05$ ). The Binomial test for pairs (SHIROI + GAIRAIGO nouns) vs. (SHIROI + WAGO/KANGO nouns) also reveals significant difference in frequencies ( $p < 0.001$ ). Therefore, for HOWAITO and SHIROI, there is obvious preference of WAGO/KANGO nouns vs. GAIRAIGO.

The Binomial test reveals significant difference ( $p < 0.001$ ) in frequencies of HOWAITO vs. SHIROI appearance – 30 vs. 156 hits, respectively. Therefore, SHIROI is used more often.

**BURAKKU vs. KUROI pair.** The results for BURAKKU and KUROI collocations are presented in Table 2.

Table 2: BURAKKU vs. KUROI collocations.

	Gairaigo nouns (%)	Wago/kango nouns (%)	Total
Burakku	14 (70%)	6 (30%)	20 (100%)
Kuroi	87 (23%)	295 (77%)	382 (100%)
Total	101	301	402

The Chi-square test of independence of categorical data has been applied to the data in Table 2. The Chi-square test revealed statistically significant dependence between origin of adjective/adjectival and origin of noun ( $\chi^2(1, 402) = 22.531, p < 0.001$ ). On the other hand, the Binomial test for pair (BURAKKU + GAIRAIGO nouns) vs. (BURAKKU + WAGO/KANGO nouns) reveals no significant difference in frequencies ( $p = 0.115 > 0.05$ ). However, the Binomial test for pair (KUROI + GAIRAIGO nouns) vs. (KUROI + WAGO/KANGO nouns) reveals significant difference in frequencies ( $p < 0.001$ ). Therefore, for KUROI there is obvious preference of WAGO/KANGO nouns vs. GAIRAIGO. Although the same tendency is developing for the BURAKKU, there is no statistical evidence to support our hypothesis.

<sup>2</sup> KOTONOHA Balanced Corpus of Contemporary Written Japanese <http://www.kotonoha.gr.jp/shonagon/>

<sup>3</sup> Some of the WAGO/KANGO in attributive position do not require NO-case marker

The Binomial test reveals significant difference ( $p < 0.001$ ) in frequencies of BURAKKU vs. KUROI appearance – 20 vs. 382 hits, respectively. Therefore, KUROI is used more often.

**REDDO vs. AKAI pair.** The results for REDDO and AKAI collocations are presented in Table 3.

Table 3: REDDO vs. AKAI collocations.

	Gairaigo nouns (%)	Wago/kango nouns (%)	Total
Reddo	2 (50%)	2 (50%)	4 (100%)
Akai	87 (26%)	247 (74%)	334 (100%)
Total	89	249	338

The Chi-square test of independence of categorical data is not applicable for the data from Table 3, since for two cells the expected count (2) less than 5. Therefore, Fisher's exact test has been applied. This test has reveals no significant dependencies ( $p = 0.284 > 0.05$ ).

In this case, the sample size for pairs including REDDO is only 4 occurrences. Therefore, due to small sample size the proper analysis of pairs (REDDO+GAIRAIGO nouns) vs. (REDDO+WAGO nouns) cannot be conducted. On the other hand, we have tested the frequencies of pairs (AKAI+GAIRAIGO nouns) vs. (AKAI+WAGO nouns). The Binomial test reveals statistically significantly difference ( $p < 0.001$ ). This result illustrates a bias towards preference of WAGO nouns to be used with AKAI.

The Binomial test reveals significant difference ( $p < 0.001$ ) in frequencies of REDDO vs. AKAI appearance – 4 vs. 334 hits, respectively. Therefore, AKAI is used more often.

**IERO: vs. KIIRO pair.** Next, we consider IERO: and KIIRO collocation data. The results are presented in Table 4.

Table 4: IERO: vs. KIIRO collocations.

	Gairaigo nouns (%)	Wago/kango nouns (%)	Total
Iero:	16 (67%)	8 (33%)	24 (100%)
Kiirō	136 (32%)	294 (68%)	430 (100%)
Total	152	302	454

The Chi-square test of independence of categorical data has been applied to the data in Table 4. The Chi-square test revealed statistically significant dependence between origin of adjective/adjectival and origin of noun ( $\chi^2(1, 454) = 12.531, p < 0.001$ ). On the other hand, the Binomial test for pair (IERO: + GAIRAIGO nouns) vs. (IERO: + WAGO/KANGO nouns) reveals no significant difference in frequencies ( $p = 0.152 > 0.05$ ). However, the Binomial test for pair (KIIRO + GAIRAIGO nouns) vs. (KIIRO + WAGO/KANGO nouns) reveals significant difference in frequencies ( $p < 0.001$ ). Therefore, for KIIRO there is obvious preference of WAGO/KANGO nouns vs. GAIRAIGO. Although the same tendency is developing for

IERO:, there is no statistical evidence to support our hypothesis. The Binomial test reveals significant difference ( $p < 0.001$ ) in frequencies of IERO: vs. KIIRO appearance – 24 vs. 430 hits, respectively. Therefore, KIIRO is used more often.

**BURAUN vs. CHAIRO pair.** The results for BURAUN and CHAIRO collocations are presented in Table 5.

Table 5: BURAUN vs. CHAIRO collocations.

	Gairaigo nouns (%)	Wago/kango nouns (%)	Total
Buraun	26 (65%)	14 (35%)	40 (100%)
Chairo	110 (28%)	289 (72%)	399 (100%)
Total	136	303	439

The Chi-square test of independence of categorical data has been applied to the data in Table 5. The Chi-square test revealed statistically significant dependence between origin of adjective/adjectival and origin of noun ( $\chi^2(1, 439) = 23.822, p < 0.001$ ). On the other hand, the Binomial test for pair (BURAUN + GAIRAIGO nouns) vs. (BURAUN + WAGO/KANGO nouns) reveals no significant difference in frequencies ( $p = 0.081 > 0.05$ ). However, the Binomial test for pair (CHAIRO + GAIRAIGO nouns) vs. (CHAIRO + WAGO/KANGO nouns) reveals significant difference in frequencies ( $p < 0.001$ ). Therefore, for CHAIRO there is obvious preference of WAGO/KANGO nouns vs. GAIRAIGO. Although the same tendency is developing for BURAUN, there is no statistical evidence to support our hypothesis.

The Binomial test reveals significant difference ( $p < 0.001$ ) in frequencies of BURAUN vs. CHAIRO appearance – 40 vs. 399 hits, respectively. Therefore, CHAIRO is used more often.

**PA:PURU vs. MURASAKIIRO pair.** Table 6 presents the results for PA:PURU and MURASAKIIRO collocations.

Table 6: PA:PURU vs. MURASAKIIRO collocations.

	Gairaigo nouns (%)	Wago/kango nouns (%)	Total
Pa:puru	12 (71%)	5 (29%)	17 (100%)
Murasakiirō	50 (24%)	161 (74%)	211 (100%)
Total	62	166	228

The Chi-square test of independence of categorical data is not applicable for the data from Table 6, since for one cell the expected count equals 5. Therefore, Fisher's exact test has been applied. This test has revealed significant dependencies ( $p < 0.001$ ).

On the other hand, the Binomial test for pair (PA:PURU + GAIRAIGO nouns) vs. (PA:PURU + WAGO/KANGO nouns) reveals no significant difference in frequencies ( $p = 0.143 > 0.05$ ). However, the Binomial test for pair (MURASAKIIRO + GAIRAIGO nouns) vs.

(MURASAKIIRO + WAGO/KANGO nouns) reveals significant difference in frequencies ( $p < 0.001$ ). Therefore, for MURASAKIIRO there is obvious preference of WAGO/KANGO nouns vs. GAIRAIGO. Although the same tendency is developing for PA:PURU, there is no statistical evidence to support our hypothesis.

The Binomial test reveals significant difference ( $p < 0.001$ ) in frequencies of PA:PURU vs. MURASAKIIRO appearance – 17 vs. 211 hits, respectively. Therefore, MURASAKIIRO is used more often.

**GUERE:/GUEREI vs. HAIIRO pair.** The search results for GUERE:/GUEREI and HAIIRO collocations are presented in Table 7.

Table 7: GUERE:/GUEREI vs. HAIIRO collocations.

	Gairaigo nouns (%)	Wago/kango nouns (%)	Total
Gure:/Gurei	207 (60%)	136 (40%)	343 (100%)
Haiiro	66 (23%)	225 (74%)	291 (100%)
Total	273	361	634

The Chi-square test of independence of categorical data has been applied to the data in Table 7. The Chi-square test revealed statistically significant dependence between origin of adjective/adjectival and origin of noun ( $\chi^2(1, 634) = 91.114, p < 0.001$ ). On the other hand, the Binomial test for pairs (GUERE:/GUEREI + GAIRAIGO nouns) vs. (GUERE:/GUEREI + WAGO/KANGO nouns) reveals significant difference in frequencies ( $p < 0.001$ ). The Binomial test for pairs (HAIIRO + GAIRAIGO nouns) vs. (HAIIRO + WAGO/KANGO nouns) also reveals significant difference in frequencies ( $p < 0.001$ ). Therefore, for both GUERE:/GUEREI and HAIIRO, there is obvious preference of WAGO/KANGO nouns vs. GAIRAIGO.

The Binomial test reveals significant difference ( $p = 0.043 < 0.05$ ) in frequencies of GUERE:/GUEREI vs. HAIIRO appearance – 343 vs. 291 hits, respectively. Therefore, GUERE:/GUEREI is used more often.

**PINKU vs. MOMOIRO pair.** Finally, the results for PINKU and MOMOIRO collocations are presented in Table 8.

Table 8: PINKU vs. MOMOIRO collocations.

	Gairaigo nouns (%)	Wago/kango nouns (%)	Total
Pinku	232 (58%)	169 (42%)	401 (100%)
Momoiro	15 (35%)	28 (65%)	43 (100%)
Total	247	197	444

The Chi-square test of independence of categorical data has been applied to the data in Table 8. The Chi-square test revealed statistically significant dependence between origin of adjective/adjectival and origin of noun ( $\chi^2(1, 444) = 8.303, p < 0.001$ ). On the other hand, the Binomial test for pairs (PINKU + GAIRAIGO nouns) vs. (PINKU +

WAGO/KANGO nouns) reveals significant difference in frequencies ( $p < 0.001$ ). The Binomial test for pairs (MOMOIRO + GAIRAIGO nouns) vs. (MOMOIRO + WAGO/KANGO nouns) also reveals significant difference in frequencies ( $p < 0.001$ ). Therefore, for PINKU and MOMOIRO, there is obvious preference of WAGO/KANGO nouns vs. GAIRAIGO.

The Binomial test reveals significant difference ( $p < 0.001$ ) in frequencies of PINKU vs. MOMOIRO appearance – 401 vs. 43 hits, respectively. Therefore, PINKU is used more often.

## Discussion and Conclusion

In present study we have introduced a new approach to differentiation between (Sino-)Japanese and English-origin near synonyms. In contrast to the previous studies, which were based on questionnaires, our approach stems from statistical analysis of corpus data.

We have shown that there is an obvious bias in the structure of collocations: nouns and adjectives/adjectivals of the same origin (WAGO/KANGO or GAIRAIGO) tend to appear together more often than nouns and adjectives/adjectivals of different origins. In all eight cases considered, we have found statistical evidence for such bias to exist for WAGO/KANGO adjectives. For GAIRAIGO adjectivals, in the case of HOWAITO, GUERE:/GUEREI and PINKU it was also possible to support this assumption with statistical evidence. In the case of REDDO, the sample size was too small. In five remaining cases, there was no statistical evidence, but the same tendency of preferring GAIRAIGO nouns against WAGO/KANGO nouns by GAIRAIGO adjectivals can be observed.

In general, for seven pairs out of eight, except for REDDO vs. AKAI, we have found statistical evidence for dependencies in categorical data.

Summarizing, we consider that this volume of evidence is enough to support our Extended hypothesis, derived from original Loveday's Foreign vs. Native Dichotomy (Loveday, 1996). On the other hand, our hypothesis refers to the structure consisting of two words, i.e. adjectives/adjectivals plus nouns, while Loveday (Loveday, 1996) has investigated only concrete GAIRAIGO and WAGO/KANGO nouns referring either to foreign or native objects, respectively.

Therefore, we illustrated an existence of Foreign vs. Native Dichotomy at the level of collocations.

We have also compared frequencies of the appearance of color terms. Our results show that among the selected pairs of color terms, there are both cases when native color terms prevail the borrowed ones and vice versa (GUERE:/GUEREI and PINKU).

The results for GUERE:/GUEREI and PINKU are in coherence with the Stanlaw's assumption of the replacement of native words with borrowed ones (Stanlaw, 1997). According to Berlin and Kay (1991), the color terms appear in language in the hierarchical order starting from more general terms covering white, black, red color categories

and ending with more specific color categories like pink, orange, grey and purple. Stanlaw (1997) suggests that the replacement of native color terms starts from the end of the Berlin and Kay's hierarchy (Berlin and Kay, 1991). That is colors like GURE:/GUREI and PINKU should be substituted earlier than other color terms. The results of our statistical analysis indicate that GURE:/GUREI and PINKU are used more often than corresponding native color terms. This finding does not provide exhaustive evidence for replacement dynamics, but we consider that the more frequent usage of one color term (loanword) against another one (native color term) can be regarded as the indication of ongoing process of substitution in accordance with the results of Stanlaw's study (Stanlaw, 1997).

The corpus-based method employed for the data collection is different from Loveday's approach (Loveday, 1996). We consider that this method offers a more profound quantitative analysis of the gathered data. To our knowledge, such approach to the analysis of loanword collocations has not yet been implemented elsewhere.

On the other hand, the results of the present research are in coherence with both Loveday's (Loveday, 1996) and Stanlaw's approaches (Stanlaw, 1997).

Therefore our method exhibits successful application for two different tasks, thus our method symbiotically amalgamates abilities and power of inference of the previously considered research approaches.

Many native speakers cannot explain a particular rule to use either of near synonyms. According to Dienes and Berry (1997), implicit learning means that information is acquired without intension and the resulting knowledge is difficult to express. Therefore, native-like linguistic sense of usage of near synonyms can be considered as an implicit knowledge possessed by native speakers. On the other hand, our statistical data uncovers essential regularities in usage of near synonyms. We assume these regularities to be a part of implicit language knowledge. Thus, the approach for analysis of near synonyms has a potential to connect the pure linguistic study of collocation with field of implicit learning and knowledge. Therefore, we consider that the results of our study can be used as a starting point for constructing the explicit rules to articulate the native-like linguistic sense (implicit knowledge).

For the purpose of our study, only the group of basic color terms has been employed. We have provided evidence that Extended Hypothesis of Foreign vs. Native Dichotomy is likely to be true for such data. However, to prove that this tendency is general among GAIRAIGO more data on various loanwords needs to be analyzed. On the other hand, corpus data represents only a part of the whole scope of Modern Japanese.

To improve the quality of analysis it is important to integrate native speakers' introspection-based analysis. Thus, two main directions for further research are increasing data set and extending methods of analysis.

## Abstract

Many philosophers of science believe that empirical psychology can contribute little to the philosophical investigation of explanations. They take this to be shown by the fact that certain explanations fail to elicit any relevant psychological events (e.g., familiarity, insight, intelligibility, etc.). We report results from a study suggesting that, at least among those with extensive science training, a capacity to render an event intelligible is considered a requirement for explanation. We also investigate for whom explanations must be capable of rendering events intelligible and whether or not accuracy is also viewed as a requirement.

**Keywords:** science; explanation; psychologism; intelligibility.

## Introduction

The nature of explanation has been a major topic of investigation in the philosophy of science for at least sixty years. While much is still disputed, a consensus has emerged that scientific explanations are not constituted by psychological events. Philosophers of science first made arguments to this effect in the middle of the 20th century in response to the charge that explanations play no useful role in science because they are constituted by subjectively variable psychological states (viz., familiarity and empathy).

Hospers (1946), Miller (1947), and Hempel (1965), for instance, argued that many legitimate explanations appeal to principles (e.g., Newton's law of gravitation) that were utterly unfamiliar when they were first introduced. Hempel (1942) also noted that historical explanations sometimes refer to individuals (e.g., paranoiacs) with whom most are incapable of empathizing. On such grounds Hempel famously rejects psychologistic theories of explanation in favor of a more "objective" account (1965, 426).

More recently, philosophers of science have viewed psychologistic theories as equating explanations with other feelings, such as insight, satisfaction, or "aha" feelings (Craver 2007; Salmon 1984; Trout 2007). Like Miller and Hempel, they rebut such psychologistic proposals by pointing to cases of explanation where the relevant feelings are absent. One common strategy is to point to a putative explanation, whether it be a passage of text describing a process of speciation (Trout 2007) or a computer simulation of the human nervous system (Craver 2007), whose complexity so outstrips the limits of human memory and attention that humans find it incomprehensible. Humans thus fail to derive from these putative explanations any feelings of insight, satisfaction, etc. It is frequently concluded on the basis of such examples that explanations are non-psychological - we term this the *objectivity*

hypothesis - and hence that psychological research will contribute little to our understanding of explanations.<sup>1</sup>

We believe that this anti-psychologistic attitude is wrongheaded for a few reasons. One is that the very process of justifying theories of explanation on the basis of how well they track philosophers' classifications (i.e., as explanations or non-explanations) of various representations are laden with psychological presuppositions. Philosophers appear to assume that they have, through their exposure to science and scientists, come to possess tacit knowledge of the norms regarding the proper use of 'explanation.' Whether or not philosophical judgments mirror scientific ones is, however, an empirical matter that is best resolved through psychological investigation. We suspect, moreover, that scientists do regard a certain kind of conscious psychological event as necessary for explanation. The type of event we have in mind is not an affect-laden *feeling*, but rather the more intellectual process of understanding how or why, at least possibly, an event came about. This state is sometimes known as finding a happening intelligible or making sense of it (cf. Machamer & Woody 1994). Familiar objections have been raised against this proposal as well - namely, that there are (e.g., hyper-complex) explanations that never render anything intelligible to anyone. Our specific hypothesis, however, is that scientists will not consider a representation an explanation unless it has the *capacity* to render intelligible, which we term *intelligibility*. It would thus not undercut our position if there were explanations that never actually render the event intelligible to anyone. Consider, by comparison, that a liquid may be a solvent of salt even if at a given time it happens not to be dissolving any salt at all or even if it never does so (viz., because the opportunity never arises). It must merely have the capacity to do so, even if it is not exercised. Likewise, we suspect that scientists require not that a representation actually renders a happening intelligible to someone, but merely that it has the capacity to do so.

Notice that even if a liquid that has the capacity to dissolve salt never exercises that capacity, it would still tell us a lot about what makes that liquid a solvent of salt if we had information about the process by which it would dissolve salt were the opportunity to arise. This is best accomplished by studying cases in which solvents of salt actually do exercise their capacity to dissolve salt. Matters are somewhat more complicated with regard to explanations, but we believe that even if a certain representation that has the capacity to make things intelligible to people never actually exercises that capacity, it may well tell us a lot about what makes that representation an explanation if we had information about the process by which it would make sense of things were the opportunity to

arise. This would be best accomplished by studying cases in which explanations actually do exercise their intelligibility.

Notice also that if the reason why a liquid has failed to dissolve any salt is that there is something about the nature of the liquid that precludes it from ever dissolving any salt, the liquid then lacks even the capacity to dissolve salt and is thus no solvent of it. Likewise, if there is something about a representation that precludes it from ever rendering an event intelligible - for instance, it is too complex to ever be comprehended by anyone at all or it refers to things like extra dimensions that are utterly incomprehensible to anyone - then it lacks even the capacity to render intelligible and scientists will thus not regard it as an explanation. We suspect that laypeople also view intelligibility as a requirement and will classify such cases in a similar way.

If a representation must have the capacity to render intelligible in order for it to be considered an explanation, a further question naturally arises: Intelligible to whom? Scientists generally interact with at least some colleagues who exceed their own intelligence, so they are almost certainly cognizant of the fact that some representations are too complex to make events intelligible to everyone. Thus, they likely do not require that a representation must have the capacity to render things intelligible to just anyone in order to be considered an explanation. However, since scientists presumably do not interact with beings that possess utterly different perceptual and cognitive abilities, they might think that a representation must have the capacity to make things intelligible to beings basically like themselves in order to be considered an explanation. Then again, they may turn out to be even more liberal, merely requiring that a representation makes sense of things for sentient beings of some sort, even ones with completely alien thought processes. There are numerous possibilities here, with regard to both scientists and laypeople, that are worth investigating.

Another widely accepted view among philosophers of science is that a high degree of accuracy is essential in order for a representation to be an explanation (Craver 2007; C.G. Hempel 1965; Humphreys 1989; Salmon 1998; Trout, 2007). We call this the *accuracy* hypothesis. We think a representation must merely specify a possible way, even if it is not the actual way, in which an event occurred for the representation to be considered an explanation. We call this the *plausibility* hypothesis. An implication of the accuracy hypothesis is that scientists will be less likely to judge that a representation is an explanation if they are told that it is merely possibly accurate (which is to say that it might be inaccurate) or that it once seemed possibly accurate but was later falsified. Cases of the latter sort mirror many cases from this history of science where a theory seemed to make sense of things (e.g., the Ptolemaic theory of planetary retrograde motion) but was ultimately proven false. If scientists and laypeople do regard such cases as explanations, telling them that a representation is merely possibly accurate or conceivably accurate but factually

---

<sup>1</sup> Trout, admittedly, seems in places to be opposed to the idea that explanations are constituted by *conscious* psychological states in that he allows that explanations sometimes involve implicit learning.

inaccurate should not undermine their tendency to regard a representation as an explanation.

We tested whether people treated either intelligibility or accuracy as a necessary condition for something to be an explanation. We tested this with regard to two groups of participants: those with and without extensive science training.

## Methods

### Participants

The participants in this study were 297 workers recruited using Amazon Mechanical Turk with varying levels of science training.

### Materials

We used stories about the origins of either life, color experiences, or gamma ray bursts, and manipulated the characteristics of these stories. Vignettes were grouped into following three sets:

Set 1: A potential explanation (viz., a passage of text) is described that has various theoretical virtues and that also supplies some level of understanding. Specifically, the representation either supplies understanding of how the target happening actually occurred (A), of a possible way in which it occurred (PA), or of a possible way in which it occurred that is eventually shown to be false (PAF).

Set 2: A potential explanation is described which is said to be incapable of rendering a happening intelligible to humans because of our cognitive limitations - that is, either the representation defies the limits of normal human working memory and attention or it refers to highly exotic, hyper-dimensional properties. The possibility is then introduced that the representation would render the happening intelligible to beings with cognitive capacities that are, roughly speaking, quantitatively better (i.e., involving augmented memory and attention span) or qualitatively different (i.e., involving the ability to think in extra dimensions). Cases of the former sort involve hyper-complex passages of text (AM). Cases of the latter sort (HD) refer to passages of text that describe hyper-dimensional properties.

Set 3: This set closely mirrors Set 2 except that the complexity and exotic nature of the putative explanation is such that it precludes the representation from rendering the target intelligible to anyone at all. This set includes passages of text (IQuant) or computer simulations (Sim) that are hyper-complex, and passages of text that refer to exotic properties (IQual).

There were three storylines and nine vignette types, yielding twenty-seven possible vignettes. Each participant read and responded to three vignettes. One vignette came from each set, and each followed a different storyline.

### Collection

Participants were recruited through the Amazon Mechanical Turk (MTurk) work-distribution website. To be

eligible, workers had to be in the U.S. and have at least a 75% approval rate. Eligible workers were redirected to SurveyMonkey, where they completed the study. Afterwards, workers were directed back to MTurk, where they were compensated with \$.50.

### Procedure

Participants were presented with a vignette (story) on a computer screen. Each vignette referred either to a typewritten description of a physical process or to a computer simulation thereof. For example, some participants saw the following vignette<sup>2</sup>:

Dr. Nikro is a little-known, very-gifted scientist investigating the manner in which color experiences arise in the brain. He spends years tinkering with the complex equations of neurochemistry and subatomic physics and considering the different possible locations in which color experiences might originate. He eventually chances upon a remarkable series of calculations, which he posts to his rarely visited public webpage. They indicate that conditions like those found in the pyramidal cells of the cortex would, over the course of hundreds of milliseconds, reliably undergo a series of changes resulting in the creation of color experiences. The calculations fit quite nicely with the most widely accepted theories and observations from a variety of related fields. Yet they merely refer to ordinary things like membranes and neural firings, of which anyone could easily conceive. As a result, Dr. Nikro comes to understand the actual manner in which color experiences are generated in the brain, as would any specialist from his field who were to study the details of the material he posted.

After reading the vignette, participants were asked to rate the extent to which they agree (-3 strongly disagree, 0 neutral, +3 strongly agree) that the representation described in the vignette constitutes an explanation. There was some concern that participants might confuse this question with the question of whether or not the representation constitutes a *good* or a *satisfying* explanation. Participants were thus informed at the outset that, insofar as they do agree that the representation constitutes an explanation, they should also specify the extent to which they agree that the representation constitutes a *good* and a *satisfying* explanation (cf. Lombrozo and Carey 2004).

Mishra & Brewer (2003) found that participants paid closer attention to the contents of their study materials (i.e., real-world explanations) if they were forewarned that they would be asked a series of simple comprehension questions. We likewise informed participants in advance that they would be asked a series of simple questions. Some of these

---

<sup>2</sup> A demonstration version of the study can be found at [www.surveymonkey.com/s/PPG6DW6](http://www.surveymonkey.com/s/PPG6DW6).

concerned aspects of the vignettes (e.g., accuracy or intelligibility) that were particularly salient to the experiment.

This sequence of instructions, vignettes, and questions repeated two more times, each time with vignettes from a different set and on a different topic (i.e., life, color experiences, or gamma-ray bursts). Participants completed a distractor task in between each vignette. At the end of the study, participants were asked some follow-up questions, including questions about their level of science training.

Six separate studies were constructed to balance the order in which participants saw the various storylines, with one study for each permutation (i.e., Life-Color Experiences-Gamma Rays, Life-Gamma Rays-Color Experiences, etc.).

## Results

Of the 297 completed studies, data from 38 of those studies were excluded because the participants involved had already completed the study at least once. After this exclusion there were 259 completed studies or 777 sets of responses to particular vignettes. If a participant failed to answer at least two of three comprehension questions correctly for a particular vignette, responses to that vignette were excluded. Using this criterion, 61 individuals had responses to one vignette eliminated, 9 individuals had responses to two vignettes eliminated, and 5 individuals had responses to all three vignettes eliminated. After eliminating these problematic responses, responses to 683 vignettes were recorded and analyzed.

We divided our sample into high-science (5 or more college-level science courses) and low-science (less than 5 college-level science courses) groups to investigate the ways in which laypeople and scientists conceive of explanations. After the division, the high-science group contained the following number of responses to the ‘constitutes an explanation’ question for each of the following conditions: 26 accurate (A), 32 possibly accurate (PA), 22 possibly accurate but false (PAF), 28 augmented memory (AM), 28 hyper-dimensional thinking (HD), 22 unintelligible-quantitative (IQuant), 30 unintelligible-qualitative (IQual), and 27 unintelligible-quantitative simulation (SIM).

The low-science group contained the following number of responses to the ‘constitutes an explanation’ question for each of the following conditions: 37 accurate (A), 58 possibly accurate (PA), 51 possibly accurate but false (PAF), 57 augmented memory (AM), 62 hyper-dimensional thinking (HD), 21 unintelligible-quantitative (IQuant), 71 unintelligible-qualitative (IQual), and 59 unintelligible-quantitative simulation (SIM).

The mean responses and standard deviations to the explanation rating task are located in Tables 1 and 2.

Table 1: Mean Responses and Standard Deviations for High-Science Participants

	A	PA	PAF	AM	HD	IQuant	IQual	SIM
Avg.	.769	.968	.090	.285	-.357	-.727	-1.1	-.370
SD	1.77	1.80	2.02	1.95	1.66	1.72	1.78	1.94

Table 2: Mean Responses and Standard Deviations for Low-Science Participants

	A	PA	PAF	AM	HD	IQuant	IQual	SIM
Avg.	1.29	1.31	-.137	.350	-.241	-.714	-.859	-.610
SD	1.66	1.42	1.78	1.67	1.64	1.87	1.87	1.65

After the division of the sample, mean ratings were measured for differences using 18 two-tailed independent samples *t*-tests. To guard against increased chance of Type I errors, we performed a Bonferroni correction to adjust  $\alpha$  (significant results were  $p < .0027$ ).

In the low-science group, descriptions – be they written text or simulations – that were unintelligible to anyone, resulted in lower ratings than descriptions that were intelligible to the scientists in the vignettes (A and IQuant ( $t(56) = 4.22, p < .0027$ ), A and IQual ( $t(106) = 5.87, p < .0027$ ) and A and SIM ( $t(94) = 5.48, p < .0027$ )). Low-science participants also gave lower ratings when *only* cognitively advanced beings – whether they be humans with augmented memory or beings capable of perceiving extra dimensions – found the descriptions intelligible (PA and AM ( $t(113) = 3.30, p < .0027$ ), PA and HD ( $t(118) = 5.49, p < .0027$ )). Significance obtained when comparing low-science participants’ ratings of descriptions described as false to descriptions described as accurate or possibly accurate (A and PAF ( $t(86) = 3.82, p < .0027$ ), PA and PAF ( $t(107) = 4.68, p < .0027$ )). Whether a description was accurate or possibly accurate, however, made no difference to low-science participants’ judgments ( $t(93) = 41, p = .96$ ).

For the high-science group, descriptions incapable of rendering the event intelligible to anyone resulted in lower ratings than those that made the event intelligible to the scientists in the vignettes (A and IQual ( $t(54) = 3.911, p < .0027$ )). However, these differences did not hold across all Set 3 vignettes (A and IQuant ( $t(46) = 2.95, p = .004$ ), A and Sim ( $t(51) = 2.25, p = .028$ )). For high-science participants, ratings were not significantly different for descriptions described as false, or only possibly accurate, as compared to those described as accurate (A and PAF ( $t(46) = 1.24, p = .222$ ), A and PA ( $t(56) = .422, p = .675$ ), PA and PAF ( $t(52) = 1.67, p = .10$ )). Likewise, these participants’ ratings were not significantly affected when a description was described as intelligible only to beings with quantitatively or qualitatively different cognitive capacities (PA and AM ( $t(58) = 1.40, p = .16$ ), PA and HD ( $t(58) = 2.94, p = .004$ )).

## Discussion of Results

This study sought to answer the following questions:

1. Does intellig-ability matter? If the objectivity hypothesis captures how laypeople and practicing scientists conceive of explanations, then altering whether a representation is described as capable of rendering a happening intelligible should not affect the judgments of either low-science or high-science participants. If the

intellig-ability hypothesis is correct, participants should be less likely to regard a representation as an explanation when told that it is, whether due to sheer complexity or to exotic constructs, incapable of rendering a happening intelligible to anyone. Low-science participants were less likely to judge a representation to be an explanation when told that the representation lacks intellig-ability. The judgments of low-science participants thus indicate that laypeople conceive of explanations in a way consistent with the intellig-ability hypothesis and inconsistent with the objectivity hypothesis.

High-science participants were less likely to regard a passage of text as an explanation when told that the representation, because of qualitative barriers (IQual), lacks intellig-ability. They were, however, not significantly less likely to regard a passage of text (IQual) or a simulation (SIM) as an explanation when told that the representation, because of quantitative barriers, lacks intellig-ability. One possibility is that quantitative barriers to intelligibility seem far less daunting than qualitative ones. Indeed, those with extensive science training should be well aware that myriad techniques have been developed for analyzing and visualizing information regarding the behaviors of complex systems with the precise point of rendering those systems intelligible to humans. This may have had enough of an impact on judgments to weaken the intellig-ability effect. Regardless, the differences in high-science ratings between (PA), on the one hand, and (IQuant) and (SIM) on the other were large enough to warrant further investigation.

The difference between (A) and (IQual) is, by itself, clearly inconsistent with the objectivity hypothesis. Admittedly, we cannot be sure that the judgments of our high-science participants mirror those of professional scientists, so further study of practicing scientists is also needed to better support our proposal that intellig-ability is a requirement for explanation. However, taken as a whole, this set of results strongly suggests that manipulating intellig-ability alters explanation judgments, and we take this to be inconsistent with the objectivity hypothesis.

2. Intellig-ability to Whom? The results above indicate that people treat intellig-ability as in some way necessary for explanation, but what is not clear is for whom a representation must be intellig-able (i.e., able to make sense of things). To address this question, participants were asked to consider cases in which potential explanations are unintellig-able to humans because of cognitive limitations. In the (AM) case, the representation exceeds the limits of normal human working memory and attention. In another case (HD), the representation refers to exotic properties such as hyper-dimensionality (see Set 2 in Materials). The possibility is then introduced that the representation may be intellig-able to beings with, roughly speaking, quantitatively augmented memory and attention or qualitatively different cognitive capacities. We take such beings to lie along a similarity continuum such that creatures who merely have augmented memory and attention are more similar to present-day humans than creatures with qualitatively different cognitive capacities.

As it turns out, relative to judgments regarding (PA) vignettes, low-science participants are less inclined to regard a description as an explanation in the (AM) and (HD) conditions. Relative to that same baseline (PA), there was no indication that high-science participants are less inclined to regard a description as an explanation in the (AM) condition. Nor were high-science participants significantly less likely to regard a description as an explanation in the (HD) condition than in the (PA) condition. Although the difference in judgments is not significant ( $p = .004$ ), it is suggestive enough to warrant further investigation.

There are a number of ways of interpreting these findings. Starting with low-science individuals, one possibility is that they believe representations must be intellig-able to present-day humans. This condition was satisfied in the (PA) vignettes but not in the Set 2 (i.e., (AM) or (HD)) vignettes. Another possibility is that these individuals' expectations are somewhat more flexible, requiring merely that representations be intellig-able to beings fairly similar to present-day humans. It may just be that they consider the differences between present-day humans and the beings described in the Set 2 vignettes to be too stark to meet this condition. It is also possible that the reason why they were less inclined to regard the representations in the Set 2 vignettes as explanations had nothing to do with intellig-ability. It may have been, rather, that the representations did not *actually* render the target happening intelligible to anyone. On this view, it is still an open question as to what sorts of beings a representation must actually make sense of things.

Within the high-science group, there were not significant differences between ratings of (PA) and any of the Set 2 vignettes (though, as mentioned, the comparison to (HD) ( $p = .004$ ) is suggestive). Thus, it appears that high-science individuals may be quite flexible about to whom a representation must be intellig-able in order for it to count as an explanation. They do not expect that representations must be intellig-able to present-day humans, but it is unclear whether there is some upper bound on their expectations. They may think a representation that is intellig-able to any kind of sentient being at all counts as an explanation, or they might require that it be intellig-able to beings relevantly similar to present-day humans. In the latter case, high-science individuals may have such a liberal understanding about what counts as relevantly similar that the beings described in the Set 2 vignettes still meet this condition.

Clearly, further studies are also warranted here in order to determine for whom, precisely, a representation must be capable of making sense of things in order to be considered an explanation and whether or not low-science individuals require that this capacity be exercised.

3. Does accuracy matter? The accuracy hypothesis suggests that high-science participants should be more likely to judge something an explanation when it is accurate than when its accuracy is in question or when it is false. This pattern of results did not obtain. There was no difference in judgments about descriptions depicted as accurate (A) and

those depicted as possibly accurate (PA). As mentioned above, the possibly accurate but false (PAF) vignettes mirror many historical examples in which a representation of a way that things could have occurred is eventually discredited. We hypothesized that there would be no difference between judgments regarding the (A) and (PAF) vignettes. Results for high-science participants were consistent with this prediction in that there was no significant difference in their judgments about the two types of vignettes. However, we did find that low-science participants were significantly less likely to judge that the descriptions in the (PAF) vignettes are explanations compared with the descriptions in the (A) vignettes. The fact that the (A) versus (PAF) manipulation produced an effect in the low-science group alleviates some of our concerns about the relevance of the null result found in the high-science group. We thus once again take our findings to supply tentative evidence that the accuracy hypothesis does not reflect the views of practicing scientists, though we acknowledge that additional research on the matter is desirable.

### Anti-Psychologism Revisited

We were motivated to undertake this project in large part because we reject the anti-psychologistic stance regarding the study of explanation that still pervades much of the philosophy of science. Philosophers often take this stance to be justified by appeal to cases which they regard as explanations but which seem not to elicit any relevant psychological events (e.g., familiarity, insight, intelligibility, etc.). Our data suggest, however, that scientists and laypeople have different intuitions from philosophers regarding some of these cases. Insofar as there is something about a representation, whether sheer complexity or exotic constructs, that positively precludes it from rendering a certain happening intelligible, high-science and low-science participants are significantly less inclined to regard it as an explanation. Thus, the anti-psychologistic position appears to rest upon intuitions that are, without discernible justification, idiosyncratic; psychological investigations are the proper methodology for determining how scientists conceive of explanations. In addition, given that the capacity to produce a certain kind of mental state (i.e., finding intelligible) seems to be the crucial factor, empirical investigation into the actual exercise of this capacity will surely be a part of any complete portrait of why certain representations are regarded as explanations and others are not. Indeed, insofar as scientists and laypeople have, with their concepts of explanation, correctly demarcated the boundaries of a real natural or sociocultural kind, then psychological research into what it means to find a happening intelligible will probably contribute much to our understanding of what explanations are, in and of themselves. Thus, for philosophers of science wishing to know what explanations are and what role they play in our lay and scholarly lives, it would seem inadvisable to turn their backs on empirical psychology and retreat to

evaluating theories based upon how well they track their own classifications of supposedly clear-cut cases of explanation and non-explanation.

## Abstract

To test predictions of a forward modeling framework for spoken language processing, we characterized effects of context speech rate on the real-time interpretation of indefinite noun phrases using the visual world paradigm. The speech rate of sentence material distal to the onset of the noun phrase was manipulated such that the segments surrounding the determiner *a* in singular noun phrases had a faster speech rate than the surrounding context and the segments surrounding the onset of plural noun phrases had a relatively slow rate. These manipulations caused listeners to fail to perceive acoustically present determiners and to falsely perceive determiners not present in the signal. Crucially, fixations to singular and plural target pictures revealed effects of distal speech rate during the real-time processing of target expressions, strongly suggesting a locus in perceptual expectations. These results set the stage for quantitative tests of forward models of spoken language processing.

**Keywords:** Speech rate; prosody; expectations; speech processing; visual world paradigm

## Introduction

Expectation-based approaches in which perceptual input is evaluated with respect to internally generated forward models provide compelling and increasingly influential explanations of phenomena in the perception and motor control literatures (e.g. Jordan & Rumelhart, 1992; Kawato, 1999). For example, DIVA, an influential model of speech production, incorporates a forward model component that predicts the auditory signal likely to result from a particular configuration of articulators within the vocal tract (Guenther & Micci Barreca, 1997). The forward model component accounts for the speed and efficiency with which the system can control speech movements, given the relatively slow mechanisms by which acoustic feedback influences speech production.

Similar forward modeling approaches may also provide a promising explanatory framework for spoken language comprehension. As in the domain of motor control, forward modeling of the perceptual attributes of upcoming speech provides a compelling explanation for the remarkable speed and efficiency of speech perception and spoken word recognition in the face of considerable variability. This is a particularly attractive feature of expectation-based approaches to higher-level language comprehension as well, which propose a central role for expectations in processes such as syntactic com-

prehension and lexical processing (e.g. Levy, 2008; Altmann & Kamide, 1999). We propose that comprehension also involves developing expectations about the acoustic realization of upcoming speech, conditioned on various contextual factors such as prosodic phrasing, speech rate, discourse history, and speaker-specific characteristics. Previous work suggests that these expectations are best characterized as probability distributions, with listeners representing not only the expected form of a spoken word given the set of contextual conditioning factors, but also a measure of the variance or uncertainty of their estimate (Clayards et al., 2008; Levy et al., 2009). The degree of congruence between these perceptual expectations and the incoming acoustic signal then contributes to the differential activation of competing lexical alternatives. Finally, when perceptual expectations are incongruent with the actual realization of a word, listeners should update their beliefs about the cues that condition their perceptual expectations, resulting in adaptation that more closely aligns listeners' expectations with the characteristics of the signal in context.

Speech prosody generates acoustic regularities that are likely to foster expectations about the acoustic realization of upcoming speech sounds, including pitch and temporal characteristics that listeners perceive as patterning. This perceived patterning has been shown to influence real-time spoken language processing. For example, manipulations of pitch and duration early in an utterance influence the interpretation of cues to prosodic structure several syllables downstream (Dilley & McAuley, 2008; Dilley et al., 2010; Brown et al., 2011). The distal locus of these effects suggests that they are rooted in listeners' expectations about the acoustic-phonetic realization of upcoming segments.

Speech rate is particularly likely to systematically influence listeners' expectations about upcoming material. Speech sounds are interpreted relative to the global speech rate of an utterance, affecting perceived phoneme distinctions such as voicing contrasts (e.g. Miller, 1987; Reinisch et al., 2011). Therefore, listeners must evaluate the incoming signal with respect to a speaker's estimated rate. Dilley and Pitt (2010) demonstrated that effects of context speech rate scale up to the perceived rate of articulation of larger constituents, in-

cluding syllables and words. They found that when the speech rate of a function word (e.g. *or* in the phrase *leisure or time*) is increased relative to the rate of the surrounding context by either speeding up the function word or slowing down the surrounding context, participants are less likely to report hearing a function word in a sentence transcription task. Conversely, when the speech rate of segments surrounding a location in which a function word would be licensed grammatically (e.g. *leisure time*) is slowed down relative to the surrounding context, participants are more likely to report hearing a function word within the relatively slow portion of speech, effectively hallucinating having heard this item.

The findings of Dilley and Pitt (2010) suggest that listeners rapidly entrain to the rate of an utterance and develop speech rate expectations that influence the perceived number of morphophonological constituents within a spectrally ambiguous stretch of speech of a certain duration. However, the task used in this study does not directly address the prediction of the forward modeling account that the observed speech rate effects have an expectation-based locus. Indeed, it is possible that the sentence elicitation task itself contributed to the observed effects by engaging the production system and inviting explicit comparison of the perceived utterance with different alternative parses. Without time course information, it is unclear whether the observed effects of speech rate on the appearance and disappearance of words are based on perceptual expectations or post-perceptual reinterpretation of the input.

## Experiment overview

As a first step toward testing the predictions of the forward model, we used the visual world paradigm (Tanenhaus et al., 1995) to assess the effect of context speech rate on the interpretation of indefinite singular and plural noun phrases. In these noun phrases, the presence or absence of the plural morpheme *-s* was phonemically ambiguous, due to the presence of a sibilant-initial word following the target expression. In addition, the speech rate of sentence material distal (i.e. non-local) to the onset of the target expression was manipulated such that the segments surrounding the determiner in singular noun phrases had a faster speech rate than the distal context and the segments surrounding the onset of plural noun phrases had a slower speech rate than the distal context. These distal context manipulations were predicted to bias listeners to fail to perceive acoustically present determiners within singular noun phrases and to falsely perceive determiners prior to plural noun phrases, thereby shifting whether the noun phrases were judged to be singular or plural. We hypothesized that listeners' expectations about the acoustic-phonetic realization of upcoming segments within an utterance would be the source of these perceptual effects, and that manipulating the speech rate of material distal to the onset of the target expression would therefore influence fixations to pictures of singular vs. plural referents during the real-time processing of the noun phrase.

## Methods

### Participants

Thirty-two native English speakers from the University of Rochester participated in the visual world experiment. All participants had normal hearing and normal or corrected-to-normal visual acuity.

### Materials

The speech stimuli used in the experiment were 24 grammatical declarative sentences containing a target noun phrase consisting of an adjective and plural noun (e.g. *(a) brown hen(s)*). Each target expression was preceded by at least six syllables of utterance context ending in a vowel or rhotic consonant (e.g. *The Petersons are looking to buy*), a phonetic context in which a high degree of coarticulation with the determiner *a* would be expected. The target expression was followed by at least two additional syllables, beginning with a sibilant-initial word (e.g. *soon*) to increase participants' reliance on the determiner, rather than the presence or absence of plural *-s*, as a cue to number.

	preceding context	determiner region	target expression
singular			
no manipulation	1480	381	598
distal manipulation	2812	381	1137
plural			
no manipulation	1480	313	598
distal manipulation	888	313	359

Table 1: Mean durations of each sentence region by target expression type and condition. For each recording, duration of the determiner region was identical between distal- and no-manipulation versions of each recording.

Spoken sentences containing singular and plural versions of the target expression were elicited from 12 speakers and recorded using a Marantz PMD 660 digital recorder sampling at 44.1 kHz in a sound-attenuated booth. A singular and plural version of two critical items were selected from each speaker's recordings. The pitch synchronous overlap-and-add algorithm was then used to create two resynthesized versions of each recording (Moulines & Charpentier, 1990), in addition to two versions not discussed here. In the *distal-manipulation condition*, the speech rate of sentence material distal to the potential location of a determiner was altered; in the *no-manipulation condition*, the speech rate of the utterance was unaltered. For singular expressions, the distal speech rate manipulation involved temporally expanding the utterance context preceding and following the determiner region (the region beginning with the word preceding the determiner and ending with the following phoneme, e.g. *buy a b-*) by a factor of 1.9. This manipulation resulted in the

determiner region having a faster speech rate than the surrounding context. Likewise, the distal speech rate manipulation for plural expressions involved temporally compressing the determiner region by a factor of .6, to slow the rate of the determiner region relative to the surrounding context and thereby encourage the perception of an acoustically absent determiner. The mean duration across each region of the stimuli in each condition is provided in Table 1.

To reduce the salience of the singular-plural ambiguity in the critical items, 18 singular and 18 plural filler items were included in which the number of the target expression was more clearly signaled (e.g. *that rusty knife*). Of these filler items, one third were temporally compressed by a factor of .6 and one third were expanded by a factor of 1.9.

## Procedure

Each trial began with the presentation of a visual display containing four clip-art pictures. Two pictures depicted singular and plural versions of the target expression. The other two were singular and plural versions of a different object whose labels were phonologically unrelated to the target word. To ensure visual similarity between singular and plural pictures, the two versions of each picture were created by manipulating a single picture, either by duplicating and superimposing copies of a single target object or by isolating a single object within a picture of multiple target objects.

After 500 ms of display preview, participants heard a spoken sentence over Sennheiser HD 570 headphones. Their task was to click on the picture referred to in the sentence. Participants were not given feedback on their performance, and incorrectly selected a distractor picture on fewer than .5% of all critical trials. Throughout the study, eye movements were tracked and recorded using a head-mounted SR Research EyeLink II system sampling at 250 Hz, with drift correction procedures performed after every fifth trial.

Two sets of three lists were constructed by randomizing picture positions and trial order, dividing the experiment into three blocks, and rotating through permutations of the blocks. Within each list, an equal number of items were assigned to each of four singular and four plural conditions. The pairing of items with conditions was counterbalanced across participants, and each participant encountered each sentence only once. All lists started with four filler items to familiarize participants with the referent identification task.

## Analyses

Response choices were analyzed with separate multilevel logistic regression models for singular and plural items. Condition, the duration of the sibilant -s in each recording, and their interactions were included as fixed effects, and random intercepts and slopes were included for participants and items. For the measure of sibilant duration, we used the duration of the sibilant in each recording prior to manipulation, to minimize collinearity between sibilant duration and condition and to account for known effects of rate normalization on the relation between phoneme duration and segmentation (e.g. Miller,

1987). The duration of the sibilant was standardized by subtracting the mean value and dividing by the standard deviation. The final model was selected by removing fixed and random effects stepwise and comparing each smaller model to the more complex model using the likelihood ratio test (Baayen, Davidson, & Bates, 2008).

Growth curve analysis was used to evaluate the proportions of fixations to singular and plural target pictures over time by condition (Mirman et al., 2008). This analysis method is a variant of multi-level regression modeling that has emerged as an alternative to other statistical methods used to evaluate effects of experimental manipulations in the visual world paradigm. In growth curve analysis, the proportions of fixations to a picture are first aggregated by participants or by items for each condition at each time point sampled within the region of interest. Orthogonal power polynomial terms are then fit to the resulting fixation proportion curves to model variations in curve parameters (e.g. the intercept and slope) that can be attributed to the independent variable(s) and to participant-wise or item-wise variation. Because it explicitly models the trajectory of change in proportions of fixations over time, growth curve analysis is a more appropriate and temporally sensitive analysis technique than traditional analysis of variance approaches, which frequently entail the violation of assumptions about the independence and distribution of data points and the loss of fine-grained temporal detail.

Separate growth curve analyses were conducted for fixations to singular and plural target pictures in response to singular and plural tokens, with the no-manipulation condition used as the reference condition in all analyses. For analysis of fixations during the processing of the target noun phrase, data were aggregated and analyzed by participants and by items (indicated throughout as  $B_1$  and  $B_2$ , respectively). Each model used a third order polynomial to capture the generally sigmoidal shape of the curves.

For analysis of fixations during the processing of the target noun phrase, we characterized the effects of condition on the shape of the fixation curve by adding to the base model the effects of condition on the intercept and linear term, which represent the overall mean curve height and the slope of the curve. The onset of the adjective was used as the reference point for consistency across analyses of singular and plural conditions. Because items varied in the extent to which the adjective in the target expression biased listeners toward the target picture relative to the distractor picture, the onset of signal-driven fixations relative to the start of the adjective was determined by visually evaluating the point of divergence between the mean proportion of fixations to either version of the target picture and the mean proportion of fixations to either version of the distractor picture, averaged across conditions. Averaging across singular and plural target pictures and across conditions permitted unbiased evaluation of the mean point of divergence (Barr, 2008), estimated to be 300 ms after the onset of the adjective. Fixation curves were therefore analyzed between 300 and 1500 ms after adjective onset.

## Results

### Responses in the picture selection task

Figure 1: Proportions of correct picture selections.

Results from the picture selection task are shown in Figure 1. The regression model of responses for singular items revealed significant effects of condition. Fewer singular target pictures were selected in the distal-manipulation condition than in the no-manipulation condition ( $B=2.12$ ,  $z=5.24$ ,  $p<.0001$ ). Analysis of responses to plural items showed the opposite effect, with more singular target pictures selected in the distal-manipulation condition than in the no-manipulation condition ( $B=-2.09$ ,  $z=-5.45$ ,  $p<.0001$ ). For both models, the duration of the sibilant and by-participants and by-items random slopes did not contribute significantly to variance in response data and were not included in the final model.

These data show a pattern similar to those in off-line response choice data obtained by Dilley and Pitt (2010) in a sentence transcription task using a wider variety of function words. Increasing the relative speech rate of the determiner by slowing the rate of the distal context decreased the likelihood of listeners perceiving the determiner, whereas speeding up the distal context biased listeners to perceive a determiner that was not present in the signal. In addition, these results confirmed that the sibilant following the target noun was acoustically ambiguous, causing listeners to base their judgments primarily on the perception of the determiner.

### Fixations during processing of target expression

Figure 2 shows the ratio of mean fixation proportions for singular target pictures to the sum of mean fixation proportions for both singular and plural target pictures, averaged across the window starting at 300 ms after the onset of the adjective and ending 300 ms after the offset of the target expression. The pattern of results was similar to the effects observed in responses in the picture selection task. During the processing of singular expressions, the proportion of fixations to the singular picture was higher overall in the no-manipulation condition than in the distal-manipulation condition. Fixations during the processing of plural expressions showed the opposite effect. The proportion of fixations to the singular picture was higher in the distal-manipulation condition than in the no-manipulation condition. This pattern of results supported

Figure 2: Ratio of mean proportions to singular target pictures to the sum of mean proportions to singular and plural target pictures between 300 ms following adjective onset and 300 ms following the offset of the target expression.

the prediction that effects of distal speech rate manipulation on listeners' judgments would manifest during real-time comprehension.

Figure 3 (left) provides more detailed information about the time course of fixations to singular and plural pictures during the processing of singular items. Growth curve analysis revealed that distal manipulation had a significant negative effect on the intercept term for fixations to the singular picture ( $B_1=-.16$ ,  $t_1=-5.33$ ,  $p<.0001$ ;  $B_2=-.15$ ,  $t_2=-4.36$ ,  $p<.0005$ ) and a significant positive effect on the intercept term for fixations to the plural picture ( $B_1=.07$ ,  $t_1=2.19$ ,  $p<.05$ ;  $B_2=.07$ ,  $t_2=1.79$ ,  $p<.1$ ), although this effect was marginal in the items analysis. Relative to the no-manipulation condition, the distal-manipulation condition elicited a lower overall proportion of fixations to the singular picture and a higher overall proportion of fixations to the plural picture. Further, the linear term showed significant effects of distal manipulation on fixations to both the singular picture ( $B_1=-1.23$ ,  $t_1=-4.07$ ,  $p<.0001$ ;  $B_2=-1.18$ ,  $t_2=-4.28$ ,  $p<.0001$ ) and the plural picture ( $B_1=.87$ ,  $t_1=2.84$ ,  $p<.0001$ ;  $B_2=.79$ ,  $t_2=19.83$ ,  $p<.0001$ ), suggesting that the rate of change was less steep overall for fixations to singular pictures and steeper for fixations to plural pictures in the distal-manipulation condition.

Figure 3 (right) shows the time course of fixations to singular and plural target pictures during the processing of plural items. For the most part, analyses of fixations during the processing of plural items yielded a pattern of results similar to that obtained for singular items. Relative to the no-manipulation condition, the intercept term was significantly higher in the distal-manipulation condition than in the no-manipulation condition for fixations to singular pictures ( $B_1=.08$ ,  $t_1=3.22$ ,  $p<.005$ ;  $B_2=.08$ ,  $t_2=3.21$ ,  $p<.005$ ), and lower for fixations to plural pictures ( $B_1=-.14$ ,  $t_1=-4.43$ ,  $p<.0001$ ;  $B_2=-.14$ ,  $t_2=-4.26$ ,  $p<.0005$ ). Further, the linear term for fixations to the singular picture differed significantly across conditions ( $B_1=.81$ ,  $t_1=3.65$ ,  $p<.0005$ ;  $B_2=-.79$ ,  $t_2=-19.83$ ,  $p<.0001$ ), but the linear term for fixations to the plural picture did not ( $B_1=.15$ ,  $t_1=.45$ ,  $p>.1$ ;  $B_2=.23$ ,  $t_2=.70$ ,  $p>.1$ ).

Figure 3: Proportions of fixations to pictures in response to singular (left) and plural (right) target noun phrases. Black and grey lines represent distal- and no-manipulation conditions; solid and dashed lines represent fixations to plural and singular pictures.

In summary, participants were less likely overall to fixate plural pictures and more likely to fixate singular pictures in the distal-manipulation condition than in the no-manipulation condition. This result demonstrates that manipulating the speech rate of an utterance distal to the potential location of a determiner influences whether a determiner is perceived during the real-time processing of indefinite noun phrases, consistent with the predictions of the forward modeling account.

## Discussion

When speech distal to the onset of an indefinite determiner at the onset of a singular noun phrase was temporally expanded, listeners were less likely to perceive the determiner and were more likely to select a plural picture as the referent of the noun phrase. Conversely, when speech distal to the onset of a plural noun phrase was temporally compressed, listeners were more likely to select a singular picture, suggesting that the distal context manipulation induced the perception of a determiner that was not acoustically present in the signal. The absolute speech rate of the determiner region of each item was identical across conditions, demonstrating that it was the speech rate of the determiner relative to its surrounding context, rather than its absolute rate, that drove these effects.

Crucially, fixations to singular and plural pictures revealed that effects of distal speech rate occurred during the real-time processing of the target expression, strongly suggesting a locus of the effect in perceptual expectations. The observed time course of speech rate effects demonstrates that listeners entrain to the overall rate at which speech sounds are articulated within an utterance and expect this speech rate to persist in upcoming material, biasing them to expect relatively long stretches of speech to contain more morphophonological constituents and relatively short stretches of speech to contain fewer. Indeed, expectations based on context speech rate may be a powerful cue in the online interpretation of natural speech, which is generally readily interpretable despite

frequently degraded or ambiguous spectral cues to segmental content.

According to a forward modeling account of spoken language processing, the language processing system includes a component that integrates relevant contextual information from a variety of sources, such as speech rate and speaker identity, to predict the acoustic-phonetic attributes of different lexical alternatives. These expectations crucially influence listeners' perception of the incoming acoustic signal and the relative activation of competing lexical alternatives. Further, mismatch between expectations and the signal is predicted to result in feedback that continuously updates the probabilistic links between contextual factors and expected outcomes.

Although most of the growing body of work demonstrating fine-grained sensitivity to acoustic detail has not been framed in terms of perceptual expectations (e.g. Gow, 2001; Hawkins, 2003; Salverda et al., 2003; though see McMurray et al., 2011), such findings are congruent with this framework. Particularly suggestive are effects of acoustic detail being conditioned by context manipulations (e.g. Salverda et al., 2007; Sumner & Gaftner, 2011) and by speaker-specific characteristics (e.g. Kraljic et al., 2008; Creel et al., 2008).

Our findings set the stage for further tests of predictions of the forward modeling account. For example, if perceptual expectations about upcoming speech are represented probabilistically, the variance of the distribution of expected acoustic forms should influence the magnitude of expectation-based effects on perception. Moreover, incongruence between expectations and the actual realization of a word in context should result in perceptual adaptation bringing expectations more in line with relevant characteristics of the signal (e.g. speaker-specific accent or idiosyncratic prosody). To test these predictions, we are manipulating the relative speech rate not only of the determiner region, but also of segments surrounding the sibilant following the target expression.

## Conclusions

This study demonstrates that perceptual expectations have sufficiently strong effects on perception to make words appear within and disappear from the signal during real-time language processing. Forward modeling of the acoustic realization of upcoming speech may be a crucial mechanism enabling listeners to cope with and exploit variability in the input, particularly when spectral cues are degraded or ambiguous. These findings establish distal speech rate manipulation as a suitable experimental paradigm for testing further predictions of the forward modeling account.

## Abstract

Two visual world experiments tested the hypothesis that expectations based on preceding prosody influence the perception of suprasegmental cues to lexical stress. Experiment 1 showed that phonemically overlapping words with different initial stress patterns compete for recognition. Experiment 2 further demonstrated that fundamental frequency and syllable timing patterns across material preceding the target word can influence the relative activation of competing alternatives with different initial stress patterns. The activation of alternatives with initial stress was higher when preceding stressed syllables had suprasegmental acoustic characteristics similar to the initial syllable of the target word. These findings suggest that expectations about the acoustic realization of an utterance include information about metrical organization and lexical stress, and that these expectations constrain the initial interpretation of suprasegmental stress cues. These results are interpreted as support for expectation-based forward models in which acoustic information in the speech stream is interpreted based on expectations created by prosody.

**Keywords:** Prosody; spoken word recognition; lexical stress; visual world paradigm; expectations; lexical competition

## Introduction

A growing body of work indicates that expectations about the acoustic realization of the phonemes and prosody of a spoken sentence influence how listeners initially interpret incoming acoustic-phonetic cues during spoken language processing. For example, manipulations of pitch and duration early in an utterance influence the interpretation of cues to prosodic and morphophonemic constituency several syllables downstream (Dilley & McAuley, 2008; Dilley et al., 2010; Brown et al., 2011; Dilley & Pitt, 2010). However, little is known about the types of representations that contribute to these perceptual expectations. The present study investigates whether perceived prosodic and metrical patterning across preceding portions of an utterance can influence listeners' expectations about the metrical organization of upcoming material, modulating their interpretation of proximal cues to lexical stress and therefore influencing the activation of potential lexical candidates.

Lexical stress is a key contributor to sentence-level prominence patterns and rhythmicity. Listeners are sensitive to

segmental and suprasegmental cues to stress during spoken word recognition (Cutler, Dahan & van Donselaar, 1997). Although vowel quality is the most potent stress cue to influence lexical processing in English, other suprasegmental cues such as duration also distinguish stressed from unstressed syllables, and judgments about these suprasegmental stress cues are modulated by surrounding prosody in off-line tasks (Niebuhr, 2009). Cues to stress may influence not only the recognition of particular words, but also the process of segmenting the speech stream more generally. For example, listeners are more likely to misperceive phrases like "she's a must to avoid" as "she's a muscular boy" than they are to mishear "in closing" as "enclosing", suggesting that listeners preferentially posit word boundaries prior to prominent syllables (Cutler & Butterfield, 1992). This metrical segmentation strategy is substantiated by the distribution of stressed syllables within the English lexicon: approximately 90% of content words in conversational English have initial stress (Cutler & Carter, 1987).

Perceived metrical patterning is a potentially powerful source of expectations in speech perception. Speech prosody often exhibits characteristics that listeners perceive as patterning (Couper-Kuhlen, 1993; Pierrehumbert, 2000). For example, listeners tend to hear stressed syllables in English as perceptually isochronous, i.e., as occurring at regular intervals (e.g., Lehiste, 1977). In addition, previous work using non-linguistic auditory stimuli (e.g. sequences of alternating tones) has demonstrated that pitch, temporal, and/or amplitude patterning in distal (i.e. non-local) auditory context can influence the processing of proximal material (e.g. the perceived relative prominence of high vs. low tones; Woodrow, 1911; Thomassen, 1982). The tendency for speakers to use recurring sequences of pitch accents within an intonational phrase (Couper-Kuhlen, 1993; Pierrehumbert, 2000) may likewise contribute to the perceived metrical structure across syllables in an utterance.

We conducted two visual world experiments to test the hy-

pothesis that expectations based on preceding prosody influence the perception of suprasegmental cues to lexical stress. Experiment 1 verified that phonemically overlapping words with different initial stress patterns compete for recognition. Experiment 2 further demonstrated that fundamental frequency and syllable timing patterns across material preceding the target word can influence the relative activation of competing alternatives with different initial stress patterns. The activation of alternatives with initial stress was higher when preceding stressed syllables had suprasegmental acoustic characteristics similar to the initial syllable of the target word, and vice versa. These findings suggest that expectations about the acoustic realization of upcoming speech include information about metrical organization and lexical stress, and that these expectations constrain the initial interpretation of suprasegmental stress cues during spoken word recognition.

## Experiment 1

The main goal of Experiment 1 was to establish that phonemically overlapping words with different initial stress patterns compete for recognition. We demonstrate that materials containing a target word with relatively neutral segmental and suprasegmental stress cues on the initial syllable elicit initial activation of both initially-stressed and initially-unstressed lexical alternatives.

### Methods

**Participants** The participants were 16 students from the University of Rochester. All participants were native English speakers with normal hearing and corrected-to-normal visual acuity, and received \$7.50 for their participation in the study.

**Materials** The 24 speech stimuli used in the experiment were grammatical declarative sentences containing either a word with initial strong-weak stress (e.g. *jury*) or a phonemically overlapping word with initial weak-strong stress (e.g. *giraffe*). The initial syllables for each related pair of words were produced with as close to the same vowel quality and pronunciation as possible. Each stimulus began with at least two disyllabic words with initial primary stress, followed by one or two monosyllabic words (e.g. *Heidi sometimes saw*). This distal context material was followed by another monosyllabic word (e.g., *that*) followed by the target word. Whereas the preceding context for each item was the same for both SW and WS target words, the sentence material following the target word differed to maximize semantic coherence (e.g. *the jury leaving the courthouse* vs. *the giraffe in the city zoo*).

To discourage participants from noticing the stress pattern manipulation, we included 48 filler items for which the visual display contained two pictures whose labels had a different phonological relation (e.g. words with onset-embedded competitor words, like *antlers* and *ant*). For half of the filler items, one of the phonologically related words was mentioned in the utterance. In addition, an equal number of SW, WS, and

monosyllabic target words were used in the filler items. Eight filler items were identity-spliced between the first and second syllables of the target word, whereas the rest were spliced at some point prior to the target word.

The first author recorded multiple tokens of each sentence as WAV files at 44.1 kHz, producing each sentence with minimal F0 excursions and slight F0 declination. Each recording was split into two halves at the end of the first syllable of the target word, at a point in the waveform with an amplitude of zero. Identity- and cross-spliced versions of the item containing the SW target word were created by splicing together the last half of a SW recording either with the first half of another SW recording or with the first half of a WS recording. Likewise, identity- and cross-spliced versions of the item containing the WS target word were created by splicing the last half of a WS recording together with the initial SW and WS sentence fragments used to create the SW items.

**Procedure** The study was divided into three phases. In the first phase, each of the 304 clip-art pictures used in the visual world experiment was presented to the participant in the center of the display, with its label printed underneath. Each picture-label pair was presented for a minimum of 3 seconds. Participants proceeded at their own pace through the set of picture-label pairs by pressing the space bar.

The visual world experiment began immediately following the picture-label exposure phase. Each trial started with the presentation of a visual display containing four pictures, two of which corresponded to the phonologically related SW and WS words on critical trials. The remaining two distractor images were selected such that they were distinct from the two potential target pictures with respect to visual and semantic properties and the phonological properties of their labels. After 500 ms of display preview, participants heard a spoken sentence, and their task was to click on the picture that was referred to in the sentence. They were not given feedback on their performance during the experiment. Throughout the study, eye movements were tracked and recorded using a head-mounted SR Research EyeLink II system sampling at 250 Hz, with drift correction procedures performed every five trials.

Immediately after the completion of the visual world experiment, we assessed participants' ability to generate the appropriate labels for both members of each stress-alternating word pair. Participants named each of the 48 associated pictures, presented in a randomized sequence, and their responses were recorded. Responses were scored as correct if they preserved the phonemes and stress pattern across the initial two syllables (e.g. *jury*, *jury box*, and *jury members* were all considered correct, but *jurors* was not).

For the visual world experiment, two lists were constructed by randomizing the positions of the images on the screen within each trial and pseudorandomizing the order of trials within the list. Within each list, half of the experimental trials had SW target words and half had WS target words, and of these, half were identity-spliced and half were cross-spliced.

The assignment of items to each of the four conditions was counterbalanced across participants, for a total of eight lists. Six practice trials were included at the start of the experiment to familiarize participants with the picture selection task.

**Analyses** For statistical analysis, proportions of fixations to the target, competitor, and distractor pictures on experimental trials were averaged across the window starting at 200 ms after the onset of the target word and ending 750 ms later, i.e., 200 ms after the mean offset of the target word. The mean proportions were then transformed using the empirical logit function (Cox, 1970). Effects of target word type and splicing condition on logit-transformed fixation proportions were analyzed in a multilevel linear regression model. Fixed effects included picture type, target word type, splicing condition, trial number, and interactions between these factors. Random effects included intercepts and slopes for participants and items. Trial number was standardized by subtracting the mean value and dividing by the standard deviation. To select the final model, effects were removed stepwise and each reduced model was compared to the more complex model using the likelihood ratio test (Baayen et al., 2008).

## Results and discussion

Figure 1: Proportions of fixations to target, competitor, and distractor pictures in Experiment 1. Line color denotes target word type (SW vs. WS); line texture denotes picture type.

Overall, participants found the referent identification task easy, and clicked on the incorrect picture on less than 3% of all experimental trials. These trials were excluded from further analysis. In addition, we excluded trials for which the target or competitor picture was not correctly named by the participant in the third phase of the experiment (18.9%), since their performance on this task revealed whether they associated the intended names with the pictures.

Figure 1 shows the proportion of fixations to the target, competitor, and distractor pictures as a function of condition starting at the onset of the target word. As expected, hearing the initial sounds of a WS word elicited transient competition from a phonemically overlapping SW competitor, starting at approximately 250 ms after the onset of the target word. The proportions of target and competitor fixations were roughly equivalent until approximately 600 ms af-

ter target word onset, when fixations began to converge on the target picture. Crucially, hearing the initial sounds of a SW word also elicited competition effects from WS competitors with approximately the same magnitude and time course.

Multilevel linear regression analyses confirmed the prediction that words with initial WS stress initially compete for recognition with phonemically overlapping words with initial SW stress. The logit-transformed proportion of fixations to the distractor pictures was significantly lower than the transformed proportions of fixations to the target ( $B=.59$ ,  $SE=.11$ ,  $t=5.16$ ,  $p<.0001$ ) and competitor ( $B=.29$ ,  $SE=.08$ ,  $t=3.70$ ,  $p<.0005$ ) pictures, after taking into account by-participant and by-item random intercepts, by-participant random slopes for picture type, and by-item random slopes for the interaction between picture type and splicing condition. Neither the target word stress pattern nor trial number contributed significantly to model fit, suggesting that competition effects were similar for SW and WS words and were stable across the experiment. Neither factor was included in the final model. Further, fixed effects of splicing condition did not contribute significantly to variance in fixation proportions. Taken together, these findings indicate that, for our materials, the competition between phonemically overlapping words with different initial stress patterns was similar for SW and WS target words.

These results verified that phonemically overlapping words with different initial stress patterns compete for recognition, and suggested that statistically-based heuristics or biases to interpret lexically stressed syllables as the onsets of content words do not dominate processing, at least when corresponding weak and strong syllables have similar vowel quality and segmental pronunciation. The overall similarity of lexical competition effects in identity- vs. cross-spliced items further suggested that we succeeded in creating items with relatively neutral segmental and suprasegmental cues to the lexical stress of the initial syllable.

## Experiment 2

The goal of Experiment 2 was to characterize the effects of preceding prosody on listeners' initial interpretation of different-stress cohort pairs. In this experiment, the acoustic characteristics of preceding portions of the utterance distal to the target word were manipulated, leaving the acoustic realization of the target word and its immediately surrounding context unchanged. Syllables in the distal context with lexical or sentence-level stress were manipulated to have the same relative F0 level (either low or high with respect to surrounding syllables) and to be roughly isochronous. We hypothesized that this prosodic manipulation would bias listeners to expect upcoming syllables with similar pitch and timing characteristics as preceding prominent syllables to be lexically stressed, and conversely to expect upcoming syllables with different pitch and timing characteristics to be unstressed.

## Methods

**Participants** The participants were 32 students from the University of Rochester who met the same inclusion criteria

Figure 2: Example item in SW-biasing (left) and WS-biasing (right) conditions. The fundamental frequency (F0) and timing of stressed syllables within preceding distal context were manipulated to bias listeners to perceive the initial syllable of the target word as stressed or unstressed. Acoustic properties of the target word and its proximal context were the same across conditions.

as for Experiment 1.

**Materials** The stimuli used in Experiment 2 were created by manipulating the prosody of the sentence material preceding the target word in each of the identity- and cross-spliced items used in Experiment 1, using the pitch synchronous overlap-and-add algorithm (Moulines & Charpentier, 1990). All distal F0 manipulations involved removing non-vocalic pitch points and shifting the remaining pitch points within each context syllable up by 35 Hz (for high syllables) or down by 25 Hz (for low syllables). This manipulation preserved the natural microvariation and F0 declination of the original recording while imposing salient periodic alternations onto the F0 contour. F0 manipulations were performed for all syllables through at least the second syllable following the offset of the target word. Whether the first syllable of the target word had low or high F0 varied between items. Temporal manipulations involved compressing or expanding the rime of the first monosyllabic word within the preceding context such that the duration of the fifth intervocalic interval (i.e. the interval between vowel onsets in the fifth and sixth syllables) either matched the mean duration of the following two intervocalic intervals or was twice the mean duration of the preceding four intervocalic intervals, following Dilley and McAuley (2008). Similar prosodic manipulations were performed on filler items.

Two versions of each item were created with different acoustic characteristics across the distal context preceding the target word but the same acoustic characteristics across its proximal context (i.e. the preceding adjacent syllable) and all subsequent material (Figure 2). In the *SW-biasing condition*, syllables in the distal context with lexical and/or sentence-level stress (e.g. *Heidi sometimes saw...*) were manipulated to have the same relative F0 level as the initial syllable of the target word (e.g. high, cf. Figure 2), and the duration of the fifth syllable was manipulated such that the timing of the sequence of prominent syllables was approximately isochronous with the timing of the first syllable of the target word. Whether the fifth syllable was shortened or lengthened to accomplish this regularity depended on the structure of the preceding context: It was shortened when the distal context ended in one monosyllabic word and lengthened when it ended in two. The SW-biasing context was predicted to bias listeners to perceive the

initial syllable of the target word as lexically stressed (consistent with e.g. *jury* rather than *giraffe*). This bias was predicted to increase the initial proportion of fixations to the SW competitor when the target word began with an unstressed syllable, and to decrease the initial proportion of fixations to the WS competitor for SW target words.

Conversely, in the *WS-biasing condition*, the F0 of stressed syllables in the distal context was manipulated to have the opposite relative F0 level as the initial syllable of the target word (e.g. low, cf. Figure 2), and the duration of the fifth syllable was manipulated such that the timing of the sequence of prominent syllables was approximately isochronous with the timing of the syllables immediately preceding and following the first syllable of the target word. The WS-biasing context was predicted to bias listeners to perceive the initial syllable of the target word as unstressed, and therefore to increase the initial proportion of fixations to the WS competitor for target words beginning with a stressed syllable and to decrease the proportion of fixations to the SW competitor for target words beginning with an unstressed syllable.

**Procedure** The procedure was the same as Experiment 1.

**Analyses** Proportions of fixations to target, competitor, and distractor pictures on experimental trials were computed and averaged across the same time window as in Experiment 1. Effects of word stress, preceding prosody, and splicing condition on logit-transformed fixation proportions were analyzed using multilevel linear regression. Fixed effects and random slopes included picture type, target word type, distal prosody condition, splicing condition, trial number (i.e. the position of the item in the sequence encountered by the participant), the initial F0 of the target word (low vs. high), and interactions between factors. Since we were primarily interested in the effects of distal prosody on the relative proportions of fixations to the target and competitor pictures, fixations to the distractor pictures were not included in the analysis. Trial number was included in the analyses due to recent work suggesting that listeners rapidly adapt to the reliability of prosodic cues, particularly in counterbalanced experimental designs (e.g. Kurumada et al., to appear; Brown et al., under review). A full explication of prosodic adaptation effects, however, is beyond the scope of the present paper.

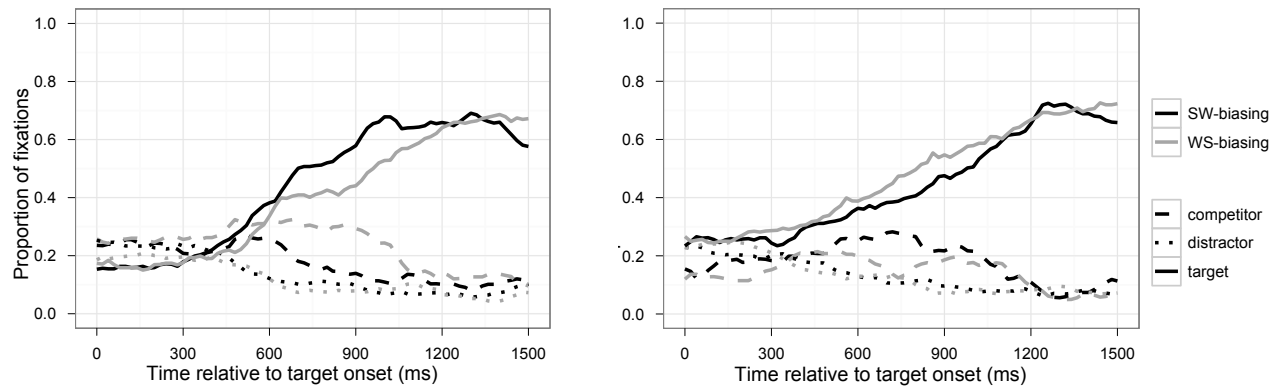

Figure 3: Proportion of fixations to target, competitor, and distractor pictures upon hearing SW (left) and WS (right) target words in SW- vs. WS-biasing contexts in Experiment 2. Line color denotes target word type; line texture denotes picture type.

## Results and discussion

Trials in which participants clicked on the incorrect picture (<2%) or for which participants generated an incorrect label for the target or competitor picture in the post-test (29.1%) were excluded from analysis. Figure 3 shows the proportion of fixations to the target, competitor, and distractor images as a function of condition starting at the onset of the target word. Starting at around 350 ms after the onset of SW target words (Figure 3, left), SW-biasing prosody resulted in higher proportions of target fixations and lower proportions of competitor fixations, with effects persisting for approximately 800 ms. For WS words (Figure 3, right), SW-biasing prosody had opposite effects, with relatively low proportions of target fixations and relatively high proportions of competitor fixations.

	<i>B</i>	<i>SE</i>	<i>t</i>	<i>p</i>
intercept	-.65	.09	-7.20	<.0001
target picture	.37	.12	3.11	<.005
WS-biasing prosody	.17	.09	1.91	<.1
trial number	-.06	.03	-2.06	<.05
target picture x WS-biasing prosody	-.29	.12	-2.39	<.05

Table 1: Parameters of the final multilevel regression model of logit-transformed fixation proportions in response to SW target words in Experiment 2. The model included by-item intercepts and slopes for picture type and prosody condition.

Multilevel linear regression analyses revealed not only the predicted three-way interaction between picture type, distal prosody condition, and target word stress pattern ( $B=.50$ ,  $SE=.25$ ,  $t=2.02$ ,  $p<.05$ ), but also a significant interaction between these three factors and trial number ( $B=-.46$ ,  $SE=.17$ ,  $t=-2.73$ ,  $p<.01$ ). To investigate the source of this significant four-way interaction, separate analyses were conducted for SW and WS words. Analysis of fixations during the processing of SW words revealed a significant interaction between target picture and prosody condition (Table 1). Participants were more likely to fixate the competitor picture in the WS-

biasing condition than in the SW-biasing condition ( $B=.17$ ,  $SE=.08$ ,  $t=2.13$ ,  $p<.05$ ); target fixations did not differ significantly by condition. Although trial number had a significant main effect, it did not enter into any significant interactions.

Analysis of fixations during the initial processing of WS words revealed not only a significant interaction between target picture and prosody condition, but also a significant three-way interaction between target picture, prosody condition, and trial number (Table 2). We explored this interaction by fitting two additional models to the data, with trial number centered one standard deviation above and below the mean. These models revealed that the interaction between target picture and prosody condition was significant early in the experiment ( $B=.56$ ,  $SE=.18$ ,  $t=3.18$ ,  $p<.005$ ). In the WS-biasing condition, target fixations were significantly higher ( $B=.32$ ,  $SE=.13$ ,  $t=2.49$ ,  $p<.05$ ), whereas competitor fixations were significantly lower ( $B=-.24$ ,  $SE=.10$ ,  $t=-2.46$ ,  $p<.05$ ). However, the interaction between target picture and prosody condition was not significant late in the experiment.

## General discussion

Results from two visual world experiments supported the hypothesis that expectations based on preceding prosody influence the perception of suprasegmental cues to lexical stress. Experiment 1 showed that initially unstressed words compete for recognition with phonemically overlapping words with initial stress, and vice versa. Experiment 2 further demonstrated that F0 and syllable timing patterns across material preceding the target word influence the relative activation of competing SW and WS alternatives. The activation of SW alternatives was higher when preceding stressed syllables had suprasegmental acoustic characteristics similar to the initial syllable of the target word, while the activation of WS alternatives was higher when preceding stressed syllables had suprasegmental characteristics dissimilar to the initial syllable of the target word.

These findings show that expectations about the acoustic realization of upcoming material within an utterance include

	<i>B</i>	<i>SE</i>	<i>t</i>	<i>p</i>
intercept	-.61	.06	-10.28	<.0001
target picture	.30	.10	3.05	<.005

Table 2: Parameters of the final multilevel regression model of logit-transformed fixation proportions in response to WS target words in Experiment 2. The model included random intercepts and picture type slopes for participants and items.

information about metrical organization and lexical stress, and that these expectations constrain the initial interpretation of suprasegmental stress cues during spoken word recognition. This indicates, in turn, that cues to lexical stress in sEnglish are not restricted to word-internal cues such as a syllable's F0, duration and amplitude, but can also include sentence-level patterning. This observation suggests that expectations from a variety of sources influence listeners' interpretation of suprasegmental stress cues.

The observation that prosodic expectations influence the interpretation of suprasegmental stress cues raises questions about the mechanisms by which various sources of contextual information are integrated with the incoming signal. Our findings are congruent with forward-modeling approaches in which perceptual input is evaluated with respect to internally generated hypotheses about the acoustic-phonetic realization of upcoming material. Forward models have been fruitfully explored within influential theories of motor control (e.g. Wolpert et al., 1995; Guenther & Micci Barreca, 1997), and may likewise provide a promising explanatory framework for aspects of spoken language understanding.

## Abstract

A process of sensemaking in reverse engineering was elicited from verbal protocols of reverse engineers as they investigated the assembly code of executable programs. Four participants were observed during task performance and verbal protocols were collected and analyzed from two of the participants to determine their problem-solving states and characterize likely transitions between those states. From this analysis, a high-level process of sensemaking is described which represents hypothesis generation and information-seeking behaviors in reverse engineering within a framework of goal-directed planning. Future work in validation and application of the process is discussed.

**Keywords:** Sensemaking; Information seeking; Human computer interaction; verbal protocol studies.

## Introduction

Sensemaking is a term used to describe a broad family of cognitive activities in which a person comes to develop a mental model to represent the elements of some situation of interest (Klein, Phillips, Rall, & Peluso, 2007; M. R. Endsley, 2000). Whereas situation awareness refers to the ability to attend to relevant information elements in a task as a situation unfolds (M. Endsley & Rodgers, 1994), sensemaking refers to the process that enables one to come to an understanding of the meaning and relevance of the elements that make up the situation (Klein, Moon, & Hoffman, 2006; M. R. Endsley, 2000). The sensemaking process has been described as an ongoing integration of knowledge from a mental model of a situation, available information about the context of a situation, and perceptual data from the environment (D. M. Russell, Stefik, Pirolli, & Card, 1993; M. R. Endsley, 2000).

Sensemaking is described as connecting inferences and observations, integrating knowledge and conjecture, finding explanations for ambiguous data, diagnosing ambiguous symptoms, and identifying problems (Klein et al., 2007). Sensemaking also refers to comprehension of the significance of ambiguous events and data in the environment (Weick, 1995). The many functions of sensemaking describe a class of distinct cognitive processes involving interactions between knowledge, information, and actions in an environment which may encompass a number of different inference and learning behaviors (Menzies, 1996; Josephson, Chandrasekaran, Smith, & Tanner, 1987). Sensemaking has been studied in naturalistic settings (Klein et al., 2007), in computer-human interaction (Pirolli & Card, 2005), in intelligence analysis (Zhang, Soergel, Klavans, & Oard, 2009), and in organizations (Weick, 1995), but no process-level description exists to characterize how people make sense of executable programs.

As part of a larger study to understand and model how people make sense of programs from executable representations, we wanted to understand the general interaction process that is involved as a person works with a debugger to make sense of a program. While sensemaking might be a general process of interacting with an environment to develop a mental model, we investigated sensemaking in a particular applied domain (reverse engineering assembly language) because it provides a restricted set of semantics to ground the investigation without being a “toy” problem. This was also essential because understanding sensemaking in that domain was the major focus of the larger study. So while the term ‘sensemaking’ has been used to mean many different things, we were interested in studying how people connect information from the task environment with background knowledge in order to develop and modify a mental model, all with a focus on applying this process to improve the information processing automation in software reverse engineering tools.

To understand this element of understanding executable programs, we undertook a study to collect verbal protocols from reverse engineers while they analyzed programs from assembly language representations. Four participants were observed performing a challenging reverse engineering task, and verbalizations from two of the participants were transcribed and coded. From the coded data, two participants’ state transitions were extracted to determine a process involving the state transitions.

First, the methods used in the study are briefly described. Next, the methods used in the analysis of verbal protocols is presented. Following that, the process of sensemaking used in the reverse engineering tasks is described in the context of complex problem-solving.

## Method

The participants were instructed to complete a problem called *Angler* that was downloaded from the *crackme.de* website (Schneider, T., 2011) in February 2011<sup>1</sup>. *Angler* is a type of crackme called a *keygen* (which stands for key generation), a type of program that typically presents text fields for the user to enter a name and a serial number and asks the participant to reverse engineer the algorithm which processes the user’s data. In keygen tasks, people disassemble and reverse engineer the program to discover a valid key for a given user

<sup>1</sup>Shortly after obtaining the crackme, the crackme.de website was taken down from the Internet. The *Angler* program can also be obtained from the website of the program’s author at <http://cyclops.ueuo.com>.

name or to write an algorithm that, when given a user name, produces a valid license key that unlocks the functionality of the program.

The Angler crackme program presents the participant with a semi-transparent visual window with two entries for text. It has three buttons, labeled “Check”, “About”, and “Exit.” When a user submits a name and serial number combination, the application tests whether it is a valid combination and informs the user.

### Selection of Participants

The researcher solicited reverse engineers to participate in a verbal protocol study through an e-mail invitation to the Air Force Institute of Technology and to a cross-organizational reverse engineering working group at Wright-Patterson Air Force Base. The solicitation requested that participants have knowledge of reverse engineering and experience using tools such as OllyDbg, WinDbg, Immunity Debugger, and the IDA Interactive Disassembler. The solicitation produced four reverse engineers from Wright-Patterson Air Force Base who participated without remuneration.

### Data Collection

Video data of the participants’ computer screen was captured and combined with audio recordings of the participants’ verbalizations during the task. The participant computer ran a Windows XP operating system that was hosted within a VirtualBox virtual machine, and which was preloaded with the software tools and documentation identified from a previous subject matter expert study of the reverse engineering task. The experimenter viewed the participant’s task environment remotely over a virtual network computing (VNC) connection using the TightVNC server and client software (TightVNC Software, 2011). The experimenter’s computer was outfitted with a microphone which was wired into the participant’s cubicle to enable the combined collection of audio and video data.

Each participant was seated at a small cubicle in an unoccupied, quiet room in front of the participant computer which contained a mouse, keyboard, monitor, and the microphone. The participants were instructed as to the different reverse engineering tools and documentation available, and were permitted as much time as was needed to become familiar with the task environment. Paper was also available so participants could make notes, as recommended by Wood (1997).

Each participant was given instructions on how to verbalize thoughts during task performance and was instructed not to try to explain the task or thought processes. The experimenter stressed this point and demonstrated examples of poor, acceptable, and high-quality concurrent verbalizations with a simulated coffee-making task to help the participants understand how they should verbalize during task performance. During the performance of each task, the experimenter was seated out of the participant’s view in the opposite cubicle and reminded participants to verbalize when they fell silent for more than a few seconds using simple prompts such

as “please remember to verbalize during the task” and “remember to talk aloud” as discussed in Trickett and Trafton (2007). Other than those reminders, the experimenter was silent throughout the task, and took notes about each participants’ goals, strategies, concepts, and problems in the task.

Audio data of each participant’s concurrent verbalizations and video data of the experimenter’s computer monitor (showing all actions on the participant’s computer monitor) were recorded using the CamStudio software. After the task, participants were asked to recall what they thought their strategies were, what parts of the task they thought were the most difficult, what would have made the task easier, and what they felt they needed to pay attention to.

### Overview of the Reverse Engineering Task

Participants were to investigate, modify, and re-implement an algorithm that an executable Windows program called “Angler.exe” (Cyclops, 2011) uses to process a user-provided serial number. Participants worked from assembly language representations of the program provided through the IDA interactive disassembler and the OllyDbg debugger without access to source code or debugging symbols.

The code in Angler consists of 15 major subroutines, including the subroutine called `WinMain` which starts the windowing process and other subroutines to present dialog boxes. The program runs within a single thread of execution in memory and does not have hidden sections, encrypted code, or code obfuscations. Angler’s file header contains pointers to four program sections that are mapped into memory at run time: the `.text`, `.rdata`, `.data`, and `.rsrc` sections, which are typical for portable executable programs compiled to run on Win32-based operating systems (Eilam, 2005).

Though there are many strategies to approaching the challenge, successful completion required that participants do the following:

1. Read and understand the goal of the task
2. Determine that a system function handles input
3. Isolate the input handling function
4. Determine the format for the serial number input
5. “Catch” the input as the program executes
6. Craft data so the program executes the success message
7. Translate the function into pseudocode
8. Write pseudocode for a key generator

An algorithm in the program composed of 27 basic blocks of assembly instructions processes the user’s serial number. The algorithm takes the first four characters of the person’s name and performs a cyclic redundancy check (CRC) to produce an even-numbered value from that character, finds four pairs of prime factors that sum to the even-numbered values, and assembles an eight-value number separated by dashes (Cyclops, 2011). Through a series of programmatic checks, the algorithm determines if the user’s serial number matches the computed serial value. In these checks, the last instructions in each basic block of code check for a data value from

Verbalization Describes	Coded As
Desired future state	Make goal representation
Activities to accomplish goal	Plan approach
Status of an ongoing activity	Carry out plan
Noticing something	Sense information
Recognizing relevance	Interpret information
More abstract statement	Update knowledge
An assumption	Create hypothesis
Question about something	Create hypothesis

Table 1: Rules Used to Code Segments

the input and then transfer the program's execution based on the result of that check. If the reverse engineer does not understand the meanings of these behaviors, the program appears to be making a large number of arbitrary numerical checks in a long sequence of assembly language instructions.

### Verbal Protocol Analysis

Participant B's video and audio data recordings were accidentally destroyed during a problem with saving the video file to disk and were not able to be recovered or transcribed. Additionally, Participant A lacked familiarity with the tools and the task and was not able to make sense of the program. Although observations of all of the participants provided valuable context and examples, only verbal data from Participants C and D were coded and analyzed to elicit the sensemaking process.

Concurrent verbal protocols were collected from Participants C and D following the method outlined in (Ericsson & Simon, 1980). We reviewed the video and verbal data from Participants C and D and transcribed it into a spreadsheet, broken into one verbal segment per row as discussed in Trickett and Trafton (2007). The participants' verbalizations were segmented during transcription in order to take advantage of other contextual clues from the audio and video. Verbalizations were segmented based on whether they represented a single idea, and when a segment contained a shift from one idea to another, the second idea was recorded in its own row as its own new segment. Where significant verbal breaks occurred, the subsequent verbalizations were recorded on a new row as a separate segment.

After all of the available data was transcribed, it was coded according to the following taxonomy of sensemaking in reverse engineering, established from a previous literature review of sensemaking in reverse engineering in Bryant et al. Bryant, Mills, Peterson, and Grimaila (2012): *Make the goal representation, Plan an approach, Carry out a plan, Sense information, Interpret information, Update knowledge, and Create a hypothesis*. This taxonomy of sensemaking steps is similar to the information-processing loop used in programming artificial agents to interface with an environment (S. Russell & Norvig, 2003), with the addition of a state to generate goals and state to generate hypotheses.

The data from the two participants were coded according to

the coding rules in Table 1. To ensure that the coding scheme was appropriate for the data, interrater reliability was computed between two independent coders. One researcher coded all of the data (592 segments) and afterwards a second coder independently coded 29.2 percent of the segments (173 sequential segments) without having seen the original coder's data, and from a starting point randomly selected by the second coder. Cohen's Kappa statistic (Cohen et al., 1960) was computed to measure interrater reliability for the 29.2 percent of segments coded by both coders. Cohen's Kappa measures the agreement between coders on positive and negative instances while taking into account the likelihood of agreement based on chance. Cohen's Kappa is computed as:

$$\kappa = (P_o - P_c) / (1 - P_c)$$

$P_o$  is the proportion of agreements between the coders and  $P_c$  is the proportion of agreement which would be predicted by chance. Generally, a Cohen's Kappa value of 0.0 to 0.4 indicates zero to very little agreement, 0.6 to 0.8 indicates significant agreement, and 0.8 and above represents near perfect agreement, though there is disagreement in the literature about specific ranges of values (Bakeman & Gottman, 1997; Trickett & Trafton, 2007). After both coders independently coded the data, the interrater reliability was calculated and the coders met to discuss disagreements. If codes had weak interrater reliability (0.4 or below), the categories were removed or changed and the data was recoded. The final interrater reliability for the dual-coded verbalizations was 0.82, which demonstrates significant to "near perfect" agreement in all categories (Table 2). Following standard practice, the remainder of the verbalizations were coded by the researcher (Trickett & Trafton, 2007).

### Computing State Transitions

The state transitions from the two participants' data were computed to determine how the reverse engineers made sense of the programs. Transitions between the states indicated movement through the problem-solving process

State	Category	Cohen's Kappa
<b>a</b>	Make goal representation	0.93
<b>b</b>	Plan approach	0.82
<b>c</b>	Carry out plan	0.78
<b>d</b>	Sense information	0.72
<b>e</b>	Interpret information	0.75
<b>f</b>	Update knowledge	0.81
<b>g</b>	Create hypothesis	0.92
	Average agreement	0.82

Table 2: Interrater Reliability of Coding Scheme (173 segments)

As described in Bakeman and Gottman (1997), matrices of state transition probabilities were computed to determine the process used in the task. For  $m$  states  $S_j$  and  $S_k$ , and  $n$  seg-

ments  $i$ , the total transitions between each state  $S_j$  and state  $S_k$  are computed as:

$$Tr(S_j, S_k) = \sum_{i=1}^n (S_{i,j} \times S_{i+1,k}) : S \in (0, 1) \quad (1)$$

The total transitions departing a state  $S_j$  are computed as:

$$Tr(S_j, out) = \sum_{k=1}^m Tr(S_j, S_k) \quad (2)$$

The total transitions entering a state  $S_k$  are computed as:

$$Tr(in, S_k) = \sum_{j=1}^m Tr(S_j, S_k) \quad (3)$$

The overall transition probabilities for state  $S_j$  to  $S_k$  are computed as:

$$P(Tr(S_j, S_k)) = \frac{1}{2} \left( \frac{Tr(S_j, S_k)}{Tr(S_j, out)} + \frac{Tr(S_j, S_k)}{Tr(in, S_k)} \right) \quad (4)$$

Using these equations to compute the state transitions, the state transition probabilities for the two participants are shown in Table 3 and Table 4.

	a	b	c	d	e	f	g
a	0.17	0.24	0.10	0.10	0.15	0.00	0.04
b	0.14	0.20	0.21	0.21	0.03	0.00	0.12
c	0.10	0.13	0.05	0.33	0.09	0.10	0.00
d	0.10	0.08	0.12	0.37	0.37	0.10	0.14
e	0.00	0.11	0.25	0.22	0.25	0.28	0.18
f	0.05	0.00	0.00	0.10	0.10	0.21	0.29
g	0.23	0.15	0.07	0.10	0.17	0.07	0.38

Table 3: Transition Probability Matrix (Participant C)

	a	b	c	d	e	f	g
a	0.21	0.26	0.22	0.15	0.14	0.00	0.04
b	0.18	0.19	0.26	0.18	0.09	0.00	0.11
c	0.08	0.12	0.07	0.22	0.11	0.10	0.13
d	0.08	0.21	0.09	0.45	0.28	0.18	0.18
e	0.18	0.06	0.08	0.22	0.24	0.20	0.03
f	0.13	0.03	0.07	0.12	0.10	0.31	0.16
g	0.25	0.07	0.04	0.15	0.03	0.08	0.10

Table 4: Transition Probability Matrix (Participant D)

The mean transition probabilities were computed as  $1/N \sum_i P(Tr(S_j, S_k))$  for  $N$  participants. The mean transition probability was  $\mu = 0.14$  and the standard deviation was  $\sigma = 0.09$ . The threshold for significance was set at  $\mu + \sigma = 0.23$ . The significant transitions at the threshold  $P(Tr) \geq 0.23$  are shown in Figure 1.

Because only two participants' verbalizations were coded, inferences cannot be made about the how the processes from these two samples apply to the broader population of reverse

engineers or the broader sensemaking process. Nevertheless, previous studies have used observations and verbal data from small samples during exploratory research as way to generate hypotheses which are to be verified with further investigation and more participants (Newell & Simon, 1972; Trickett & Trafton, 2007). The verbal protocols from the two participants and the observed problem-solving processes from all four participants are useful to provide a framework for understanding how reverse engineers make sense of executable programs.

## Discussion

Figure 1 shows a process of how the sensemaking behaviors were used by reverse engineers attempting to solve the Angler task. When the participants were working on problems in the task, they continually moved through a loop of activities, which included the establishment of a goal representation, a plan to achieve the goal, carrying out the actions of the plan, sensing information from the task environment, interpreting the information, potentially updating knowledge if the information was relevant, and developing hypotheses based on the new knowledge. The sensemaking loop in Figure 1 shows this cycle as a Markov model populated with the probabilities that each state transition would occur.

Figure 1: Sensemaking Processes from the Reverse Engineering Task

While progressing through this process, the participants gathered information to help them construct and refine their mental models of the Angler program. As the participants worked on the problem, they gained information about components such as functions, the program's execution paths, data in the program, and sequences of instructions. They were then able to relate these elements to items in the task environment.

## Plans, Goals, and Actions

Once the participants had verbalized a goal, this often was immediately followed with the development of a partially-constructed plan of actions which would enable the attainment of the goal. If the goal was to gather information from the task environment, the plan involved actions which the person could use to help gather the required information. Likewise if the goal was to configure the program or the reverse engineering tools in a particular way, then the plan involved sequences of actions which led the person to be able to change elements in the situation.

In some cases, a participant's goal did not directly lend itself to a plan, so the person deliberated over different ideas to construct and evaluate an approach that would generate a usable plan. Sometimes the deliberation was verbalized, and others it was inferred by the presence of long pauses.

Participants appeared to determine the best actions for their situation by thinking through hypothesized behaviors and inferred future states of the program. When participants verbalized plans, their plans involved sets of actions in which some of the actions were sequenced. Sometimes the participants did not order their actions into a sequence until they were already taking some initial actions and detecting conflicts in how those actions would affect the state of the situation.

Other plans the participants expressed included searching information from the reverse engineering tool about text strings, debugging the program to see how the program's memory stack changes, labeling a function so it can be identified later, inserting a breakpoint after the initialization routine to "catch" the program, and tracing data as it flows through a function during simulated program execution.

## Information Processing and Interpretation

Participants processed information by actively seeking it out and by passively noticing information during the performance of some other action. When participants passively sensed the information, they executed the Angler program to gather information about its behaviors or looked through the disassembled code to gather clues that might be useful.

When participants actively sought out information, they set a goal for the information they were interested in obtaining, made a plan to acquire that information, and followed the plan by carrying out actions in the task environment. In one example, a participant wrote down the addresses of system calls and used the search features of the debugger to find each of the calls.

Participants actively sought out information about the program's behavior by isolating phenomena. To do this, participants used the debugger to move the program's execution past a system call (which performs some action for the program), and then looked through the current register values and disassembled code in the debugger to determine what had changed in the state of the program.

In either active or passive information processing, the participants seemed to perform some initial processing to deter-

mine whether the information was relevant to one of their goals, and consequently ignored or attended to the information. If participants deemed the information as relevant, they interpreted it to connect it to concepts they already understood. If the information element and its connected concept provided the person with a new perspective or more insight that was relevant to one of their goals, the person verbalized a phrase indicating they had updated their knowledge. These phrases were typically summarized or distilled statements that captured the essence of how the different concepts were related.

During coding discussions, the second coder characterized this process as when the person "compiled" their information in an analogous manner to how a compiler converts a program's source code into executable code.

## Mental Models and Hypotheses

Once participants had added new summarized knowledge to their mental model of a program, they often came up with a hypothesis directly afterward. Participants appeared to generate hypotheses in the task after deducing the logical conclusions of new knowledge they had acquired.

Hypotheses and assumptions were generated mainly after participants sensed and interpreted information and updated their knowledge with the implications of this information. The participants' hypotheses took the form of verifiable statements such as: "it looks like `GetDlgItem` creates a handle to some part of the dialog that's open." In this case, the participant started a subsequent loop through the sense-making process with the goal of verifying whether or not the `GetDlgItem` function creates such a Window handle.

The hypotheses that resulted from this process were typically used to generate a new goal, such as to seek out information from the environment to confirm or refute a fact or to investigate another line of investigation about how the program works. However, when participants did not progress through the process to the development of a hypothesis, they were not able to generate information-seeking goals and got "stuck" in the task. In these cases, participants reverted to exploring instructions or behaviors of the code, since they did not have specific hypotheses about the Angler program to investigate.

## Conclusions

A process of sensemaking in reverse engineering was described and characterized through observations and analysis of verbal protocols from participants reverse engineering programs from assembly language representations. Verbal protocols were analyzed to extract state transition patterns from two reverse engineers' performance, and from that data a process of sensemaking was elicited and the steps of that process were described in a theory of how people make sense of executable programs. Participants were observed forming goals, creating plans to achieve their goals, and carrying out plans. Participants also sensed information from the task environment, interpreted the information, updated their mental

model with the information, and generated hypotheses from that integration which led to new goals.

This research represents a necessary step toward increasing the autonomy of reverse engineering tools, and can be used to determine a general theory of sensemaking that can improve the ways in which people interact with other complex systems. The work is limited in that it only involved observations of four participants and collection of verbal protocols from two participants, and its generality is potentially limited by the nature of the task; nevertheless the results provide insight which can be used to develop a more general computational theory of sensemaking through future empirical study.

Future work is needed to determine the generality of how people work through this process in similar information-processing tasks. Future research is also needed in determining how these processes can be realized as models within established computational cognitive architectures. Finally, work is needed in employing these findings to improve humans' interactions with complex systems such as reverse engineering tools.

## Abstract

Like language, the human capacity to create music is one of the most salient and unique markers that differentiates humans from other species (Cross, 2005). In the following study, the authors show that people's ability to perceive emotions in infants' vocalizations (e.g., cooing and babbling) is linked to the ability to perceive timbres of musical instruments. In one experiment, 180 "synthetic baby sounds" were created by rearranging spectral frequencies of cooing, babbling, crying, and laughing made by 6 to 9-month-old infants. Undergraduate participants (N=145) listened to each sound one at a time and rated the emotional quality of the "synthetic baby sounds." The results of the experiment showed that five acoustic components of musical timbre (e.g., *roll off*, *mel-frequency cepstral coefficient*, *attack time* and *attack slope*) could account for nearly 50% of the variation of the emotion ratings made by undergraduate students. The results suggest that the same mental processes are probably applied for the perception of musical timbres and that of infants' prelinguistic vocalization.

**Keywords:** Emotion; Language; Music

## Introduction

Infants use a variety of vocal sounds, such as cooing, babbling, crying, and laughing, to express their emotions. Infants' prelinguistic vocal communications are highly affective in the sense that they evoke specific emotions—happiness, frustration, anger, hunger, and/or joy—without conveying concrete ideas. In this sense, infants' vocal communication parallels music. Music is highly affective; yet it is conceptually limited (Cross, 2005; Ross, 2009).

The interaction between music and language has attracted much attention recently (Chen-Haffteck, 2011; Cross, 2001; Masataka, 2007). However, despite their similarities, little attention has been paid to the relationship between music and prelinguistic vocalizations (Chen-Haffteck, 2011; Cross, 2001; He, Hotson, & Trainor, 2007; Masataka, 2007). If music and language are highly related, what is the relationship between infants' vocal communications such as babbling, and music?

In the study described below, we analyze acoustic cues of infants' vocalization and demonstrate that emotions created by prelinguistic vocalization can be explained to a large extent by the acoustic cues of sound that differentiate timbres of musical instruments, potentially implicating that the same mental processes are applied for the perception of musical timbres and that of infants' vocalizations.

The paper is organized as follows: we review related work examining the link between prelinguistic vocalization

and music followed by an overview of the experiment. After discussing our timbre extraction and sound creation method, we introduce one experiment that investigates the connection between music and prelinguistic communication.

## Related Work

Infants begin life with the ability to make different sounds—first cooing and crying, then babbling. Next they form one word, and then two, followed by full sentences and speech. In the first ten months, infants progress from simple sounds that are not expressed in the phonetic alphabet, to babbling, which is an important step in infants learning how to speak (Gros-Louis, West, Goldstein, & King, 2006; Oller, 2000).

Musical instruments and infants' vocalizations both elicit emotional responses, while conveying little information on what the sender is trying to express. Music can have a very powerful effect on its listeners, as we all have a piece of music that will bring back emotions. Music can convey at least three universal emotions, happiness, sadness and fear (Fritz et al., 2009). These emotions are similar to the emotions expressed by infants with their limited sounds (Dessureau, Kurowski, & Thompson, 1998; Zeifman, 2001; Zeskind & Marshall, 1998). Both infants and music convey meaning without the use of words. Infants rely on their voices and non-verbal/non-word sounds to communicate and it is these sounds that inform the listener of how important and of what type of danger the infant is facing, such as being too cold, hungry or of being left alone (Dessureau et al., 1998; Zeifman 2001; Zeskind & Marshall, 1998).

Across cultures, songs sung while playing with babies are fast, high in pitch, and contain exaggerated rhythmic accents, whereas lullabies are lower, slower and softer. Infants will use cues in both music and language to learn the rules of a culture. Motherese, a form of speech used by adults in interacting with infants, often consists of singing to infants using a musical, sing-song voice, that mimics babies' cooing by using a higher pitch. An infant's caregiver will use higher pitch when speaking to an infant, as it helps the infant learn and also draws their attention (Fernald 1989).

In summary, research shows that there is a close link between infants' vocal communication and music. This link is demonstrated through the babbling and cooing sounds used by infants' to communicate, and also by mothers' use of motherese to assist infant's learning of language in a sing-song manner. Infants are able to use the same cues

from both music and language to facilitate learning in both domains. Given these close connections, it is likely that the same mental processes are involved for the perception of instrumental sounds and the perception of infants' vocalizations. The beginning stages of this idea are investigated in one experiment by examining the emotion perception of synthetic baby sounds.

## Overview of the Study

In the Emotion Rating Experiment described below, we tested the general hypothesis that the same mental process is involved for the perception of infants' vocalization and that of timbres of musical instruments. More specifically, we hypothesize that the acoustic components of timbre will be significant predictors of emotion. If this is true, then there should be a plausible link between musical timbre and prelinguistic vocal timbre, also indicating a link for mental processing in the two domains. We employed an audio synthesizer program and created 180 different "synthetic baby sounds" by combining spectral frequencies of real baby sounds. In the experiment, our undergraduate participants ( $N=145$ ) listened to the "synthetic baby sounds" one at a time and rated affective qualities of these sounds. Later, we extracted "musical timbres" from the synthetic baby sounds, and examined the extent to which the emotional ratings made by our undergraduate students were accounted for by the timbres of the synthetic baby sounds.

Timbre is an important perceptual feature of both music and speech. Timbre is defined as the "acoustic property that distinguishes two sounds"—for example, those of the flute and the piano—"of identical pitch, duration, and intensity" (Hailstone et al., 2009; McAdams & Cunible, 1992). The classic definition of timbre states that two different timbres result from the sound of different amplitudes (of harmonic components) of a complex tone in a steady state" (Helmholtz, 1885). Timbre is a sound quality that encompasses the aspect of a sound that is used to distinguish it from other sounds of the same pitch, duration, and loudness.

The timbre properties of *attack time*, *attack slope*, *zero-cross*, *roll off*, *brightness*, *mel-frequency cepstral coefficients*, *roughness*, and *irregularity* are well known in music perception research as the main acoustic cues that correlate with the perception of timbre of musical instruments (Hailstone et al., 2009). Our assumption is that if infants' vocal sounds are perceived in the same manner as the timbres of musical instruments are perceived, these same acoustic properties can account for the perception of emotions in infants' vocalization.

Using principal components analysis (PCA), we summarized emotional ratings made by our undergraduate participants into two principal dimensions, to reduce the data, and applied a stepwise regression to evaluate the extent to which our predictors—the acoustic timbre components—accounted for emotion ratings for synthesized baby sounds.

Below, we briefly describe our timbre extraction method and the method of creating "synthetic baby sounds."

## Timbre Extraction

This section describes acoustic cues relating to timbre in detail, as well as the computational procedure of extracting these cues. The purpose of using these acoustic cues is to act as predictors in regression analyses that can explain perceived emotions of our "synthetic baby sounds." The acoustic cues were chosen based on their use in musical timbre (see Lartillot & Toivainen, 2007).

Eight acoustic properties of timbre: attack time, attack slope, zero-cross, roll off, brightness, mel-frequency cepstral coefficients, roughness, and irregularity were extracted from all sound stimuli using MIRToolbox in Matlab (Lartillot, Toivainen, & Eerola, 2008). These acoustic properties are known to contribute to the perception of timbre in music independently of melody and other musical cues (Hailstone et al., 2009). The acoustic features were extracted from synthesized sounds rated in the Emotion Rating Experiment.

*Attack time* is the time in seconds it takes for a sound to travel from amplitude of zero, to the maximum amplitude of a given sound signal, or more simply the temporal duration. Some features of timbre such as attack time contribute to the perception of emotion in music (Gabrielsson & Juslin, 1996; Juslin, 2000; Loughran, Walker, O'Neill & O'Farrell, 2001); which suggests that features of timbre can at least in part determine the emotional content of music (Hailstone et al., 2009).

**Figure 1.** Attack times of an audio file. *A* through *d* are separate attack times; indicated by the distance from the black line, to the red line.

Attack time is computed using the equation of a line,  $y = mx + b$ , it is part of a sounds amplitude envelope where  $m$  is the slope of the line and  $b$  is the point where the line crosses the vertical axis ( $t=0$ ). Figure 1 gives an illustration of attack time. The horizontal segments below the x-axis indicate the time it takes in seconds to achieve the maximum peak of each frame for which the attack time was calculated.

*Attack slope* is the attack phase of the amplitude envelope of a sound, also interpreted as the average slope leading to the attack time. This can also be calculated using the equation of a line  $y = mx + b$ , where  $m$  is the slope of the line and  $b$  is the point where the line crosses the vertical axis ( $t=0$ ), see Figure 2. The red line in Figure 2 indicates the slope of the attack.

**Figure 2.** Attack slope of a audio file. The red arrow indicates the duration (attack time) for which the attack slope is calculated.

$$Z_t = \frac{1}{2} \sum_{n=1}^N |sign(x[n]) - sign(s[n-1])|$$

*Roll off* is the amount of high frequencies in a signal, which is specified by a cut-off point. The roll-off frequency is defined as the frequency where response is reduced by -3 dB. This is calculated using the following equation where  $M_t$  is the magnitude of the Fourier transform at frame  $t$  and frequency bin  $n$ .  $R_t$  is the cutoff frequency, see Figure 3.

$$\sum_{n=1}^{R_t} M_t[n] = 0.85 * \sum_{n=1}^{R_t} M_t[n]$$

*Brightness* is the amount of energy above a specified frequency, typically set at 1500 Hz – this is related to spectral centroid. The term brightness is also used in discussions of sound timbres, in a rough analogy with visual brightness. Timbre researchers consider brightness to be one of the strongest perceptual distinctions between sounds. Acoustically it is an indication of the amount of high-frequency content in a sound, and uses a measure such as the spectral centroid, see Figure 3.

**Figure 3.** Brightness of an audio file. To the right of the red dashed line is the amount of energy above 1500 Hz, or the brightness of the sound.

peaks, dissonant sounds have irregularly placed spectral peaks as compared to consonant sounds with evenly spaced spectral peaks.

Formally, roughness is calculated using the following equation where  $a_j$  and  $a_k$  are the amplitudes of the

*Zero-cross* is the number of times a sound signal crosses the x-axis, this accounts for noisiness in a signal and is calculated using the following equation where sign is 1 for positive arguments and 0 for negative arguments.  $X[n]$  is the time domain signal for frame  $t$ .

components, and  $g(f_{cb})$  is a ‘standard curve.’ This was first proposed by (Plomp & Levelt, 1965).

$$\rho = \frac{\sum_{j,k}^n a_j \cdot a_k \cdot g(f_{cb})}{\sum_j^n a_j^2}$$

Following extraction of the value for roughness from the sound stimuli, principal components analysis was used to reduce the dimensions of the roughness data.

*Mel-frequency Cepstral Coefficients* (mfcc) represent the power spectrum of a sound. This power spectrum is based on a linear transformation from actual frequency to the Mel-scale of frequency. The Mel scale is based on a mapping between actual frequency and perceived pitch as the human auditory system does not perceive pitch in a linear manner. Mel-frequency cepstral coefficients are the dominant features used in speech recognition as well as some music modeling (Logan, 2001). Frequencies in the Mel scale are equally spaced, and approximate the human auditory system more closely than a linearly spaced frequency bands used in a normal cepstrum. Due to large data output, prior to analyses mfcc data were reduced using principal components analyses to create a workable set of data. A cutoff criterion of 80% was used to represent the variability in the original mfcc data. Figure 4 shows the numerical Mel-frequency cepstral coefficient rank values for the 13 mfcc components returned. Thirteen components are returned due to the concentration of the signal information in only a few low-frequency components.

**Figure 4.** Mel-frequency cepstral coefficients (mfcc) of an audio file. This figure shows the acoustic component mfcc. Each bar represents the numerical (rank coefficient) value computed for the thirteen components returned.

*Irregularity* of a spectrum is the degree of variation between peaks of a spectrum (Lartillot et al., 2008). This is calculated using the following equation where irregularity is the sum of the square of the difference in amplitude between adjoining partials in a sound.

$$\frac{\sum_{k=1}^N (a_k - a_{k+1})^2}{\sum_{k=1}^N a_k^2}$$

## Creating Synthetic Baby Sounds

We created 180 short, 2 second, synthetic baby sounds from ten real infant sounds: five males and five females ranging from ages 6 to 9 months making screaming, laughing, crying, cooing and babbling sounds. These sounds were chosen to create novel stimuli emulating human prelinguistic sounds. Among these sounds, four (one screaming boy, one crying boy, one screaming girl and one crying girl) were audio-recorded directly from two volunteer infants in Nacogdoches, Texas using an Olympic Digital Voice WS-400S recorder. The sounds of babbling and cooing boys and girls were taken from audio-files downloaded from a sound effects website (<http://www.freesounds.org>), and the sounds of laughing boy and girl were taken from files downloaded from YouTube (<http://www.youtube.com>).

These infant sounds were decomposed by four laboratory assistants into amplitude and spectral frequency components by applying fast Fourier transform using a sound editing software program (SPEAR, Klingbeil, 2005). Arbitrarily chosen spectral frequencies of one sound (e.g., a babbling sound of a boy) were mixed with arbitrarily chosen spectral frequencies of another sound (e.g., cooing girl) and then modified by means of amplitude, or shifting frequencies, to convey one of the basic emotions, happy, sad, anger, or fear (Ekman, 2002).

For each sound pair, four sounds were created to sound happy, sad, angry, and fearful. In this manner, each sound pair (45 pairs in total, all possible pairs of the 10 real sounds), was used to create four affective sounds, which was decided subjectively by the laboratory assistants. The total 180 sound stimuli were normalized and white noise was taken out prior to and after creation of each sound stimulus.

## Emotion Rating Experiment

The goal of the experiment was to obtain empirical ratings of college students examining the emotional quality of the synthetic baby sounds that we created. To analyze the link between emotion ratings and acoustic cues, a stepwise regression analysis was employed.

**Participants.** A total of 145 undergraduate students (73 males, 73 females) participated in this experiment for course credit. Participants were randomly assigned to one of two groups that listened to 90 or 89 sounds of 179 total sounds. Stimuli were randomly assigned to one of two groups; no participants were in both groups.

**Materials.** Stimuli were taken from the 180 synthetic baby sounds that were created from a group of a total of ten recorded real infants' sounds (see the "Creating Synthetic Baby Sounds" section for the details of the sound creation).

**Procedure.** Participants were presented with 90/89 sounds using customized Visual Basic software through JVC Flats stereo headphones. Each stimulus's maximum volume was

adjusted and normalized. Participants were instructed to listen to sound stimuli, and rate each sound on five emotion categories, happy, sad, angry, fearful, and disgusting (Ekman, 1992; Johnson-Laird & Oatley, 1989). Each scale ranged from 1 to 7—1 being *strongly disagree* (the degree to which the stimuli, sounded like one of the five emotions), and 7 being *strongly agree*. Stimuli were presented in a random order.

## Results

This section starts with descriptive statistics of emotion ratings followed by the results from stepwise regression analysis, which examined the extent to which emotion ratings given to the synthetic baby sounds were explained by their timbre properties. For the regression analysis, average emotion scores were calculated for individual synthetic sounds by collapsing over individual participants, yielding a 179 sounds x 5 emotion dimension matrix. By applying principal component analysis (PCA), this matrix was summarized in a 179 x 2 matrix with the two columns corresponding to two principal components identified by the PCA procedure. The first two orthogonal components explained 88.1% and 7.1% of the variance of the emotion rating data, respectively.

*Descriptive Statistics.* Behavioral data, Figure 5, shows overall observations for each emotion from the emotion rating data. From the whiskers of the box plot for the emotion data, it is apparent that there is variation within the data. The highest rating for the emotion data did not exceed a value of 6, on the scale of 1-7. The median of the ratings for emotion varied between approximately 2.5 and 4.75 within the emotion rating data.

For all 179 sounds rated, most were rated as angry, indicated by the median of the data for anger. The sounds were rated least like the emotion happy, as the median for this emotion was the lowest for all sounds rated on the five emotions.

**Figure 5.** Box plot of observations for emotion ratings. Each box in the figure indicates one emotion rated by participants. The median is indicated by the red line in the center of each box, and the edges indicate the 25<sup>th</sup> and 75<sup>th</sup> percentiles, the whiskers of each plot indicate the extreme data points, and outliers are plotted outside of the whiskers.

**Regression analysis.** A step-wise regression analysis was used to analyze the collected rating data and timbre components, to determine which component could best explain the emotion rating data. Seventeen total predictors were used in the stepwise regression to analyze the emotion ratings made by participants. These were *attack time*, *attack slope*, *zero-cross*, *roll off*, *brightness*, *mel-frequency cepstral coefficients 1-6*, *roughness 1-4*, and *irregularity*. Due to large data output, mfcc data were reduced using principal components analyses to create a workable set of data. There were originally 13 numerical Mel-frequency cepstral coefficient rank values returned. These 13 rank values were reduced to 6, accounting for 78% of the total mfcc data. Roughness was also reduced in the same way using PCA, from 79 components to four components that described 80% of the original roughness data. These predictors were used to analyze the emotion ratings made by participants.

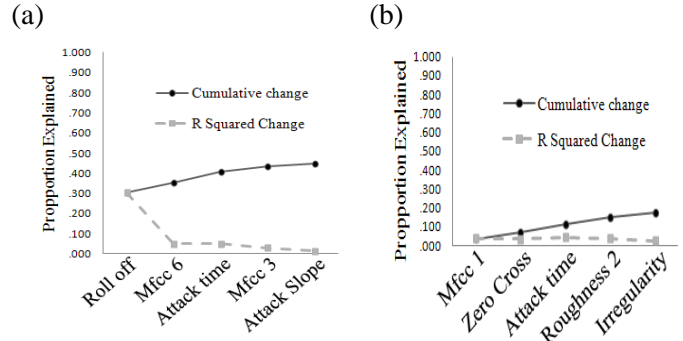

The results of the regression for the first principal component (PCA1) indicated four acoustic features significantly predicted emotion ratings; roll off ( $\beta = -.386$ ,  $p < .001$ ), mfcc 6 ( $\beta = .218$ ,  $p < .001$ ), attack time ( $\beta = .248$ ,  $p < .001$ ), and mfcc 3 ( $\beta = -.202$ ,  $p < .002$ ), and attack slope ( $\beta = .034$ ,  $p < .034$ ), see Table 1 for percent explained by principal component 1.

**Table 1:** Significant acoustic components for emotion PCA 1 and PCA 2

Predictors	PCA 1	PCA 2
% explained	88%	7.1%
Attack time	.23***	.31***
Attack slope	.12*	
Irregularity		-.16*
Mfcc 1		-.24**
Mfcc 3	-.19**	
Mfcc 6	.22***	
Roughness		.21**
Zero-cross		.25**
Roll off	-.41***	

\*  $p < .05$ , \*\*  $p < .01$ , and \*\*\*  $p < .001$ .

The second principal component (PCA 2) showed that five acoustic features significantly predicted emotion ratings; mfcc 1 ( $\beta = -.244$ ,  $p < .001$ ), zero cross ( $\beta = .250$ ,  $p < .002$ ), attack time ( $\beta = .305$ ,  $p < .000$ ), roughness 2 ( $\beta = .208$ ,  $p < .006$ ), and irregularity ( $\beta = -.159$ ,  $p < .024$ ), (Table 1).

**Figure 6.** R-squared. Emotion judgment principal components 1 (PCA 1) and 2 (PCA 2). This figure shows the proportion of R-squared contributed for each addition of a predictor to the model for principal component I and II from the emotion judgments.

Figure 6 shows the proportion of R-squared contributed for each addition of a predictor to the model for PCA 1 – (a) and PCA 2 – (b). Looking at the values of R-squared, it is apparent that roll-off was best able to describe the emotion ratings, accounting for 30% of the emotion ratings for PCA 1. The second principal component does show several significant acoustic cues that predict emotion; however, none are as strong as in the first principal component.

## General Discussion

Music and language are perhaps two of the most cognitively complex and emotionally expressive sounds invented by humans. Recently, the evolutionary origins of music and language have attracted much attention in researchers of a broad spectrum (Cross, 2001, 2005; Hauser et al., 2002; Kirby, 2007). The present study, examining the relationship between infants' vocalizations—cooing, babbling, crying and screaming—and the perception of musical timbres, suggests that the link between music and language can go even further back to the prelinguistic level of development.

Our Emotion Rating Experiment indicates that nearly 50% of emotions created by synthetically produced infant sounds can be explained by a small number of acoustic cues pertaining to musical timbres. Among those, *roll off*, which quantifies the amount of high frequencies in a signal, turned out to be the most important cue. The second most important property, *mfcc* (*mel-frequency cepstral coefficients*), corresponds to perceived pitch in the human auditory system, and are the dominant features used in speech recognition and music modeling (Logan, 2001). Given these findings, we conjecture that high-frequency sounds are probably taken as the robust cue of emotion attribution, and more fine-grained distinctions of emotion are made by extracting speech-related cues.

The ability to discriminate sounds is said to be present even in primitive animals such as carp (Chase, 2001), implying that this ability evolved early in history. Some animals have sounds and or calls that can convey the emotions of finding something of interest or of fear (Hauser,

Chomsky, & Fitch, 2002). Such abilities were probably present even before music was fully developed in the current form.

## Acknowledgments

We would like to thank Na Yung Yu and Ricardo Gutierrez-Osuna for their valuable comments. The first two authors, MB and CB, contributed to this study an equal amount and the order of their authorship was determined by a coin toss.

## Abstract

Some profoundly deaf individuals without conventional linguistic input develop gestures, called “homesign,” to communicate. We examined homesign systems (HSs) used by four deaf Nicaraguan adults (ages 15-27), and evaluated whether homesigners’ mothers are potential sources for these systems. Study One measured mothers’ comprehension of descriptions of events (e.g., “A man taps a woman”) produced in homesign and spoken Spanish. Mothers comprehended spoken Spanish descriptions (produced by a hearing child) better than homesign descriptions, suggesting a greater degree of sharedness for spoken Spanish. Study Two compared the homesign comprehension of each homesigner’s mother to that of a native user of American Sign Language (ASL). ASL Signers performed better than mothers, confirming that homesign productions contain comprehensible information, to which mothers are not fully sensitive. Taken together, these results suggest that mothers are not the source of their deaf child’s HS, and add to evidence that HSs are more like language than like gesture.

Keywords: Language acquisition; homesign; deafness; language creation; gesture; sign language; Nicaragua

## Introduction

The language sciences have long grappled with the question of what drives language acquisition. At the heart of this debate is the question: What are the contributions of language input versus the contributions of the learner? It can be difficult to disentangle these two factors in typical language acquisition situations, as such situations do not offer the opportunity to experimentally manipulate the presence of linguistic input.

Studying spontaneously occurring cases of degraded linguistic input can help discern human predispositions for language learning. Previous research has shown that children can surpass their linguistic input (e.g., Singleton & Newport, 2004, Senghas & Coppola, 2001). In addition, some deaf children born into hearing families have no access to signed or spoken linguistic input. While their parents primarily speak, and do not use gesture with them, these children nevertheless use a system of manual gestures, called “homesign,” to communicate. Homesign has many, but not all, of the features of fully developed languages (e.g., a stable lexicon, basic syntax and morphology, Goldin-Meadow,

2003). The gestures and gesture combinations produced by the mothers of child homesigners lack the morphological and syntactic structure observed in the children’s productions (e.g., Goldin-Meadow & Mylander 1984, 1990; Goldin-Meadow et al. 1994, Goldin-Meadow 2003). While mothers’ gestures may serve as an initial foundation for their deaf child’s homesign system, children surpass whatever “input” they might receive from their mother. These mothers tended not to engage in gestural communication with the child homesigners, and such child homesigns are used for a relatively short time, until the children reach school age. It is possible that, given increased gestural communication and a lengthier period of use, mothers might play a greater role in the development of homesign systems.

This research examines homesign systems developed *with communication partners who engage homesigners using gesture*, unlike the young deaf children studied by Goldin-Meadow and her colleagues. In Nicaragua, we can locate rare cases in which deaf individuals develop and use homesign systems as their primary means of communication for their entire lives. These individuals are not part of the Deaf community that uses the recently emerged Nicaraguan Sign Language (NSL) (Senghas, 1995; Senghas & Coppola, 2001). The homesigners do not learn conventional sign language, and they have not acquired the Spanish spoken around them.

These mature homesign systems display many linguistic features, for instance, the grammatical relation of Subject (Coppola & Newport, 2005), proto-pronouns (Coppola & Senghas, 2010), use of space, and devices for establishing reference (Coppola & So, 2005). Given the accumulated interactions over time between a homesigner and his or her family members, and the more abstract, language-like devices that homesigners produce, it is possible that these family members may have contributed more to the development of the homesign system than the mothers of the homesigners Goldin-Meadow & colleagues observed. One step in determining the source of the linguistic features we observe in mature homesign is evaluating family members’ potential contributions.

## Study One

We begin by evaluating homesigners’ mothers as potential sources, because they each have significant gestural

communication experience with their deaf child, and because this type of transmission (mother to child) parallels that of typical language acquisition situations. One approach would be to compare Mothers' and homesigners' gesture productions. However, comparing their productions now does not allow us to assess Mothers' role in the *development* of their child's homesign system, especially in cases where Mothers' and homesigners' productions are similar. Looking instead at how well Mothers comprehend homesign productions can address this. We reason that, if mothers served as models for homesigners' abstract linguistic devices, they should comprehend their child's homesign productions.

### Study One: Predictions

If mothers invent and pass down homesign systems to their deaf children in the same way that they serve as models for the spoken Spanish acquired by their hearing children, we would expect mothers to comprehend descriptions of events produced by their deaf child at least as well as they comprehend spoken Spanish descriptions of the same events produced by one of their hearing children.

### Participants

**Producers:** Four deaf adult Nicaraguan homesigners (1 female), ages 16-26 *at the time of production*, produced the descriptions used as stimuli for this task. All four homesigners were deaf, with *very* minimal knowledge of spoken or written Spanish. Some could produce and/or comprehend a limited number of common spoken Spanish words, such as "mamá," "papá," and "agua" (water). All find writing their names effortful. They had had little to no formal education, had not acquired Nicaraguan Sign Language (NSL), and *do not interact with each other*.

Four hearing siblings of homesigners (1 female), ages 17-43. The siblings were native monolingual Spanish speakers, had an average of 8.5 years of education (range 0-14), and had not acquired NSL.

**Receivers:** Four hearing mothers (henceforth "Mothers") of homesigners, ages 45-60. The mothers were native monolingual Spanish speakers, had an average of 2.25 years of education, and had not acquired NSL.

### Materials

The stimuli were **descriptions** of 83 simple videotaped events involving live actors and real, everyday objects. The events had one or two participants; the two-participant events included all combinations of animate and inanimate. The two animate participants in the events were the same man and woman throughout, and the inanimate participants were objects such as "cup," "banana," and "flower." Example events include "A man kisses a woman" and "A sheet of paper falls".

The comprehension array used in this task included four pictures. One picture always depicted the target event. For one-participant events, the non-target foil pictures could

depict: a) the same participant/object involved in a different action *or* state ("Other Action"); b) a different participant/object involved in the same action/state ("Other Entity"); or c) a different participant/object involved in a different action/state ("Unrelated"). For two-participant events, the non-target foil pictures could depict: a) the same participants involved in reversed thematic roles ("Reverse"); b) one participant involved in the same action with a different entity ("Other Entity"); c) the same two participants involved in a different action ("Other Action"); or d) one participant involved in an unrelated action (either with or without a second entity; "Unrelated"). Because these materials were originally designed as an elicited production task (Coppola & Newport, 2005, which also lists the stimulus items), the comprehension arrays are not standardized across all items, and contain different combinations of foil types.

**Homesign descriptions** were produced by the homesigners described above. We videotaped these descriptions, then clipped and compiled them into QuickTime video files.

**Spoken Spanish descriptions** of these same events were produced by a hearing sibling of each homesigner, in the presence of their Mothers.

### Procedure

Each Mother watched the videotaped homesign descriptions (83 total) produced by her own deaf child. The task is divided into two subtests, each beginning with 3 practice items, to ensure that mothers understood how to do the task<sup>1</sup>. Mothers watched each description as many times as they wanted, then selected, from an array of four pictures, the picture that best matched that description. One picture was a still from the target (correct) event, and the others were distracters.

Mothers also completed the task using spoken Spanish descriptions of events produced by one of their hearing children in real time. The order of the homesign and spoken Spanish tasks was counterbalanced.

### Results & Discussion

The Mothers comprehended homesign descriptions at rates significantly better than chance (25%; exact binomial test,  $p < 0.001$ ).

However, despite performing above chance, Mothers comprehended spoken Spanish descriptions better than they comprehended homesign descriptions of the same events (For 3 mothers,  $p < 0.05$ , McNemar's Test for Correlated Proportions; fourth mother,  $p = 0.057$ ). This result acts as a built-in control, showing that Mothers are not having trouble with the task itself, but rather with the content of the homesign descriptions.

---

<sup>1</sup> We are confident that mothers understand how to do the task, as all of them have completed it in the past, though typically with live descriptions from their deaf child.

Comparing Receivers' comprehension to different reference levels of performance (e.g., 25%, 33%, 50%) can give us clues as to how much of the descriptions (homesign or spoken Spanish) they understand. For example, in an event like "A man kisses a woman," the picture choices show: a) A man pushing a chair; b) A man sitting; c) A man kissing a woman (the correct choice); and d) A woman kissing a man. One homesigner's description of this event was glossed as MAN WOMAN KISS. If the Receiver understands the gestures for the participants, or even just the action gesture the homesigner produced for this event description, picture choices (a) and (b) could be eliminated. It is also possible for Receivers to narrow their choices based solely on a general, non-linguistic strategy. They might have noticed, for instance, that two of the picture choices contained the same two actors, engaged in the same action (although in different thematic roles), and reasoned that the correct choice must be one of those two pictures.

The performance of three of the four Mothers does *not* differ significantly from 50%. Regardless of the strategy they might be using to complete the task, Mothers' performance indicates that they do not understand enough of the homesign description to reliably select the right picture; however, we may not be able to make claims from these data about exactly what Mothers do understand. In future work, will more carefully control participants' cognitive ability (including use of general strategies to complete tasks such as these), and be designed to isolate which aspects of the homesign descriptions mothers do understand (see the Results & Discussion section of Study Two for a brief attempt at the latter with these data).

Mothers' poorer comprehension of homesign versus spoken Spanish descriptions suggests that Mothers play a different role in the communicative development of their hearing and deaf children: they share, and are likely a main source of spoken Spanish input for their hearing children, but do not share or transmit homesign to their deaf children. This finding accords with previous studies of the structure in child homesign, which is also not attributable to the deaf children's mothers (Goldin-Meadow & Mylander, 1984).

## Study Two

Each mother has had between 20 and 30 years of experience communicating with her deaf child; why should their comprehension levels be so low? One could argue that the homesign descriptions themselves are the cause; perhaps Mothers fully understood the descriptions, but the descriptions themselves did not contain sufficient information for mothers to succeed at the task. It also might be the case that factors such as age of exposure to a visual communication system, and quantity and/or length of time of experience with that system, play a role in comprehension.

### Study Two: Predictions

If ASL Signers comprehend homesign productions at levels equal to or worse than homesigners' Mothers, it might be

the case that those productions do not contain sufficient information to allow *any* Receiver to succeed at the task. If, however, ASL Signers comprehend homesign descriptions better than Mothers, the descriptions do contain enough information to succeed at the task.

## Participants & Methods

Four fluent Deaf users of ASL (3 females), ages 21-66, who did not know the homesigners or their homesign systems, participated in this study. The ASL Signers had all been exposed to ASL before the age of five, used ASL every day, and had an average of 15.25 years of education. We paired each ASL Signer with one homesigner's Mother; that ASL Signer watched the same homesigner's productions as did the Mother, and chose, from the same picture array, the photo that matched each event description.

Unlike the Mothers, at the start of the task the ASL Signers saw the 6 practice items, which all involved the man and/or the woman, to ensure that they had learned the homesigner's lexical items for "Man" and "Woman." As previously mentioned, the man and the woman in the events were always played by the same male and female actor; thus, neither the producers nor receivers in the task ever had to distinguish one man or woman from another. ASL Signers were, as Mothers were, allowed to watch each description as many times as they wanted (they watched most descriptions no more than once). ASL Signers and Mothers thus had roughly equal exposure to these stimuli (although each Mother still had vastly more experience with her deaf child's homesign system than the ASL Signer with whom she was matched).

## Results & Discussion

Like homesigners' Mothers, ASL Signers comprehended homesign descriptions at rates significantly better than chance (25%; exact binomial test,  $p < 0.0001$ ). Furthermore, ASL Signers comprehended the homesign descriptions they viewed better than that homesigner's Mother (For 3 pairs,  $p < 0.01$ , McNemar's Test for Correlated Proportions; fourth pair,  $p = 0.851$ ). Thus, the homesign descriptions *did* contain sufficient information to allow a receiver to successfully complete the task. Mothers did not succeed for some other reason; we explore this further in subsequent analyses.

**Item Type and Error Analyses** In order to better understand which aspects of homesign production drive comprehension (or non-comprehension) by receivers, we examined how features of the items themselves might influence comprehension of homesign descriptions. The events had one or two animate or inanimate participants; all events with two animate participants, that is, "Reversible" events (e.g. "A man kisses a woman"), included a distracter picture that depicted reversed roles for the participants (e.g. "A man kisses a woman").

To show correct comprehension of "Reversible" event descriptions Receivers need to understand how the arguments represented by the lexical items relate to the

verb. That is, they need to understand the structure of these descriptions. Comprehension of “Non-Reversible” event descriptions, in contrast, only necessitates that the Receiver recognize and remember the lexical items produced by the homesigner.

On the Non-Reversible events (collapsing across number of participants,  $n=52$  items), all four ASL Signers performed significantly better than chance (25%; exact binomial test,  $p<0.0001$ ). Mother also performed significantly above chance on this subset of items ( $p<0.01$ ).

Comparing Mothers to ASL Signers, we see the same pattern as for the overall analyses: the same three out of four ASL Signers do significantly better than the Mothers with whom they are paired at comprehending the non-reversible events (For three pairs,  $p<0.001$ , McNemar’s Test for Correlated Proportions; fourth pair,  $p=0.359$ ). This indicates that even when comprehension relies only on recognizing and remembering the lexical items, Mothers did not succeed. This is particularly surprising given that: a) Mothers were allowed to view the descriptions as many times as they wanted; and b) Mothers have had much more practice with homesigners’ lexical items (indeed, with each homesign system in general) than did the ASL Signers (20-30 years interacting with the homesigner and using the homesign system, as opposed to one hour viewing homesign descriptions for the ASL Signers). The Mothers’ apparent lack of comprehension of lexical items does not necessarily indicate that they did not recognize them—they might have difficulty processing the lexical items in real time, even with repeated viewings.

Table 1 presents an analysis of the incorrect foil types chosen for Non-Reversible items (again, collapsing across 1- and 2-Participant items).

Table 1: Errors on Non-Reversible Items  
(Proportion of each foil type chosen)

Participant	Unrelated	Other Entity	Other Action	Total Number of Errors
ASL 1	0.22	0.22	0.56	9
Mother 2	0.31	0.45	0.24	29
ASL 2	0.38	0.38	0.25	8
Mother 2	0.23	0.77	0.00	13
ASL 3	0.33	0.00	0.67	6
Mother 3	0.43	0.30	0.26	23
ASL 4	0.13	0.38	0.50	8
Mother 3	0.32	0.48	0.20	25

Each Mother chose the “Other Entity” foil more often than the ASL signer with whom she was paired. This indicates that Mothers are poorer than ASL Signers at understanding or remembering the homesign gestures produced for the participants in these items.

Comparing Mother-ASL Signer pairs on the Reversible 2-participant events ( $n=16$ ), only 1 ASL signer performed significantly better than the Mother with whom he was paired ( $p<0.05$ , McNemar’s Test for Correlated

Proportions). However, this lack of a difference between Mothers and ASL Signers may be due to the small number of items on which the comparison is based.

If, as discussed in Study One, Receivers understand something about the lexical items the homesigner produces in a description (either for the participants *or* the action in an event), they should be able to narrow their picture choices to two for the Reversible items. Previous work with three of the four homesigners who produced these event descriptions has demonstrated that they reliably place the noun phrase expressing the subject in clause-initial position (Coppola & Newport, 2005). If Receivers are further sensitive to the systematic way homesigners represent argument structure, we would expect to see comprehension of these reversible event descriptions at rates significantly above 50%.

Table 2: Proportion Correct on Reversible Items

Participant	Number Correct	Number of Reversible Items	Difference from 50%, Exact Test, p-value (2-tailed)
ASL1	8	16	0.598
Mother 1	9	16	0.402
ASL 2	11	15	0.059†
Mother 2	11	15	0.059†
ASL 3	15	16	<0.001*
Mother 3	8	16	0.598
ASL 4	11	15	0.059†
Mother 4	5	15	0.941

\*: significant †: marginally significant

Three out of the four ASL signers performed significantly or marginally better than 50% correct on the reversible items, compared with only one of the Mothers (Table 2).

An analysis of the incorrect foil types chosen for Reversible items can be found in Table 3.

Table 3: Errors on Reversible Items  
(Proportion of each foil type chosen)

Participant	Unrelated	Other Entity	Other Action	Reverse	Total Errors
ASL 1	0.13	0	0	0.88	8
Mother 1	0.14	0.14	0	0.71	7
ASL 2	0	0	0	1.00	4
Mother 2	0	0	0	1.00	4
ASL 3	0	0	0	1.00	1
Mother 3	0	0.13	0	0.88	8
ASL 4	0	0	0	1.00	4
Mother 4	0.30	0.10	0	0.60	10

Both Mothers and ASL Signers chose the “Reverse” foil most often when they erred, although Mothers showed slightly more variability than ASL Signers. The fact that Mothers mostly selected the “Reverse” foil means that they were likely narrowing the picture choices for this type of item to just the “Correct” and “Reverse” pictures. As

outlined in the Results & Discussion section of Study One, for most of the Reversible items, it is possible to narrow choices using three strategies: 1) By understanding the gesture produced for the two participants in the event; 2) By understanding the gesture produced for the action in the event; or 3) By using a general test-taking strategy that assesses the similarity of the different foil pictures. The data from the Error Analysis of Non-Reversible items indicate that Mothers do *not* always recognize or remember the gestures produced for the participants in an event, which allows us to eliminate the first candidate strategy. It is likely, therefore, that Mothers are able to narrow their options for the correct picture either via an understanding of the action or event gesture produced by the homesign (which tends to be highly iconic), or via a direct comparison of the picture foils to one another.

The results of the comparison to fifty percent and the Error Analysis for Reversible items indicate that, although ASL Signers' comprehension of homesign descriptions is not error-free, they comprehended enough of both the lexical items and the structure to outperform the homesigners' Mothers. Indeed, the ASL Signers' errors are understandable, since their experience with the homesign systems is so limited.

The success of ASL signers indicates that the homesign descriptions do contain systematic, comprehensible information. Homesigners' Mothers, despite their much greater experience with the individual homesign systems, are apparently not sensitive to the information that ASL Signers are presumably using to succeed in the task.

## General Discussion

Taken together, the results of Studies 1 and 2 suggest that Mothers do not directly transmit homesign systems to their deaf children. Mothers' comprehension of their adult child's homesign system is relatively poor; this lack of understanding apparently persists despite the fact that Mothers report regularly using gesture to communicate since their now-adult offspring were children. These findings do not preclude the possibility that Mothers' gestures served as a foundation for their child's homesign system. However, these data do indicate that Mothers are *not masters* of their adult child's homesign system, which tells us that, at present, homesign is qualitatively different for Mothers than it is for homesigners. This, in turn, suggests that it is homesigners rather than Mothers who drive the development of their homesign systems.

Our failure to find a statistically significant difference between Mothers' and ASL Signers' comprehension of reversible events is likely due to the small number of items of that type. We are currently designing new stimuli that will include greater numbers of these informative events.

Our dataset is obviously limited by the small number of homesigning participants, and the logistical difficulty of working with them. Though we have a small number of Mother-ASL Signer pairs, each participant contributes a relatively large number of data points. A hierarchical linear

model will allow us to better account for sources of variability at the levels of Item (Reversible vs. Non-reversible events); Receiver Type (ASL Signer, Homesigner Sibling, etc.) and Homesigner Family Unit.

Mothers' poor comprehension of their child's homesign systems compared with that of ASL Signers raises several questions: Which factors distinguish Mothers from ASL Signers? Which of these factors drives comprehension (or non-comprehension) of homesign descriptions?

One difference between Mothers and ASL Signers is their length of experience with the homesign system itself; Mothers have significantly greater experience with the homesign system than do ASL Signers. However, given this, we would expect mothers to comprehend homesign production *better* than ASL Signers, which they do not.

Mothers and ASL Signers also differ in their age of exposure to a visual communication system. This factor could explain Mothers' poorer comprehension of homesign. Brentari, Coppola, Mazzoni & Goldin-Meadow (2012) show that the handshapes produced by homesigners pattern more like those of established sign languages than like the gestures produced by hearing individuals in terms of phonological features (specifically, finger complexity in Object and Handling handshapes used in classifier predicates). These comprehension data could provide further evidence that homesign is closer to a linguistic system than to gesture; that is, homesign must be acquired beginning at an early age in order to reach proficiency (Johnson & Newport, 1989; Newport, 1990).

The mother of Homesigner 2, who shows the best comprehension compared to the ASL Signer with whom she is paired, began using homesign with her son at an earlier age than the other mothers in our study (she was 16 years old when he was born). Although well beyond the critical period for language acquisition established by Newport and colleagues, her relative youth might have conferred a crucial advantage in acquiring her deaf child's homesign system.

It might also be the case that ASL Signers' early and significant experience with an established visual-manual language helped them perform better than Mothers in comprehending homesign productions. Perhaps the ASL Signers are drawing on their (implicit) knowledge of how visual languages are structured to understand homesign.

Comparing our two current groups with two additional groups could further distinguish the effects of the age of exposure to a visual communication system, and the type of system (homesign vs. an established language), on homesign comprehension (summarized in Table 4).

First, we can measure the comprehension of homesign by siblings of those homesigners. The siblings of homesigners who are close to them in age likely started using homesign at a young age to communicate with their deaf sibling. Comparing homesigners' siblings to their mothers will tell us whether early exposure to homesign can also drive better comprehension. In addition, comparing the comprehension of homesigners' siblings to that of native ASL Signers will reveal whether the nature of the visual communication

matters (e.g., homesign vs. an established visual language like ASL).

Second, we can look at comprehension of homesign by signers who acquired ASL later in life (e.g. in adolescence or beyond). In our current groups of native ASL Signers, age of exposure is confounded with knowledge of a complex, established language. Measuring the comprehension of late-learning ASL signers can tell us whether (and if so, how much) experience with an established visual language supports homesign comprehension.

Table 4: Comparison groups and their characteristics

Group	Type of visual system	Age of Exposure	Length of exposure
Mothers of Homesigners	HS	late	significant
Native ASL Signers	ASL	early	significant
Siblings of Homesigners	HS	early	significant
Non-native ASL signers	ASL	late	Range from minimal to significant

These comparisons will help elucidate the nature of homesign systems. If more experience with an complex, established visual communication system (ASL) supports better comprehension of homesign, we can, in conjunction with data regarding the systematicity of homesign production, provide further support that homesign systems are themselves linguistic. Moreover, if better comprehension of homesign is predicted by factors that are associated with acquiring linguistic systems (namely, age of exposure), such results would accord with Brentari et al.'s findings, providing evidence that homesign systems are more like language than like gesture.

More work must be done to create a full and accurate characterization of the structure and development of homesign systems. If such research supports our claim that homesigners and not their mothers drive the development of homesign systems, this will have interesting implications regarding the capacity of the human brain for language. To the degree homesigners *are* innovating their systems and to the degree that their systems resemble existing visual languages, we can say there is something in the learner that is capable of producing language. As others have suggested (e.g., Senghas & Coppola 2001), it may be that the capacities that evolved to support language acquisition are also capable of creating language, to some degree. Future work involving converging methods—spontaneous and elicited production and comprehension—and different populations—such as homesigners and different cohorts of users of Nicaraguan Sign Language—will help further clarify the specific contributions of the brain, and the environmental conditions necessary for different features of language to emerge.

## Acknowledgments

We gratefully acknowledge the Nicaraguan and American participants. We thank Deanna Gagne, Julia Fanghella, Diane Lillo-Martin, Letitia Naigles, Cris Ortega, and Russell Richie for assistance with data collection and processing, as well as helpful discussions. This research was supported by NIH grant P30 DC010751 to the second author and Diane Lillo-Martin.

## Abstract

This study used a word search puzzle paradigm to examine the effects of task environment and individual differences in ability on information foraging. Younger and older adults attempted to maximize the number of items found in a set of 4 puzzles in which they were at liberty to search within a puzzle or switch between them. Younger adults demonstrated faster uptake (i.e., number of words found as a function of time) from individual puzzles than older adults but experienced more deceleration of rates during the search. Additionally, older adults switched less often and their switching was less dependent on the uptake rate compared to younger adults. Both younger and older adults stayed longer than was optimal in a patch, older adults were especially likely to persevere suboptimally. Collectively, these results suggest that individuals may differentially optimize information gain through self-regulation of exploration and exploitation.

**Keywords:** Information foraging; information uptake; cognitive aging; adaptive behavior.

## Introduction

Self-regulation of cognition in natural environments almost always involves alternating phases of *exploration*, which entails search in the service of deciding how effort will be allocated, and *exploitation*, or task engagement in which effort is allocated to meet task-specific goals. Information Foraging (IF) models are predicated on an analogy between these regulatory processes and the way in which animals forage for food in the wild. Information foraging has been used to account for how people search for information in external environments, such as the WWW (e.g., Fu & Pirolli, 2007; Payne et al., 2007; Pirolli & Card, 1999) and in memory (Hills et al., 2010, 2012). However, even though IF presents a compelling metaphor, there is actually very little empirical research investigating the alignment between IF principles and how people interact with the environment to search and make use of information sources (Metcalf & Jacobs, 2010). There is also little work that has examined how individual differences afford or constrain search in and uptake from information sources. In this study, we used a simple word search puzzle to explore these issues.

According to the IF theory (Fu & Pirolli, 2007; Pirolli & Card, 1999), certain basic properties of animal foraging can be applied to the way human seek and consume information. First, food is distributed in the wild in clusters, or “patches,” that vary in their profitability (i.e., potential yield) and in

their tractability (i.e., how much of an investment of resources is needed for exploitation; e.g., apples on low branches or high branches). Resources in the patch are often finite and unknown to the foragers in advance, though “scent cues” may provide hints about profitability of the patch. Second, as patches become depleted, the rate of uptake decelerates. Third, the forager faces a tradeoff between gaining nutrients from exploiting a patch and consuming energy from exploring for food (e.g., to move among patches). The optimal foraging theory predicts that animals will stay in a patch until the expected rate of gain falls below the overall rate of gain, which takes into account the cost of moving to a new patch (Charnov, 1976; Stephens & Krebs, 1986). Finally, because food is crucial to survival, foragers work to maximize their food uptake and rarely revisit a depleted patch (Stephen, Brown & Ydenberg, 2007; Stephens & Krebs, 1986).

There are similarities and differences between animal foraging and human information foraging. For example, information is often clustered into patches (e.g., particular forms of print resources, webpages), though units of information are often hard to quantify in everyday life. Although information seekers may sometimes find it difficult to estimate profitability and tractability before visiting a patch, they may judge the richness or relevance of information based on their knowledge or expertise. Learners often selectively allocate their attention to materials as long as they perceive themselves to be learning, and disengage if they perceive their rate of learning to decrease below a threshold (e.g., Metcalfe, 2002; Metcalfe & Kornell, 2005). While information seekers have been found to adjust their search behavior to the statistical structures of the task environments (e.g., Fu & Pirolli, 2007), given the limited computational capacity and imperfect knowledge of human beings, the decision to explore a new task or exploit the current one is often suboptimal due to the biased representation of the local environment (e.g., Simon, 1956). For example, Payne, Duggan and Neth (2007) found, in a series of cognitive foraging experiments, that switch decisions could not be entirely predicted by the rate of gain from a patch. Rather, people tended to switch more than optimal without monitoring the real-time change of expected gain. Finally, empirical studies show that information seekers often revisit information patches (e.g. Payne et al., 2007). In fact, unlike food, information will not be exhausted after consumption. Therefore, the benefit of

“revisiting a patch” is particularly ecologically important in information foraging.

Little research has examined adult age differences in foraging behavior. Aging brings changes in both processing capacity and knowledge that would likely impact both uptake rates and exploratory behavior (Beier & Ackerman, 2005). In fact, older information seekers have been found to adopt different strategies to adapt to the environment. Mata, Wilke and Czienskowski (2009) showed that older adults were adaptive to the task characteristics in a fish foraging task, such as staying longer in one pond while between-ponds travel time was high. Interestingly, older adults have been found to search/explore less information but use simple heuristics or knowledge-driven strategies to achieve good performance in decision-making or ill-defined information search tasks (e.g., Chin, Fu & Kannampallil, 2009; Mata & Nunes, 2010). However, older adults’ information uptake behavior in a foraging task has generally received little attention. To investigate information foraging behavior in unknown environments, the goals of the current research were to examine: 1) the effects of task environments and individual differences on information uptake (measured as the rate of information gain), and 2) the effects of task environments and individual differences on the decisions to switch between sources.

Methods

The word search puzzle paradigm was modified from previous research (e.g., Chin, Fu & Stine-Morrow, 2011; Experiment 4 in Payne, Duggen & Neth, 2007). Participants were asked to maximize the number of items found in a set of 4 word search puzzles on an iPad. One puzzle was visible at a time and participants switched between puzzles at liberty, with a 10-minute limit (See Figure 1).

Participants

Sixty-one participants were recruited from the community. Four participants (3 young, 1 old) were

excluded due to technical problem or failure to comply with the instructions. Among remaining 57 participants, 28 young adults (Mean Age = 19.79, SD = 1.23; 19 female) and 29 old adults (Mean Age = 70.57, SD = 6.33, Range = 62-85; 20 female) were analyzed. All participants had graduated from high school. There was no age difference in the frequency of iPad use ( $t(56)=0.55$ ,  $p=0.59$ ). Young adults used computers more often than old adults ( $t(56)=2.83$ ,  $p<.01$ ), and old adults did word puzzles more often than young adults ( $t(56)=-2.63$ ,  $p<.05$ ). Older adults had better vocabulary than younger adults as measured by the Advanced Vocabulary Test (Ekstrom et al., 1976) ( $t(56)=-4.77$ ,  $p<.001$ ). On the other hand, younger adults had better working memory than older adults, as measured by Reading Span task (Stine & Hindman, 1994) ( $t(56)=2.87$ ,  $p<.01$ ).

Materials

The 4 puzzles, each containing 16 words from a different semantic category, were presented in three conditions: all easy, containing mostly high-prototypical category exemplars in canonical orientations in the puzzle (forward, down, left-right diagonal); all difficult, containing mostly low-prototypical exemplars in any orientations; and mixed (2 easy, 2 difficult). Measurement of exemplar prototypicality was based on category norms from Van Overschelde, Rawson, and Dunlosky (2004), in which prototypicality was indexed as the proportion of participants generating the word when given the category; there was significant difference in the mean prototypicality of words in the easy and hard puzzles ( $F(1,10)=20.82$ ,  $p<.001$ ). There were no differences in the mean log word frequency (Balota et al., 2007,  $F(1,10)=0.69$ ,  $p=.42$ ) or mean word length ( $F(1,10)=0.20$ ,  $p=.66$ ) between items in the easy and hard puzzles. Thus, given that the words in the easy puzzles were easier to generate from semantic memory and in a canonical orientation, they were more likely to “pop-out” than those in the hard puzzles. While controlling the density of the easy

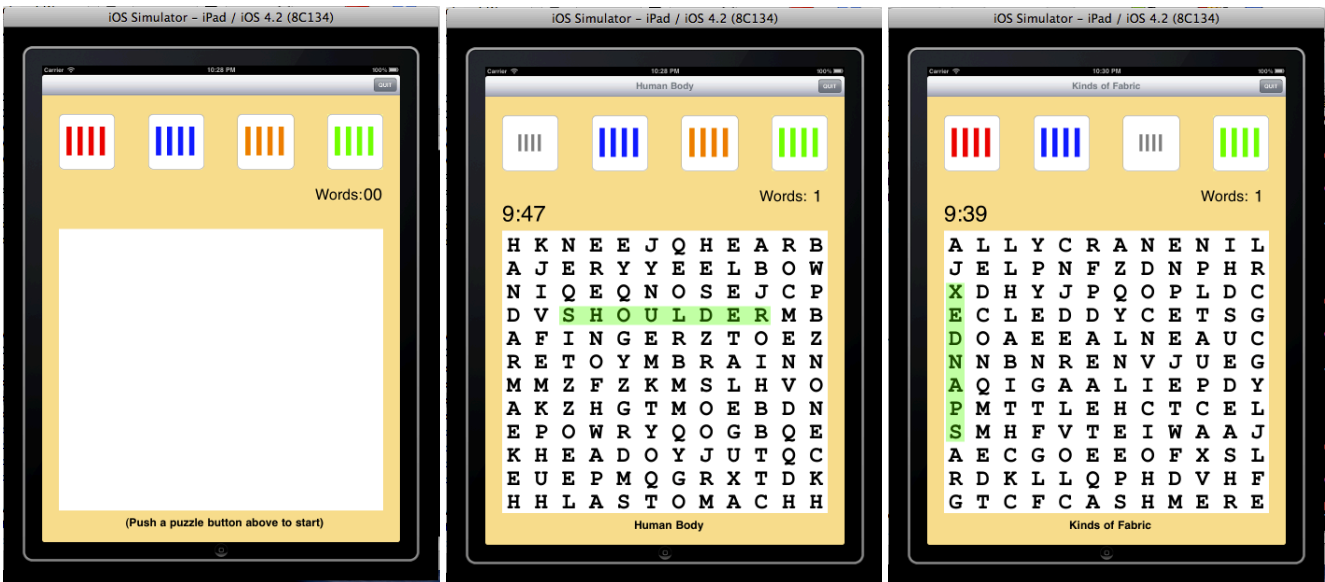

Figure 1. Layout of the word search puzzle experiments

and hard puzzles, we manipulated the profitability of the puzzles to see if participants were effective in monitoring their uptake rates.

The interface for word search puzzle was programmed in iPad (see Figure 1). Participants first saw the interface with four colored buttons. Each button referred to a puzzle of different semantic category. Participants could press any of the four buttons to start the experiment. When the participant pressed any of the four buttons, a countdown timer of 10 minutes started. A word search puzzle appeared with its category name shown on the top and bottom of the interface. Participants saw one puzzle at a time, and used their fingers to swipe the words they found. The found words were highlighted in different colors and remained highlighted during the whole session. Participants could check the number of words they found in each puzzle on the right corner, but would not know the number of words remaining in each puzzle. During the experiments, participants could press the button to switch to the other puzzles. In the mixed condition, the order of buttons of easy and hard puzzles was in counterbalanced order. Every meaningful touch (such as button touch, letter touch) on the iPad was recorded with time stamps.

### Experimental Design

The experiment followed a 2 x 3 mixed factor design with between-subject variable, age (young vs. old) and within-subject variable, task condition (all easy vs. mixed vs. all hard). The order of the three conditions was counterbalanced across participants.

### Procedures

At the beginning of the experiment, participants completed cognitive measures after the consent process. Participants then practiced locating words in the puzzles and switching among puzzles for 20 minutes. After the practice, participants performed the experimental task. Each condition took 10 minutes. Participants had been told explicitly that some puzzles might be easier than others, and they could go back and forth among four puzzles and decide how long they want to spend in each puzzle on their own. After all three conditions, the experimenter briefly interviewed the participants about their self-observed search and switch strategies. Participants were debriefed at the end.

## Results

A 2 x 3 Repeated Measures Analysis of Variance showed significant main effects of age and condition on the number of words found in each condition (Age:  $F(1,55)=35.37$ ,  $p<.001$ ; Condition:  $F(2,55)=191.78$ ,  $p<.001$ ). Both younger and older adults found the most words in the Easy condition, then the Mixed condition, followed by the Hard condition. Younger adults found more words than older adults across all the conditions. The Age by Condition interaction was not significant (see Table 1). However, younger and older adults varied in the extent to which they found words on their first encounter (Bout 1) versus successive encounters (Bout>1) with the puzzles (Figure 2). Older adults tended to find most words in their first bout at

the puzzle, while younger adults tended to find relatively more words in later bouts (i.e., more revisiting), especially in the hard puzzle (Age:  $F(1,54)=11.00$ ,  $p<.005$ ).

Table 1. Descriptive statistics of word search performance

Mean (SD)	Easy	Mixed	Hard
Young	38.93(6.35)	31.86(5.63)	23.39(7.40)
Old	29.24(6.95)	23.34(5.47)	15.72(6.15)

Figure 2. Age difference in the percent of words found in the first attempt

### Age Differences in Uptake Rates

Mixed-effects modeling was conducted to estimate uptake rates in the different conditions. Uptake rate was defined as the cumulative number of words found as a function of time with data modeled based on 2-sec intervals. As showed in Figure 2, participants found most words in their first bouts across different conditions; thus, we modeled the uptake rates for the first bout only. There were 37,763 observations in total. Following the growth curve analysis method (Mirman, Dixon & Magnuson, 2008), we started with the

Figure 3. The uptake rates for younger and older adults in different puzzles

“average uptake rate model.” The uptake rate function (cumulative number of words per unit time) was calculated as :

$$Y_{ij} = \gamma_1(\text{time}) + \gamma_2(\text{time}^2) + U_{1j}(\text{time}) + U_{2j}(\text{time}^2) + e_{ij} \quad (1)$$

In (1),  $Y_{ij}$ ,  $\gamma$ ,  $U$ , and  $e_{ij}$  represented the cumulative number of words, the fixed effects, the random effects of subjects, and the error term respectively. Because we are interested in capturing both the linear and non-linear components of the random effects of subjects, it was divided into:  $U_{1j}$  – the linear “rate” and  $U_{2j}$  – the non-linear “rate of change”. Then we added fixed effects of age and condition and its interaction terms to the model “conditional uptake rate model”, as follow:

$$Y_{ij} = \gamma_1(\text{Time}) + \gamma_2(\text{Time}^2) + \gamma_3(\text{Age} \times \text{Time}) + \gamma_4(\text{Age} \times \text{Time}^2) + \gamma_5(\text{Condition} \times \text{Time}) + \gamma_6(\text{Condition} \times \text{Time}^2) + \gamma_7(\text{Age} \times \text{Condition} \times \text{Time}) + \gamma_8(\text{Age} \times \text{Condition} \times \text{Time}^2) + U_{1j}(\text{time}) + U_{2j}(\text{time}^2) + e_{ij} \quad (2)$$

The condition update rate model in (2) was developed to test how uptake rates changed (both linearly and non-linearly) with conditions and age. The model shows that the uptake rate (which measured how quickly subjects found a word in a puzzle) for the easy puzzles was higher than for the hard ones ( $F=2377.28$ ,  $p<.001$ ). Interestingly, the uptake rate for the hard puzzles was higher when they were embedded in the mixed condition with easier puzzles relative to those in the pure condition. This was true for both younger and older adults, suggesting a facilitation effect in the mixed condition, in which there were 2 easy and 2 hard puzzles. Figure 3 showed best fitting curves of uptake rates of younger and older adults in four puzzles to the empirical data. The length of curves represents the mean duration of uptakes (exploitation). As shown in these plots, older adults stayed longer in the puzzle than younger adults.

Younger adults had higher uptake rates than older adults, especially in the easy puzzles (Age x condition x time:  $F=108.32$ ,  $p<.001$ ). Younger adults also showed a larger rate of change, such as quicker deceleration of uptake rate across time, than older adults ( $F=16.30$ ,  $p<.001$ ). The difference in rates of change was larger in the easy, mixed puzzles than the hard ones ( $F=93$ ,  $p<.001$ ). Thus, the uptake rates grew more quickly for younger adults but reached the asymptote quicker (with larger reduction of rates across time) than older adults.

### Age Differences in Switch

Given the individual difference in uptake rates across different conditions, we examined whether age differences in uptake rates were related to frequency of switching. A 2 x 3 Repeated Measures Analysis of Variance (Age x Condition) was conducted on the number of switches in the easy, mixed, and hard condition. Younger adults switched more often than older adults in all conditions (Figure 4)

Figure 4. Age differences in number of switches of different conditions

( $F(1,55)=30.39$ ,  $p<.001$ ). There was also a main effect of condition showing that people switched more in the hard condition, then the mixed condition, followed by the easy condition ( $F(2, 55)=5.21$ ,  $p<.01$ ). The Age x Condition interaction was not significant.

Given that younger and older adults experienced different degrees of rates of change, we examined if the age differences in rates of change over time were associated with their switch behavior, and the extent to which they were moderated by individual differences in working memory and verbal ability. We first extracted the best linear unbiased predictors of rates of change from the average uptake rate model ( $U_{2j}$ ). Then we did a median split on the estimates of rates of change to create two groups – those with uptake rates dropping more and those with uptake rates dropping less. We did a 2 (Age) x 2 (dropping more or less) ANCOVA to examine the relationship between the number of switches and the deceleration of uptake rates across time by treating individual differences in working memory and verbal ability as covariates.

Results showed a significant Age x Rate of change interaction ( $F(1,51)=7.21$ ,  $p<.01$ ) in addition to the effects of age, rate of change, and working memory (Age:  $F(1,51)=19.29$ ,  $p<.001$ ; Rate of change:  $F(1,51)=9.87$ ,  $p<.01$ ; Working memory:  $F(1,51)=6.28$ ,  $p<.05$ ). The interaction of Age x Rate of change on the number of switches was shown in Figure 5. People with more reduction of uptake rates (the dropping more group) across time tended to switch more, and the difference was bigger in younger adults than older adults. In the other words, older adults were less sensitive to their rates of change in uptake—they were less likely than younger adults to switch puzzles as the rate of uptake diminished. On the other hand, younger adults were more sensitive to changes in uptake rates, which led to more switches. Also, the covariates of working memory had association with switch behavior – people with higher working memory capacity tended to switch more often. However, the age-differences in associations between rates of change and switch behavior were shown regardless of the individual differences in working memory.

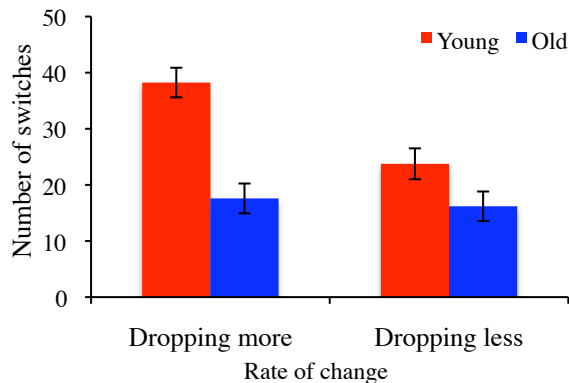

Figure 5. Interaction of age and rate of change on switch

### Suboptimal Leaving and Longer Perseverance for Older Adults

Given that younger adults switched more than older adults, and also showed higher uptake rates and rates of change, the next question we addressed was whether younger and older participants switched optimally. According to the optimal foraging theory, the marginal value theorem predicts the optimal patch departure time – the time at which the marginal uptake rate is equal to the mean uptake rate of the entire habitat (Charnov, 1976). We calculated the ratio of marginal uptake rate at each word and the mean uptake rate of the corresponding patch for each participant. The optimal time to switch to a different puzzle is when the ratio equals 1. When the ratio is larger than 1, it is advantageous to stay because the current marginal rate is higher than the average expected return (estimated based on previous experiences). As the marginal value decreases with decelerated uptake rates, the value becomes increasingly smaller than 1, and it is advantageous to switch because the expected uptake from the habitat as a whole exceeds the current marginal value.

Both younger and older adults were suboptimal based on the criterion derived from the marginal value theorem, as they left the puzzle late (Figure 6a). Mean ratio of the last word in the puzzle was smaller than 1, suggesting that the marginal uptake rate of the last word was slower than the mean uptake rate in the corresponding puzzle. Though people tended to leave the puzzle when the uptake rate was low, Figure 6a shows that participants would have been more optimal if they left the puzzle about 2 words earlier (the ratio of the third word back was close to 1). Additionally, among puzzles of different profitability, people tended to switch more optimally in the hard puzzles than in the easier puzzles. This finding suggests that both younger and older adults were more sensitive to the change of uptake rates and switched earlier in the hard puzzle condition (Figure 6b).

While both younger and older adults switched later than was optimal, they persevered differently in the puzzles. Perseverance was measured by the give up time, which was defined as the duration from finding the last word to leaving

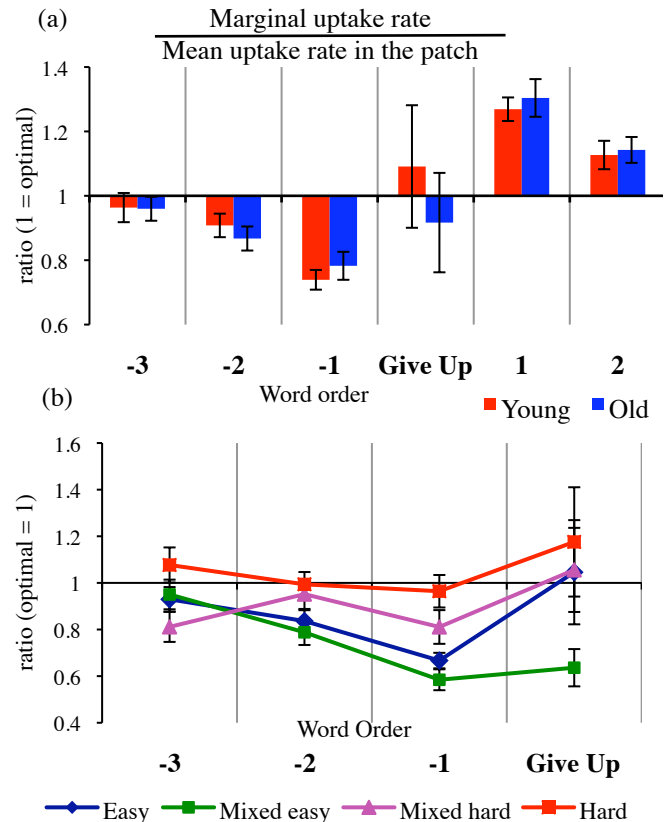

Figure 6. The ratio of marginal uptake rate of the word and mean uptake rate in the corresponding patch for younger and older adults (a) and different puzzles (b)

the puzzle (e.g., Payne et al, 2007) – i.e., the amount of time participants persevere in a patch without finding a word.

A 2 x 4 Repeated Measures Analysis of Variance (Age x Puzzle type: easy, mixed easy, mixed hard, hard) was conducted to explore the effects of age and puzzle type on give up time. Give up time was longer for older adults than for younger adults. In other words, older adults persevered longer in the current patch before moving to a new patch compared to younger adults. Figure 6a also showed that while younger adults tended to persevere for a shorter time than their mean uptake time for the puzzle, older adults tended to persevere longer than their mean uptake time. Furthermore, people persevered longer in the hard puzzles than the easy ones (puzzle type:  $F(1,53)=2.55$ ,  $p<.05$ ; age:  $F(1,53)=13.15$ ,  $p<.001$ ). Interestingly, the give up time in the mixed easy puzzles was relatively longer than the time in the all easy condition, suggesting that participants were influenced by the mixed context.

### Conclusion

The study used the word search puzzle paradigm to study the information search behavior of younger and older adults in the patches of different profitability. Although the gain functions of puzzles were unknown to the participants, individuals were able to allocate their effort to uptake and switch when uptake decreased. Older adults showed slower

uptake rates and smaller change of rates than younger adults across different puzzles. Thus, older adults relied less on the deceleration of uptake rates to decide when to switch to a different puzzle. Older adults switched less often and persevered longer in the puzzles, especially in the difficult condition. To maximize the search performance, older adults allocated more time to exploitation (i.e., task engagement in the puzzles) and younger adults did more exploration to the new puzzles than the older adults. Overall, older and younger adults showed adaptive self-regulation patterns through differential attention to exploitation and exploration.

Older adults were found to be less explorative in information search in decision making (Mata & Nunes, 2010) and web information search (Chin, Fu & Kannampallil, 2009), and they explored (i.e., switched to another puzzle) less often in the current study as well. Less exploration might be adaptive given the heavy demands on processing capacities of switching behavior in information search (e.g., Chin et al., 2009, 2011). In addition to the higher switch cost of older adults, results suggested that older adults seemed to use different policies (i.e., less relying on the rates of change) to make switch decision than younger adults. As the optimal foraging model suggests, foragers will leave while the marginal uptake rates is lower than the mean uptake function of a patch. However, given the uptake function of the puzzles were unknown to the participants, people needed to track their uptake behavior after entering a puzzle across time to estimate the expected gain of the puzzle. This process was so information intensive and resource demanding that older adults might experience more difficulty executing which was partly shown in our results. Thus, age differences in learning from experiences in a given information patch and the corresponding patch-leaving policy should be further examined in future studies.

Despite the age differences in switch, both younger and older adults were suboptimal in terms of the later departure time in the patches. Interestingly, past studies also found that foragers were suboptimal in external search task (e.g., Mata et al., 2009), but closer to optimal in memory search (Hills et al., 2012). Hills and his colleagues used cross-modal priming to show that external search patterns can be transferred to internal search patterns, suggesting that there is a central executive control process monitoring both internal and external search behavior. Therefore, the difference of patch-departure behavior in internal and external search task might be due to the fact that foragers have more knowledge about the gain function of a patch in the internal search task than the external search task. Similarly, in the condition of mixed uptake functions, results showed that people were farther away from the optimal (i.e., late departure) in the mixed easy, mixed hard puzzles than the easy and hard puzzles respectively suggesting that the knowledge of a patch might be important to determine the optimal departure in the task.

## Abstract

Left-right asymmetries have been noted in tasks requiring the classification of many visual stimuli, including Navon figures, spatial frequency gratings, and faces. The Double Filtering by Frequency (DFF) model (Ivry & Robertson, 1998), which postulates asymmetric frequency filtering on task-relevant frequency bands, has been implemented to account for asymmetric processing of each stimulus type above, but does not provide a fully mechanistic explanation, nor does it have direct neural correlates. The Differential Encoding (DE) model (Hsiao, Shahbazi, & Cottrell, 2008), which postulates that a known asymmetry in patch connectivity drives visual processing asymmetries, has previously been used to account for only one stimulus type. Here, we refine the DE model to match the published patch asymmetry more precisely and show that the DE model generalizes to three of the four datasets mentioned above. Examination of the failure to match all datasets suggest a possible reinterpretation of the original dataset itself.

**Keywords:** local/global processing, left-side bias, hemispheric asymmetry, visual perception, Differential Encoding, Double Filtering by Frequency, computational model

## Introduction

A large literature of experimental psychology and cognitive imaging studies has established the existence of a wide range of left-right asymmetries in the classification of many visual stimuli. A typical paradigm consists of briefly presenting a stimulus to the left or right of fixation, then requiring subjects to perform a classification task, such as whether a target stimulus was present or not. Because information from the left visual field (LVF) is initially directed only to the right cerebral hemisphere (RH), and right visual field (RVF) to the left cerebral hemisphere (LH), comparisons of task performance between LVF/RH and RVF/LH can indicate asymmetries in hemispheric processing. Visual stimuli which have shown such asymmetries in these types of tasks include Navon figures (Sergeant, 1982) consisting of a large, “global”-level figure composed of smaller, “local”-level figures (see Figure 3b), spatial frequency gratings (Christman, Kitterle, & Hellige, 1991; Kitterle, Hellige, & Christman, 1992), and faces (Young & Bion, 1981; Brady, Campbell, & Flaherty, 2005).

Ivry and Robertson (1998) developed the Double Filtering by Frequency (DFF) theory to account for these asymmetries.

The computational model they implemented aimed to account for three particular experiments from the literature, thought to express core features of the data:

- Sergeant (1982): showed the basic hemisphere  $\times$  level interaction of the local/global literature, with responses to targets presented at the smaller, “local” level showing faster reaction times when presented to the RVF/LH, and responses to targets presented at the larger, “global” level showing faster reaction times when presented to the LVF/RH.
- Kitterle et al. (1992): showed that reaction times in two different classification tasks, using the same stimuli but requiring use of information at different spatial frequencies, interacted with the visual field/hemisphere of presentation. Responses to the task requiring high spatial frequency (HSF) information showed faster reaction times when presented to the RVF/LH, and responses to the task requiring low spatial frequency (LSF) information showed faster reaction times when presented to the LVF/RH.
- Christman et al. (1991): showed that discrimination between two stimuli which differed by a single spatial frequency interacted with the visual field/hemisphere of presentation, based on the *relative* frequency of the discriminative spatial frequency compared to the rest of the spatial frequencies contained in the stimuli. When the discriminative frequency was higher than the frequency content of the rest of the stimulus, responses were faster for presentation to the RVF/LH; when the discriminative frequency was lower than the frequency content of the rest of the stimulus, responses were faster for presentation to the LVF/RH.

The DFF model replicated the core features of each of the above studies. Later, Hsiao, Shieh, and Cottrell (2008) showed that the DFF theory could also account for the so-called ‘left-side bias’—the tendency for people to associate face identity with the right-side of a person’s face (appearing in the LVF of the viewer) (Brady et al., 2005).

The DFF model, while it accounts for all these data, requires a homunculus to input the frequency range of interest for the particular task being modeled, rather than discovering

the task-relevant frequency range through training. In addition, no neurophysiological evidence has been found for spatial frequency filtering in cortex.

Hsiao, Shahbazi, and Cottrell (2008) took a very different approach to the problem of explaining visual processing asymmetries. Rather than starting with a theory of the algorithms behind the asymmetries (Marr’s “algorithmic” level), they created a model of an anatomical asymmetry (Marr’s “implementation” level) and asked whether it could account for the asymmetries in classification of visual stimuli observed in behavioral studies. They used an asymmetry in inter-patch connectivity (Galuske, Schlote, Bratzke, & Singer, 2000), one of the few known network-level asymmetries, and the only one suggested to be related to local/global processing asymmetry (Galuske et al., 2000; Hutsler & Galuske, 2003). This asymmetry was found in BA22, an auditory association area, and not in primary auditory cortex. This matches current theory in the local/global literature, where it has been suggested that local/global processing differences occur beyond early primary sensory areas (Sergent, 1982; Ivry & Robertson, 1998), motivating the use of this asymmetry to model tasks involving local/global processing.

Hsiao et al. used this connectivity pattern as inspiration to implement a simple “autoencoder” neural network with differential connectivity (see Figure 2) to encode the stimuli, and a simple perceptron to perform the task using the autoencoders’ learned representations (see Methods section for details on this model). They tested it to see whether this anatomical asymmetry could account for a subset of the data modeled by Ivry and Robertson. Using precisely the same small, 1-dimensional inputs that Ivry and Robertson created for modeling a reduced version of Sergent’s study, Hsiao et al.’s “Differential Encoding” (DE) model showed a hemisphere  $\times$  level interaction that matched Sergent’s human data more closely than that of Ivry and Robertson’s DFF model. Hsiao et al. then constructed realistic 2D bitmaps of Sergent’s Navon stimuli, trained 2D versions of the DE models on these realistic stimuli, and again showed a hemisphere  $\times$  level interaction that was a better quantitative match to the original human data than the results published by Ivry and Robertson using their DFF model.

The DE model was able to address issues with the DFF model by implementing an anatomical asymmetry. The use of a secondary network for classification allows the learning algorithm to select task-relevant information, rather than manually selecting frequency bands as does the DFF model.

However, the DE model did not address most of the data accounted for by the DFF, including two local/global studies (Kitterle et al., 1992; Christman et al., 1991), one face-processing study (Young & Bion, 1981), and the relationship between local/global processing and spatial frequency processing. In addition, the DE model used parameters for number of connections and distribution shape that were very different from the parameters reported in the literature.

Here we improve the model’s fidelity to neural data. We

show that this model accounts for three of the four studies described above. We also show that this model filters frequencies in a manner consistent with the human literature.

## Methods

The “Differential Encoding” (DE) model is based on an asymmetry in “patch” connectivity found in BA 22 (Galuske et al., 2000). “Patches” are found in many cortical areas across species (monkeys, humans, cats, rodents) and across sensory and association areas. Patches are thought to be a level of organization akin to a macro-column, consisting of thousands of selectively interconnected neurons within a cortical area. These patches selectively interconnect to a small subset of other local patches through horizontal connections through the grey matter. These patches are named because an injection of dye into the cortical surface will label cortex at the injection site, as well as rather discrete “patches” of surrounding cortex (see Figure 1) (Amir, Harel, & Malach, 1993; Levitt & Lund, 2002).

Figure 1: Drawing of “patches” in V4. Dark arrow indicates site of dye injection. Reproduced (without permission) from Amir et al. (1993).

The function of these inter-patch connections is not known. Briefly, we propose here that horizontal connections lead to interconnected patches, biasing each other to process features shared across the interconnected group. We therefore implement a feed-forward model, where the hidden units discover the correlated features shared across interconnected input “patches” across a set of input stimuli.

The “Differential Encoding” (DE) model includes two autoencoder neural networks with differences in connectivity, one for each hemisphere. Unlike most autoencoders, the hidden units of these models connect to a small subset of the input and output banks (see Figure 2). Each hidden unit has a position in the input (and output) arrays, and a fixed number of connections to the input (and output) arrays are sampled from a Gaussian distribution centered at that hidden unit’s position in the input (and output). The LH and RH autoencoders have the same number of hidden units and sample the same number of connections to the input (and output) for each hidden unit. The only difference between the networks, then,

is the width ( $\sigma$ ) of the Gaussian distribution. In accordance with the findings of Galuske et al. (2000), the left hemisphere network had a wider distribution than the right hemisphere network (see Figure 2).

Figure 2: Representation of two hidden units for LH (left) and RH (right) autoencoder networks, along with their connections. The connections are randomly sampled from a Gaussian distribution centered on each hidden unit's position in the input array. The Gaussian distribution used for the LH is wider than that used for the RH. Not pictured are the classification networks which operate on the hidden unit encodings extracted from the autoencoder networks after training.

The number of hidden units was varied from extremely small (13) to extremely large (800) values. Results did not differ qualitatively when the number of connections per hidden unit varied to allow for the same number of overall weights to be used to learn the images. If too few weights were used, the networks could not learn the training set well enough for a meaningful analysis. After these initial explorations, the final simulations were run with the number of connections per hidden unit fixed to be within the range reported by Amir et al. (1993) in visual cortex (between 8 and 15), and the number of hidden units were chosen to allow equal spacing across the input image with enough total parameters to learn the images.

Each LH and RH network is constructed by randomly sampling connections for each hidden node. Gaussian distributions were used such that inter-patch distance values were similar to those calculated from data reported in (Galuske et al., 2000). On average, patches had 1.75 times the width of a single patch between them in the RH, and 2.05 in the LH. Here, we considered the size of a patch to be a pixel, and chose sigmas such that when inter-patch distance was measured after randomly sampling connections, on average there were 1.75 pixels between connections in the RH, and 2.05 in the LH.

Greyscale images are constructed for each task stimulus. The autoencoders are trained via of backpropagation of error (Rumelhart, Hinton, & Williams, 1986) to reproduce these greyscale images from the input to the output. Once the autoencoders reach a pre-determined performance level, training stops. Each stimulus image is then presented to the

trained autoencoder network, and the activation of the hidden units is recorded. These encodings, which differ only due to the differences in connectivity structure between LH and RH networks, are then used as inputs to a separate feed-forward neural network, which is trained to classify these encodings according to the behavioral task for the experiment.

For a single experiment, multiple “instances” of each LH and RH network are constructed and trained; each “instance” differs only in the random samples of its connections. The number of instances is determined by matching the total number of trials used both in the modeling experiment and in the corresponding behavioral experiment, such that the statistical power of each experiments are equated. Performance is evaluated on each model individually, then performance over all “instances” of a hemisphere are averaged. Average model error for each model hemisphere is compared to average reaction time of the corresponding visual field in the human experiment, with both measures conceived as measures of difficulty or uncertainty in processing.

In order to examine how the different connectivity structures affect spatial frequency encoding, each stimulus image is presented to a trained autoencoder. Each output image produced is examined for spatial frequency content, and a 2D power spectrum across all images in the stimulus set is constructed. Each 2D power spectrum is translated to a 1D power spectrum by measuring the linear distance from the pixel carrying the  $f_0$  (intensity) power to each pixel in the 2D power spectrum, then sorting all linear distances and averaging over any pixels with the same linear distance. Each 1D power spectrum is then compared to the power spectrum of the original image. The difference in 1D power spectrums is then compared across hemispheres, showing for each frequency which hemisphere has encoded information closer to the original image than the other.

## Experiments and Results

### Sergent (1982) simulations

16 binary images (31x13 pixels) of Navon stimuli (letters [H, T, F, L] each appeared at local and global levels in all possible combinations) (see Figure 3b for example stimuli) were presented to 68 LH ( $\sigma = 6.0$ ) and RH ( $\sigma = 3.0$ ) autoencoder models to match the total number of trials in Sergent's human data. Each autoencoder network had 360 hidden units, with each hidden unit connecting to 8 input and output units. Each autoencoder network was trained to 0.005 average error per output unit, then hidden unit encodings were extracted. A perceptron classifier with 360 input units and one output unit was trained to classify each of the 16 Navon stimuli as containing a target or not.

As in Hsiao, Shahbazi, and Cottrell (2008), the network showed a significant hemisphere  $\times$  level interaction (Two-factor, within-subject repeated measures ANOVA;  $F(1,67)=8.62$ ;  $p < 0.01$ ). We ran this same modeling experiment and analysis for all 6 combinations of target and distracter letters, to see if results would generalize. This only

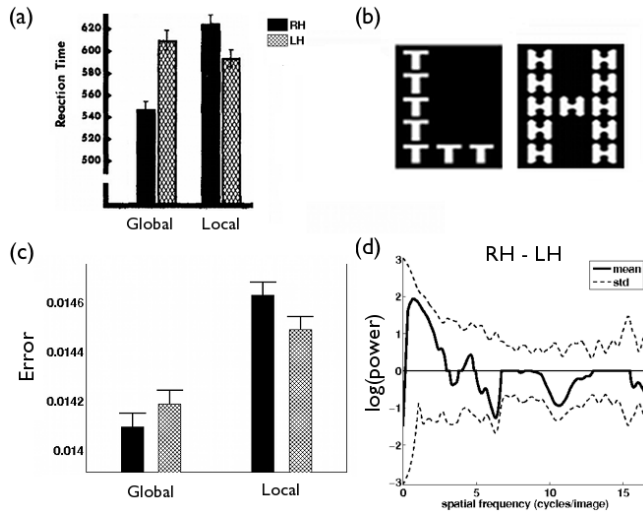

Figure 3: Original and model results for Sergent task

- (a) Original hemisphere  $\times$  level interaction; reproduced (without permission) from Sergent (1982)
- (b) Sample Navon stimulus used in our modeling experiment
- (c) DE model hemisphere  $\times$  level interaction

required training new classification neural networks, as the stimuli in each experiment remained the same. Each of these experiments showed a statistically significant hemisphere  $\times$  level interaction.

Comparing the 1D power spectrums created from the output images of the autoencoder neural networks, we saw a clear tendency for the RH network to be closer to the power spectrum of the original image for LSFs, and the LH network to be closer to the power spectrum of the original image for HSF (see Figure 3d). These trends matched the large literature reporting better performance on LSF for LVF/RH and better performance on HSF for RVF/LH.

### Kitterle et al (1992) simulations

40 greyscale images (31x13 pixels), each consisting of a low or high frequency grating, the grating either being a sine or square wave, and shown at one of 10 phases (see Figure 4b for example stimuli), were presented to 40 LH ( $\sigma = 6.0$ ) and RH ( $\sigma = 3.0$ ) autoencoder models. Each autoencoder network had 360 hidden units, with each hidden unit connecting to 8 input and output units. Each autoencoder network was trained to 0.005 average error per output unit, then hidden unit encodings were extracted. Two identical neural networks with 360 input units, ten hidden units, and one output unit were trained to classify each of the 40 stimuli. One classification network was trained to discriminate between wave type (sine vs square) and to ignore the frequency of the waves; this task required use of HSF information. The other classification net-

work was trained to discriminate between the two frequencies of the waves and to ignore the wave type; this task required use of LSF information. Both networks were trained with the same training parameters.

The first classification network showed a significant effect of hemisphere ( $F(1,39)=4.06$ ;  $p < 0.05$ ), with the LH network showing better performance. The second classification network showed a significant effect of hemisphere ( $F(1,39)=4.53$ ;  $p < 0.04$ ), with the RH network showing better performance. Across the two tasks, the networks showed a significant hemisphere  $\times$  task interaction (Two-factor, within-subject repeated measures ANOVA;  $F(1,39)=9.89$ ;  $p < 0.002$ ). Note that the main effect of task-type was not preserved; our models found discriminating the wave type to be an easier task than discriminating between two frequencies; Kitterle et al. (1992) reported the opposite result for their human participants.

### Face Processing simulations

**Young and Bion (1981): Face Recognition** Young and Bion (1981) (and other) studies have shown a RH advantage for face recognition. We set out to replicate this general finding.

The same face stimuli used in Hsiao, Shieh, and Cottrell (2008), which used the DFF model to show a left-side bias, were used to construct greyscale images in this study. The dataset contained 30 individuals with 8 expressions each; 4

expressions used in training, and 4 different expressions were used in the data collection/testing phase. These face stimuli were more complex, and so required more parameters to train to a lesser error criterion. The face stimuli were presented to 40 LH ( $\sigma = 8.0$ ) and RH ( $\sigma = 3.0$ ) autoencoder models. Each autoencoder network had 360 hidden units, with each hidden unit connecting to 12 input and output units; ; the wider LH gaussian was selected to space out the greater number of connections per hidden unit. Each autoencoder network was trained to 0.01 average error per output unit, then hidden unit encodings were extracted. A neural network with 360 input units, 25 hidden units, and 30 output unit was used to classify each of the 120 test images as one of the 30 individuals.

A significant effect of hemisphere on face identification accuracy was found (ANOVA;  $F(1,39) = 10.33$ ,  $p < 0.002$ ). These effects were consistent across the training and test sets.

Figure 5: Stimuli and power spectrum for left-side bias task

(b) DE model classification of individual face recognition identity (Young & Bion task); error-bars represent standard error of the mean  
(c) DE model spatial frequency analysis of output images, showing a RH advantage (above zero on Y-axis) for LSF (towards left side of X-axis) and a LH advantage (below zero on Y-axis) for HSF (towards right side of X-axis)

**Brady et al. (2005): Left-Side Bias** The same face stimuli used in Hsiao, Shieh, and Cottrell (2008), which used the DFF model to show a left-side bias, were used to construct greyscale face images. 240 greyscale face images (34x25 pixels; 30 individuals; 4 expressions used in training, 4 different expressions used in testing) were used to create left and right chimeric faces: faces with one side duplicated across the mid-line to the other. The same network parameters were used as the face recognition simulation above for training.

For each set of chimeric faces, a significant effect for hemisphere was found, with a RH advantage for face recognition in each case (left chimeric:  $F(1,39) = 7.58$ ,  $p < 0.01$ ; right chimeric:  $F(1,39) = 8.83$ ;  $p < 0.01$ ), again replicating a RH advantage for face identification. Comparing across left and right chimeric faces, both hemispheres showed a significant preference for left chimeric images, replicating the left-side bias effect.

## Christman et al. (1991) simulations

Two sets of 16 greyscale images (31x13 pixels) were constructed, each consisting of a two types of stimuli. The first type stimulus consisted of two frequency gratings at different relative phases to each other. The second stimulus type consisted of the first set of stimuli, with a third frequency grating superimposed upon them. In one stimulus set, the third frequency grating was at a higher spatial frequency than the other two frequency gratings; in the second stimulus set, it was at a lower spatial frequency than the other two. Importantly, the third frequency grating was of exactly the same spatial frequency in both stimulus sets (see Figure 6b for example stimuli). There were 4 phase variations for each stimulus type in each stimulus set.

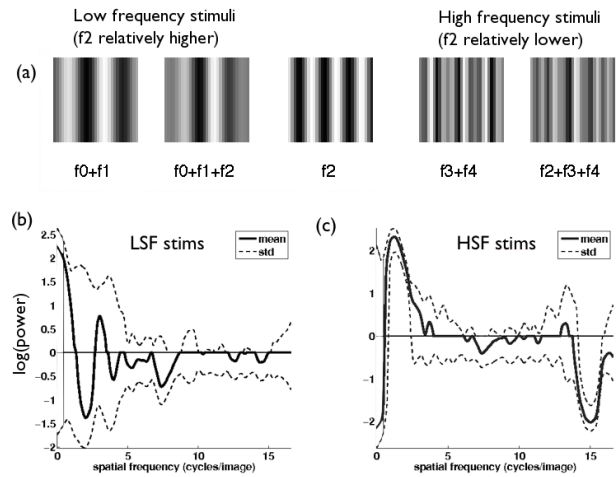

Figure 6: Original results, sample model stimuli, and model power spectrum  
(a) Sample stimuli created to train DE models  
(b) DE model spatial frequency analysis of output images, showing much flatter power spectrum differences than all other stimuli, with weak RH advantage (above zero on Y-axis) for LSF (towards left side of X-axis) and a weak LH advantage (below zero on Y-axis) for HSF (towards right side of X-axis)

Each set of greyscale images was presented to 64 LH ( $\sigma = 6.0$ ) and RH ( $\sigma = 3.0$ ) autoencoder models. Each autoencoder network had 360 hidden units, with each hidden unit connecting to 8 input and output units. Each autoencoder network was trained to 0.005 average error per output unit, then hidden unit encodings were extracted. For each set of greyscale images, a neural network with 360 input units, ten hidden units, and one output unit were trained to classify each of the 16 stimuli.

For both stimulus sets (LSF and HSF), there was a significant effect of stimulus class, with the 3-component stimulus being harder to classify than the 2-component stimulus. However, there was no hemisphere  $\times$  stimulus class interaction. Looking at the power spectrum differences between

the two stimulus classes (Figure 6b and 6c), and comparing them to the previous power spectrum differences, it is clear that there is much less encoding asymmetry between the two model hemispheres for these stimuli as compared to all other stimuli used in model experiments within this paper.

We tested a few possible explanations for this. We tried many different combinations of spatial frequency gratings; this varied which model hemisphere showed better performance, but no reliable hemisphere  $\times$  stimulus class interaction. We tried larger images, to expand the range of spatial frequencies that could be encoded, but again no consistency was found. Lastly, we tried training the autoencoder on separate dataset, then extracting hidden unit encodings on the task-relevant stimuli. Again, this did not show any consistent interaction.

Further work is warranted to better characterize whether the DE model can account for this critical dataset. We have created (elsewhere) a developmental model of this asymmetry which suggests that this dataset may be modeled by engagement of more than one cortical area showing asymmetry. This pattern is seen in neuroimaging results reported by (Hopf et al., 2006), for example, where a leftward asymmetry of an earlier visual processing area is engaged by a task at the “local” level, and a rightward asymmetry of a later visual processing area is engaged by a task at the “global” level. Variations in average inter-patch distance based on cortical area Amir et al. (1993) suggest that different areas may have different frequency preferences. This would suggest that “relative frequency” processing may in fact be simply selecting different absolute frequency filters, implemented in different cortical areas, based on task demands. We are currently investigating whether this might provide an alternate explanation to these data, and the idea of relative frequency encoding in general.

## Conclusions

Here, we showed that an asymmetry in local connectivity can account for local/global behavioral data, face processing data, and matches spatial frequency asymmetries reported in the literature. This model provides a biologically grounded implementation for these phenomena, and the analyses here showing consistent frequency filtering differences in the model hemispheres are consistent with the current algorithmic explanation for visual processing asymmetries via frequency filtering. Unlike the DFF model, however, these frequency filtering differences are found at a post-sensory encoding stage. Further work must be done to investigate whether our failure to model the results of Christman et al. (1991) is due to practical modeling concerns, or suggests a fundamentally different approach to modeling local/global processing asymmetry.

## **Abstract**

The face inversion effect (FIE) is a reduction in recognition performance for inverted faces compared to upright faces that is greater than that typically observed with other stimulus types (e.g. houses; Yin, 1969). Nevertheless, the demonstration that the inversion effect in recognition memory can be as strong with images of dogs as with faces when the subjects are experts in specific dog breeds (Diamond & Carey, 1986), suggests that there may be other factors, such as expertise, which give rise to the FIE. Event-related potentials (ERPs) were recorded while subjects performed an Old/New recognition study on normal and scrambled faces presented in upright and inverted orientations. We obtained the standard result for normal faces: The electrophysiological activity corresponding to the N170 was larger and delayed for normal inverted faces as compared to normal upright ones. On the other hand, the ERPs for scrambled inverted faces were not significantly larger or delayed as compared to scrambled upright stimuli. These results, in combination, show how the effect of inversion on the N170 is reliably greater when the faces are normal compared to scrambled, which suggests the disruption of configural information affects the FIE.

**Keywords:** Face recognition; Face inversion effect; N170; First and second order relational information; Old/new recognition task

## **Introduction**

Recognition of objects that are usually seen in one orientation is sometimes strongly impaired when the same objects are turned upside down, showing how intrinsically difficult it is to identify them. This has been found to be particularly the case for faces, leading to a phenomenon known as the face inversion effect (FIE). Thus, the fact that recognition of human faces is more impaired by inversion than is recognition for other stimuli has underlined how

faces are, in some sense, special. Some of the first evidence for the FIE reported by Yin (1969) presented participants with upright or inverted pictures of faces, airplanes, houses, and other stimuli. Following the study phase, participants were then tested with stimuli in the same orientation in a recognition task paradigm. The results showed that when the stimuli were studied and tested in an upright orientation, faces were better recognized than other sets of stimuli. However, when the same stimuli were presented and tested in an inverted orientation, recognition for faces decreased more than was the case for the other classes of stimuli. Yin (1969, experiment 3) replicated this result in an experiment using line drawings of facial stimuli and period costumes, thus controlling for the effect of subtle shadow information in an inverted face as a potential explanation for the large effect of inversion. In this experiment faces were not the easiest stimuli to be recognized when presented in an upright orientation. Therefore, the large FIE could not be attributed to the overall difficulty in discriminating within a stimulus category. Yin interpreted his results in terms of a face-specific process.

Over the past two decades more behavioral evidence has emerged that challenges the assumption that facial stimuli are special, not the least of which is the demonstration presented by Diamond and Carey (1986) that the inversion effect on recognition memory can be as strong with pictures of dogs as with faces when the subjects are experts in the identification and assessment of specific dog breeds. Given that the only stimuli that result in a substantial inversion effect are the ones for which the subjects have the necessary expertise, this suggests that the FIE may not be due to the fact that facial stimuli are subject to special processing because they are facial in nature, but instead that there are

other factors, such as expertise, which give rise to this effect. They distinguished between three types of information that can be used in recognition: isolated features, first-order relational features and second-order relational features. Isolated or local features are the independent constituent elements of an object. First-order information consists of spatial relations between constituent elements of an object, for example, the arrangement of the nose above the mouth. It is the first-order information that organizes a set of facial features into a face. Second-order information defines the relative size of these spatial relationships with regard to a base prototype. All faces tend to possess the same set of first-order relations, the essential manner in which faces differ from each other is captured by second-order relational information. These two kinds of relational information are both examples of configural information. Diamond and Carey suggested that large inversion effects will be obtained only if three conditions are met. Firstly, the members of the class of stimuli must share a configuration. Secondly, it must be possible to individuate the members of the class through second-order information. Finally, observers must have the expertise to exploit such second-order information. They proposed that the elements that distinguish faces lie on a continuum from isolated/local to second-order relational. Thus, recognition of members within the class differs from other types of recognition in its reliance on second-order relational features and in requiring expertise to use these features.

Searcy and Bartlett (1996) and Leder and Bruce (1998) have provided very clear evidence on the effect of disrupting configural information by inversion. In one of their experiments, Searcy and Bartlett (1996) made faces grotesque by either changing local elements, such as blackening teeth, blurring the pupils, or by changing the facial configuration. When shown in an inverted orientation, faces that were distorted through configural changes seemed to be more similar to the normal version, while the “locally distorted face” still looked grotesque. Thus, configural changes did not survive the inversion process as well as local ones. In another experiment, Leder and Bruce (1998) distorted faces so as to be more distinctive, either changing local features by giving them darker lips, bushier eye brows, etc. or by changing configural information to give a shorter mouth to nose spatial relation, etc. Distinctiveness impressions caused by distorted configural information disappeared when faces were presented in an inverted orientation compared to both upright faces and faces distorted in their local aspects. These results all provide evidence for the powerful effect that relational information has in the processing of upright faces relative to inverted faces. But there is still a question as to what precisely is the difficulty caused by any disruption of configural information consequent on inversion. The suggestion from some theories of perceptual learning (e.g. McLaren, 1997) is that expertise for faces can act directly on configural information, and confers the ability to make better use of it by effectively reducing the salience of first order relational

information (which is also configural but shared by most faces), leaving second order relational information relatively salient which aids discrimination. Thus, once configural information in upright faces has been disrupted (or at least our ability to make use of it), the benefits conferred by our expertise with those faces would tend to decrease, making them less easy to discriminate from one another. This explanation for the effect of expertise in face processing has some empirical support. The key finding is that it has been shown that experience with exemplars of a category that can be represented by a prototype (and have second order relational structure as a result of their variation about that prototype) leads to an increased ability to discriminate between members of that category. This improvement is lost when the stimuli are presented in an inverted orientation (McLaren, 1997). Recently, Civile *et al.*, (2011) provided some evidence that disrupting second order relational information by inverting (rotating by 180°) the eyes and the mouth, producing Thatcherised faces, whilst leaving other types of information (first order and local) intact reduces, even if it does not entirely eliminate, the FIE. However, in that same study they proposed that the FIE was still present for Thatcherised baseline stimuli (but significantly smaller than for normal faces) because Thatcherised faces still had some second-order information which had not been disrupted by the manipulation. Thus, in a second experiment they created a set of faces with all the second-order information disrupted. To do this they scrambled the faces by shuffling at random each of the features within a face. The effect of this was, in part, the expected one in that any inversion effect for the scrambled faces disappeared. The new finding was that performance for scrambled faces, whether in an upright or inverted orientation, was now below not only that for upright normal faces but also below that obtained for inverted normal faces. A possible explanation for this finding was that using scrambled faces may have affected both first and second order relational structure. In particular, when the ears were moved inside the face and replaced with other features, the typical shape of every face was changed to the point where it was no longer easily recognizable as a face.

In this present study, we aimed to replicate behaviorally those results obtained by Civile *et al.*, (2011), but this time we used a slightly different design. Participants were presented with two old/new recognition tasks, one including male faces and another female faces. All together the sample of faces seen in this experiment was more than double that used in the Civile *et al.*, (2011) study. This was done so that we could measure event-related potentials (ERPs) recording subjects’ neural activity while performing the tasks. There have been previous ERPs studies that have compared the presentation of normal upright faces and normal inverted faces. Rossion *et al.*, (1999) recorded neural activity in a delayed-matching task. A larger amplitude and delayed activity on the N170 was found for inverted faces compared to upright faces suggesting that inversion may slow down and increase difficulty in face processing.

Following the ERP literature on the N170 (de Haan *et al.*, 2002; Eimer, 2000; Tanaka & Curran, 2001; Rossion *et al.*, 2002) we predicted a larger inversion effect on the N170 for normal faces compared to scrambled faces which suffer from disrupted configural information. We expected to obtain significantly larger and delayed N170 amplitudes for normal inverted faces compared to normal upright faces. This follows from the assumption that inversion effects the expertise needed to exploit configural information, and that the N170 depends on the ability to make use of this information. Thus, this difference is expected to be significantly larger than the one between the amplitudes for scrambled upright and inverted faces as the influence of expertise here will be minimal. We also looked for neural activity correlates to the disadvantage that scrambled faces have compared to normal inverted faces.

## Materials

The study used 320 images in total, half female and half male. These were photographs of faces of former students at the University of Cambridge. The faces were standardized in grey scale format using Adobe Photoshop. A program called Gimp 2.6 was used to manipulate the 320 stimuli. Any given face stimulus was prepared in four different versions i.e. normal upright, normal inverted, scrambled upright and scrambled inverted which were used in a counterbalanced fashion across participants so that each face was equally often used in each condition of the experiment. Six facial features were used for scrambling i.e. the mouth, nose, two ears and the two eyes (including eyebrows). Scrambling was done by selecting at random one feature of the face and moving it to the forehead (chosen because this is the widest space inside the face and so can accommodate any feature). Following this, a second feature was selected and moved to the space left empty by the first feature, and so on until all the six facial features had been moved. Examples of the stimuli used are given in Figure 1. The experiment was run using E-prime software Version 1.1 installed on a PC computer.

**Figure 1;** Examples of stimuli used in the experiment showing the four different facial conditions. The dimensions of the stimuli were 5.63cm x 7.84cm. The stimuli were presented at a resolution of 1280 x 960. Participants sat 1m away from the screen on which the images were presented.

## Participants

24 undergraduates and postgraduates at the University of Exeter took part in the experiment.

## Procedure

The experiment consisted of an initial ‘study phase’ followed by an ‘old/new recognition phase’ using only male faces, and then another ‘study phase’ and ‘old/new recognition phase’, but this time using only female facial stimuli. After the instructions, the first part of the experiment involved participants looking at 80 male faces (presented one at a time in random order). The participants saw a fixation cross in the centre of the screen that was presented for 500 ms, followed by a black screen for 500 ms and then by a facial stimulus that was presented for 3000ms. Then the fixation cross and the black screen were repeated, and another face presented, until all stimuli had been seen. These faces will be termed the “familiar” (designated as type 1) faces for that participant because they were presented again later on in the old/new recognition task. The face types were: Normal Inverted faces (1NI); Normal Upright faces (1NU); Scrambled Inverted faces (1SI) and Scrambled Upright faces (1SU). Following the study phase, after further instructions, there was an old/new recognition task in which participants were shown (in random order) the 80 male faces they had already seen (i.e. the familiar faces) intermixed with a further 80 unseen male faces which were designated as type 2 and split into the same four face sub-types as in the study phase. During this old/new recognition task participants indicated whether or not they had seen the male face during the study phase by pressing the ‘.’ key if they recognized the face or to press ‘x’ if they did not. Each face never appeared as more than one face sub-type at a time during the experiment. The facial stimuli available were divided into sets of 20 giving 8 sets of stimuli, and each participant group was shown a different combination of the 160 facial stimuli split over the 8 sets as shown in Table 1. Because there were 160 male faces to consider (80 in the study phase and 80 in the recognition task), four participant breaks were incorporated. These allowed participants to rest their eyes after they had viewed 40 male faces. The second part of the experiment followed the same procedure as that used in the first part of the experiment. The only difference this time was that participants saw female faces.

Face Type	Part. Group1	Part. Group2	Part. Group3	Part. Group4	Part. Group5	Part. Group6	Part. Group7	Part. Group8
1(1NI)	Set1	Set4	Set3	Set2	Set5	Set8	Set7	Set6
2(1NU)	Set2	Set1	Set4	Set3	Set6	Set5	Set8	Set7
3(1SI)	Set3	Set2	Set1	Set4	Set7	Set6	Set5	Set8
4(1SU)	Set4	Set3	Set2	Set1	Set8	Set7	Set6	Set5
5(2NI)	Set5	Set8	Set7	Set6	Set1	Set4	Set3	Set2
6(2NU)	Set6	Set5	Set8	Set7	Set2	Set1	Set4	Set3
7(2SI)	Set7	Set6	Set5	Set8	Set3	Set2	Set1	Set4
8(2SU)	Set8	Set7	Set6	Set5	Set4	Set3	Set2	Set1

**Table.1.**Combinations of facial stimuli presented to each

participant group. The same face set combinations were used in the first and second half of the experiment for the male and female faces.

## EEG Apparatus

The EEG was sampled continuously during study and recognition phases at 500 Hz with a bandpass of 0.016-100 Hz, the reference at Cz and the ground at AFz using 64 Ag/AgCl active electrodes and BrainAmp amplifiers. There were 61 electrodes on the scalp in an extended 10-20 configuration and one on each earlobe. Their impedances were kept below 10 k $\Omega$ . The EEG was filtered offline with a 20 Hz low-pass filter (24 dB/oct) and re-referenced to the linked ears.

## EEG Analysis

Peak amplitudes of the N170 in study and recognition phases were examined for differences between the experimental conditions. To improve the estimates of N170 amplitude and latency given the relatively small number of ERP segments in each condition (leading to a low signal-to-noise ratio), N170 extraction was aided by linear decomposition of the EEG by means of Independent Component Analysis (ICA, Bell & Sejnowski, 1995). ICA was run separately for each subject using all scalp channels and the entire dataset. For analyses of the recognition phase, segments associated with incorrect responses were discarded (there were no responses in the study phase). The remaining EEG segments were averaged for every participant and experimental condition. In each subject, we identified ICA components that: (1) showed a deflection (peak) in the N170 time-range (at 150-200 ms following stimulus onset), and (2) had a scalp distribution containing an occipital-temporal negativity characteristic of N170 (the scalp distributions of components are the columns of the inverted unmixing matrix). This resulted in 1-4 ICA components corresponding to the N170 identified in most subjects (mean 2.6; SD 1) - these were back-transformed into the EEG electrode space (by multiplying the components with the inverted unmixing matrix that had the columns corresponding to other components set to zero) and submitted to statistical analysis of N170 peak amplitude and latency.

## Results

### Behavioral Results

The data from all 24 participants contributed to the signal detection  $d'$  analysis. Responses for male and female faces were collapsed and transformed into  $d'$  measures. A significant interaction was found between face type and orientation,  $F(1,23) = 20.77$ ,  $p < .01$ . Figure 2 shows the results for the mean  $d'$  obtained for each face type. A planned comparison was used to examine whether or not there was a significant inversion effect for normal facial stimuli. This gave a highly significant advantage  $F(1,23) = 34.37$ ,  $p < .001$ , for normal upright faces vs. normal

inverted faces, and another planned comparison revealed no significant effect of inversion for scrambled upright vs. scrambled inverted faces,  $F(1,23) = 0.026$ ,  $p = \text{ns}$ . The effect of face type on the recognition of upright faces was also analyzed. Normal upright faces were recognized significantly better than scrambled upright faces  $F(1,23) = 56.75$ ,  $p < .001$ , but there was no significant difference in the recognition of normal inverted faces and scrambled inverted faces. Finally, scrambled upright were recognized significantly above chance,  $F(1,23) = 19.63$ ,  $p < .01$ , as were scrambled inverted faces,  $F(1,23) = 28.04$ ,  $p < .01$ .

**Figure 2;** Behavioral results from old/new recognition task. The X-axis shows the four different stimulus' conditions, whereas the Y-axis shows the  $d'$  means for each of the four facial conditions.

### N170 analysis

N170 latency and amplitude analyses were run in electrode PO8 which was the electrode showing most of the activity during our experiment. We attempted to run the same analyses on the N170 data as on the  $d'$  behavioral data considered earlier to facilitate comparison.

### Study phase (see Figure 3)

Latency analysis: The Face Type by Orientation interaction was significant, i.e. the effect of face inversion on N170 latencies was reliably larger when faces were Normal compared to Scrambled,  $F(1,23) = 7.79$ ,  $p < .05$ . In particular, the face inversion effect was highly reliable for Normal faces,  $F(1,23) = 24.54$ ,  $p < .001$ , with N170 latencies peaking 10 ms earlier for upright faces (at 175 ms) compared to inverted faces (186 ms). For scrambled faces, peaks for inverted faces were delayed compared to upright faces by less than 1 ms failing to reach significance,  $F(1,23) = 0.18$ ,  $p = \text{ns}$ . Latencies of upright faces peaked earlier (by 5 ms) when faces were Normal compared to Scrambled. This difference was reliable,  $F(1,23) = 5.36$ ,  $p < .05$ .

Peak amplitude analysis: The difference in peak amplitudes between upright and inverted faces was larger when faces were Normal ( $-0.61\mu\text{V}$ ) than when they were Scrambled ( $0.18\mu\text{V}$ ), but this was only marginally reliable,

$F(1,23) = 3.13$ ,  $p < .1$ . The effect of inversion neared significance for Normal faces,  $F(1,23) = 3.28$ ,  $p < .1$ , with more negative amplitudes for inverted ( $-1.56\mu V$ ) compared to upright ( $-0.94\mu V$ ) faces. For scrambled faces, the inversion effect did not approach significance  $F(1,23) = .075$ ,  $p = ns$ . The effect of Face Type was not reliable for upright faces,  $F(1,23) = 0.30$ ,  $p = ns$ . Amplitudes for inverted faces were significantly larger when the faces were Normal compared to Scrambled ( $-0.711\mu V$ )  $F(1,23) = 4.23$ ,  $p < .05$ .

#### **Old/new recognition task (see Figure 4)**

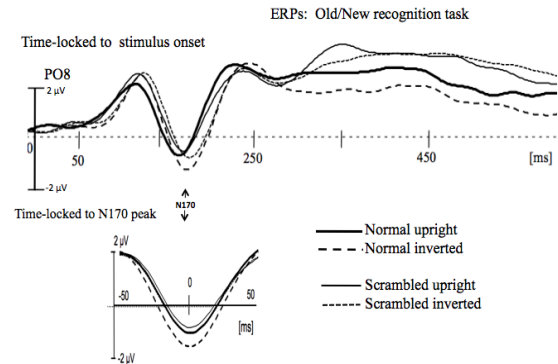

**Latency analysis:** A significant Orientation by Face Type interaction was found  $F(1,23) = 6.45$ ,  $p < .025$ . A significant inversion effect was observed for normal faces  $F(1,23) = 37.34$ ,  $p < .001$ , with N170 latencies peaking 9 ms earlier for upright faces (at 167 ms) compared to inverted faces (178 ms). A trend towards significance was found for the inversion effect related to scrambled faces  $F(1,23) = 2.51$ ,  $p = .13$  with N170 latencies peaking at nearly 4 ms earlier for upright Scrambled faces (at 176.3 ms) compared to inverted (179.90 ms). A final comparison revealed a significant effect for upright normal stimuli compared to scrambled upright stimuli  $F(1,23) = 9.06$ ,  $p < .01$ .

**Peak amplitude analysis:** No reliable Orientation by Face Type interaction was found. Means show a near significant inversion effect for Normal faces, with more negative amplitudes for inverted ( $-1.815\mu V$ ) vs. upright ( $-1.200\mu V$ ),  $F(1,23) = 3.67$ ,  $p = .06$ . No reliable difference was found for scrambled faces amplitudes  $F(1,23) = 0.79$ ,  $p = ns$ . No significant effect was found for upright normal stimuli compared to upright scrambled ones,  $F(1,23) = 1.03$ ,  $p = ns$ . However a significant effect was found for normal inverted faces compared to scrambled inverted ( $-1.216\mu V$ ),  $F(1,23) = 5.91$ ,  $p < .05$ .

**Figure.3.** The X-axis shows the elapsed time after a stimulus was presented, whereas the Y-axis shows the amplitudes ( $\mu V$ ) of the electrophysiological reactions in the study phase of the experiment. The insert in this figure is the ERP time-locked to the N170 peak, as identified in individual subjects. The time-scale of the inserts is stretched

relative to the main stimulus-locked ERP, the amplitude scale is the same in the insert as in the main figure.

**Figure.4.** The X-axis shows the elapsed time after a stimulus was presented. The Y-axis shows the amplitudes ( $\mu V$ ) of the electrophysiological reactions in the old/new recognition phase of the experiment. The insert in this figure is the ERP time-locked to the N170 peak, as identified in individual subjects during the old/new recognition task.

#### **Discussion**

On the behavioral side, and in agreement with the literature, we have obtained a strong inversion effect for normal faces. This has been eliminated entirely with scrambled faces. We have clear evidence here that configural information does indeed play an important role in driving the inversion effect for faces. Analyses on both the amplitude and latency of the N170 indicate a numerically larger inversion effect for normal faces than for scrambled faces. Running the same planned comparisons on the ERP data as for the behavioral data produces a very similar pattern of results, i.e. a strong inversion effect for the normal faces, and no inversion effect for scrambled faces, and a difference in N170 latencies between the upright normal and scrambled faces. The new finding here is that the scrambled stimuli (both upright and inverted) elicit a very similar N170 to one elicited by normal upright stimuli.

#### **General Discussion**

From the behavioral results of this study we have confirmed we can obtain a significant inversion effect with normal faces that can be eliminated entirely by disrupting both sources of configural information in the scrambled faces. This is consistent with our hypothesis that participants when presented with scrambled faces in an upright orientation would have no applicable expertise for those upright faces. Thus, when the same scrambled faces are presented in an inverted orientation, participants would not suffer any loss of expertise, as there was none to start with. Hence, we do not observe any inversion effect with scrambled faces. This supports the idea that the inversion effect observed with normal faces can at least in part be

explained by our ability to exploit configural information for categories of stimuli that possess both the necessary structure and are sufficiently familiar. If this structure is disrupted, then so is the inversion effect.

The ERP results provide neural correlates of our behavioral findings. In particular, in the study phase where participants were only asked to look at the faces and try to memorize them, analyses on both the amplitude and latency of the N170 gave a larger inversion effect for normal faces than for scrambled faces, and this result was highly significant for the latencies. Running the same planned comparisons on the ERP data as used for the behavioral data produces a very similar pattern of results, i.e. a strong inversion effect for the normal faces, none for the scrambled faces. However, If we study the waveforms that are time-locked to stimulus onset, then the new finding here is that both upright and inverted scrambled stimuli elicited a similar N170 to that for normal upright stimuli. This presents us with something of a mismatch with the behavioral patterns of results. According to the literature on face inversion and the N170, the ability to use configural information facilitates face processing, and this is supported by our behavioral results. The loss of configural information on inversion could have resulted in a selective amplification of the neural activity linked to faces because of an increase in difficulty due to a decrease in expertise for those faces presented in an inverted orientation (de Haan *et al.*, 2002; Eimer, 2000; Tanaka & Curran, 2001; Rossion *et al.*, 2002). In favor of this hypothesis is the correspondence between the behavioral data for the effects of inversion on normal faces and N170 for normal faces. This can also explain the lack of an inversion effect for the scrambled faces. Participants do not have expertise for these latter stimuli, thus the level of difficulty in processing them whether upright or inverted is the same leading to a similar N170 for both. However, according to this hypothesis we should have expected to obtain a larger and delayed N170 for scrambled faces compared to the N170 for normal upright faces and we did not. Instead, they are more similar to the N170 for normal upright faces.

Our results do agree with ERP studies using normal upright faces and familiar objects such as shoes or houses or chairs, in which it was found that the N170 elicited for these objects was more similar to that for normal upright faces. We can contrast this with the result obtained by Rossion *et al.* (2000), which compared the N170 elicited by a novel class of stimuli called Greebles which shared a common configuration to that obtained with faces and found it to be more like the N170 to inverted faces. This may suggest that our study may suffer from a lack of a correct baseline. Our scrambled stimuli were constructed by shuffling at random each of the features presented within a face. If our normal faces could be represented by a prototype, this was not the case for our scrambled faces, which instead varied a great deal in configuration because of the many different ways we shuffled the features within the face. It may be that our results show that participants perceived those scrambled

stimuli as many different types of object rather than as a set of new stimuli that could be represented by a prototype and shared a new configuration.

## Conclusion

In conclusion further research will be needed to evaluate the full implications of our results, but our data clearly suggest that there is a role for both first and second order structure in face recognition, that we argue can be understood in terms of experience-based expertise. And we have also shown that the elimination of the FIE can be correlated with a reduction of differences in neural activity in the N170.

### **Abstract**

The face inversion effect (FIE) refers to the decline in performance in recognizing faces that are inverted compared to the recognition of faces in their normal upright orientation (Yin, 1969). Event-related potentials (ERPs) were recorded while subjects performed an Old/New recognition study on normal and Thatcherised faces presented in upright and inverted orientation. A large difference in processing between normal upright faces and normal inverted faces was observed at occipital-temporal sites about 165 ms following stimulus onset, mainly in the right hemisphere. Thus electrophysiological activity, which corresponds to the previously described N170, had larger amplitude and was delayed for normal inverted faces as compared to normal upright ones. By contrast, the activity for Thatcherised inverted faces was not significantly changed or delayed as compared to Thatcherised upright stimuli. These results combine to show how the effect of face inversion on the N170 is reliably greater when the faces are normal rather than Thatcherised. Finally, these findings complement, at a neural level, our behavioral studies which suggest that the loss of some configural information affects the FIE.

**Keywords:** Face inversion effect; N170; configural information.

### **Introduction**

The face inversion effect (FIE) is a reduction in recognition performance for inverted faces compared to upright faces that is greater than that typically observed with other stimulus types (e.g. pictures of houses; Yin, 1969). Nevertheless, the demonstration that the inversion effect in recognition memory can be as strong with images of dogs as with faces when the subjects are experts in specific dog breeds (Diamond & Carey, 1986), suggests that there may be other factors, such as expertise, which give rise to the FIE. Diamond and Carey (1986) proposed that there is a special type of information, “second order relational information” that we depend on with increasing expertise.

Their analysis was that human faces all have the same group of features (eyebrows, eyes, nose, mouth, etc.). All these faces tend to have in common the same basic disposition of components, such that the eyes are always above the nose and so on. Thus, “first order relational information” corresponds to the spatial relationship between the features of a face, and “second order relational information” corresponds to the small variations in the spatial relationships between these features that individuate the faces. This information can also be considered to be a type of configural information. Diamond and Carey (1986) suggested that a large inversion effect will be obtained only if three conditions are met. Firstly, the members of the class of stimuli must share a basic configuration. Secondly, it must be possible to individuate the members of the class through second-order information. Finally, individuals must have the expertise to exploit such second-order information. Thus, recognition of exemplars of such a class differs from other types of recognition in its reliance on second-order relational features and requires a certain expertise to use these features. This interpretation of the effect of expertise is supported by the role of a prototype in face recognition. In one of their papers Valentine and Bruce (1986a) suggested that a face prototype was a result of overlaying many examples of faces in a distributed memory network (e.g. as in McClelland & Rumelhart, 1985). Therefore, the emergence of a face prototype is not something special for faces, but occurs simply because facial stimuli constitute a homogeneous category of which many exemplars are experienced. Thus, prototype extraction would be expected to arise for any set of stimuli that satisfies the three conditions previously described for a large inversion effect. Conversely then, evidence of prototype extraction can be used to determine whether or not an observer possesses expertise in discriminating within a stimulus category. The

suggestion from some theories of perceptual learning (e.g. McLaren, 1997) is that expertise for faces acts directly on the representation of the information in a face, and confers the ability to make better use of it by effectively reducing the salience of first order relational information, leaving second order relational information relatively salient which aids discrimination. Thus, if the configural information in upright faces is disrupted, or our ability to extract it is (e.g. by inversion), the benefits conferred by our expertise with those faces would tend to decrease, making them less easy to discriminate from one another. This explanation for the effect of expertise in face processing has some empirical support. The key finding is that it has been shown that experience with exemplars of a category that can be represented by a prototype (and so have second order relational structure as a result of their variation about that prototype) leads to an increased ability to discriminate between members of that category (McLaren, Leewers and Mackintosh, 1994). This improvement is lost when the stimuli are presented in an inverted orientation (McLaren, 1997). Thus, the results from these studies taken together support the view that experience with stimuli may have a role in driving the specialization of processes subserving learning and memory.

This view receives support from event-related potentials (ERPs) studies such as Rossion, Gauthier, Goffaux, Tarr and Crommelinck (2002) who have shown that it is possible to obtain an electrophysiological inversion effect for an experimental non-face stimulus class called 'Greebles' once participants are trained in recognizing them. Rossion *et al.* (2002) trained participants with a three-phase experiment in which there was first, a baseline phase, where ERPs were recorded from responses to face and Greeble presentations in both upright and inverted orientations. Following this, there was a training phase using only upright Greebles. Finally, during the last phase of the experiment ERPs were measured using new faces and new Greebles presented in both upright and inverted orientations. ERPs prior to the training phase revealed the inversion effect to be larger for faces than for Greebles. Following training with upright Greebles, the N170 (negative deflection occurring between 150-200 ms) latencies for the upright faces and Greebles were similar. The ERPs for inverted faces remained roughly constant before and after the training phase with Greebles, but ERPs to Greebles showed a significant training effect, in that there was an increased delay and increased amplitude for inverted Greebles as compared with Greebles presented in an upright orientation. In conclusion, although the inversion effect for faces was larger in both experimental sessions, the inversion effect for Greebles increased with increasing expertise with that category of stimuli. Furthermore, Tanaka and Curran (2001) investigated the neural basis of object expertise while recording the brain activity of experts when categorizing images of common dogs and birds. Results showed that the magnitude of the N170 was larger when the participants categorized objects in the domain in which they were expert than when they

categorized objects in the domain in which they were novices. Finally, de Haan, Pascalis & Johnson (2002) investigated the inversion effect and the link to expertise using human and monkey faces, as the latter have a similar configuration of features to human faces. These two categories of stimuli were presented to participants in both upright and inverted orientations. Results revealed that the N170 amplitude evoked by upright faces was smaller than for other stimuli, and the amplitudes for monkey faces both upright and inverted, and inverted human faces did not differ significantly from one another. Thus, inversion increased the amplitude and latency for human faces but not for monkey faces. The same experiment conducted on 6-month-old infants produced a component with similar morphology to the N170. However, this infant component differed from the N170, both because it peaked 100 ms later and it was not affected by inversion. Thus, for adults the orientation of faces played a role in determining the N170 (Eimer, 2000), but for infants the influence of orientation appeared only at later processing stages. This absence of an inversion effect in the infant ERPs is consistent with the idea that adults develop expertise for face processing, including both species and orientation, as a consequence of experience with that stimulus category (de Haan *et al.*, 2002). These results also suggest that ERP inversion effects are tied to expertise with a suitable category, rather than to the category of faces *per se*.

## EXPERIMENT

In this study we investigated the link between second-order relational structure and the face inversion effect suggested by Diamond and Carey (1986). The argument is that the improvement brought about by our expertise with faces is lost on inversion because this disrupts the ability to exploit second order relational information, leading to a strong inversion effect. In the behavioral part of this study, we aimed to demonstrate the typical strong inversion effect for normal face stimuli (for which we have expertise), and for comparison purposes ran a condition using what are known as Thatcherised face stimuli (see Fig. 1 for examples). These latter stimuli serve as our experimental manipulation in the sense that they suffer from somewhat disrupted second order-relational information (even when upright) caused by the 180° rotation of the eyes and the mouth, which should reduce at least some of the effect of expertise in the upright orientation. Another useful characteristic of these stimuli is that they are still faces, and are well matched for complexity with the normal faces. We also investigated the electrophysiological responses to normal faces in comparison with the responses obtained to Thatcherised faces and predicted that the N170 would correlate with our behavioral results. That is, the N170 for upright normal faces was expected to be different from that obtained in our other conditions. We expected to observe larger and delayed N170 amplitudes for inverted normal faces, as well as for upright and inverted Thatcherised faces, by analogy with the results of de Haan *et al.* (2002). This

follows from the assumption that the disrupted second order relational information in Thatcherised faces in part reduces the effect of expertise in the same way that inversion also reduces its impact, and that the N170 depends, at least in part, on the effect of expertise. Hence we expect the effect of expertise to only be evident for normal upright faces, and to manifest as a smaller amplitude and latency, leading to a large inversion effect (in the ERPs) for normal faces but not for Thatcherised faces.

### Materials

The study used 320 images in total, half female and half male. These were photographs of faces of former students at the University of Cambridge. The faces were standardized in grey scale format using Adobe Photoshop. A program called Gimp 2.6 was used to manipulate the 320 stimuli. Any given face stimulus was prepared in four different versions i.e. normal upright, normal inverted, Thatcherised upright and Thatcherised inverted, which were used in a counterbalanced fashion across participants so that each face was equally often used in each condition of the experiment. For the Thatcherised faces, each of the eyes and the mouth were flipped about the horizontal axis. Examples of the stimuli used are given in Figure 1. The experiment was run using E-prime software Version 1.1 installed on a PC computer.

**Figure 1;** Examples of stimuli used in the experiment showing the four different conditions for male and female faces. The dimensions of the stimuli were 5.63cm x 7.84cm. The stimuli were presented at a resolution of 1280 x 960 . Participants sat 1m away from the screen on which the images were presented.

### Participants

32 undergraduates and postgraduates at the University of Exeter took part in the experiment.

### Procedure

The experiment consisted of a ‘study phase’ and an ‘old/new recognition phase’ using only male faces, followed by another ‘study phase’ and ‘old/new recognition phase’, but this time using only female facial stimuli. After the instructions, the first part of the experiment involved participants looking at 80 male faces (presented one at a time in random order).The participants saw a fixation cross

in the centre of the screen that was presented for 500 ms. This was followed by a black screen for 500 ms and then by a facial stimulus that was presented for 3000ms. Then the fixation cross and the black screen were repeated, and another face presented, until all stimuli had been seen. These faces will be termed “familiar”(designated as type 1) faces for that participant because they will be presented again later on in the old/new recognition task. The face types during the study phase were: Normal Inverted faces (1NI); Normal Upright faces (1NU); Thatcherised Inverted faces (1TI) and Thatcherised Upright faces (1TU). Following the study phase, after further instructions, there was an old/new recognition task in which participants were shown (in random order) the 80 male faces they had already seen (i.e. the familiar faces) intermixed with a further 80 unseen male faces which were designated as type 2 (novel) and split into the same four face sub-types as the familiar set. During this old/new recognition task participants indicated whether or not they had seen the male face onscreen during the study phase by pressing the ‘.’ key If they recognized the face or by pressing ‘x’ if they did not. Each facial stimulus had a unique identifying number, to make sure that individual faces never appeared in more than one face type at a time during the experiment. To simplify their use in the experiment, the facial stimuli available were divided into sets of 20 giving 8 sets of stimuli, and each participant group was shown a different combination of the 160 facial stimuli rotated over the 8 sets as shown in Table 1. Because there were 160 male faces to consider (80 in the study phase and 80 in the recognition task), four participant breaks were incorporated. These allowed participants to rest their eyes after they had viewed 40 faces. The second part of the experiment followed the same procedure as that used in the first part of the experiment. The only difference this time was that participants saw female faces.

Face Type	Participant Group 1	Participant Group 2	Participant Group 3	Participant Group 4	Participant Group 5	Participant Group 6	Participant Group 7	Participant Group 8
1 (1NI)	Set 1	Set 4	Set 3	Set 2	Set 5	Set 8	Set 7	Set 6
2(1NU)	Set 2	Set 1	Set 4	Set 3	Set 6	Set 5	Set 8	Set 7
3(1TI)	Set 3	Set 2	Set 1	Set 4	Set 7	Set 6	Set 5	Set 8
4(1TU)	Set 4	Set 3	Set 2	Set 1	Set 8	Set 7	Set 6	Set 5
5(2NI)	Set 5	Set 8	Set 7	Set 6	Set 1	Set 4	Set 3	Set 2
6(2NU)	Set 6	Set 5	Set 8	Set 7	Set 2	Set 1	Set 4	Set 3
7(2TI)	Set 7	Set 6	Set 5	Set 8	Set 3	Set 2	Set 1	Set 4
8(2TU)	Set 8	Set 7	Set 6	Set 5	Set 4	Set 3	Set 2	Set 1

**Table.1.**Combinations of facial stimuli presented to each participant group. The same face set combinations were used in the first and second half of the experiment for the male and female faces.

### EEG Apparatus

The EEG was sampled continuously during both the study and test phases at 500 Hz with a bandpass of 0.016-100 Hz, the reference at Cz and the ground at AFz using 64 Ag/AgCl active electrodes and BrainAmp amplifiers. There were 61 electrodes on the scalp in an extended 10-20 configuration and one on each earlobe. Their impedances

were kept below 10 k $\Omega$ . The EEG was filtered offline with a 20 Hz low-pass filter (24 dB/oct) and re-referenced to the linked ears.

## EEG Analysis

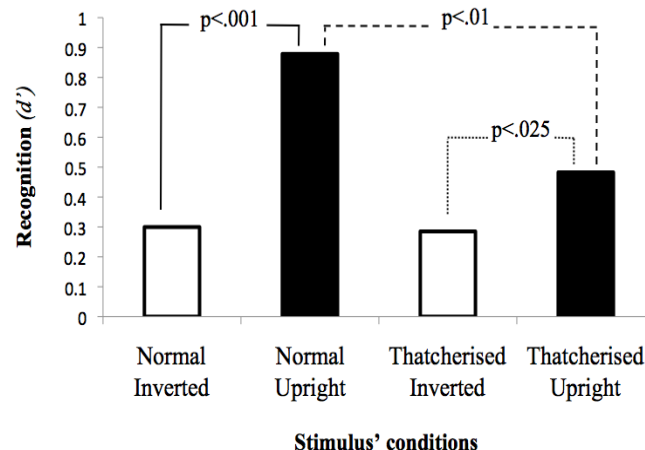

Peak amplitudes of the N170 in study and recognition phases were examined for differences between the experimental conditions. To improve the estimates of N170 amplitude and latency given the relatively small number of ERP segments in each condition (leading to a low signal-to-noise ratio), N170 extraction was aided by linear decomposition of the EEG by means of Independent Component Analysis (ICA, Bell & Sejnowski, 1995). ICA was run separately for each subject using all scalp channels and the entire dataset. For analyses of the recognition phase, segments associated with incorrect responses were discarded (there were no responses in the study phase). The remaining EEG segments were averaged for every participant and experimental condition. In each subject, we identified ICA components that: (1) showed a deflection (peak) in the N170 time-range (at 150-200 ms following stimulus onset), and (2) had a scalp distribution containing an occipital-temporal negativity characteristic of N170 (the scalp distributions of components are the columns of the inverted unmixing matrix). This resulted in 1-4 ICA components corresponding to the N170 identified in most subjects (mean 2.6; SD 1) - these were back-transformed into the EEG electrode space (by multiplying the components with the inverted unmixing matrix that had the columns corresponding to other components set to zero) and submitted to statistical analysis of N170 peak amplitude and latency.

## Results

### Behavioral Results

The data from all 32 participants contributed to the signal detection  $d'$  analysis. Responses for male and female faces were collapsed and transformed into  $d'$  measures. There was a significant interaction between face type and orientation,  $F(1,31) = 8.30$ ,  $p < .01$ . This reflected the fact that the inversion effect in the normal faces was significantly greater than that in the Thatcherised faces. Figure 2 shows the results for the mean  $d'$  obtained for each face type. A planned comparison gave a highly significant advantage  $F(1,31) = 29.99$ ,  $p < .001$ , for normal upright faces vs. normal inverted faces, and another planned comparison showed a similar (although smaller) inversion effect for Thatcherised upright vs. Thatcherised inverted faces,  $F(1,31) = 6.24$ ,  $p < .025$ . To further investigate this result, the effect of face type on the recognition of upright faces was also analyzed. Normal upright faces were recognized significantly better than Thatcherised upright faces  $F(1,31) = 13.71$ ,  $p < .01$ , but there was no significant difference in the recognition of normal inverted faces and Thatcherised inverted faces. Thus, it would seem that the reduction in the inversion effect for Thatcherised faces is more due to the impact that

Thatcherisation has on the upright faces rather than on the inverted ones.

**Figure 2;** Results for the old/new recognition task. The X axis shows the four different stimulus' conditions, the Y axis shows the mean  $d'$  for each condition.

### N170 analysis

Three participants had to be excluded because ICA did not find any components containing the N170 (nor was there an N170 visible in the original ERP). N170 latency and amplitude analyses were run in electrode PO8 which was the one showing most of the activity during our experiment. We attempted to run the same analyses on the N170 data as on the  $d'$  behavioral data considered earlier to facilitate comparison.

### Study phase (see Figure 3)

**Latency analysis:** The Orientation x Face Type interaction, i.e. the effect of inversion on N170 latencies, was reliably larger when faces were Normal compared to Thatcherised,  $F(1,28) = 4.73$ ,  $p < .05$ . In particular, the effect was highly reliable for Normal faces,  $F(1,28) = 21.19$ ,  $p < .01$ , with N170 latencies peaking 9 ms earlier for upright faces (at 165 ms) compared to inverted faces (174 ms). For Thatcherised faces, peaks for inverted faces were delayed compared to upright faces by 3 ms. This delay did not reach significance,  $F(1,28) = 1.54$ ,  $p = \text{ns}$ . Latencies of upright faces peaked earlier (by 4 ms) when faces were Normal compared to Thatcherised. This difference was only marginally reliable,  $F(1,28) = 3.24$ ,  $p = .082$ .

**Peak amplitude analysis:** The difference in peak amplitudes between upright and inverted faces was significantly larger when faces were Normal ( $-0.46\mu\text{V}$ ) than when they were Thatcherised ( $0.002\mu\text{V}$ ),  $F(1,28) = 4.18$ ,

$p=.05$ . The effect of inversion was reliable for Normal faces,  $F(1,28) = 7.06$ ,  $p < .025$ , with more negative amplitudes for inverted ( $-0.513\mu V$ ) compared to upright ( $-0.046\mu V$ ) faces. For Thatcherised faces the inversion effect did not approach significance  $F(1,28) = .0001$   $p=ns$ . The effect of Face Type was marginally reliable for upright faces,  $F(1,28) = 3.82$ ,  $p=.06$ , with more negative amplitudes for Thatcherised ( $-0.451\mu V$ ) compared to Normal ( $-0.046\mu V$ ) faces.

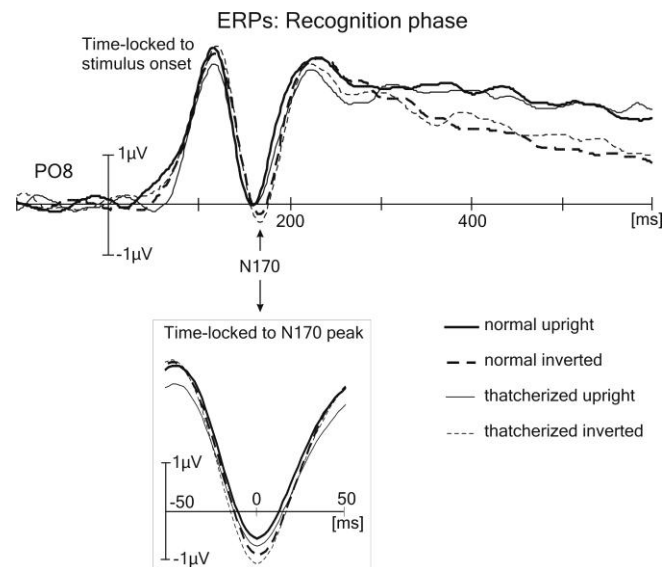

#### Old/new recognition task (see Figure 4)

**Latency analysis:** No significant Orientation by Face Type interaction was found. A significant inversion effect was obtained for normal faces  $F(1,28) = 16.36$ ,  $p < .01$  with N170 latencies peaking 5 ms earlier for upright faces (at 163 ms) compared to inverted faces (168 ms). A reduced but still significant inversion effect was found for Thatcherised faces  $F(1,28) = 6.62$ ,  $p < .025$  with N170 latencies peaking at nearly 5 ms earlier for upright Thatcherised faces (at 165.31 ms) compared to inverted (169.72 ms). A planned comparison revealed a trend towards significance for upright normal stimuli compared to Thatcherised upright ones  $F(1,28) = 2.27$ ,  $p=.15$ .

**Peak amplitude analysis:** As for latencies, no reliable Orientation by Face Type interaction was found. Means show a trend towards significance for Normal faces, with more negative amplitudes for inverted ( $-0.73\mu V$ ) vs. upright ( $-0.39\mu V$ ),  $F(1,28) = 2.50$ ,  $p=.13$ . For Thatcherised faces amplitudes are reliably more negative when they are inverted ( $-0.91\mu V$ ) vs. upright ( $-0.54\mu V$ ),  $F(1,28) = 4.59$ ,  $p < .05$ .

**Figure.3.** The X axis shows the elapsed time after a stimulus was presented, whereas the Y axis shows the amplitudes ( $\mu V$ ) of the electrophysiological reactions in the study phase of the experiment. The insert in this figure is the ERP time-locked to the N170 peak, as identified in individual subjects. The time-scale of the inserts is stretched relative to the main stimulus-locked ERPs, the amplitude scale is the same in the insert as in the main figure.

**Figure.4.** The X axis shows the elapsed time after a stimulus was presented. The Y axis shows the amplitudes ( $\mu V$ ) of the electrophysiological reactions in the old/new recognition phase of the experiment.

#### Discussion

This study has, in essence, confirmed our predictions. On the behavioral side we have obtained a strong inversion effect for normal faces and a reduced one for Thatcherised faces. The ERP results provide the sought after correlates of our behavioral findings in the study phase where participants were only asked to look at the faces and try to memorize them. Analyses on both the amplitude and latency show a larger inversion effect on the N170 for normal faces than for Thatcherised faces. Running the same planned comparisons on the ERP data as for the behavioral data produces a very similar pattern of results, i.e. a strong inversion effect for the normal faces, a greatly reduced effect for the Thatcherised faces, and a difference in N170 amplitude between the upright normal and Thatcherised faces but not between the two face types when inverted.

#### General Discussion

The behavioral results of this study show that we have obtained a significant inversion effect with normal faces, and have demonstrated that it is significantly larger than the inversion effect obtained with Thatcherised faces. To some extent, then, we have confirmed the basic face inversion finding. We have some evidence here that second order relational information plays a role in driving the inversion effect for faces. The most straightforward explanation of the difference in performance to the two face types when upright is that the Thatcherised faces have lost some (but not all) of the benefit of our expertise in dealing with second order structure. Because the Thatcherised faces are still essentially faces, then the application of our expertise with normal faces may lead to positively unhelpful results for upright Thatcherised faces, in that the changed features

stand out and command processing. Because these features are not those best suited to individuate faces, i.e. our processing is being dominated to a greater extent by what is common to Thatcherised faces (because they are surprising) rather than what would aid us in discriminating between them, performance for upright Thatcherised faces would be expected to be worse than for normal upright faces. The lack of any difference in recognition performance between normal and Thatcherised faces when inverted can be explained by arguing that in these circumstances second order relational information is not in play, and the two types of face are otherwise equated in terms of features and other factors (e.g. overall shape of the face).

The results from the ERPs bolster our interpretation of the effects we obtained in the behavioral results. As we predicted, the N170 to upright normal faces was different to that of our other stimuli, an effect that we can now argue reflects in part the high degree of expertise participants had for them. One of our findings is that this difference was a great deal clearer in the study phase of our experiment than in the test phase. This is not an entirely unexpected result. Firstly, if the modulation of the N170 reflects an effect of expertise, then this should occur when simply perceiving the stimulus – the effect is not tied to having to do anything in particular, except perhaps attend to the stimulus. Secondly, as a result of the study phase, the Thatcherised stimuli will start to become familiar, in particular the Thatcherised upright faces will tend to become progressively more equivalent to normal upright faces. Thus, any effect in the study phase will be a relatively pure comparison of the two stimulus types, one highly familiar, the other novel (at least in part); but in the test phase this distinction, and the effects that flow from it, will be attenuated by participants' increasing familiarity with the Thatcherised stimuli. If we study the waveforms that are time-locked to stimulus onset then the pattern at the N170 exactly corresponds to that observed in the behavioral data. As we predicted, upright normal faces occur earlier and with smaller amplitude in the N170, upright Thatcherised faces are somewhat later and have greater amplitude, and both the inverted face types are slightly later still and have slightly greater amplitude than upright Thatcherised faces. We suggest that the N170 is indexing, at least in part, the effect of expertise with the stimulus category. Inversion of the faces increases the amplitude of the N170 and delays its onset in agreement with a number of other studies which have found a greater delay and larger amplitude for the inverted stimulus (Rossion *et al*, 2002; Tanaka and Curran, 2001; de Haan *et al*, 2002). We note that the FIE for our Thatcherised stimuli is still significant, suggesting that simply disrupting second order information does not completely eliminate the FIE. A possible explanation for this is that by rotating the eyes and the mouth we have not disrupted all the second order information in a face. Thus, our baseline stimuli still have some second order information which participants may have expertise for. Another explanation could be that not only second order information is involved in the FIE but

there may be an important role for other types of information. Perhaps by disrupting both first and second order configural information we would be able to eliminate the FIE entirely. Our claims about the magnitude of the inversion effect are secure, but we cannot tell if performance in all our conditions is still benefiting from the effects of expertise (all the stimuli are, after all, recognizable as faces). One obvious way in which this might happen is by virtue of all the face types containing standard facial features that have not been themselves changed apart from a rotation or reflection. Another would be to appeal to the basic envelope of the stimuli remaining unchanged under Thatcherisation and inversion. Clearly it would be unwise to assume that all effects of expertise disappear under inversion, Thatcherisation or a combination of the two manipulations. What we can conclude, however, is that Thatcherisation interacts with stimulus inversion in a way that strongly suggests that experience with these stimuli helps us to better exploit that information.

# Strength of Perceptual Experience Predicts Word Processing Performance Better than Concreteness or Imageability

## Abstract

Abstract concepts are traditionally thought to differ from concrete concepts by their lack of perceptual information, which causes them to be processed more slowly and inaccurately than perceptually-based concrete concepts. We examined this assumption by comparing concreteness and imageability norms to a set of perceptual strength norms in five separate modalities: sound, taste, touch, smell and vision. Results showed that that concreteness and imageability do not actually reflect the perceptual basis of concepts: concreteness ratings appear to be based on two different intersecting decision criteria, and imageability ratings are visually biased. Analysis of lexical decision and word naming performance showed that maximum perceptual strength (i.e., strength in the dominant perceptual modality) consistently outperformed both concreteness and imageability in accounting for variance in response latency and accuracy. We conclude that so-called concreteness effects in word processing emerge from the perceptual strength of a concept's representation and discuss the implications for theories of conceptual representation.

**Keywords:** abstract concepts; imageability; concreteness effects; perceptual strength; lexical decision; word naming

## Introduction

What exactly constitutes an abstract concept? Traditionally, abstract words such as *truth* or *impossible* are assumed to refer to things that are not perceptually experienced, while concrete words such as *chair* or *turquoise* are assumed to refer to perceptible, material entities. A long history of research has examined processing differences between such abstract and concrete concepts. In particular, concreteness effects refer to a behavioral advantage for words that refer to concrete concepts, which are processed more quickly and accurately than abstract concepts in tasks such as lexical decision and word naming (e.g., Binder et al., 2005; James, 1975; Kroll & Merves, 1986; Schwanenflugel, Harnishfeger & Stowe, 1988; Schwanenflugel & Stowe, 1989).

A number of different theories have been proposed to account for concreteness effects in word processing performance. Dual coding theory (Paivio, 1986, 2007) holds that both concrete and abstract concepts have a verbal code representation, but that concrete concepts alone also have a nonverbal, perceptual code that “gives rise to conscious (reportable) imagery when activated” (Paivio, 2007, p. 39). Abstract words are slower to process because they can only be imaged indirectly, via related concrete words. Context availability theory (Schwanenflugel &

Shoben, 1983; Schwanenflugel et al., 1988) instead argues that the type of information is less important than the quantity, and that concrete concepts are strongly linked to a narrow range of supporting contexts in memory whereas abstract concepts are weakly linked to a wide range. People are slower to process abstract words because they find it more difficult to retrieve associated contextual information. More recently, situated simulation views of conceptual representation (Barsalou & Wiemer-Hastings, 2005; Barsalou, Santos, Simmons & Wilson, 2008; see also Kousta, Vigliocco, Campo, Vinson & Andrews, 2011) have drawn together several aspects of both dual coding and context availability theories. Concrete concepts are represented in a narrow range of situations that focus on perceptual and motor information, while abstract concepts have a wide range of situations that focus on social, introspective and affective information. Abstract words are slower to process because people find it more difficult to access their situations.

However, despite their reputation as a textbook effect, concreteness effects do not always reliably emerge in semantic processing. Null effects are rarely publishable, but lack of concreteness effects in response times and error rates are not uncommon in cognitive neuroscience studies where significant findings on other measures are reported alongside null behavioral results (e.g., Fiebach & Friederici, 2003; Papagno, Fogliata, Catricalà & Miniussi, 2009; Sabsevitz, Medler, Seidenberg & Binder, 2005; Tyler, Russell, Fadili, Moss, 2001). Furthermore, reverse concreteness effects – a processing advantage for abstract concepts rather than concrete – have also been found in studies of healthy adult participants (e.g., Adelman, Brown & Quesada, 2006; Kousta et al., 2011). Such null and reversed concreteness effects are problematic for theories that claim fundamental representational differences between concrete and abstract concepts.

One reason for inconsistencies in empirical tests of concreteness effects may be that the intuitive and theoretical assumption is valid (i.e., that concepts with perceptual information are faster to process), but that the typical basis for selecting experimental items (i.e., concreteness or imageability ratings) does not offer an accurate measure of the perceptual basis of concepts. Most researchers select items from published norms such as the MRC psycholinguistic database (available online at [http://www.psy.uwa.edu.au/MRCDataBase/uwa\\_mrc.htm](http://www.psy.uwa.edu.au/MRCDataBase/uwa_mrc.htm)).

However, when we examined the original norming instructions used to collect these norms, we found it questionable that participants would have simultaneously considered their sensory experience across all modalities and then managed to aggregate this experience into a single, composite rating per word. Instructions for concreteness ratings, for example, define concrete words as referring to “objects, materials, or persons” and abstract words as referring to something that “cannot be experienced by the senses” (Paivio, Yuille & Madigan, 1968, p. 5). The resulting ratings, therefore, may reflect different decision criteria at the concrete and abstract ends of the scale, which is consistent with previous observations that the concreteness ratings scale has a bimodal distribution (e.g., Kousta et al., 2011). Imageability ratings are frequently used interchangeably with concreteness ratings (e.g., Binder et al., 2005; Sabsevitz et al., 2005) because of their high correlation and theoretical relationship in dual coding theory. Instructions for imageability ratings repeatedly refer to arousing a “mental image” (Paivio et al., 1968, p. 4), which is likely to lead naïve participants to focus on vision at the expense of other modalities. Both concreteness and imageability ratings could therefore add considerable noise to any dataset that assumed the ratings reflected a smooth continuum of perceptual experience across all modalities.

Our goals in the present paper were twofold. First, we aimed to establish whether concreteness and imageability norms actually reflect the degree with which concepts are perceptually experienced, as is commonly assumed. Second, we examined whether so-called concreteness effects in word processing are better predicted by concreteness/imageability ratings or by strength of perceptual experience. If the former, then forty years of empirical methodology have been validated but the reasons for null and reverse concreteness effects remain unclear. If the latter, then concreteness and imageability ratings are unsuitable for the tasks in which they are employed, and null and reverse concreteness effects are due to the unreliability of perceptual information in these ratings.

## Experiment 1

Rather than ask participants to condense their estimations of sensory experience into a single concreteness or imageability rating, modality-specific norming asks people to rate how strongly they experience a variety of concepts using each perceptual modality in turn (i.e., auditory, gustatory, haptic, olfactory or visual: Lynott & Connell, 2009, in prep.; see also Connell & Lynott, 2010; Louwerse

& Connell, 2011).

If concreteness and imageability are a fair reflection of the degree of perceptual information in a concept, then ratings of perceptual strength in all five modalities should be positively related to concreteness and imageability ratings, and these relationships should remain consistent across the rating scale. On the other hand, if we were correct in our hypothesis to the contrary, then we would expect some perceptual modalities to be neglected (i.e., no relationship) or even misinterpreted (i.e., negative relationship) in concreteness and imageability ratings. Specifically, concreteness norming instructions may have led to different decision criteria and therefore distinctly different modality profiles at each end of scale, whereas imageability instructions may have led to a predominantly visual bias.

## Method

**Materials** A total of 592 words were collated that represented the overlap of the relevant sets of norms, so each word had ratings of perceptual strength on five modalities as well as concreteness and imageability (see Table 1 for sample items). Perceptual strength norms came from Lynott and Connell (2009, in prep.), in which participants were asked to rate “to what extent do you experience WORD” (for nouns) or “to what extent do you experience something being WORD” (for adjectives) through each of the five senses (i.e., “by hearing”, “by tasting”, “by feeling through touch”, “by smelling” and “by seeing”), using separate rating scales for each modality. Perceptual strength ratings therefore took the form of a 5-value vector per word, ranging from 0 (low strength) to 5 (high strength). Concreteness ratings were taken from the MRC psycholinguistic database for 522 words, with ratings for the remaining 70 words coming from Nelson, McEvoy and Schreiber (2004). Imageability ratings for 524 words also came from the MRC database, and were supplemented with ratings for a further 68 words from Clark and Paivio (2004). All concreteness and imageability ratings emerged from the same instructions as Paivio et al.’s (1968) original norms, and ranged from 100 (abstract or low-imageability) to 700 (concrete or high-imageability).

**Design & Analysis** We ran stepwise regression analyses with either concreteness or imageability rating as the dependent variable, and ratings of auditory, gustatory, haptic, olfactory and visual strength as competing predictors. For analysis of consistency across the scales, each dependent variable was split at its midpoint before

Table 1: Sample words, used in Experiments 1 and 2, for which perceptual strength ratings [0-5] match or mismatch ratings of concreteness and imageability [100-700].

Word	Perceptual strength					Concreteness	Imageability
	Auditory	Gustatory	Haptic	Olfactory	Visual

regression: concreteness ratings formed abstract (rating [100-400],  $N = 294$ ) and concrete ([401-700],  $N = 298$ ) groups, whereas imageability ratings formed low ([100-400],  $N = 167$ ) and high ([401-700],  $N = 425$ ) groups. A priori sensitivity analysis confirmed that the sample size of the smallest group (low-imageability words) was still large enough to capture even a low degree of fit (minimum  $R^2 = .074$ ) in a five-predictor regression model at power of 0.8.

## Results & Discussion

**Concreteness** Analysis showed clear dissociations between concreteness and modality-specific perceptual experience, with little consistency across abstract and concrete groups (see Figure 1). Abstract words' ratings were predicted by three of the five modalities,  $F(3, 290) = 8.64$ ,  $p < .0001$ ,  $R^2 = .082$ , but with a low degree of fit and inconsistency in the direction of the relationship: positively related to vision, and negatively to auditory and olfactory strength. In contrast, concrete words' ratings were predicted positively by olfactory and visual strength,  $F(2, 295) = 33.52$ ,  $p < .0001$ ,  $R^2 = .185$ , but these two perceptual modalities offered a higher degree of fit than the model for abstract words.

Most perceptual modalities therefore failed to retain a consistent relationship with concreteness across the scale (auditory, olfactory) or had no predictive value at all (gustatory, haptic). However, the most serious conflict concerned the inversion of the olfactory effect: more olfactory meant more abstract, but more olfactory also meant more concrete. Such inconsistency in behavior poses serious problems for the assumption that abstractness and concreteness represent two ends of the same continuum, and rather indicates that participants applied different decision criteria at the concrete and abstract ends of the norming scale. While perceptual strength can explain more than twice the concreteness variance in concrete words (19%) than it did in abstract words (8%), participants are clearly basing their concreteness rating on non-perceptual information. It therefore appears that participants in concreteness norming studies treated the scale as two intersecting continua, neither of which reliably reflects the extent of sensory experience.

**Imageability** Analysis of imageability showed a clear visual bias at the expense of other perceptual modalities (see Figure 2). Ratings of low-imageability words were predicted by two perceptual modalities: visual strength (positively) and olfactory strength (negatively),  $F(2, 164) = 16.42$ ,  $p < .0001$ ,  $R^2 = .167$ . High-imageability ratings, on the other hand, were related to three perceptual modalities with a similar degree of fit,  $F(3, 421) = 36.32$ ,  $p < .0001$ ,  $R^2 = .206$ : positively for both visual and olfactory information, and negatively for gustatory.

Participants therefore tend to rely on visual experience when generating imageability ratings: visible things are highly imageable and invisible things are not. However, this focus on vision led other modalities to be neglected or misinterpreted. Neither auditory nor haptic experience was reflected at either end of the scale, and people tended to

Figure 1: Modality predictors of concreteness ratings in Experiment 1 (\*  $p < .05$ , \*\*  $p < .01$ ).

Figure 2: Modality predictors of imageability ratings in Experiment 1 (\*  $p < .05$ , \*\*  $p < .01$ ).

misconstrue olfactory information and ignore gustatory information for low-imageability concepts, yet follow olfactory strength while misinterpreting gustatory strength for high-imageability concepts. Results indicate that people do not find it equally easy to generate imagery across the range of modalities that constitute perceptual experience. Participants in imageability norming studies seem to have had difficulty in extending the meaning of “image” beyond its conventional interpretation as a visual impression.

## Experiment 2

Since neither concreteness nor imageability ratings reflect the full range of sensory experience, it raises the question of whether textbook concreteness effects in word processing are actually due to (a) the degree of perceptual information in each referent concept's representation, or (b) some other conceptually meaningful information that makes up most of

the variance in concreteness and imageability ratings. The present experiment aimed to resolve this question by comparing the unique predictive abilities of concreteness ratings, imageability ratings and perceptual strength in lexical decision and word naming performance.

If concreteness effects are due to the degree of perceptual information in each referent concept's representation, then perceptual strength should outperform concreteness and imageability in predicting latency and accuracy in word processing. In this case, we would expect perceptual strength to exhibit an independent effect in the presence of concreteness / imageability predictors, but not vice versa, because most of the variance in concreteness and imageability ratings reflects decision criteria that are unrelated to processing performance. On the other hand, if concreteness effects are actually due to some other non-perceptual representation that is captured by concreteness and imageability ratings, then they would maintain an independent effect even when perceptual strength has already been partialled out. In this sense, concreteness effects would subsume perceptibility effects, because the variance in concreteness and imageability ratings would reflect conceptually meaningful information in addition to perceptual differences.

## Method

**Materials** The same set of 592 words from Experiment 1 was used in this study, along with lexical decision and naming data from the Elexicon database (Balota et al., 2007; available online at <http://elexicon.wustl.edu>), which also provided lexical characteristics for each word to act as independent regression variables (see below).

**Design & Analysis** Hierarchical regression analyses determined the proportion of variance each candidate rating could explain. The dependent variables were mean lexical decision and naming times for each word ( $M = 633$  ms,  $SD = 64$  ms;  $M = 622$  ms,  $SD = 53$  ms; respectively), and their accompanying mean accuracy rates ( $M = 96.6\%$ ,  $SD = 5.4\%$ ;  $M = 98.9\%$ ,  $SD = 3.3\%$ ). As well as raw RT in ms, we also analysed standardized RT based on the mean z-scores of the original participants in the Elexicon data, which offers a more reliable measure of latency by partialing out individual differences in overall speed and variability (Balota et al., 2007). As independent variables in all regressions, we used a basic model found by Brysbaert and New (2009) to provide the best fit for RT and accuracy: log contextual diversity,  $\log^2$  contextual diversity, number of letters in the word, and number of syllables in the word.

The independent (unique) effects of concreteness ( $M = 427$ ,  $SD = 107$ ) and imageability ( $M = 461$ ,  $SD = 92$ ) were ascertained by adding the relevant predictor to a model containing maximum perceptual strength<sup>1</sup> and examining

<sup>1</sup> Maximum perceptual strength represents the highest rating in the concept's dominant modality, which analysis showed was the best method of compressing the five-value vector of perceptual strength into a single variable (necessary for equitable comparison with concreteness and imageability).

whether it led to an increase in fit. The independent effect of perceptual strength ( $M = 3.78$ ,  $SD = 0.75$ ) was calculated twice: once by entering it in a model that already contained concreteness, and once by adding it to a model that contained imageability. The correlation between imageability and concreteness was high,  $r(590) = .828$ ,  $p < .0001$ , and comparable to previous studies (e.g.,  $r = .83$  in Paivio et al., 1968). Maximum perceptual strength had a much weaker relationship with both concreteness,  $r(590) = .429$ ,  $p < .0001$ , and imageability,  $r(590) = .502$ ,  $p < .0001$ .

## Results & Discussion

Only perceptual strength emerged as a unique predictor of variance in word processing (see Figure 3 and Table 2). When either concreteness or imageability had already been included in the model, perceptual strength still accounted for an extra proportion of variance in all measures except naming accuracy. Critically, the inverse was not true. When maximum perceptual strength was included as a predictor, there was no model where the addition of concreteness or imageability produced an increase in  $\text{fit}^2$ . It is important to note that perceptual strength was in all cases acting in the expected direction (see Table 2): RT decreased and accuracy increased with higher perceptual strength. In other words, the independent predictive ability of perceptual strength never counteracted any facilitation by concreteness or imageability. Maximum perceptual strength thus captures meaningful information about conceptual structure that other ratings do not, and this information impacts directly on word processing performance.

One other striking difference emerged. Previous research has found that contextual diversity is inversely correlated with concreteness and imageability (i.e., abstract words appear in more diverse contexts than do concrete words: Schwanenflugel & Shoben, 1983; Schwanenflugel et al., 1988). Our data was consistent with this established pattern: zero-order correlations showed that concreteness was negatively related to log contextual diversity,  $r(590) = -.108$ ,  $p = .009$ , though the weaker trend for imageability was not significant,  $r(590) = -.024$ ,  $p = .560$ . Yet, in sharp contrast, perceptual strength was *positively* correlated with contextual diversity,  $r(590) = .117$ ,  $p < .0001$ . That is, although concrete-rated words have a narrower variety of contexts than abstract-rated words, perceptually strong words have a *wider* variety than perceptually weak words. We return to this issue in the general discussion.

## General Discussion

In the present paper, we show that concreteness and

<sup>2</sup> Our approach and findings thus differ considerably from those of Juhasz et al., (2011), who found that a sensory experience rating predicted lexical decision times after imageability was partialled out. However, they did not examine concreteness ratings or word naming times, their rating asked people to aggregate all sensory experience on a single scale (which our Experiment 1 indicates that people find very difficult) rather than collecting ratings on separate modalities, and they did not show which of imageability and their own rating had better predictive power.

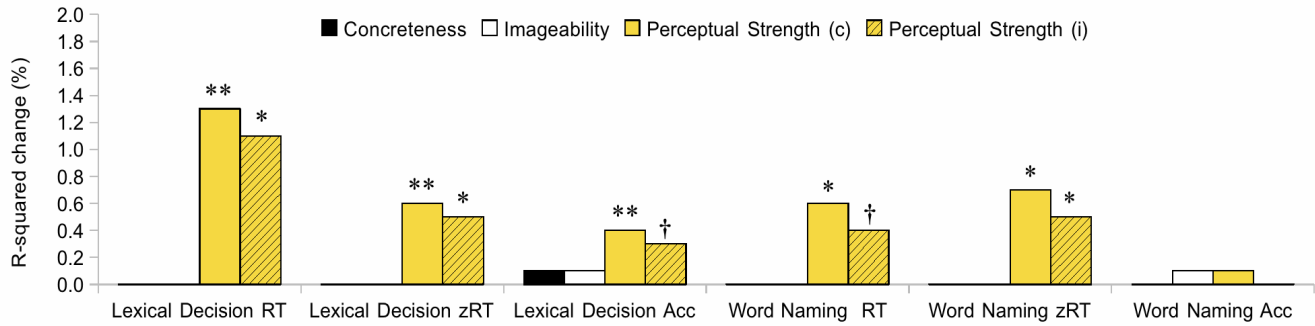

Figure 3: Independent (unique) effects of each predictor in Experiment 2, showing proportion of explained variance ( $R^2$  change in %) of Elexicon reaction time and accuracy data, over and above that of perceptual strength, concreteness (c) or imageability (i) (†  $p < .1$ , \*  $p < .05$ , \*\*  $p < .01$ ).

Table 2: Standardized regression coefficients for independent effects of each predictor over and above that of perceptual strength, concreteness (c) or imageability (i), in models of Elexicon reaction time and accuracy data in Experiment 2.

Perceptual strength (c)	−0.132**	−0.091**	+0.097**	−0.089*	−0.095*	+0.038
Perceptual strength (i)	−0.127**	−0.080*	+0.067†	−0.072†	−0.082*	+0.006

†  $p < .1$ , \*  $p < .05$ , \*\*  $p < .01$

imageability ratings do not accurately reflect the perceptual basis of concepts, and that concreteness effects in lexical decision and naming are better predicted by perceptual strength ratings than by concreteness or imageability ratings. These findings support the intuition that perceptual concepts are faster to process, and show that textbook concreteness effects in word processing are actually a function of the degree of perceptual information in each referent concept's representation. However, our results also suggest that concreteness and imageability ratings are unsuitable for the tasks in which they are employed, because most of their variance comes from non-perceptual decision criteria that is unrelated to word processing performance. Concreteness effects could therefore be better characterized as perceptibility effects, which can be sometimes nullified or inverted (e.g., Kousta et al., 2011; Papagno et al., 2009) when elicited from relatively noisy concreteness or imageability ratings.

While the connection between concreteness effects and perceptual information might at first glance seem like old news (e.g., Barsalou & Wiemer-Hastings, 2005; Paivio, 1986, 2007), the present findings have some important ramifications for how such effects should be interpreted. Concreteness effects, by their very name, are assumed to result from an ontological difference between concrete and abstract concepts carrying through to a representational difference that affects speed and accuracy of processing. Labeling a word as “concrete” or “abstract” has an intuitive appeal, but we would argue that these terms lacked proper operationalization during norming and hence it is unclear exactly what information is captured by concreteness

ratings. Of course, any set of ratings can only ever be an approximation of an underlying representation, and we are not suggesting that one should expect a perfect fit between concreteness ratings and behavioral effects. That said, the poor performance of concreteness ratings in the current data lies in sharp contrast to the robust performance of perceptual strength ratings. We suggest that the concrete / abstract ontological distinction must be disentangled from concreteness / imageability norms because empirical concreteness effects are not in themselves well predicted by concreteness / imageability.

Theoretically, the present results poses some problems for dual coding, context availability, and situated simulation explanations of concreteness effects. It is a central tenet of dual coding theory that highly perceptual concepts are those with the most direct connections between the verbal and nonverbal imagery codes, and people therefore find it difficult to generate perceptual imagery for words that lack these direct connections (Paivio, 1986, 2007). However, imageability (i.e., the ease of consciously generating imagery) is not well related to perceptual experience (Experiment 1), and its effects were entirely subsumed by larger effects of perceptual strength (Experiment 2). In other words, it is the extent of perceptual information in a concept's representation that matters to word processing, not the ease of generating imagery, which casts some doubt on the idea that processing delays for abstract concepts emerge from their lack of direct inter-system connections. Both context availability (Schwanenflugel & Shoben, 1983; Schwanenflugel et al., 1988) and situated simulation (Barsalou & Wiemer-Hastings, 2005; Barsalou et al., 2008)

views share the idea that abstract concepts are slowed in processing because they have a wider variety of potential situational contexts. This idea, however, is not borne out by our data. Strongly perceptual concepts (i.e., those that are generally assumed to be concrete, regardless of what concreteness ratings say) actually have greater contextual diversity than weakly perceptual concepts.

In sum, we believe that the operationalisation of abstract and concrete concepts deserves much closer scrutiny than it has received to date. Whether researchers want to investigate the ontological distinction between abstract and concrete concepts, or the variables that affect latency and accuracy in word processing, then they should reconsider the automatic tendency to reach for concreteness and imageability ratings that have little to do with the perceptual basis of concepts. Strength of perceptual experience has a powerful bearing on how people represent concepts during word processing, and these perceptibility effects are stronger than those elicited by concreteness or imageability.

# Learning of Relational Categories as a Function of Higher-order Structure

Daniel Corral (daniel.corral@colorado.edu) & Matt Jones (matt.jones@colorado.edu)

Department of Cognitive Psychology, University Colorado Boulder,  
Boulder, CO 80309 USA

## Abstract

Higher-order relations are important for various cognitive tasks, such as analogical transfer. The current study tested people's ability to learn new relational categories, using a learning test of pure higher-order relations. Each stimulus consisted of 4 objects varying on 3 dimensions. Each category was defined by three binary relations between pairs of objects, producing six logically different conditions. Every category was composed of the same number of relations, but differed in the manner that the relations were linked (i.e., by operating on shared objects). Various learning models were compared and the significance of their performance on the experimental task is discussed. The current findings may advance understanding of the cognitive mechanisms involved in relational learning and the manner in which people naturally represent higher-order relational structures.

**Keywords:** higher-order relations; schema refinement; schema elaboration; structure acquisition.

## Introduction

The ability to generalize and transfer knowledge from a given problem to an analogous task has been of great interest to cognitive scientists and has led to an extensive amount of research. The large body of work on analogical transfer has converged on the idea that transfer is driven by discovering the common relational structure between two analogous scenarios (Gentner, 1983; Gick & Holyoak, 1983). Penn, Holyoak, and Povinelli (2008) posit higher-order relations are critical for most other higher cognitive processes as well, including inference, causal reasoning, and theory of mind. Nevertheless, there is little understanding of the cognitive mechanisms that subserve learning and recognition of higher-order relations.

The purpose of the current study is to explore how people learn different higher-order relations. We define a *higher-order relation* to be a system of first-order (i.e., primitive) relations operating on a common set of objects. Different higher-order relations differ in how the first-order relations are linked together by shared role-fillers. We report an experiment using a relational category-learning task, in which each subject learned a category defined by a higher-order relation, by learning to distinguish category members from non-members. The category in each experimental condition was defined by three binary relations among four objects. In the spirit of Shepard, Hovland, & Jenkins' (1961) classic study on learning feature-based categories, we conduct an exhaustive comparison of the six logically different categories of this type.

The dominant view of how people acquire relational concepts is schema refinement (e.g., Doumas, Hummel, & Sandhofer, 2008), but the present results highlight a number

of conceptual problems with this approach. As an alternative, we introduce schema elaboration as a mechanism that is more psychologically plausible and better able to match human performance. We consider four variants of schema elaboration, motivated by different theoretical perspectives, and compare their ability to predict the relative learnability of different higher-order relations.

## Structure-Mapping Theory

Since its initial proposal (Gentner, 1983), structure-mapping theory has provided a great deal of insight into the process of analogical learning and transfer. Structure-mapping theory posits that analogy involves aligning the relational structures of two scenarios. A relational structure is composed of multiple first-order relations that are linked together in a specific manner (i.e., the manner in which they operate on shared objects). Consider the classic solar system-atom analogy (Figure 1): Planets revolve around the sun, and planets are smaller than the sun; electrons revolve around the nucleus, and electrons are smaller than the nucleus. Although the same first-order relations are present in both scenarios (i.e., *smaller than* and *revolves around*), the analogy only works because the first-order relations share objects in the same way, such that their first roles are filled by the same object (i.e., planet and electron). In structure-mapping theory, this property is formally known as *parallel connectivity* (Gentner, 1983).

Thus, analogy can be viewed as the recognition that two scenarios are instances of the same higher-order relation, that is, first-order relations connected in the same manner. When the same first-order relations are present in two or more scenarios, but are shared differently between objects, different higher-order relations are formed. Hence, to successfully transfer between two analogous scenarios, people must learn the exact manner in which the first-order relations are connected to form a specific higher-order relation.

Figure 1. Diagram of solar-system-atom analogy.

## Schema Refinement

Formation of an analogy has been proposed to lead to induction of a schema, an abstract representation that captures the relational structure common to both analogues (Gick & Holyoak, 1983; Hummel & Holyoak, 2003; Kuehne, Forbus, Gentner, & Quinn, 2000). Subsequent analogy between a schema and a new episode can result in a new schema (replacing or supplementing the original schema) that contains only the structure that is common to the original schema and the new episode. This process is referred to as *schema refinement*, and it has been proposed to operate by a mechanism of *intersection discovery* (Doumas et al., 2008). An analogy between two episodes may lead to a “dirty” schema that includes idiosyncratic properties common to both episodes but not universal to other instances of the abstract concept being acquired (Doumas et al., 2008; Hummel & Holyoak, 2003). Through comparison to successive instances of the abstract concept (as they are encountered), the schema can be refined to contain only information that belongs to the concept.

As a model of relational learning, schema refinement has several shortcomings. First, because refinement models only allow for a schema to decrease in size, the model cannot add new information. Consequently, upon its first encounter with a member of a relational category, the model must retain all information contained in the exemplar, as it may be necessary in defining the category. Contrary to the results presented below, this assumption leads to a prediction of no false alarms during learning of a relational category. A false alarm can only occur when a subject’s current schema is missing relational constraints for what constitutes category membership. Under an idealized model of pure schema refinement, there is no way for the model to delete relations that are present in all category members.

A related assumption of schema refinement is that the model can start off with and maintain highly complex schemas. Given the processing constraints of working memory (Baddeley, 2003), such an assumption seems psychologically implausible. Instead, subjects should be expected to quickly forget a large amount of the information that was initially processed. When the number of objects and predicates contained within a higher-order relation exceeds the processing capacity of working memory, schema refinement may not accurately reflect how the concept is acquired. Thus, we propose that a more complete model of relational learning must incorporate forgetting, and, consequently, the ability to add information to the schema rather than only simplifying it.

## Schema Elaboration

When a learning model contains processing constraints similar to those of working memory, the ability to elaborate upon a schema (i.e., to add new information) may be better suited than schema refinement alone for the acquisition of higher-order relations. We propose that in cases where a schema is insufficiently complex (i.e., is missing appropriate relational constraints), people are capable of

updating their schema by adding new relations. We refer to this process as *schema elaboration*.

Because the pure schema refinement model is unable to add new information, the model has no room for error if true relational constraints are mistakenly discarded. This makes schema refinement an unrealistically rigid learning model. The schema elaboration model described in detail below is more flexible, as it is able to reincorporate information that it has mistakenly discarded or forgotten.

## Experiment

The current study investigated people’s ability to learn arbitrary new higher-order relations. The study used a standard category-learning paradigm, with an A/not-A design in which subjects were asked to decide whether each stimulus did or did not belong to the category. The category to be learned was manipulated between subjects. The category structures all contained the same number and types of first-order relations but differed in how those relations were connected (i.e., in the higher-order relation they formed). We aimed to test models of relational concept acquisition by assessing how this manipulation of higher-order structure affects learning.

Figure 2 shows an example stimulus. Each stimulus comprised four objects, known in the literature as *Shepard circles*, arranged in a square configuration. The objects varied along three separable dimensions: brightness, size, and radius tilt. Each dimension had four levels, assigned without replacement to the four objects on each trial.

Each dimension defines a comparative binary relation among the objects (i.e., brighter, larger, steeper). The category to be learned by each subject was defined by three such relations, one on each dimension. Thus, a stimulus was a member of the category if it satisfied all three of these relations (e.g., upper-right object must be larger than upper-left object, lower-left object must be brighter than lower-right object, and lower-right object must have its radius more tilted than upper-left object). The category structures varied in how the relations were connected to each other, in terms of the objects they were defined on. For example, any two relations could operate on the same pair of objects, on disjoint objects, or on one shared object with one unique object for each relation. This design leads to six topologically unique category structures, shown schematically in Figure 3. The manner in which these topological structures were instantiated (i.e., the roles of the four spatial locations) was counterbalanced across subjects within each condition.

Figure 2. Example stimulus from main task.

## Method

137 undergraduates were randomly assigned to six (between subjects) conditions, differing in the category structure to be learned. Subjects were given a cover story in which the stimuli were optical key cards for a building; their task was to learn which key cards would open a door.

To familiarize subjects with each of the first-order relations, they were given three training tasks prior to the main task, one for each first-order relation (i.e., brighter, larger, and steeper). The training tasks were the same as the main task, except that each stimulus contained only two objects instead of four, and each category was defined by only one relation (e.g., right object must be darker than left object). Each training task ended once the subject answered eight consecutive correct responses. The order of training tasks was counterbalanced.

All four tasks followed the same procedure. On each trial, a stimulus was sampled randomly, subject to equal probability of choosing a stimulus in or out of the category. The subject responded by pressing Y or N (indicating the key card does or does not open the door), and then the correct answer was displayed. The instructions for each task indicated the categories were different (i.e., each task was about a different door of the building) and included a random, positive example (i.e., a key card that opens the current door). The full experiment (i.e., training and main tasks combined) was programed to end after 55 minutes.

Figure 3. Diagram of each category condition. Lines connecting objects indicate first-order relations.

## Models

Before presenting the results, we describe a series of models that were compared to the data. These models were designed to test the need for augmenting theories of schema refinement with mechanisms of forgetting and schema elaboration. Only the main task was modeled.

### Control Models

Three control models—pure refinement, refinement with forgetting, and refinement with forgetting and elaboration—were formulated to provide a baseline for the more sophisticated elaboration models discussed below.

All of the models operate by maintaining a schema from trial to trial that contains some set of relations among the objects within the stimuli. Each stimulus is classified as in the category if it satisfies all relations currently in the

schema. The schema is initialized as a complete representation (i.e., all 18 binary relations) of the example stimulus provided in the instructions for the main task.

The pure refinement (PR) model learns only following a miss, meaning a trial on which the stimulus belongs in the category but is mistakenly classified as a nonmember. This can occur when the schema includes relational constraints that are not part of the true category rule. Feedback after a miss causes the schema to be updated (refined) by intersection discovery, discarding all relational constraints the stimulus violates. All other relations in the schema are retained. This learning process will continue until all incorrect relational constraints are removed, at which point the schema will necessarily coincide with the true category rule.

The refinement-with-forgetting (RF) model incorporates processing constraints meant to mimic those of working memory. Soft capacity limitations result in the model losing (i.e., forgetting) relational constraints prior to each trial. Each relation has an independent probability  $p$  of being forgotten, which depends on the total number of relations currently in the schema ( $r$ ):

$$p = 1 - \frac{L}{r} (1 - e^{-r/L}), \quad (1)$$

where  $L$  is a processing-capacity parameter. This formulation has the property that the expected number of retained relations equals  $L * (1 - \exp(-r/L))$ , that is, exponential approach to some limiting capacity  $L$ .

The random elaboration model (RE) includes refinement, forgetting, and elaboration. The interplay between refinement and elaboration leads the model to add and remove constraints one at a time until the schema converges on the true category structure. The forgetting mechanism in the model allows for false alarms, as true relational constraints can be lost, making the schema under-constrained. Indeed, a subject may commit a false alarm if his or her working schema lacks a relational constraint that is part of the category rule.

According to the elaboration assumption, false alarms lead to the appendage of a new relation, which the stimulus satisfies but was not part of the initial hypothesis. This mechanism allows the schema to increase in size and complexity. Unlike with misses, after receiving feedback of a false alarm the subject does not know which relational constraints must be added (i.e., which relation in the stimulus constitutes a violation of the rule). Therefore, the model identifies all relations in the stimulus that are absent from the schema, and treats each as a candidate to be added. For simplicity, we assume exactly one relation is added to the schema following any false alarm. In the RE model, this choice is made at random among the candidates.

The PR model is an ideal observer for the present task, and hence performance was expected to be high for all conditions. In the RF model, once a true relational constraint is forgotten, it has no way of being reincorporated into the schema; hence all relations will eventually be lost and the

model should asymptote chance performance. In the RE model, elaboration and forgetting can combine to produce intermediate levels of performance (depending on the capacity parameter  $L$ ). However, it was expected that none of the three control models would predict any learning differences among the different category conditions. Indeed, all relations are treated independently (except for a global effect of schema size on the forgetting probability), and hence the manner in which relations are linked through operating on shared objects should have no effect on model performance.

### The Search for Relational Constraints

The RE model assumes schema elaboration involves random selection of a candidate relation that is in the stimulus but not in the schema. Alternatively, the selection could be preferential, sensitive to higher-order structure. Different assumptions about preferences guiding the relations that are added lead to different models of preferential elaboration, each making unique predictions about the relative learnability of the category structures in the current study. Here we consider four possibilities, motivated by different theoretical perspectives in the literature. Importantly, each model is inspired by the corresponding theoretical perspective but is not meant to be a formal implementation of that theory.

Each of the four models presented below works in the following manner. Following a false alarm, each candidate relation for addition to the schema is assigned a score that determines its probability of being selected. The probability each candidate is selected is given by

$$\frac{e^{\phi s}}{\sum_{s'} e^{\phi s'}} \quad (2)$$

where  $s$  is the score for the candidate,  $s'$  ranges over all candidates, and  $\phi$  is a parameter determining the degree of stochasticity in the decision process. The models differ in how the scores are determined by higher-order structure.

### Conceptual Coherence

Murphy and Medin (1985) proposed that people's lay theories about the world make categories conceptually coherent. One reason for this may be that a theory provides a conceptual filter through which relational information can be processed and organized around. Furthermore, research has shown that features that are central to a concept more strongly influence the concept's conceptual coherence (Sloman, Love, & Ahn, 1998). Taken together, these ideas suggest that a category composed of a central object that participates in all three relations will be more conceptually coherent than other category structures, as the category representation can be organized around the central object, providing a critical conceptual reference point. Thus, performance should be higher for conditions 2, 4, and 6 than for other category structures. To formalize this principle, the score ( $s$ ) for each candidate relation was defined as the sum,

over the two objects that relation operates on, of how many relations already in the schema each object participates in. This assumption leads the conceptual coherence (CC) model to prefer relations built on already more central objects, thus favoring categories with a centralized structure.

### Economy of Objects

Due to the processing constraints of working memory (Baddeley, 2003), it may be easier to discover an analogy that requires mapping fewer objects between scenarios. Therefore, when elaborating a schema, subjects may be inclined to select relations that minimize the total number of objects involved. This hypothesis predicts that learning will be superior for category structures involving a smaller number of objects, such as condition 6 and to a lesser extent 3 and 4. This principle was formalized in the economy of objects (EO) model, by defining the score for each candidate relation as the number of its objects (0, 1, or 2) that participate in other relations already in the schema.

### Plurality of Objects

In contrast to the EO model, cognitive load theory (van Merriënboer & Sweller, 2005) suggests that objects that do not participate in any of the category's relations will act as extraneous distractors. Therefore, subjects' attention may be drawn to such objects, making them more likely to add relations on new objects when elaborating the schema. Because people often struggle to recognize surface features as irrelevant information (Cooper & Sweller, 1987), irrelevant objects may place an unnecessary amount of strain on working memory, while concurrently obscuring the category's higher-order structure. Consequently, category structures that contain the greatest number of irrelevant objects (condition 6, followed by 3 & 4) would be most difficult to learn. This principle was formalized in the plurality of objects (PO) model, by defining the score for each candidate relation as the number of its objects (0, 1, or 2) that do not participate in any relations currently in the schema. This scoring rule is opposite that used in the EO model, and the two models are equivalent under a substitution  $\phi \rightarrow -\phi$ .

### Relational Chaining

Lastly, learning may be better for category structures composed of relations that are chained together (e.g., condition 1), as people may be intuitively inclined to link known relational structure to new objects. Such a preference might arise from a causal learning perspective, in which subjects seek to discover causal chains among the objects. For example, upon learning that object A must be bigger than object B, people may be inclined to test whether object B must be brighter than object C. Thus, structures composed of relations that can be more readily chained together may be easier to acquire. This principle was formalized in the relational chaining (RC) model, by defining the score for each candidate as

$$s = \frac{1}{c_{\min} + 2} + \frac{\frac{1}{c_{\min} + 1} - \frac{1}{c_{\min} + 2}}{c_{\max} - c_{\min} + 1}, \quad (3)$$

where  $c_{\min}$  and  $c_{\max}$  are the counts of relations currently in the schema in which the candidate's two objects participate. This rule was designed to implement a lexicographic preference for small values of  $c_{\min}$  followed by small values of  $c_{\max} - c_{\min}$ . As a special case, the score for relations with  $c_{\min} = c_{\max} = 0$  was set to zero, to implement a preference not to add isolated relations. Thus, the ideal candidate is one that extends an existing chain:  $c_{\min} = 0$ ,  $c_{\max} = 1$ .

### Summary of Models

The preceding subsections fully specify the models tested. The categorization response is determined by whether the stimulus satisfies all relations currently in the schema. Refinement follows misses, by intersecting the schema with the stimulus. Forgetting precedes each trial, following Equation 1. Elaboration follows a false alarm, adding a single relation from the stimulus, chosen by Equation 2 (or randomly, in the RE model). The models differ in whether they include forgetting and elaboration, and in the preferences guiding elaboration.

### Experiment and Model Results

Subjects varied in how much time they took to learn the training tasks, and hence in how much time they had for the main task. To reduce statistical noise and ensure all subjects had enough time to learn their condition's category structure, a selection criterion was used to exclude subjects who spent over 35 minutes on the training tasks (leaving less than 20 minutes for the main task). Because this criterion is based on events prior to the experimental manipulation, it introduces no bias in estimating differences among conditions. The selection left 104 subjects in the analysis. Of these subjects, the fewest number of trials completed on the main task was 245.

An ANOVA comparing average proportion correct on the first 245 trials across conditions revealed a non-significant trend,  $F(5, 98) = 1.83$ ,  $p = .114$ ,  $MSE = .004$ . Because of the complexity of the main task, 245 trials may be insufficient for learning. Therefore, we repeated the analysis while excluding the 6 additional subjects who had completed the fewest trials. The remaining 98 subjects all completed over 350 trials. An ANOVA on these subjects' performance on the first 350 trials indicates a significant main effect of category structure,  $F(5, 92) = 2.76$ ,  $p = .023$ ,  $MSE = .012$ . Figure 4 shows the mean performances by condition, compared to model predictions. Importantly, the ordering among conditions remained unchanged from the initial analysis, and means were nearly unchanged. Finally, the 6 excluded subjects were re-included, with their proportions correct defined based on the number of trials actually completed. The analysis again revealed a significant effect of condition,  $F(5, 98) = 2.75$ ,  $p = .023$ ,  $MSE = .012$ . Again, the ordering of performance between

conditions was unchanged, and condition means were nearly identical to the previous analyses.

Figure 4 shows the behavioral results and the simulated predictions of all models. Model parameters (as applicable) were the same for all models and were chosen by hand, with  $L = 9$  and  $\phi = 10$ .

Evaluation of the models in sequence provides support for each of our theoretical proposals (see Table 1). As predicted, the PR model far outperformed the subjects, suggesting the need for some sort of forgetting mechanism in addition to schema refinement. However, the RF model performed nearly at chance, because it eventually forgot all relations, suggesting a further need for some sort of schema elaboration mechanism. The RE model can match subjects' intermediate performance level, but it fails to predict differences among conditions. The last four models predict condition differences because they are sensitive to higher-order structure. However, the differences are all weaker than in the empirical data. The predicted condition differences are greater when  $L$  is increased to produce levels of performance (Figure 5, with  $L = 40$ ), but still none of the models reproduces the correct ordering among conditions. Therefore, further work is required to understand exactly how higher-order structure affects relational learning.

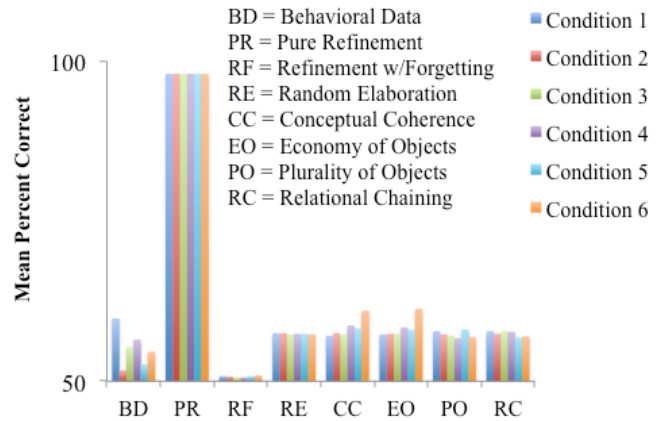

Figure 4. Mean performance for subjects and models.

Figure 5. Predictions of structure-sensitive models at higher levels of performance, to accentuate condition differences.

Table 1. Strengths (+) and weaknesses (–) of the simulated models.

	Model						
	PR	RF	RE	CC	EO	PO	RC
Performs within the range of subject data	–	–	+	+	+	+	+
Predicts differences across conditions	–	–	–	+	+	+	+
Predicted differences match subjects	–	–	–	–	–	–	–

## Discussion

Although previous research has not directly addressed how readily people learn different types of higher-order relations, the acquisition of such concepts is integral to the development of expert representations (Chi, Feltovich, & Glaser, 1981). The current behavioral data suggest that acquisition of higher-order relations is indeed affected by the manner in which the elementary relations within a relational structure are connected. Subjects' performance was best for conditions in which relations could be chained together and where single objects participated in multiple relations (i.e., Conditions 1, 4, and 3).

Although schema refinement has been the dominant model of relational learning (e.g., Doumas et al., 2008), the PR model incorrectly predicts no learning differences across the different category conditions. Further, the model's performance differed dramatically from that of subjects. As expected, when processing constraints were introduced, the RF model failed to retain any of the relational constraints in the category, performing at chance in all conditions. Taken together, these results suggest that schema refinement alone is an insufficient explanation of human relational learning.

The predictions from the elaboration models allow us to address several important issues. That the elaboration models make predictions within the range of the subjects' performance supports the proposal that people employ elaboration mechanisms (in addition to schema refinement) when acquiring higher-order concepts. Additionally, the differences that were found across conditions in the behavioral data provide support for the idea that people indeed have preferences for seeking out certain types of higher-order relations, as formalized in the four structure-sensitive elaboration models.

However, the condition differences predicted by these models were weaker than those exhibited by subjects, and none of the models reproduces the correct ordering across conditions. Thus, it remains an open question as to the specific mechanisms that drive people's search for higher-order relations.

Understanding what drives the differences among the present experimental conditions may provide important theoretical insight into the mechanisms of relational learning, as well as the manner in which people acquire

more abstract, higher-order concepts. Such results may also have practical applicability for areas where the recognition of higher-order structures is important for deep learning, such as education, problem solving, and decision-making.

## Abstract

Cognitive scientists have begun collecting the trajectories of hand movements as participants make decisions in experiments. These response trajectories offer a fine-grained glimpse into ongoing cognitive processes. For example, difficult decisions show more hesitation and deflection from the optimal path than easy decisions. However, many summary statistics used for trajectories throw away much information, or are correlated and thus partially redundant. To alleviate these issues, we introduce Gaussian process regression for the purpose of modeling trajectory data collected in psychology experiments. Gaussian processes are a well-developed statistical model that can find parametric differences in trajectories and their derivatives (e.g., velocity and acceleration) rather than a summary statistic. We show how Gaussian process regression can be implemented hierarchically across conditions and subjects, and used to model the actual shape and covariance of the trajectories. Finally, we demonstrate how to construct a generative hierarchical Bayesian model of trajectories using Gaussian processes.

**Keywords:** Trajectory analysis; Gaussian processes; Bayesian statistics.

## Introduction

Cognitive scientists are gradually turning toward more fine-grained measures to gain more insight into the continuous nature of the cognitive processes that underly behavior. Perhaps the most widespread of these measures is eye tracking, in which we assume that where people gaze is the current focus of attention and processing. For example, when reading a syntactically ambiguous sentence, people tend to make eye movements back toward the function word or pronoun that best helps resolve the ambiguity (Frazier & Rayner, 1987). Or, when hearing continuous speech, people will tend to look more at objects whose names are consistent with a partially-heard word (e.g., people will look at either a “ball” or a “bear” if they have just heard the syllable “b”), indicating that people make continuous predictions about the content of speech based on partial information (Spivey, Grosjean, & Knoblich, 2005). Thus, a continuous measure of behavior, like eye tracking, appears to provide insight into ongoing cognitive processes.

More recently, researchers have begun to collect explicit continuous behavioral measures in the form of mouse or stylus movements (e.g., Freeman & Ambady, 2010). These may easily be used in place of any task that requires an explicit choice on the part of the participant, which includes most experimental paradigms in cognitive psychology. Rather than simply pressing a key to make their response, a participant can instead move their hand (as well as an attached mouse or stylus) toward the option of their choice before selecting

(clicking) it. Similar to eye tracking, the trajectories of these continuous motor movements provide a way of measuring the ongoing cognitive processes that lead to the participant’s final choice.

A major hurdle with any new measure is the need for appropriate analytical tools and statistical tests that allow researchers to draw inferences from trajectory data. Due to the richness of this data, many measures are possible and can lead to principled inferences (for an overview, see Freeman, Dale, & Farmer, 2011). When moving their hand while making a decision, people may deviate more from a straight trajectory if there is a tempting alternative, making viable such measures as maximum deviation, curvature area, and switches in direction.

In this paper, we introduce a new method for analyzing trajectory data. Our method is based on treating trajectories as a Gaussian process, for which there is much well-developed statistical theory. We begin by providing a brief overview of Gaussian process regression and show how it may be applied to motor response trajectories and—more fruitfully, we argue—their derivatives. Finally, we show how Gaussian process regression can be incorporated into a generative hierarchical Bayesian model of trajectories.

## Gaussian Process Regression

Gaussian process regression (GPR) is a statistical technique with a long history in spatial statistics, and more recently in function estimation and prediction (Griffiths, Lucas, Williams, & Kalish, 2009). The interested reader is directed to the excellent text on Gaussian processes by Rasmussen and Williams (2006).

## Gaussian Processes

A Gaussian process (GP) is simply a collection of random variables, all of which are jointly Gaussian distributed. What differentiates a Gaussian process from the more familiar multivariate Gaussian distribution is the fact that a Gaussian process may have an infinite index set, that is, it may specify an infinite number of jointly Gaussian variables. Thus, it is possible to define a Gaussian process over a continuous variable, like time. Just as a multivariate Gaussian distribution is defined entirely by its mean vector and covariance matrix, a Gaussian process is defined by its mean *function*  $m(x)$  and covariance kernel,  $k(x, x')$ , where  $x$  and  $x'$  are two (possibly multidimensional) values of some predictor variable  $\mathcal{X}$  (e.g., time). We denote the fact that a function  $f(x)$  is a Gaussian

process by

$$f(x) \sim \mathcal{GP}(m(x), k(x, x')).$$

A Gaussian process can be considered a distribution over functions, with  $m(x)$  expressing the mean value of all of these functions at  $x$  and  $k(x, x')$  represented the expected covariance between the function value at  $x$  and that at  $x'$ , i.e., the amount of “information” that the function  $f(x')$  carries about the value at  $f(x)$  (and vice versa). Thus, if we encounter data (like trajectory data) for which we do not know or cannot guess the form of the function that generated it, we can *infer* the form of this function if we assume that it is a Gaussian process. This kind of inference is termed “Gaussian process regression”.

**Bayesian Inference with GPs** Gaussian process regression (GPR) seeks to model an unknown function  $f(x)$ , which is assumed *a priori* to be a Gaussian process. To do this, we need two things: a set of function observations  $\mathbf{f}(\mathbf{x})$  at some known values of the predictor  $\mathbf{x}$ ; and an expression for the covariance kernel  $k(x, x')$ . The data come from some experiment (e.g., a set of cursor coordinates  $f(x)$ ). We must, however, assume a particular covariance kernel. Although many kernels are possible, for the purposes of this paper, we will confine ourselves to the squared exponential (SE) or “radial basis function” kernel:

$$k(x, x') = f \exp \left[ -\frac{1}{2} \left( \frac{|x - x'|}{l} \right)^2 \right]. \quad (1)$$

The SE kernel is symmetric, is strictly positive, and most important for our purposes later, is infinitely differentiable. Notice that this kernel has two “hyperparameters”:  $f$ , which scales the maximum possible covariance; and  $l$ , which functions as a length scale. Later, we will consider how the values of these hyperparameters may themselves be estimated from data, but for the moment we shall assume they are known and fixed.

Armed with a set of observations and knowledge of the covariance kernel, we now wish to perform inference on the function that is presumed to have generated the observations. In other words, we are following the logic of Bayes’ rule:

$$p(\theta | \mathbf{x}, \mathbf{f}(\mathbf{x})) = \frac{p(\mathbf{x}, \mathbf{f}(\mathbf{x}) | \theta) p(\theta)}{\int p(\mathbf{x}, \mathbf{f}(\mathbf{x}) | \theta) p(\theta) d\theta},$$

where  $\theta$  are the parameters of the Gaussian process. Unlike in other regression settings (e.g., linear regression), where the parameters are a finite number of regression coefficients, the parameters of a Gaussian process may be infinite in number, since a GP prior allows nonzero probability to any functional form. We can, however, express our knowledge of the parameters of the GP *implicitly* via the posterior predictive distribution over *novel* function observations  $\mathbf{f}(\mathbf{x}^*)$ . This distribution is obtained by marginalizing over the parameters of the GP:

$$\mathbf{f}(\mathbf{x}^*) | \mathbf{x}^*, \mathbf{x}, \mathbf{f}(\mathbf{x}) = \int p(\mathbf{f}(\mathbf{x}^*) | \theta) p(\theta | \mathbf{x}, \mathbf{f}(\mathbf{x})) d\theta. \quad (2)$$

This distribution captures both the residual uncertainty about the underlying function  $f(x)$  and the knowledge gained about it from the observed data.

**Posterior Predictive Distribution** Computing the posterior predictive distribution begins with a prior on the mean and covariance functions of the GP, i.e.,  $p(\theta)$ . For the moment, we shall assume that the underlying function has a constant mean of zero, with a SE covariance function (equation 1). Expressing the likelihood of the observed function values,  $p(\mathbf{x}, \mathbf{f}(\mathbf{x}) | \theta)$ , is straightforward because they are assumed to come from a Gaussian process, and hence are jointly normally distributed. The parameters of this distribution come from our prior, i.e., the prior mean of each observation is taken to be zero, and the covariance between function values is dictated by our prior covariance kernel (the SE kernel given in eq. 1). Denoting the matrix of pairwise covariances between each observed datum as  $K(X, X)$ , we have

$$\mathbf{f}(\mathbf{x}) \sim \mathcal{N}(\mathbf{0}, K(X, X)).$$

Now, say we wish to express a posterior predictive distribution over function values at set of novel predictor values, denoted  $X^*$ . We can similarly compute a matrix of covariances between these points,  $K(X^*, X^*)$ , and between these novel points and the observed points,  $K(X, X^*)$ . Because both these novel points and the previously observed data values are presumed to have been generated by the same GP, they are all jointly normally distributed with mean zero and block covariance matrix:

$$\begin{bmatrix} \mathbf{f}(\mathbf{x}) \\ \mathbf{f}(\mathbf{x}^*) \end{bmatrix} \sim \mathcal{N} \left( \mathbf{0}, \begin{bmatrix} K(X, X) & K(X, X^*) \\ K(X^*, X) & K(X^*, X^*) \end{bmatrix} \right).$$

We can then express the conditional posterior over  $\mathbf{f}(\mathbf{x}^*) | \mathbf{f}(\mathbf{x})$  as another multivariate Gaussian distribution, using known identities regarding the Gaussian distribution:

$$\mathbf{f}(\mathbf{x}^*) | \mathbf{f}(\mathbf{x}) \sim \mathcal{N}(K(X^*, X)K(X, X)^{-1}\mathbf{f}(\mathbf{x}), K(X^*, X^*) - K(X^*, X)K(X, X)^{-1}K(X, X^*)). \quad (3)$$

The posterior predictive distribution given just a few data points is shown in figure 1a. This figure also depicts three functions randomly drawn from this posterior. Note that they all pass through the observed function values (and the posterior variance at those points goes to zero). This is because we have assumed thus far that our function observations are noiseless; thus, we have absolute certainty that, whatever the true generating function is, it *must* pass through the values we have thus far observed. In addition, our (assumed) knowledge of the covariance kernel allows us to estimate the function’s behavior between and, to a certain extent, beyond the observed values.

In reality, we will rarely have noiseless observations of our function of interest. Luckily, observation noise is easily incorporated into the GPR framework by adding a noise term,  $\sigma^2$ , to the diagonal elements of the observed covari-

(a) No observation noise. (b) With uniform, uncorrelated Gaussian noise ( $\sigma^2 = .1$ ).

Figure 1: Examples of GPR given a set of function observations. The open circles are the observed values. The black line is the mean of the posterior predictive distribution, while the gray region is the 95% confidence region around that mean. The three colored lines are functions randomly drawn from the posterior. Covariance was assumed to be SE with  $f = 1$  and  $l = 1$ .

ance matrix, i.e.,  $K(X, X) + \sigma^2 I$ . The resulting joint observed/predicted distribution becomes

$$\begin{bmatrix} \mathbf{f}(\mathbf{x}) \\ \mathbf{f}(\mathbf{x}^*) \end{bmatrix} \sim \mathcal{N}\left(\mathbf{0}, \begin{bmatrix} K(X, X) + \sigma^2 I & K(X, X^*) \\ K(X^*, X) & K(X^*, X^*) \end{bmatrix}\right)$$

and the posterior predictive distribution changes accordingly:

$$\begin{aligned} \mathbf{f}(\mathbf{x}^*)|\mathbf{f}(\mathbf{x}) &\sim \mathcal{N}\left(K(X^*, X) [K(X, X) + \sigma^2 I]^{-1} \mathbf{f}(\mathbf{x}), \right. \\ &\quad \left. K(X^*, X^*) - K(X^*, X) [K(X, X) + \sigma^2 I]^{-1} K(X, X^*)\right). \end{aligned} \quad (4)$$

This assumes that noise is uniformly distributed and independent between observations, but if there is correlated noise between observations, this may be incorporated directly into the covariance kernel. An example of a posterior predictive distribution with observation noise is given in Figure 1b.

**GP Likelihood** In order to fit a GPR model to data, we require an expression for the likelihood of a set of function observations that are assumed to come from a GP. Luckily, as is clear from above, these observations can be treated as coming from a multivariate Gaussian with mean zero and covariance matrix  $K(X, X)$ . Thus, the likelihood is merely the multivariate Gaussian likelihood:

$$p(\mathbf{f}(\mathbf{x})) = (2\pi)^{-\frac{n}{2}} |K(X, X)|^{-\frac{1}{2}} \exp\left[-\frac{1}{2} \mathbf{f}(\mathbf{x})^T K(X, X)^{-1} \mathbf{f}(\mathbf{x})\right] \quad (5)$$

where  $n$  is the number of observed data points and  $K(X, X)$  may be replaced by  $K(X, X) + \sigma^2 I$  if observation noise is assumed.

**Multiple Observed Functions** If multiple functions are observed simultaneously, e.g., the  $x$  and  $y$  coordinates of a cursor on a screen, they can each be treated as *a priori* independent Gaussian processes and the above reasoning applied to each individually.

## Derivatives of Gaussian Processes

Because differentiation is a linear operation, the derivative of a GP is itself a GP. Function derivatives are useful in the event that we actually have observations of the derivative (as in Solak, Murray-Smith, Leithead, Leith, & Rasmussen, 2003). However, we also argue that the derivatives of a continuous response like a mouse movement are more informative about the underlying cognitive process that generates them. For example, the acceleration is critical for finding inflection points, which could indicate that the participant is considering changing his or her mind, or that they have just incorporated new information into their decision process.

In the cases we consider below, we have direct observations only of position information, not of its derivatives (e.g., velocity and acceleration). To compute a posterior predictive distribution over function derivatives, we need only compute the covariances between each function observation and its derivatives at the points at which we are seeking predictions. This, in turn, requires expressions for the covariances between function values and derivatives, which are given for the SE covariance kernel below:

$$\frac{\partial}{\partial x} k(x, x') = -\frac{k(x, x')}{l^2} (x - x') \quad (6)$$

$$\frac{\partial^2}{\partial x^2} k(x, x') = \frac{k(x, x')}{l^2} \left[ \left( \frac{x - x'}{l} \right)^2 - 1 \right] \quad (7)$$

$$\frac{\partial^2}{\partial x \partial x'} k(x, x') = \frac{k(x, x')}{l^2} \left[ \left( \frac{x - x'}{l} \right)^2 + 1 \right] \quad (8)$$

$$\begin{aligned} \frac{\partial^4}{\partial x^2 \partial x'^2} k(x, x') &= -\frac{k(x, x')}{l^4} \left[ \left( \frac{x - x'}{l} \right)^2 \left( 3 - \left( \frac{x - x'}{l} \right)^2 \right) \right. \\ &\quad \left. + 3 \left( \frac{x - x'}{l} \right)^2 - 3 \right]. \end{aligned} \quad (9)$$

We can then compute a posterior predictive distribution over any desired derivative, given only raw function observations, by constructing the covariance matrices  $K(X^*, X)$  and  $K(X^*, X^*)$  from equation using the appropriate partial derivative above, rather than the original SE kernel  $k(x, x')$ . For example, to compute the posterior predictive distribution for the velocity,  $\dot{\mathbf{f}}^*(\mathbf{x}^*)|\mathbf{f}(\mathbf{x})$ , compute  $K(X^*, X)$  using equation 6 for each pair of predicted and observed  $x$  values and  $K(X^*, X^*)$  using equation 7 for each pair of predicted  $x$  values.

## Applications of GPR to Trajectory Analysis

In this section, we provide several examples of applications of GPR to trajectory analysis. In so doing, we introduce several extensions to the GPR modeling framework that place it in the realm of hierarchical generative models which can enable principled Bayesian inferences regarding the cognitive processes that underly observed motion trajectories.

### Estimating Hyperparameters

Although the posterior distribution in GPR is easily expressed analytically given knowledge of the covariance kernel and its

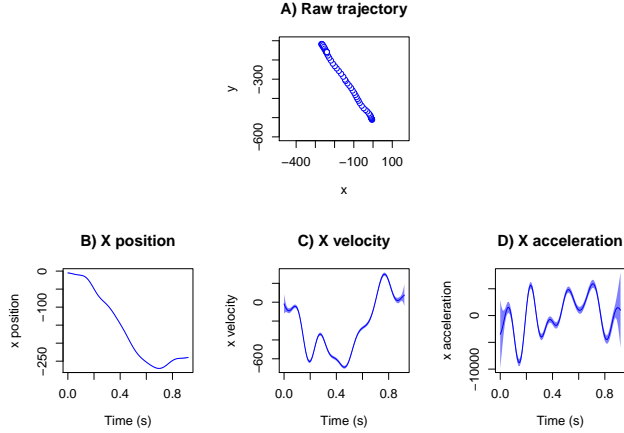

Figure 2: Example of GPR on a single two-dimensional trajectory. In B, C, and D, the light blue region depicts a 95% credible region about the mean posterior predictions.

hyperparameters, we are left with having to estimate  $f$ ,  $l$ , and  $\sigma^2$  (if we assume there is noise in the observations). In particular, we would like to be able to express our beliefs over these hyperparameters in the form of a posterior distribution. Unfortunately, this posterior will not in general be expressible analytically. Thus, we must turn to Monte Carlo methods to estimate the posterior over these parameters.

**A Single Trial** Let us assume we have a single mouse trajectory in two dimensions, as shown in Figure 2A. This trajectory is a single trial from the experiment reported by Spivey et al. (2005). On each trial of this experiment, participants saw two objects, the names of which either had similar phonological onsets (i.e., were members of the same “cohort”) or had phonologically unrelated names (the control condition). An audio recording instructed the participant to move their mouse cursor from a box in the lower center of the screen and click on one of the two objects (thus ending the trial).

The single trajectory consists of a series of  $(t, x, y)$  triples, with  $x$  and  $y$  coordinates and the times  $t$  at which they were observed. We treat the times  $t$  as a univariate predictor (i.e., in the role of  $x$  in the previous section) and  $x$  and  $y$  as conditionally independent Gaussian processes operating on  $t$ , with zero mean and SE covariance kernel (i.e., in the role of  $f(x)$  in the previous section). There are three hyperparameters that must be estimated: the parameters of the covariance kernel,  $f$  and  $l$  (see equation 1), and a noise term,  $\sigma^2$ , which is assumed to apply to measurements in both the  $x$  and  $y$  directions (isotropic noise is assumed here merely for simplicity). We choose very vague priors on each of these hyperparameters, such that they are informed almost entirely by the data, rather than our priors (although these priors could be informed by knowledge, e.g., of the accuracy of mouse position measurements). We assign a Gamma prior to  $f$  and  $l$  with shape and scale parameters set to 0.001 and an inverse-Gamma prior to  $\sigma^2$  (also with shape and scale parameters of 0.001). The

likelihood of the observed trajectory, conditional on particular values of the hyperparameters, is then given by equation 5. This model was implemented in JAGS (Plummer, 2011), drawing 1000 samples from the joint posterior over hyperparameters after 1000 steps of “burn-in”.

The estimated posterior mean of each hyperparameter is  $\bar{f} = 14760$ ,  $\bar{l} = 0.1146$ , and  $\bar{\sigma}^2 = 0.9471$ . The bottom three graphs of Figure 2 (B, C, and D) show the mean and 95% credible region of the posterior predictive distribution for the  $x$  coordinate (as well as its velocity and acceleration), marginalized over the samples of the hyperparameters.

**Multiple Trials** While this simple example illustrates how GPR can be applied to a single trajectory, we usually have several trials per participant per condition. In this case, we have multiple sets of triples,  $\{(\mathbf{t}_1, \mathbf{x}_1, \mathbf{y}_1), (\mathbf{t}_2, \mathbf{x}_2, \mathbf{y}_2), \dots, (\mathbf{t}_n, \mathbf{x}_n, \mathbf{y}_n)\}$ , and we can treat them all as having been generated by the same underlying GP. In other words, even if two observations  $(x_1, y_1)$  and  $(x_2, y_2)$  were from different trials, we can still compute their covariance  $k(t_1, t_2)$  as a function of the times  $t_1$  and  $t_2$  at which they were observed, as if they were part of the same trial (and thus they also share hyperparameters). Collecting the observed function values  $\mathbf{x}_i$  and  $\mathbf{y}_i$  (where  $i$  indexes the trial), we can write

$$\begin{bmatrix} \mathbf{x}_1 \\ \mathbf{x}_2 \\ \vdots \\ \mathbf{x}_n \end{bmatrix} \sim \mathcal{N} \left( \mathbf{0}, \begin{bmatrix} K(\mathbf{x}_1, \mathbf{x}_1) & K(\mathbf{x}_1, \mathbf{x}_2) & \cdots & K(\mathbf{x}_1, \mathbf{x}_n) \\ K(\mathbf{x}_2, \mathbf{x}_1) & K(\mathbf{x}_2, \mathbf{x}_2) & \cdots & K(\mathbf{x}_2, \mathbf{x}_n) \\ \vdots & \vdots & \ddots & \vdots \\ K(\mathbf{x}_n, \mathbf{x}_1) & K(\mathbf{x}_n, \mathbf{x}_2) & \cdots & K(\mathbf{x}_n, \mathbf{x}_n) \end{bmatrix} \right)$$

where  $K(\mathbf{x}_i, \mathbf{x}_j)$  denotes the covariance matrix between each sample in trial  $i$  and trial  $j$  (and a similar multivariate Gaussian likelihood is defined for  $\mathbf{y}$ ).

The assumption leading to the above likelihood is only valid if we assume that trajectories generated by the same participant in the same condition in fact represent samples from the same underlying process. If we assume that different trials from the same participant may be come from different processes that nonetheless share some underlying characteristics, the hierarchical extension of GPR that we introduce in the next section may be employed instead.

## Hierarchical GPR

Having shown how GPR can be applied to single trajectories and to multiple trajectories that may be assumed to share the same hyperparameters (i.e., to have been generated by the same underlying GP), we now turn to the case of multiple conditions and multiple participants per condition.

**Multiple Conditions** When there are multiple conditions in an experiment, we assume that a trajectory produced in one condition is conditionally independent of a trajectory produced in another condition, that is, that the trajectories are generated by different GP’s that nonetheless share hyperparameters. The rationale for sharing hyperparameters across conditions is simple: measurement noise (the  $\sigma^2$  parameters,

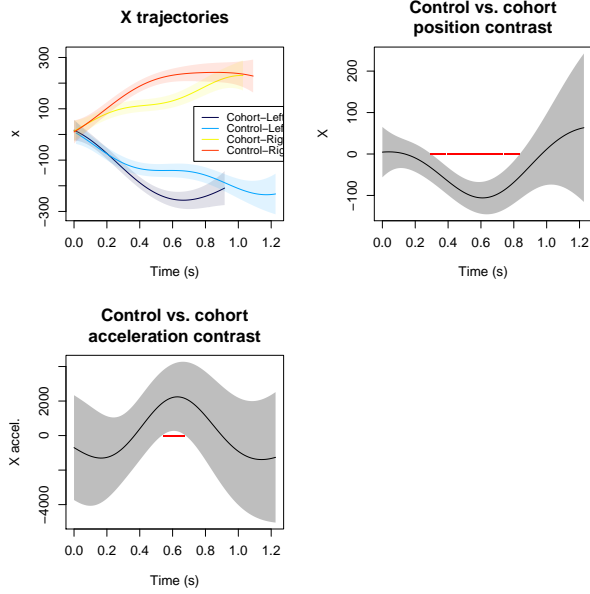

Figure 3: Posterior predictive distributions for trajectories inferred from a single subject from Spivey et al. (2005). The upper right plot shows the contrast computed between the  $x$ -positions in two cohort and two control conditions, while the lower left plot depicts the same contrast with the  $x$ -accelerations. Solid lines show the posterior predictive mean while the colored regions depict 95% credible regions around the corresponding mean.

one for each observed function) should depend only on the apparatus (e.g., the mouse or stylus). The hyperparameters of the covariance kernel, meanwhile, may be interpreted to reflect properties of the motor system of the participant, which are, of course, shared across conditions:  $f$  reflects the degree of “hysteresis”, or the tendency for the participant to produce trajectories with points that lie near one another, while  $l$  is indicative of the typical size of deviations from a straight line<sup>1</sup>.

We can again express the conditional likelihood of a set of function observations as a zero-mean multivariate Gaussian. Similar to the multiple-trial situation above, we can denote the observed trajectory points in condition  $j$  by  $\{\mathbf{x}_i\}_j$  and the covariance between each observation in condition  $j$  as  $K(\{\mathbf{x}_i\}_j, \{\mathbf{x}_i\}_j)$ . Then, we construct a block covariance matrix for the likelihood that reflects our assumptions about conditional independence between conditions:

$$\begin{bmatrix} \{\mathbf{x}_i\}_1 \\ \{\mathbf{x}_i\}_2 \\ \vdots \\ \{\mathbf{x}_i\}_n \end{bmatrix} \sim \mathcal{N} \left( \mathbf{0}, \begin{bmatrix} K(\{\mathbf{x}_i\}_1, \{\mathbf{x}_i\}_1) & 0 & \cdots & 0 \\ 0 & K(\{\mathbf{x}_i\}_2, \{\mathbf{x}_i\}_2) & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \cdots & K(\{\mathbf{x}_i\}_n, \{\mathbf{x}_i\}_n) \end{bmatrix} \right)$$

And, again, we can follow the same logic to construct a similar likelihood for  $y$  or any other observed component of the trajectory.

To assess differences in trajectories between each condition, we can compute functional “contrasts” by taking the difference of the posterior predictive distributions for two conditions. This is done for one subject’s data from Spivey et

al. (2005) and shown in Figure 3. In this case, the contrast is between two pairs of conditions: the two cohort conditions (left and right) and the two control conditions. Zero lies outside the 95% credible region of the position contrast function between roughly .30 and .83 seconds, indicating that the trajectories produced by this subject to cohort and control stimuli are credibly (“significantly”) divergent over this region. This divergence results from the additional complexity of the cohort trajectories, which is shown by the acceleration contrast: The cohort trajectories include an additional “nudge” between .55 and .67 seconds after stimulus onset, as the subject reconsiders what he or she has heard.

This example illustrates two useful features of GP’s as trajectory models: First, when analyzing contrasts, they do not risk inflating the probability of false alarms due to comparisons at multiple time-points. Because a GP represents a distribution over *functions*, there is only one comparison actually taking place. Second, because GP’s allow one to compute the higher derivatives of a trajectory, they afford greater insight into the functional behavior that gives rise to observed differences between trajectories, leading to potentially useful insights into the cognitive processes that generate them.

**Multiple Participants** We further expand the scope of the analysis by allowing for multiple participants, each of whom contributes data in multiple conditions, perhaps in many trials. Researchers typically obtain trajectory measurements from multiple participants in the same condition in order to better estimate a general property that is presumed to hold across the population. In a memory experiment, this general property might be the probability of correctly recognizing a previously studied item. There may be great variability between participants in their ability to recognize the item, but each observation is presumed to be a sample from a general group tendency.

In the case of trajectory analysis, we similarly assume that each participant produces a trajectory (or trajectories) that are samples from a distribution of possible trajectories. A GP expresses just such a distribution. Hence, we assume that there is a group-level GP for each condition, the covariance kernel of which has its own hyperparameters  $f_G$  and  $l_G$ . This group level GP captures the covariance between different trials generated by different participants in the same condition. Meanwhile, the covariance between different trials generated by the *same* subject have their own covariance structure that is added to the group-level covariance. For example, if  $x_1$  and  $x_2$  are two data points observed in different conditions, their covariance  $k(x_1, x_2) = 0$ , as before. If, however,  $x_1$  and  $x_3$  come from the same condition, but different subjects, their covariance will be a function of the group-level covariance, parameterized by  $f_G$  and  $l_G$ , denoted  $k_G(x_1, x_3)$ . Finally, if  $x_1$  and  $x_4$  are two data points generated by the same subject (subject  $s$ ) in the same condition, their covariance will be the group covariance plus the covariance resulting from individual variation around the group trajectory, i.e.,  $k_G(x_1, x_4) + k_s(x_1, x_4)$ , where  $k_s(\cdot, \cdot)$  is a covariance kernel parameterized by subject-

<sup>1</sup>Of course, other choices of covariance kernel would have their own parameters which would have their own characteristic interpretations.

specific parameters  $f_s$  and  $l_s$ . As before, we can construct from these terms a covariance matrix for the entire dataset.

To perform inference in this case requires placing priors on both the group-level hyperparameters and the subject-level hyperparameters. When using vague priors, as we have thus far, it is often advisable to make use of hyperpriors. Thus, we let  $\mu_f \sim \text{Gamma}(0.001, 0.001)$  and  $\sigma_f^2 \sim \text{Inverse Gamma}(0.001, 0.001)$  be top-level priors on the mean and variance of the distribution of  $f_s$  values per subject. Then, by moment matching, we draw each  $f_s \sim \text{Gamma}\left(\frac{\mu_f^2}{\sigma_f^2}, \frac{\mu_f}{\sigma_f^2}\right)$ .

We do the same for each  $l_s$  (i.e., place a hyperprior on the mean and variance). By using hyperpriors in this way, we obtain “shrinkage” of the estimates of the subject-specific parameters, such that they can mutually inform one another.

## Generative GPR

Thus far, we have employed GPR solely in the way it was originally intended: as a nonparametric approach to function approximation—as a purely *descriptive* model. However, we can use GPR as a *generative* model in the following way: Say that we expect all trajectories in a particular condition to possess characteristic *landmarks*. These landmarks may be actual positions, or they may be particular values of one of the derivatives of the trajectory. For example, an inflection point—a point where the acceleration of the trajectory in a particular direction reverses—may have a special cognitive interpretation. In our ongoing example from Spivey et al. (2005), such a point may reflect the instant at which the word in the cohort condition has been completely processed, and the participant moves his or her cursor away from the distractor and toward the named object.

To implement this idea in a Bayesian fashion, we place a prior on the number of inflection points in the group-level trajectory. In principle, this number could be infinite, but in practice we assume this is a multinomial draw between 1 and 8 (the maximum allowed number of inflection points may, of course, vary depending on application). This multinomial is, in turn, parameterized by a draw from a Dirichlet distribution, which itself reflects a prior on the overall probability that the trajectory has a certain number of inflection points (from 1 to 8). Finally, for a given number of inflection points, the points themselves are presumed to be *a priori* uniformly distributed in time across the range of data points.

We can make use of the same formalism we have previously used to obtain the posterior predictive distribution for GPR to compute the likelihood, conditional on a certain set of sampled inflection points  $i_1, i_2, \dots, i_n$ . This involves computing the covariance matrix  $K(i, i)$  between the inflection points using the kernel in equation 9 and between the inflection points and observed values  $K(X, i)$  via equation 8. The conditional covariance of the data is then  $K(X, X) - K(X, i)K(i, i)^{-1}K(i, X)$ . The posterior predictive distribution, along with a sample of inferred inflection points, is shown in Figure 4. Notice that only the cohort conditions have inflections in the central region, reflecting the greater complexity of

Figure 4: Posterior predictive distributions with a sample of the inflection points (+) inferred by the generative model.

both the trajectories and their underlying cognitive processes.

## Discussion

We have presented a general statistical method for modeling trajectories, and shown how it can be used to capture effects at multiple levels. A main advantage of Gaussian process regression over the various summary statistics used previously (e.g., maximum deviation) is that less information is thrown away: looking at the posterior density shows a normatively correct summary of the data, given the general assumptions made by the model. GPR balances functional complexity with capturing the underlying data, and is thus both more general and more principled than other forms of regression. Hierarchical GPR may be used to distinguish individual, group, and condition differences.

By accurately tracing and modeling the movement of the body, we can find evidence of ongoing cognitive processes, and literally see the shape of their influence. Many have wondered when psychology will reach paradigmatic maturity—like physics. Trajectories, tracing movement through space over time, are a fundamental property that all organisms and matter create.

# Mathematical Modeling of a Biological Odometry

Somayeh Danafar (somayeh@idsia.ch)

Istituto Dalle Molle di Studi sull'Intelligenza Artificiale (IDSIA),  
Galleria 2, Manno-Lugano, 6928, Switzerland

## Abstract

Flexible and robust biological navigation are role models for robots. Biological odometry data from experiments with human subjects are explained by our novel mathematical model of biological path integration. We show the equivalence of neural representations of Polar and Cartesian egocentric path integration.

**Keywords:** Odometry; Path integration; Egocentric; Mathematical modeling.

## 1 Introduction

Navigation can be defined as a process that answers the following questions (a) “where am I?” (b) “where are other places with respect to me?” (c) “how do I get to other places with respect to me?” (Levitt and Lawton, 1990). Navigation is different from other forms of spatial behavior such as exploration, or foraging, in that there is an explicit reference to a goal location (Franz & Mallot, 2000). While many animals normally use landmarks or familiar positions to navigate, arthropods, many mammals and humans can reach their goal relying solely on their own locomotion signals. This type of navigation is known as *path integration* in biology or *odometry* in robotics.

Path integration has been studied extensively in desert arthropods and mammals (Weber et al., 1997; Séguinot et al., 1998; Etienne & Jeffery, 2004; Merkle, 2007). For humans, path integration is normally studied through triangle completion experiments (e.g. Riecke et al.). Wiener and Mallot (2006) studied visual path integration on human subjects using more complex paths with a greater number of segments and turning angles.

In robotics, sensory inputs are used to build and update a global representation of the environment. Thereafter, motor actions are derived by an inference procedure from this representation (McKerrow, 1991). The flexibility and navigation performance of biological organisms (e.g. migrating birds, arthropods) has motivated robotics researchers to adopt biologically-inspired approaches in order to achieve more accurate and robust navigation. Viewed in the opposite direction, such robots can help us to understand the behavior and biomechanics of biological systems. For instance, Möller et al. (1998) used an autonomous agent to study path integration in a type of desert ant. Lambrinos et al. (1997) studied the encoded signals of robot's wheels to estimate the moved distance. Polarized light was used as an allothetic signal. The navigation ability of a mobile robot using only visual

sensory input was investigated by Chahl and Srinivasan (1996). Weber et al. (1997) studied image motion information to estimate the travelled distance by the robot. In this paper, we address the problem of odometry through the mathematical modeling of a path integration system which matches the results from experiments conducted on human subjects (Riecke et al., 2002). In this way, we investigate what is happening at the neuronal level during the execution of the task which can later be used in biomimetic robots.

Generally speaking mathematical models of path integration can be divided in two types: geocentric and egocentric. In the present work, we focus on the egocentric model, described in section 2.1. Section 2.2 defines different sources of noise that arise in path integration. In section 2.3. the experimental data obtained from path integration with human subjects is described. In section 2.4 the mathematical model of this system is explained. To find the noise parameters which define the best mathematical model according to the experimental data, we need to solve an optimization problem which we elaborate on in section 3. The results are provided in section 4.

## 2 Path Integration (Odometry)

Mittelstaedt and Mittelstaedt (1980) established the term “path integration” and were the first to study it from a computational standpoint. They hypothesized that the signals derived from locomotion are used continuously to estimate the so-called global vector (travelled distance). This vector connects the reference point (e.g. the nest position) to the current position of the agent (e.g. the goal or target point) in a fixed coordinate system. These models of path integration are known as *Geocentric models*.

In contrast, *Egocentric models* center the coordinate system on the body of the moving agent. The agent computes and updates the sensory signals pertaining to its position and orientation in each time step (Gallistel, 1990; Benhamou and Séguinot, 1995). This approach is computationally efficient and particularly important in e.g. ants, given their limited computational resources.

Both models can be defined in terms of Polar and Cartesian coordinates. The models investigated here are based on an egocentric computation to formulate the path integration task conducted in an experiment on human subjects.

## 2.1 Egocentric Models

For path integration in egocentric models, two velocities are measured, the forward (translational) velocity,  $v$ , and the angular velocity,  $\omega$  (Figure 1). Egocentric related differential equations formulated by Banhamou and Séguinot (1995) are obtained considering small time steps. In the polar coordinates they are,

$$\frac{dr}{dt} = -v \cos \delta \quad (1)$$

$$\frac{d\delta}{dt} = v \frac{\sin \delta}{r} - \omega \quad (2)$$

The differential equations in Cartesian coordinates (by Banhamou and Séguinot, 1995) are,

$$\frac{dx}{dt} = -v + \omega y, \quad (3)$$

$$\frac{dy}{dt} = -\omega x. \quad (4)$$

This egocentric model linearly applies the parameters  $v$ , and  $\omega$ , as additive or multiplicative terms.

## 2.2 Noise Type

Homing in mammals and arthropods is imperfect. The lack of familiar positions or salient objects in identifying the starting position produces errors during path integration (Riecke et al., 2002). There are two types of errors in path integration that should be distinguished: random and systematic errors. Merkle (2007) mentioned that “there is evidence that random errors can originate from the inaccurate measurement of angles or distances, whereas systematic errors probably arise at the neural level of the organism”.

We examine the effect of both types of noise in path integration which is modelled by Monte-Carlo simulation in each unit of path movement. The first type of noise affects the sensors which measure  $v$  and  $\omega$ . This is considered due to the imperfectness of sensors. As the agent moves, it uses path integration to update its position across movement steps in relation to the reference point (nest position). The second type of noise is added to these calculated values to obtain the agent's position (Figure 2).

## 2.3 Experimental Data

To examine whether only vestibular cues are required for navigation, Riecke et al. (2002) conducted experiments on spatial orientation tasks. The experiments were conducted in the 180° Virtual Reality (VR) environment lab, with a half-cylindrical screen, where the participant is seated behind a

Figure 1: Egocentric path integration schema. The global vector,  $G$ , represented in Cartesian coordinates as  $G = (X, Y)$ , and the polar coordinates  $G = (r, \delta)$  (Merkle, 2007).

Sensors measure the actual translational speed  $v$  and rotational velocity  $\omega$

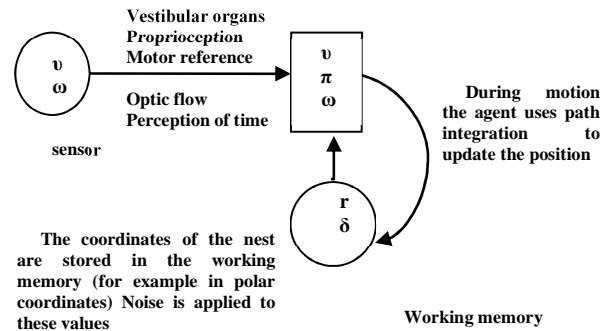

Figure 2: The types of noise in the navigation system.

table in the centre of the screen with a three button mouse, and is presented with visual cues. Pressing the middle button was used for forward translation and releasing for ending the motion. The left and right buttons were used for left or right rotations, respectively. Since there is minimum proprioceptive feedback in the button-based motion model, it is normally used as a model in VR related tasks. The experimental landscapes were streets, trees and houses. In each trial participants were presented with yellow and blue light beams, respectively, as the first and the second goal. The goals disappeared on contact. After the second goal disappeared there was a 2 second period of darkness. The task was then to return to the starting position accurately. The experiment was also done without reliable landmarks in a 3D field of blobs and with the naturalistic town environment and temporal landmarks. The reader is referred to Reicke et al. (2002) for a more detailed description.

Reicke et al. (2002) chose triangle completion since this task is “the simplest nontrivial combination of translations and rotations”. Each participant was presented with sixty isosceles triangles in random order; five different turning

angles (30°, 60°, 90°, 120°, and 150°) and two turning directions (left or right) which were repeated six times. Experimental results showed that participants could use their proprioceptive signals to estimate their travelled distance and turn back to the starting point with some bias (Figure 3). If we look at the homing trajectory end points for each participant over all his/her trials in Figure 3, we end up with a distribution over these sets of end points. We mainly work with this distribution in the next sections.

### 3 Mathematical Modeling

As in the experiment above, we model movement along isosceles triangles with 20 units and five different rotation angles between equal sides of a triangle. After passing one side of a triangle and reaching the first goal, the agent rotates and crosses the second side to reach the second goal and now it has to compute the third side of triangle. We used Monte Carlo simulations to simulate the path integration equations of section 2.1 and the noise of section 2.2. Sensor noise was added by Monte Carlo simulation as follows:

$$v' = v + N(\alpha_1 | v | + \alpha_2 | \omega |), \quad (5)$$

$$\omega' = \omega + N(\alpha_3 | v | + \alpha_4 | \omega |), \quad (6)$$

where  $v'$  and  $\omega'$  are the noisy sensor values, and  $\alpha_1$ ,  $\alpha_2$ ,  $\alpha_3$  and  $\alpha_4$  are user-defined free parameters.

The second type of noise was added to the calculated parameters which define the position of the agent in Polar or Cartesian coordinate systems. The noise can be added by Monte Carlo simulation in two ways: in a partial form, eqs. 7, 8 (Cartesian coordinates), 9 and 10 (Polar coordinates),

$$X' = X + N(\sigma).X \quad (7)$$

$$Y' = Y + N(\sigma).Y \quad (8)$$

$$r' = r + N(\sigma).r \quad (9)$$

$$\delta' = \delta + N(\sigma).\delta \quad (10)$$

or in an absolute form, eqs. 11, 12 (Cartesian coordinates), 13 and 14 (Polar coordinates).

$$X' = X + N(\sigma) \quad (11)$$

$$Y' = Y + N(\sigma) \quad (12)$$

$$r' = r + N(\sigma) \quad (13)$$

$$\delta' = \delta + N(\sigma) \quad (14)$$

Tuning the noise parameters of the Monte Carlo simulation yields different ending distributions around the reference point of the modelled triangular path. To evaluate the simulated results predicted by the mathematical model and the real experimental data, we

compared the home-ending distributions by means of a Homogeneity test (section 3.1). Determining the best noise parameter that provides the distribution closest to the real home-ending distribution of experimental data required solving an optimization problem (section 3.2). An example simulated path from our mathematical model, and the home-ending distributions are depicted in Figure 4.

Figure 4: Left: Monte Carlo simulation generated noise. The agent's rotation angle of the agent is 45 degrees. Right: the red ellipse indicates the home-ending distribution of experimental data, the blue ellipse is the one obtained by Monte Carlo simulation.

#### 3.1 Homogeneity Testing to Compare the Distributions

Suppose  $\{x_1, \dots, x_m\}$  and  $\{y_1, \dots, y_n\}$  are two-samples drawn i.i.d. from distributions  $P$  and  $Q$ , respectively, a two-sample test tests whether  $P \neq Q$  (hypotheses are,  $H_0: P=Q$ , against the alternative  $H_1: P \neq Q$ ). We used Maximum Mean Discrepancy (MMD; Gretton et al., 2007) as our homogeneity test.

**Theorem1.** *Let  $(X, B)$  be a metric space, and let  $P$ , and  $Q$  be two Borel probability measures defined on  $X$ . The kernel function  $k: X \times X \rightarrow \mathbb{R}$  embeds the points  $x \in X$  into the corresponding reproducing kernel Hilbert space  $H$ . Then  $P = Q$  if and only if  $\text{MMD}[P, Q] = 0$ , where*

$$\text{MMD}[P, Q] := \left\| \mathbb{E}_p[k(x, \cdot)] - \mathbb{E}_q[k(y, \cdot)] \right\|_H,$$

where  $\| \cdot \|_H$  represents the RKHS norm.

For a predefined significance level (e.g. 5%), MMD values closer to zero indicate higher similarity between the distributions.

#### 3.2 Optimization

To find the noise parameters providing the modeled distribution closest to real home-ending distributions, we need to solve an optimization problem, i.e. find the maxima or minima of a so-called objective function. If the objective function is differentiable, we can use derivative-based methods to solve the optimization problem. Direct search methods are used in cases in which we do not have explicit information about the objective function, or are unable to compute the derivatives. The Nelder-Mead simplex method (Lagarias et al., 1998) is a direct search method which is widely used to optimize multidimensional objective functions with no constraints. We use the Nelder-Mead

simplex method since our objective function is a routine that does not have an analytical form. The input arguments of this routine are the noise parameters and the output is an MMD value. It has 6 free noise parameters ( $\alpha_1, \alpha_2, \alpha_3, \alpha_4, \sigma_x$ , and  $\sigma_y$ ), e.g., of the noise which is generated for instance in a Cartesian coordination system. Without loss of generality we simplify equations 5 and 6 by setting  $\alpha_1, \alpha_2, \alpha_3, \alpha_4$  equal to 1:

$$v' = v + N(\sigma) \quad (15)$$

$$\omega' = \omega + N(\sigma) \quad (16)$$

Then our goal is minimization of the simplified objective function  $f(\sigma_v, \sigma_\omega, \sigma_x, \sigma_y)$  under the constraints of non-negative parameters (standard deviations). The solution is the minimal MMD values. As mentioned before, the Nelder-Mead simplex method is used to solve unconstrained problems; then, we need to convert our constrained problem to an unconstrained one. This is done with the algorithm introduced by J. D'Errico which uses the transformation values related to each bound, such as a quadratic function for inge bounds and a sinusoidal function for dual bounds.

## 4 Results

To make sure our objective function is not affected by sudden unexpected changes due to changing noise parameters, we approximately cover the variable space by changing steps of 0.01 to plot the function values (Table 1). To get a smoothly changing objective function we tuned the triangular side lengths to 20 meters. This value is 40 m in real experiments. There are 1000 Monte Carlo-generated home-ending data points. For MMD we use the Gaussian kernel with automated standard deviation tuning by the median sample data distance in distributions. We report results for the 5% significance level. Results for relative noise (eq. 7 and 8) and absolute noise (eq. 11 and 12) are obtained in both Cartesian and Polar coordinate systems. Results of simulated distributions in polar coordinates with absolute noise are depicted in Figure 5. Table 2 and 3 compare simulated distributions around the reference point of the navigation path with the distribution of home-ending points in experimental data for absolute and relative noise types.

An interesting question is whether polar or Cartesian coordinates are used on the neural level. Our results show they provide similar results. We also generated final distributions compatible with experimental data.

## 5 Conclusion

We introduced a novel mathematical model of egocentric path integration that uses Monte Carlo simulation of both the path integration equation and the noise. The home-ending distributions of data collected from experiments with human subjects were compared to those predicted by Monte Carlo. The closest matching distribution simulated by the model was found using the Nelder-Mead simplex method to

minimize the Maximum Mean discrepancy between the model and human data. We showed that at the neuronal level, the perceived advantage, in terms of both computational overhead and representational power, between Polar and Cartesian representations, is non-existent.

## 6 Acknowledgments

I want to thank Prof. H.A. Mallot, Prof. J. Schmidhuber, Dr. K. Basten, Dr. F. Gomez, and M. Aschoff for the profound discussions and help to prepare this paper.

## Abstract

We study solvers of nonogram puzzles, which are good examples of constraint-satisfaction problems. Given an optimal solving module for solving a given line, we compare performance of three algorithmic solvers used to select the order in which to solve lines with a reinforcement-learning-based solver. The reinforcement-learning (RL) solver uses a measure of reduction of distance to goal as a reward. We compare two methods for storing qualities ( $Q$  values) of state-action pairs, a lookup table and a connectionist function approximator. We find that RL solvers learn near-optimal solutions that also outperform a heuristic solver based on the explicit, general rules often given to nonogram players. Only RL solvers that use a connectionist function approximator generalize their knowledge to generate good solutions on about half of unseen problems; RL solvers based on lookup tables generalize to none of these untrained problems.

**Keywords:** Nonograms; problem solving; reinforcement learning; distance-based reward; SDCC.

## Nonogram puzzles

Invented in Japan in the 1980s, nonograms (also called Hanjie, Paint by Numbers, or Griddlers) are logic puzzles in which problem solvers need to determine whether each cell of a rectangular array is empty or filled, given some constraints. Nonograms are interesting problems to study because they are good examples of constraint satisfaction problems (Russell & Norvig, 2003), which are ubiquitous in real life (Shultz, 2001). Furthermore, despite their popularity among puzzle players, little work on nonograms exists in cognitive science, either in the form of empirical studies or modeling work. But nonograms have attracted attention in other areas. For instance, as we will see in the literature review section, solving nonograms has been studied mathematically, and a number of machine solvers exist. Finally, many rules and strategies for human players are described in web sites.

In nonograms, constraints take the form of series of numbers at the head of each line (row or column) indicating the size of blocks of contiguous filled cells found on that line. For example, in Figure 1, the first row contains 2 blocks of 2 filled cells, whereas row 5 contains no block of filled cells. Blocks have to be separated by at least one

empty cell. At the beginning, the state of all cells is unknown (often portrayed visually by a grey color), and the goal is to determine if each cell is empty (white) or filled (black), while satisfying all of the numerical constraints.

Figure 1 - Example of a 5x5 nonogram puzzle. In the initial state presented here, all cells are grey to indicate that the problem solver does not know yet if they should be filled (black) or empty (white).

## Strategies for solving nonograms

To solve nonograms, two important activities are necessary. First, the problem solver needs to decide which line (row or column) to solve next, and then to actually solve that line. Problem solvers typically need to iterate through the lines, progressively gathering more and more information about whether cells are empty or filled, until the actual state of every cell is known. Just as in crossword puzzles where the found words provide letters as clues or constraints for the orthogonally intersecting words, partially solving the cells on a nonogram line provides additional constraints for the intersecting lines.

A survey of popular web sites giving advice and tips on how to solve nonogram puzzles was performed, focusing on categorizing advice on *selection* of a line to solve, or on how to *solve* a given line. The majority of the advice relates to solving lines. For instance, an exhaustive set of rules can be found on Wikipedia (January 10, 2012 version). In contrast, there is comparatively little advice on how to appropriately select the next line to solve, and much of this

advice is given implicitly in commented solutions of specific problems. When available, explicit and general-purpose advice for line selection can be summed up as follows: begin with lines for which the constraint is either 0 (in which case all cells on that line are empty) or equal to the length of the line (in which case, all cells are filled). Occasionally, advice is also given to the effect that, by adding the different constraints (including an empty cell between each block) one can look for those that fill up a complete line (e.g., the first row in Figure 1 with constraints 2 2 is completely known as XX\_XX, with X as filled cells and \_ as empty cells). Skilled players also realize that lines that contain blocks of large sizes are often a good place to start. Finally, another general piece of advice is to pay attention to lines that have changed due to updates of the cells of intersecting lines. Except for the last one, these general advice rules often consider block constraints only, and do not take into account additional constraints imposed by cells already known to be filled or empty.

To sum up, strategies for solving lines are well-described as explicit, symbolic rules. In contrast, strategies for selecting lines appear more difficult to capture in explicit, symbolic terms, except for simple cases.

Figure 3 - Solution of the example 5x5 nonogram, where all cells are known to be filled (black) or empty (white) and where the solution satisfies all the block sizes constraints.

Figure 2 presents an example of a partial solution of a nonogram puzzle after three steps. Column 3 and row 5 contain no block of filled cells, and thus all cells on them are empty. As described above, the first row is completely known. At this point, the position of the block of size 4 in column 4 is known, and so is the position of block 3 in column 5. Even though position of the blocks of size 1 in rows 2 and 4 cannot be determined yet, by propagating constraints from solving columns, their positions can

eventually be determined. The final solution of the puzzle is given in Figure 3.

In solving nonograms, the order in which lines are solved influences how many steps are necessary to complete the solution. A step is defined here as a single iteration on a specific line to extract the maximum information possible.

## Research on solving nonograms

Nonograms have been studied mathematically, and are known to be NP-complete (Benton, Snow, & Wallach, 2006), making search-based solution techniques practical only for small problems. More sophisticated solving approaches include rule-based techniques (e.g., Yu, Lee, & Chen, 2011), use of some intersection mechanism to prune inconsistent configurations (e.g., Yen, Su, Chiu, & Chen, 2010), linear programming (Mingote & Azevedo, 2009), genetic algorithms (e.g., Batenburg & Kusters, 2004) and a combination of relaxations and 2-satisfiability approaches (Batenburg & Kusters, 2009).

Nonograms also have been used as a tutorial for teaching university students about optimization using evolutionary or genetic algorithms (Tsai, Chou, & Fang, 2011).

To our knowledge, there have been no attempts to use reinforcement learning to solve nonograms.

## Research objectives

Our objective is to compare a solver for selecting the order in which to solve lines in nonograms based on reinforcement learning with three algorithmic methods: randomly, heuristically, and optimally (in the shortest number of steps).

We thus ask if an RL-based solver can learn good solutions, that is, solutions that are close to the optimum (i.e., shortest solution); and how they generalize to unseen problems.

## Methods

### Generated nonogram puzzles

Puzzles used for training and testing of the system have a size of 5 rows by 5 columns. The state of each cell (filled or empty) is randomly selected. The puzzle presented in Figure 1 was generated in this way, and used in the simulation. Only puzzles that have a unique solution are kept that is, puzzles for which block values correspond to one and only one board configuration. An example of non-unique problem is presented in Figure 4.

		1	1	0	4	3
2	2					
1	2					
	2					
2	1					
	0					

Figure 4 - Example of a non-unique puzzle. The right and the left configurations both satisfy the block size constraints.

## Training and testing regimes

RL solvers are incrementally trained on 3 different problems (starting with a single problem, and gradually increasing to three problems interleaved in the training set), and tested on a novel problem. A justification for these choices is presented in the Discussion section. Training proceeds on a single problem for 40 episodes, then training proceeds with problems 1 and 2 for 40 more episodes and finally the solver is trained on all three problems for 40 final episodes. Thus training involves 120 episodes in total. The reason for using this interleaved, incremental training (which rehearses problems already learned) is to avoid catastrophic interference (McCloskey & Cohen, 1989).

## Optimal solver for lines

Before discussing approaches to the selection problem, it is important to emphasize that simulations use an optimal line solver for solving a given line once it is selected. This optimal line solver can find all the new cells that can be declared as filled or empty.

To find these cells, the optimal line solver module first generates every possible position of all blocks (constraints) in the line consistent with the cells already determined as filled or empty. Second, it computes the intersection of all these possible positions. Finally, it identifies cells that are always filled or always empty in these intersections as such cells are now known for sure to be filled or empty.

This approach covers rules and strategies typically given to players for solving lines of nonograms, and implements rules described in other solvers (e.g., Yu et al., 2011). For instance, with a line that is currently blank (all unknowns), this method implements the rules described in Wikipedia (January 10, 2012 version) under "Simple Boxes" and "Simple spaces".

## Modules for selecting lines to solve

Given this optimal line solver for solving lines, we turn to the issue of selecting the next line (either a row or a column) to solve.

### Random solver

A random solver randomly selects the next line to solve, with replacement, from lines that are not completely solved already. Selection with replacement allows taking the same line twice in a row.

### Heuristic solver

A heuristic solver, inspired by the advice given to humans described above, selects order as follows. First, it chooses lines that have no block (easy case to solve because all cells are blank) and lines that are filled completely (e.g., 2 2). Then other lines are sorted and chosen in decreasing order of the largest block value. Lines with the same score (i.e., ties) are selected in the order in which they appear in the puzzle (rows then columns). Selection of the next line to solve is done without replacement until all lines have been

visited, after which a new round of visits is performed starting from the best remaining candidate lines.

Similarly to the general advice and rules that can be found online, the heuristic solver does not take into account the current state of the problem.

## Optimal nonogram solver

Here, a breadth-first search finds the minimal number steps. While this is feasible for the 5x5 puzzles considered here, experiments with larger puzzle sizes suggest that search time is prohibitively long -- a well-established result for NP-complete problems, as mentioned<sup>1</sup>.

## Reinforcement learning (RL) solver

The reinforcement learning (RL) solver learns the expected value of lines using a reinforcement algorithm called SARSA (Sutton & Barto, 1998). SARSA learns estimates of the expected value or quality (Q) of future rewards for every state-action pair. Its learning rule is

$$Q(s_t, a_t) \leftarrow Q(s_t, a_t) + \alpha [r_{t+1} + \gamma Q(s_{t+1}, a_{t+1}) - Q(s_t, a_t)]$$
where  $Q$  is the predicted reward (sometimes called Quality),  $s$  is a state,  $a$  is an action,  $r$  is a reward, and indices  $t$  and  $t+1$  are used for current and next states and actions respectively;  $\alpha$  is the learning rate, and  $\gamma$  is the discount factor. The name SARSA is based on the quintuple that the algorithm uses ( $s_t, a_t, r_{t+1}, s_{t+1}, a_{t+1}$ ).

In the present simulations, we use a learning rate of 0.9, and a discount factor of 0.9 to reward the shorter solutions more highly. States, actions and rewards are described below.

### States

For a given action (a choice of a line), the state given to the RL solver consists of the states of the cells on the corresponding line. In other words, the RL solver gets information that is directly relevant to the line considered, as the action will only affect the cells in the line considered. In human problem solvers, this corresponds to an attention mechanism that focuses on the relevant elements, rather than seeing the complete problem configuration.

The state of a line consists of two elements: (1) the value of the block sizes coded using the integer corresponding to the number of cells in the block; and (2) states of cell on the line, which can take three values: unknown (U), filled (F) or empty (E). For example, in Figure 2, the state of column 1 is [1, 1, 0, F, U, U, U, E]. Note that learning begins in the initial state in which all cells of the board are Unknown, and that, for lines or columns composed of 5 cells, there cannot be more than three blocks

<sup>1</sup> As an approximation, if each line had to be solved once and only once, there would be  $(n+n)!$  combinations of sequences, which quickly increases with  $n$ . For  $n = 5$ , we get 3.6 million combinations, for  $n = 6$ , we get 479 millions; and  $n = 7$ , we already have  $8.7 \times 10^{10}$  (In practice, lines often need to be visited multiple times; or in rare cases not need to be visited at all).

## Actions

An action is a choice of the next line to solve. As there are 5 rows and 5 columns, the maximal number of actions available is 10. As soon as a line is completely solved, it is not further included in the list of actions considered for selection.

Given a list of actions and associated  $Q$  values, the RL solver needs to choose an action to execute. Action selection is performed with replacement (i.e., the same action can be taken again before all actions are visited). In testing mode, the solver uses a greedy technique called Hardmax which always selects the action with the largest  $Q$  value. In contrast, the solver uses a Softmax approach when in learning mode to allow exploration of the problem space. Under Softmax, every possible action can potentially be selected with a probability of selection increasing with the  $Q$  value.

We limit the number of steps that are allowed for finding a solution to 25, a value that is large enough to find a solution by randomly selecting actions (see Random in Figure 5). When failing to solve within 25 episodes in testing mode, the RL solver is typically stuck repeatedly selecting an action which does not yield any progress.

## Rewards

To provide rewards for line selection, we use a variant of a distance-reduction heuristic called distance-based rewards (Dandurand, Shultz, & Rey, 2012). Here, we return a reward equal to the proportion of the currently unknown cells that are determined as filled or empty as a result of selecting this action (i.e., solving this line). For instance, if cell states of the line are [U F U U E] before performing the action and [U F F U E] after, then 1 of the 3 unknowns were discovered, and this action would be rewarded with 0.33.

## Storing $Q$ values

We compare two systems for storing the rewards associated with state-action pairs. The first one is a classical lookup table which, for each unique state-action pair encountered, stores the value of the reward. Values need to be initialized to a non-zero value (here, we used 0.05) so that probabilities of selection are non-null under Softmax.

The second system consists of a connectionist function approximator. Instead of explicitly storing all  $Q$  values, a neural network is used to generate an approximation of the  $Q$  value as a single, real-valued output, taking the state-action pair as input. The three possible cell states are coded using 2 bits: Filled (1 0), Empty (0 1) or Unknown (0 0). Thus, a line state is a 13x1 vector (3 block values + 5 cells \* 2 bits per cell). Actions are coded as a 10x1 vector (5 rows then 5 columns) of binary values with the bit at the corresponding location set to 1, all others set to 0. Thus, for column 1 in Figure 2, the neural network function approximator receives as input the vector [1 1 0 1 0 0 0 0 0 0 0 0 1 0 0 0 0], corresponding to the concatenation of state and action.

The neural network used is called sibling-descendent cascade-correlation (SDCC: Baluja & Fahlman, 1994), a variant of cascade correlation (CC: Fahlman & Lebiere, 1990) with reduced network depth. CC has been successfully used to model learning and cognitive development in numerous tasks (Shultz, 2003). Whereas default SDCC parameters are optimized for pattern classification, more appropriate parameter values were selected here for function approximation, namely to allow for longer input and output phases (see details in: Dandurand et al., 2012). Input and output phases were allowed to last for 200 epochs with a patience of 50 epochs. Change threshold was set to 0.01 for input phases, and 0.002 for output phases. Finally, the score threshold parameter was set to 0.025, a value that is small enough to approximate the targets well while limiting overfit.

A cache system is used to interface SARSA and SDCC because they have different processing requirements. More specifically, SARSA updates its approximation function  $Q$  after every action (called online learning). In contrast, learning in SDCC involves multiple patterns (input-output pairs) at once (called batch learning). SARSA updates the cache buffers until there are enough patterns to make a batch to train CC; details can be found in Rivest and Precup (2003).

## Results

First, we investigate the characteristics of the puzzles used for testing and training using the three algorithmic solvers. A sample of 20 simulations was run, with each simulation learning 3 different puzzles and different random initializations of neural networks. The numbers of steps necessary to solve these puzzles, plotted in Figure 5, suggest that puzzles are well-matched across training sessions and testing.

Figure 5 - Number of steps necessary to solve test and training nonogram puzzles using the three algorithmic solvers. Error bars represent standard errors (SE).

Figure 6 shows performance results for the lookup table. As we can see, it learns near-optimal solutions for the training material ( $M = 8.5$  and  $M = 7.6$  for RL and optimal nonogram solvers respectively); outperforming the heuristic

solver. However, RL solvers based on a lookup table do not generalize at all; performance on the test set reaching the maximal 25 steps on all 20 replications.

Figure 6 - Number of steps to solve nonogram puzzles with the RL solver using a lookup table, compared with the three algorithmic solvers, with standard error (SE) bars

Figure 7 - Generalization performance (i.e. test set) of RL solvers using connectionist function approximators and lookup tables, with a ceiling at 25 steps, compared with the three algorithmic solvers, with standard error (SE) bars

Next, we investigate generalization performance comparing the lookup table with the connectionist function approximator (see Figure 7). As we can see, the connectionist function approximator does generalize to good solutions of 9.1 steps (in the second column) for 7 of the 20 simulations. The other 13 are at ceiling, which, when included makes the average shown in the first column. Networks that reach the ceiling value typically get stuck selecting repeatedly an action that does not yield progress, due to the use of Hardmax and a selection strategy with replacement. Because Hardmax is only sensitive to the action with the largest Q value, the choice of action does not reflect learning all other actions<sup>2</sup>. In particular, Hardmax may select a poor action that obtains the best Q value, even

<sup>2</sup> We have considered presenting results with Softmax, which does reflect learning of all actions. However, we found too much variability, and that performance was inflated due to capitalization on chance (randomly selecting good actions within the ten available).

when good action is just below. We get back to this issue in the discussion.

Finally, we compare the rewards learned by the SDCC-based RL solver with the scores given by the heuristic solver for the first move (i.e., step 1). We find a small but significant correlation of  $r = 0.18$ ,  $p = 0.01$ . This suggests that RL solvers learned good solutions without needing to fully implement the advice often given to human players for solving the initial board condition. This is unsurprising, as the rules given to humans may not be optimal, and, with many steps necessary to solve these puzzles (at least about 9 steps), there are many possibilities to the optimization process beyond step 1.

## Discussion

In general, performance differences between the heuristic and the RL solvers can be explained by the better choices that RL solvers make beyond the first solution step when the board is in its initial state. As mentioned, it is difficult to describe explicit and general purpose strategies for choosing lines to solve when the cells already solved place additional constraints. In fact, none of the online advice gives such explicit rules, but some advice implicitly provides guidance when describing solutions for specific problems. Similarly, RL solvers implicitly learn good choices for the next line to solve at any point in the solution, leading to near optimal solutions.

## Constraints on the choice of actions

As mentioned, by choosing the most flexible selection strategy, the one with replacement, networks need to learn their way out of repeatedly selecting the same action, leading to no further progress. In future research, different ways to handle this issue could be explored by placing additional constraints on action choice. For instance, RL solvers could keep track of the last  $N$  action choices made, and avoid selecting from these. With  $N = 0$ , we get the present "with replacement" scenario, whereas  $N = 10$  (5 rows and 5 columns) would correspond to the "without replacement" scenario. Imposing this constraint would sidestep the need to learn their way out of repeated action choices.

## Cognitive modeling

To our knowledge, there are no experimental studies of humans solving nonogram puzzles. The present simulations make testable quantitative predictions about how humans choose which lines to solve, thus providing some guidance for such research

As a cognitive model, the present system is hybrid, with a symbolic system for solving a given line, and a reinforcement learning with neural network support for choosing an appropriate ordering of lines. This modeling approach is grounded in evidence for both implicit and explicit cognitive processes (e.g., Reber, 1989). With Clarion (Sun, 2006) as a notable exception, modeling work on problem solving has mostly focused on explicit symbol

manipulation. The present work addresses the implicit aspects of learning how to solve problems. The fact that advice and strategies found online have little to say about the order in which to select lines suggests that it may well be an implicit task, difficult to verbalize as explicit rules.

### Towards a universal solver

Our reinforcement learning (RL) solvers learn near-optimal ordering of lines to solve nonogram puzzles, outperforming a heuristic solver based on general purpose rules for line selection. Our solvers show that multiple problems (here, 3) can be learned by a single system, and that about half of them generalize to a novel problem when coupled with a function approximator to compute, rather than merely stores, expected rewards. These results are so far limited to puzzles of relatively small size.

For future work, we could study generalization to larger puzzle sizes. Long term goals could include the design a universal solver that could solve any nonogram puzzle of various sizes nearly optimally. We tried training a RL solver with different, randomly generated nonograms on every learning episode, exploring some of the many simulation parameters (e.g., learning rates). These early attempts suggest that the task is difficult. In addition to the search space being very large, the function approximator appears to have difficulty learning stable representations when there is very high variability. Future research could also explore how to learn a larger number of problems (e.g., 10 or 100) in a reasonable time. Preliminary results suggest that it may be beneficial to gradually increase puzzle size.

### Acknowledgments

We thank Arnaud Rey for helpful comments on an earlier draft. This work is supported by a post-doctoral fellowship to FD and a grant to TRS, both from the Natural Sciences and Engineering Research Council of Canada.

## Abstract

An important component of many, if not all, real-world retrieval tasks is the decision to terminate memory search. Despite its importance, systematic evaluations of the potential rules for terminating search are scarce. Recent work has focused on two variables: the total time spent in memory search before search is terminated and the exit latency (the time between the last retrieved item and the time of search termination). These variables have been shown to limit the number of plausible rules for terminating memory search. Here, we introduce an alternative stopping rule based on a rational moment-to-moment cost-benefit analysis. We show its ability to capture critical latency data and make testable predictions about the influence of changing the relative costs and benefits of memory search. Results from an experiment are presented that support the model's predictions. We conclude that the decision to terminate memory search is based on moment-to-moment changes in subjective value.

**Keywords:** Stopping rule; memory retrieval; free recall.

## Introduction

One of the most influential developments in cognitive psychology and cognitive science is that of a detailed theoretical framework of memory processes. In the late 1960s, Murdock (1967) summarized a view held by many theorists into the “modal model”, a model in which information (memoranda) transfers from sensory memory to short-term memory and then to long-term memory, with each subsequent system having greater memory persistence. The modal model was mainly a framework of memory encoding and the details of memory retrieval were left less-specified. Later theories explicated the retrieval processes in more detail (Anderson, 1972; Metcalfe & Murdock, 1981; Raaijmakers & Shiffrin, 1980, 1981). A common aspect in these theories is the assumption that retrieval from memory can be seen as a search process (Yntema & Trask, 1963) which takes time to complete. Importantly, in order to characterize this search process, models of memory were endowed with stopping rules that prevent the models from continuing search indefinitely. Despite the fact that theoreticians have been quick to incorporate stopping rules into models of memory, research evaluating the class of

stopping rules that might characterize people's decision to terminate memory search is limited.

The evaluation of stopping rules in models of recall is of both theoretical and practical interest. From a theoretical perspective, the goal of developing a comprehensive model of memory retrieval necessitates that we specify the control systems that operate on the memory representations (Newell, 1973). Any particular memory model might yield qualitatively different predictions depending on the specification of the control structures. This is particularly true for stopping rules, since the particular stopping rule employed will affect how long the model will persist in search, which can potentially affect the output of the model (number of items retrieved) and retrieval latencies.

From a practical perspective, understanding stopping rules in the domain of memory retrieval can be informative for the development of artificial intelligence and decision support systems, as well as for cognitive models of diagnostic hypothesis generation and judgment (Thomas, Dougherty, Sprenger, & Harbison, 2008). Within these systems, different stopping rules may yield qualitatively different solutions to diagnostic problems, with optimal solutions requiring different stopping rules depending on the task requirements.

In this paper, we extend the analytical work by Harbison et al., (2009) and implemented a stopping rule that is motivated by a rational analysis of memory (Anderson & Milson, 1989). The resulting rational model is tested against new data.

## Stopping rules

Atkinson and Shiffrin (1968, page 121) suggested a number of stopping rules, which have been implemented in models by a number of authors. These different stopping rules are: an internal time limit (Davelaar, et al., 2005; Davelaar, 2007; Diller, Nobel & Shiffrin, 2001; Farrell & Lewandowsky, 2002; Metcalfe & Murdock, 1981), a strength threshold (Anderson, et al. 1998; Diller, Nobel & Shiffrin, 2001), and an event-counter that would terminate search after a prespecified number of events (Raaijmakers & Shiffrin, 1980; Shiffrin, 1970).

Given the various stopping rules employed in the literature, it is clear that little heed has been paid to how a chosen stopping rule might affect the model's retrieval dynamics. Furthermore, the empirical research on which to test candidate stopping rules has been missing. The presence of self-terminating stopping rules in models of memory is in recognition of the fact that human observers are often required to self-terminate retrieval. Yet, most empirical studies of free recall have masked the contribution of stopping rules by providing participants with a pre-set retrieval interval. The use of pre-set retrieval intervals eliminates the need for the participant to utilize a stopping rule and even if participants were to use such a rule there would be no method of measuring it.

In order to address stopping rules in recall, one needs to allow participants to terminate their own retrieval episode. Consequently, the procedure of interest here is one in which the participant is given all the time they need for retrieval, but allowed to terminate retrieval whenever they wish (Dougherty & Harbison, 2007; Harbison, et al., 2009). This paradigm yields two temporal variables anticipated by models of memory that are important for understanding search termination, but which have received relatively little attention in the literature. The first of these reaction time measures is total time. Total time indexes the elapsed time between the onset of a retrieval cue (i.e., the initiation of the retrieval episode) and the decision to terminate retrieval (i.e., termination of the retrieval episode). The fact that models of memory incorporate stopping rules suggests that these models yield total time predictions. Obviously, different stopping rules will yield different total time predictions, but on an intuitive level one would expect total time to be monotonically related to total number of items retrieved: Total time should increase with the number of items retrieved.

The second reaction time measure is what Dougherty and Harbison (2007) called the exit latency. Exit latencies index the amount of time between the final successful retrieval and the decision to terminate of search. In contrast to total time, there is no obvious, intuitive prediction regarding how long participants will persist in retrieval as a function of number of successful retrieval attempts. Thus, exit latencies provide a potentially diagnostic source of data for evaluating stopping rules, particularly when considered in conjunction with the total time measure.

Few published studies report data on the two temporal variables relevant for measuring termination decisions (Dougherty & Harbison, 2007; Harbison, et. al., 2009; Unsworth, Brewer & Spiller, 2011). In the study by Dougherty and Harbison (2007), participants were visually presented with a cue word and 10 target words (A-X<sub>1</sub>, A-X<sub>2</sub>, ..., A-X<sub>10</sub>). They were told to remember the target words that were presented with each cue word. Each list of 10 target words had a unique cue word. Twelve such lists were presented in blocks of three. After each block of lists were presented, participants were given a cue word and had to report verbally as many words studied with that cue word

(A-?) as they could. Responses were recorded and participants pressed the space-bar to indicate that they could not generate additional words. The total time participants spent in search was measured as the time between presentation onset of the cue for retrieval and the time of pressing the space-bar. The exit latency was measured as the time interval between the last retrieved item and the time of pressing the space-bar.

The pattern of results regarding the stopping and exit latencies as a function of the number of words retrieved in that trial has been shown to be consistent across experimental manipulations (Harbison, et al., 2009). Typically, total time is an increasing function of the number of words retrieved in that trial, whereas exit latency is a negatively decelerating function of the number of words retrieved in that trial.

### Evaluating Stopping Rules

Harbison et al. (2009) conducted a simulation study to compare several of stopping rules suggested by Atkinson and Shiffrin (1968). They used the Search of Associative Memory (SAM; Raaijmakers & Shiffrin, 1981) and implemented the different stopping rules. The models were evaluated on their fit to data. Of the rules tested, only the total number of failures rule fitted the data both qualitatively and quantitatively. This is the rule that was used in the original SAM paper. The total number of failures rule is a special case of an iterative rule that is only concerned with the current sample from memory and the total accumulated number of failures. This lends itself to a rational analysis of the same rule which can make novel predictions.

We see memory retrieval as a form of information sampling for which a cost is incurred with every sampling attempt and a benefit is obtained for successful retrievals. We define the memory value function in which the total net value during the retrieval phase is a function of the total number of items retrieved at the elapsed retrieval time.

Elsewhere (Davelaar, Yu, Harbison, Hussey & Dougherty, submitted) we have derived a closed-form expression for the exit latency, where the decision to terminate search depends only on the information of the last time-step. We converged on the following rule (cf. Anderson & Milson, 1989):

*Terminate search when the additional cost of retrieving the next item starts to outweigh the relative or marginal benefit of having retrieved that item.*

We assume that a cost,  $a$ , is incurred with every sampling attempt,  $t$ , and a benefit,  $b$ , is obtained with every successful retrieval. We define the memory value function as:

$$V_t = Q + bN(t) - at \quad (1)$$

where  $b$  and  $a$  are the benefit and cost parameters.  $N(t)$  is the total number of items retrieved at time  $t$ . The net\_value,  $V_t$ ,

has a constant,  $Q$ , which is interpreted as the starting value that is related to factors such as motivation or time-pressure.

This stopping rule is based on the additional cost of retrieving the next item compared to the relative benefit of having retrieved that item. In other words:

$$\text{cost}(t + 1) - \text{cost}(t) > b/V_t \quad (2)$$

This equation states that when the difference in cost at time  $t$  and time  $t + 1$  is greater than the relative benefit, the memory search will be terminated.

We implemented this rule in SAM, replacing the retrieval failures rule. Figure 1 (top panel) shows the latency functions for the original SAM model. The retrieval failures rule captures both the increase in total time with total number of words recalled and the convex exit latency function. The bottom panel of Figure 1 shows the latency functions of SAM with relative benefit stopping rule. This model also captures the typical data patterns. In addition, when the relative cost is increased, the model predicts that both latency functions are lowered. That is, increased cost decreases the total time spent in memory search and decreases the time spent after the last item before deciding that further retrieval is futile. Importantly, these changes are independent of the total number of items retrieved.

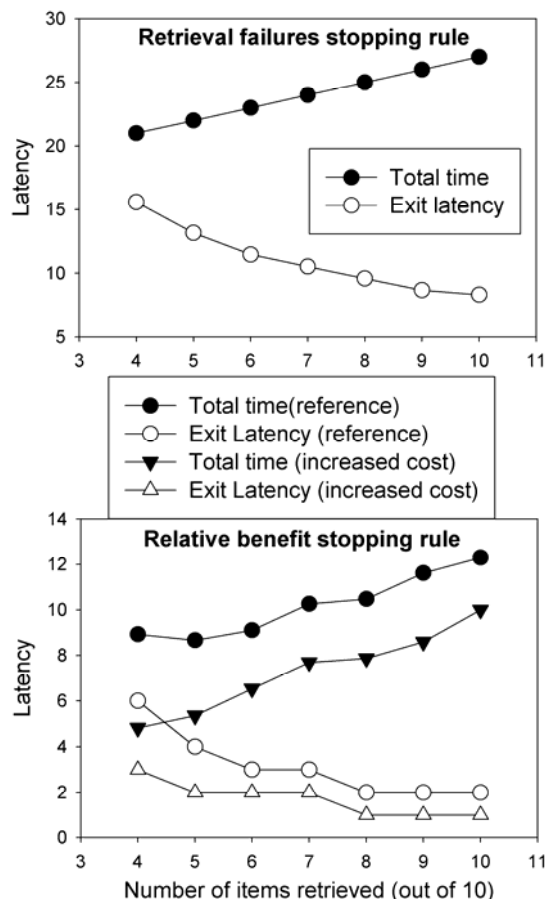

Figure 1. Simulation results of SAM with a retrieval-failures (top) and a relative-benefit stopping rule (bottom).

To summarize, a SAM implementation in which the decision to stop memory search is based on a moment-to-moment cost/benefit analysis predicts that when the cost increases (or benefit decreases) the search will terminate sooner. The next experiment tested these predictions.

## Experiment

### Methods

#### Participants

Forty-five college-aged participants were recruited from the University of Maryland subject pool and received performance-based compensation (\$15 or \$20) for participation in the study. Two participants were removed from analysis due to data collection errors.

#### Design and materials

The design used a delayed free recall paradigm whereby participants studied word lists, completed distractor math problems, and verbally recalled words from the most recent list using a PC-based microphone. The session was presented in two blocks. The first was a baseline block of 16 trials with the same payoff structure across participants (+100 for a correct recall, -100 for each second spent and incorrect recall). In the second block, cost and reward were varied between participants: one group was given an increase in reward (+150) for a correct recall and a simultaneous decrease (-50) in each second spent and each incorrect recall; the other group was given the inverse (+50 rewards, -150 cost). Retrieval protocol followed the self-terminated search paradigm used by Dougherty and Harbison (2007): participants were instructed that they had unlimited time to recall words and could end the recall period at any time by pressing the spacebar. The experimenter monitored the participant's recall and updated the participant's score in real-time, providing feedback to the participant on screen. Thirty-two lists of monosyllabic words were randomly created for each participant. List length was varied between 5, 7, 9, and 11 words and presentation order was randomized to prevent strategy use.

#### Procedure

Participants were informed they would complete a verbal recall task. The study words were sequentially presented in the center of the computer monitor for 2 s each. Following each study list, a distractor task was presented, which consisted of two simple, timed math problems. Problems contained three digits and two operands (e.g.,  $3 * 2 + 1 = ?$ ) and always resulted in a single-digit answer (digits 0-9). A question mark prompted the participant to enter an answer. Components of the math problem were presented sequentially for 1 s each. After two math problems, participants were prompted to begin verbally recalling words from the most recent study list and press the spacebar when they were finished retrieving. After the spacebar press, participants were prompted to press the spacebar again to begin the next study list when they were ready.

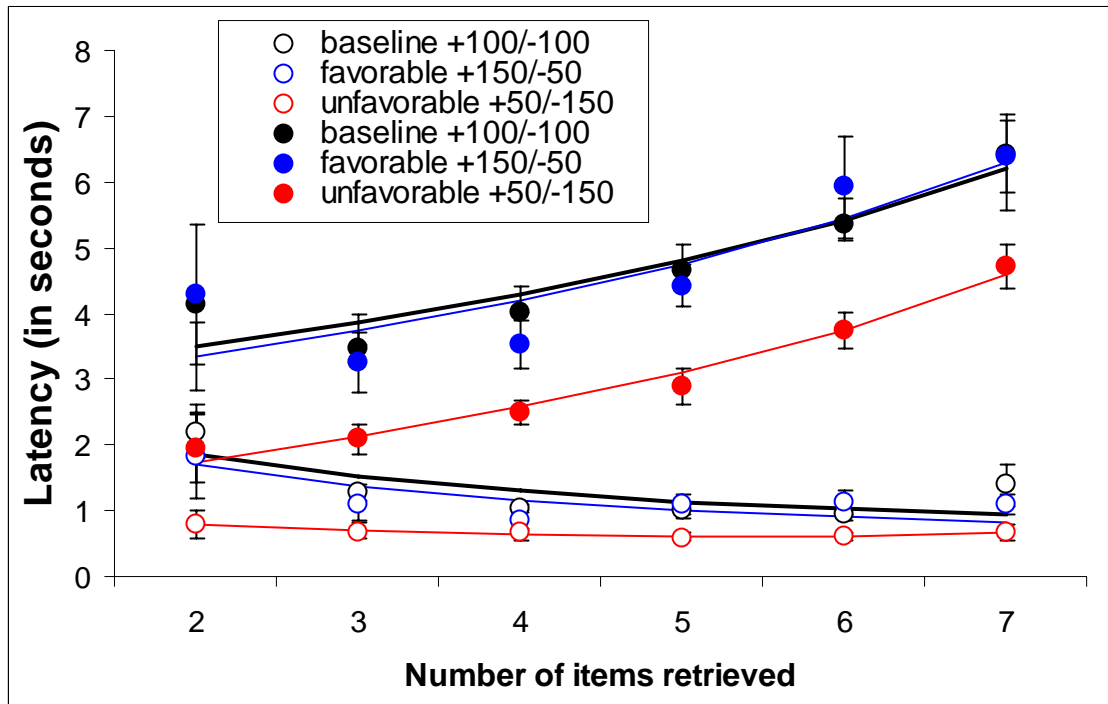

Figure 2. Total time and exit latency functions for the baseline block (both groups combined) and the second block (favorable and unfavorable condition). Error bars are standard errors of the mean. Only the last 8 trials of each block were used. Lines represent the best-fitting regression equation (Davelaar, et al., 2012).

### Coding

Using PennTotalRecall audio-analysis software, verbal retrieval data were retrospectively analyzed with millisecond accuracy. Two coders independently coded: 1) all words that were produced by each participant on each trial, 2) the time stamps of the verbal onset of all generated words, and 3) the time stamps of retrieval termination (i.e., times associated with spacebar presses). From these data, number of items retrieved, number of intrusions including repetitions and intra- and extra-list false alarms, inter-retrieval times, and exit latencies (i.e., time between end of final word retrieved and retrieval termination) were calculated. Each subject's trials were averaged before summarizing across subjects.

### Results

A 2x2 mixed design included an initial baseline control environment (+100 correct recall, -100 second spent or incorrect recall) and a second payoff environment varied between subjects (favorable: +150, -50; unfavorable: +50, -150). Due to steep learning curves in each new environment, only the last 8 of the 16 trials in each block were included in the following repeated measures ANOVA analyses.

The net points (rewards for correct recalls less the penalties for incorrect recalls and time spent) were updated in real-time for participants to use as feedback to monitor their own retrieval performance. As predicted, net points earned in each block increased over time [ $F(1,41) = 6.77$ ,  $p < .013$ ,  $\eta_p^2 = .14$ ] and the participants for whom the rewards

increased and costs decreased earned more points overall [ $F(1,41) = 15.23$ ,  $p < .001$ ,  $\eta_p^2 = .27$ ]; while net points in the baseline block were equivalent across conditions (favorable:  $M = -23.21$ ,  $SE = 41.04$ ; unfavorable:  $M = -35.80$ ,  $SE = 40.10$ ), performance splits drastically in the second block (favorable:  $M = 281.85$ ,  $SE = 54.97$ ; unfavorable:  $M = -161.08$ ,  $SE = 53.71$ ; condition x time:  $38.80$ ,  $p < .001$ ,  $\eta_p^2 = .49$ ), showing that the manipulation worked.

Total number recalled, including intrusions and repetitions, did not vary due to time, payoff environment, or an interaction of the two [conditions:  $F(1,41) = 1.61$ , ns,  $\eta_p^2 = .04$ ; time:  $F(1,41) = 3.36$ , ns,  $\eta_p^2 = .08$ ; condition x time:  $F(1,41) = 3.84$ , ns,  $\eta_p^2 = .09$ ]. Overall, the rate of intrusions was low (0.3 intrusions per list).

Temporal measures were sensitive to learning across the experiment: total time and exit latency both improved significantly for all participants [total time:  $F(1, 41) = 22.19$ ,  $p < .001$ ,  $\eta_p^2 = .35$ ; exit latency:  $F(1,41) = 12.95$ ,  $p < .001$ ,  $\eta_p^2 = .24$ ]. This performance improvement came primarily from the participants for whom the rewards decreased and the costs increased: the interaction between time and payoff structure was significant for both measures [total time:  $F(1,41) = 29.01$ ,  $p < .001$ ,  $\eta_p^2 = .41$ ; exit latency:  $F(1,41) = 9.98$ ,  $p < .003$ ,  $\eta_p^2 = .20$ ], but the main effects of condition were not significant [total time:  $F(1,41) = 1.14$ , ns,  $\eta_p^2 = .03$ ; exit latency:  $F(1,41) = 2.54$ , ns,  $\eta_p^2 = .06$ ].

Figure 2 shows the data on the retrieval latencies broken down by block and condition. Only those trials for which there were sufficient datapoints were included for the model

fit. The solid lines are the best-fitting regression equation derived in Davelaar et al. (2012). This regression model is based on the rational analysis and is a closed-form expression of the simulation rule in equation 2. The use of a closed-form expression facilitates identification of misfits that are due to theoretical misfits instead of sampling noise. The regression model also speeds up the simplex fitting procedure, which requires extremely large samples to fit the latencies at very low and very high total recall. The prediction was that increase in cost or decrease in benefit would lower the latencies. Compared to the baseline condition, making the test hard by increasing the cost and decreasing the benefit did indeed lower all retrieval latencies. Nevertheless, the opposite manipulation, decreasing the cost while simultaneously increasing the benefit, did not change the latencies compared to baseline. We address this asymmetry in the general discussion.

## General Discussion

The purpose of this paper was to extend our earlier work on stopping rules by proposing a stopping mechanism that is motivated by a rational analysis of decisions made on a moment-to-moment basis. The resulting rational SAM model produces the typical latency functions that several commonly used stopping rules failed to capture. The model makes testable predictions about the influence of monetary payoff structure on retrieval latencies and the decision to stop memory search.

The prediction was that making it harder to gain points would lower the retrieval latencies due to higher probability of stopping, whereas the reversed would be the case when it was easier to gain points. Interestingly, only the former prediction was borne out by the data and model fits. The results might be seen as an instance of loss aversion by suggesting what could be called an “it-ain’t-broke” hypothesis. Loosely put, when it is harder to obtain points, the cognitive system readjusts itself to avoid losing too much. However, when the environment changes to such an extent that it becomes easier to gain points, the system will not calibrate itself to then minimize the gains. Hence, if the cognitive system is not losing by what it does (i.e., it-ain’t-broke) then there is no reason for adjusting the cognitive parameter (i.e., don’t-fix-it).

Anderson and colleagues provided a rational analysis of the free recall task (Anderson & Milson, 1989; Anderson & Schooler, 1991), in which each item has a need probability associated with it. Only those items are retrieved whose need probability is larger than a certain criterion, which increases with the time spent inspecting an item before accepting or rejecting it. Anderson and Milson (1989) were able to capture a number of basic memory phenomena using their adaptive perspective. However, their analysis only provided the time of the last retrieved item and not of the exact time of terminating memory search. A possibility would be to use the criterion to estimate the termination time, but this would require knowing the functional form of how the criterion changes during item inspection.

Nevertheless, the success of Anderson’s rational analysis and our current results warrants investigating how these can be combined and would allow analyzing the consequences of different retrieval processes on stopping rules. This also applies to research based on the animal foraging literature, such as problem solving (Payne & Duggan, 2011) and information foraging (Pirolli & Card, 199). We leave such an endeavor for the future.

Our analysis suggests that stopping rules should play a more central role in the development and testing of models of memory. The choice of stopping rule has major impact on the overall model behavior. Obviously, one of the ultimate goals of memory theory is to characterize memory retrieval in general, both in and out of the lab. By focusing more on how people terminate memory search, we can bring our models more in line with the type of retrieval tasks that characterize retrieval tasks outside of the free-recall paradigm.

Investigating stopping rules has important implications for understanding tasks other than free-recall. For example, within the medical decision making literature, it is clear that physicians entertain costs when determining when to terminate their retrieval of diagnostic hypotheses from memory (Weber et al., 1993). More recently, Dougherty and Hunter (2003a; 2003b) showed that the perceived probability of any particular event (a hypothesis) is partially dependent on the number of alternatives retrieved from memory, which was affected by time pressure. This suggests that the decision to terminate memory search will affect his or her perceived probability of a particular hypothesis. Within the frequency judgment literature, Brown and colleagues (Brown, 1995; 1997; Brown & Sinclair, 1999; Conrad, Brown, & Cashman, 1998) have shown that participants’ responses to survey questions often are a monotonically increasing function of total time spent searching memory. Thus, the magnitude of participants’ frequency judgments on behavioral survey questionnaires should be affected by when they terminate search of long-term memory. Although the above tasks are all quite distinct, they serve to underscore the ubiquity of stopping rules in real-world retrieval tasks. Therefore, understanding how people terminate memory search, and the psychological variables that affect search termination, is paramount to the development of comprehensive models of memory retrieval and to understanding the dynamics of memory retrieval outside the lab.

In summary, in this paper we obtained further evidence for the view that participants are making adaptive choices to search termination that are based on a cost-benefit analysis.

## Abstract

Research into word meaning and similarity structure typically focus on highly related entities like CATS and MICE. However, most items in the world are only weakly related. Does our representation of the world encode any information about these weak relationships? Using a three-alternative forced-choice similarity task, we investigate to what extent people agree on the relationships underlying words that are only weakly related. These experiments show systematic preferences about which items are perceived as most similar. A similarity measure based on semantic network graphs gives a good account for human ratings of weak similarity.

**Keywords:** similarity; semantic networks; word associations.

Although similarity is a fundamental concept in cognitive science, it is still not yet well understood. Any two entities have a potentially infinite number of features or predicates in common, making it always possible to construct *post hoc* explanations for why any items are similar to each other (Goodman, 1972; Medin, Goldstone, & Gentner, 1993). Even if similarity is logically vacuous, of course, it is not necessarily psychologically vacuous: there may indeed be a small or at least finite number of shared *represented* predicates (Medin & Ortony, 1989). However, while shared representations may well explain why people share clear intuitions about the similarity of strongly related items like CATS and MICE, the notion of shared representations may not apply when the items are only weakly related. After all, the only predicates that apply to such disparate items as RAINBOW and TUNAFISH are so vague and generic that appealing to them to explain similarity begins to make it nearly as underconstrained psychologically as Goodman first showed it was in a logical sense.

Despite the questions that weak similarity raises about the nature of our underlying mental representations, it is almost entirely unstudied. Almost all investigations into stimulus similarity have focused on items that tend to be quite similar to one another – we ask people to compare the similarity of CATS to MICE, or of MICE and MEN. Rarely if ever do we ask people questions about weak similarities. We can get a sense of how extreme this bias is by examining the empirical data for a set of 372 concepts belonging to 15 natural categories (e.g., fruit, tools, sports), as in Ruts et al. (2004). We used numerical methods to calculate theoretical values for the similarities between all pairs of words in a database of 12,000 word associations. Comparing the two, we found that the *weakest* similarities for which we have empirical data were *stronger* than 97% of the similarities that were predicted according to the word association data base. This suggests

that research into similarity has focused almost exclusively on similarities between only the most related items.

From a methodological point of view, this is not surprising: if asked to rate how similar HAIL and TEACHER are to each other, most people would struggle to know how to answer. Yet this struggle does not necessarily imply that no underlying representation of similarity exists. As Goodman (1972) and others have pointed out, it is always possible to find some basis for saying that HAIL and TEACHER are similar. The real question is which of these bases form part of human mental representations, and whether there exist any systematic regularities in how people spontaneously assess these weak relationships. The goal in this paper is to investigate (a) whether these regularities exist, and (b) whether they can be accommodated by existing theories of semantic representation.

Viewed as a problem of rating the stimuli between two entities that are only weakly related, the challenge seems intractable. Intuitively it feels like the similarity between HAIL and TEACHER is zero, and there is little underlying structure to be found. However, suppose the task were framed as a three-alternative forced-choice problem (e.g., Navarro & Lee, 2002). Which of the following three concepts is the odd one out: CUP, TEACHER and HAIL? Framed in this fashion, the problem seems less intractable, and many people have very strong intuitions about what the answer should be. Sometimes the intuition can be so strong that it may be difficult to see why the answer to the question is not obvious.

As an illustration, in our discussions of this specific triple, one author strongly felt that TEACHER was obviously the odd one out because teachers are people and the other two are not (an “animate vs inanimate” distinction). Another strongly felt that HAIL is the odd one out because it is a mass noun and the other two are count nouns (a “things vs stuff” distinction). In both cases the choice also invokes quite abstract ontological categories, and relies on very broad general knowledge about the world. Obviously the decision to rely on a particular category to guide the decision making is the result of “on the fly” reasoning about the items. Although nobody felt that CUP was the odd one out, it is interesting that for both authors the intuitions were quite strong, so much so that they were somewhat surprised to discover that the supposedly “obvious” choice was not, in fact, so obvious.

This leaves us with an open question: how deep does the structure in our mental representations go? One possibility is that there is significant agreement and constraint in our mental representations only when considering the relationship between entities that are strongly related to each other.

In other words, the Medin and Ortony (1989) argument about shared predicates may only apply between items that are already highly related. If this is the case, then one might expect Goodman's problem to arise when we try to measure weak similarities, causing each person's judgment to be essentially arbitrary and there to be few stable preferences across people. The other possibility is that there is enough shared structure in our mental representations that there is a strong agreement even for such strange pairings as RAINBOW and TUNAFISH, HAIL and TEACHER and so on.

In the first half of this paper we present two experiments exploring weak similarity structure in humans. We show that similarity ratings of weakly related items are nevertheless surprisingly regular across people, and moreover that similarity judgments can be manipulated in sensible ways. In the second half, we investigate the nature of the underlying representations that might give rise to these similarity judgments. Computational modelling demonstrates that weak similarities like those found in our experiments can be at least partially captured by semantic network models constructed from word association data.

## Experiment 1

Our main goal in this experiment was to investigate whether people reliably agree in their similarity judgments even between weakly related entities. In order to avoid the difficulties inherent in asking for similarity ratings between two very different items, we had participants choose which pair out of three possible pairs in a triple was the most similar one.

### Method

**Participants** Sixty-nine native Dutch speaking psychology students participated in exchange for course credit.

**Stimuli and Materials** The stimuli were 300 nouns taken from a set of 12,000 Dutch words used as cues in the word association task described in De Deyne and Storms (2008b) and De Deyne, Voorspoels, Verheyen, Navarro, and Storms (2011).<sup>1</sup> These items were used to produce triples, which were sampled at random given two constraints. Each item in a triple was required to have approximately the same frequency and imageability rating, in order to ensure that participant responses reflected underlying semantic relatedness rather than superficial similarities in concreteness or familiarity. Word frequency was calculated based on the log-transformed lemma frequencies taken from the CELEX database (Baayen, Piepenbrock, & van Rijn, 1993), while imageability was derived from judgments on a seven-point scale found in De Deyne and Storms (2008a). Within any triple, the maximum standard deviation was  $SD_{max} = 0.52$  for lemma frequency and  $SD_{max} = 0.84$  for imageability.

**Procedure** On each trial three words were presented at the corners of a triangle, as shown in Figure 1. Participants were instructed to click on the circle corresponding to the side of the triangle that connected the most related pairs. We stressed in these instructions that we were interested in the meaning of words rather than their orthographic similarity or phonological relatedness. To illustrate what we meant, we gave par-

Figure 1: Example triple stimulus used in Experiment 1. The black circles indicate the controls used to select a pair with the mouse.

ticipants two example triples: in the first one (COLD - HOT - SQUARE) the first two words are related, and in the second one (MOIST - COLD - COOL) the last two are. Participants were asked to do their best even if the task seemed difficult, and not to dwell too long on a single trial but to complete the task in a spontaneous manner. The task was presented as a web questionnaire during a collective testing session.

### Results

Our key question was to what extent people tended to select the same pairs. If weak similarities do not exist or are not reliably shared by different people, we would expect all three possible pairs from every triple to be selected equally frequently. We test this in two different ways.

The first test of inter-rater reliability is to measure how often the most frequent pair from every triple is chosen. Since there are three possible pairs in any given triple, chance responding is 0.33. However, the median value was 0.67 – well above what one might expect by chance. Moreover, as Figure 2 illustrates, for 97 of the 100 triples the most commonly chosen response was selected significantly more frequently than would be expected by chance.<sup>2</sup>

Instead of just looking at the most frequent pair of any triple, we can also measure how much people's weak similarity judgments agree with one another in a more conventional way. We therefore ran  $\chi^2$  goodness-of-fit tests comparing the observed frequencies across the three responses to a null hypothesis that all three responses are equally likely for each triple separately. Taking this approach, the frequencies of 89 out of the 100 triples were significantly different from the null hypothesis,  $\chi^2(2)$ ,  $p < 0.05$ .

The results so far suggest that people encode weak regularities from the environment and do this in a systematic and measurable way. How robust is this finding? We consider this question in the next experiment.

## Experiment 2

The goal of this experiment is to investigate how robust the results from the first experiment are. If weak similarities are not "hard coded" in some way, then they must be derived or constructed somehow. Perhaps people are deriving them by searching a semantic network for the proximity of the two

<sup>1</sup>The complete list of stimuli including English translations is available at <http://ppw.kuleuven.be/concat/simon/>

<sup>2</sup>Note that the hypothesis tests here were conducted using a numerically simulated null distribution, since the sampling distribution of the maximum frequency is an extreme-value statistic and is not correctly described by a binomial distribution; it is, however, trivial to simulate numerically. Using this sampling distribution, the critical value was 0.39, corresponding to the cutoff shown in Figure 2.

Figure 2: Distribution of the most frequently chosen pairs in Experiment 1. The vertical line indicates the 95% confidence boundary for the frequency one would expect if pairs were chosen randomly. Participants agreed with each other in selecting the pairs for almost all of the stimuli in the experiment.

items to each other, or constructing them on the fly based on some other underlying representation. In either case, we would expect that time pressure would cause less accurate estimations and more disagreement between individuals, resulting in more uniform choice probabilities than were found in Experiment 1. We therefore repeated the experiment, with the variation that this time we put participants under time pressure by asking them to decide which pair is more related as quickly as possible.

## Method

**Participants** Thirty native Dutch speaking students participated in exchange for course credits.

**Stimuli and Materials** The stimuli and materials were identical to those presented in Experiment 1.

**Procedure** The procedure was based on Experiment 1, but a few changes were made to allow for the accurate measurement of reaction times. Instead of using the mouse, participants were asked to use the keyboard, and to decide as quickly as possible which pair of words was related. At the beginning of each trial, the triple triangle was presented without the words until the participant pressed the space bar, which displayed the words at each corner. Unlike in Experiment 1, the black circles in Figure 1 were now labeled with either *J*, *K*, or *L*, and participants indicated which pair was most related by pressing the corresponding *J*, *K* or *L* key.

In order to make sure participants understood the task and were answering as quickly as possible, the main test was preceded by 20 practice items that had the words *word1*, *word2* and *word3* as labels at randomized locations. The participants were asked to click on the letter connecting word1 and word2 as quickly as possible. During this time a warning was shown when reaction times were slower than 3600ms, and participants were asked to try to make a faster response.

## Results

Before evaluating what effect the time pressure manipulation had, we first needed to clean up the reaction time data. For each individual we therefore removed any responses with reaction times higher than three standard deviations above their

Figure 3: Distribution of the most frequently chosen pairs in Experiment 2. The vertical line indicates the 95% confidence boundary for the frequency one would expect if pairs were chosen randomly. As before, participants agreed with each other in selecting the pairs for most of the stimuli in the experiment. However, agreement was somewhat lower, suggesting that the time pressure made them unable to fully access their semantic representations, adding noise to their responses.

average, as well as reaction times faster than 300ms. The average reaction time was 3771ms ( $SD = 2131$ ). A log-transformation was used to reduce the skew in the reaction times. Next, for each participants the reaction times were transformed to *z*-scores, resulting in a Spearman-Brown split reliability ( $r_{RT}$ ) of 0.83. Since we did not record reaction times in the first experiment, it is not certain that the participants actually payed attention to the instructions and responding faster, as asked. We investigated if this was the case by running 18 new participants in Experiment 1, this time measuring their reaction times registered by keyboard response. The resulting reaction times had a mean of 4705ms ( $SD = 2864$ ), about one full second slower than the speeded judgments in Experiment 2.

We can now explore the answer to our central question: what effect did time pressure have on the reliability of weak similarity judgments? As before, we can measure how often the most frequent pair from every triple was chosen. Remembering that chance responding would be reflected in a value of 0.33, we find a median value of 0.57. As predicted, this is lower than the 0.67 of Experiment 1, but higher than what one would find if responses were random. We also found that for the vast majority of triples (93 out of 100), the most common response was selected significantly more often than would be expected by chance. Figure 3 shows the distribution of responses. It is evident that, while putting people under time pressure increases the uniformity of the distribution of responses, there is still substantial agreement. This intuition is supported by the  $\chi^2$  goodness-of-fit tests done for each triple, which finds that the frequencies within 89 out of the 100 triplets were significantly different from a null hypothesis under which all three pairs would be equally likely ( $\chi^2(2)$ ,  $p < 0.05$ ).

The results of these two experiments demonstrate that there is consistent and reliable agreement on similarity judgments, even when the entities involved are only weakly related, like CUP and TEACHER. On some level, this agreement is surprising, because such items only share features if so many

features are represented that we begin to run afoul of Goodman's problem. Even then, it is unclear that the items on which there is agreement are the items with more shared features. A more likely explanation of this finding may be that people show strong agreement because they share the kind of semantic representation that is at least partially captured by a semantic network. In the next section, we explore this possibility by modelling the similarities from the two previous experiments based on semantic graphs.

## Graph based models for weak similarity

In this section we investigate the hypothesis that at least some of the agreement between people about weak similarities arises due to shared semantic network representations. Network-based models for similarity have been proposed in related domains (e.g., the NETSCAL model by Hutchinson (1989) or the feature centrality model of Sloman and Rips (1998)), but the most similar models in psychology are the spreading activation models which accounted for a number of interesting semantic effects (e.g. Quillian, 1968).

Why might we expect semantic networks to capture some of the representation with which weak similarities are generated? Such networks probably reflect something about the way words are combined and used in the real world. For instance, the average American is exposed to about 100,500 words every day (Bohn & Short, 2009). The numerous ways that this vast amount of information can be combined may lead to an immense amount of mostly weak contingencies between items. Indeed, in recent years, the increasing availability of co-occurrence information to researchers has led to the development of models that derive representations of meaning from that co-occurrence. These models, which include latent semantic analysis (LSA, Landauer & Dumais, 1997) and topic models (Griffiths, Steyvers, & Tenenbaum, 2007), use statistical methods to extract the regularities underpinning the co-occurrence data. They thereby produce structured, meaningful representations that can be used to capture and explain human behavior and performance.

The goal behind network models is similar, though the approach is different. The network itself is derived from word associations which presumably reflect the patterns of co-occurrence in the world. We can then use the network as the core representation from which similarity measurements are derived. We theorize that although associations between individual entities may be too sparse to account for people's judgments about triples like CUP-TEACHER-HAIL, the network may capture broader relationships that *can* account for such judgments. If broad ontological distinctions like animacy or the count/mass noun distinction are reflected in the structure of the semantic network, we might expect a suitably chosen measure of network-based similarity to be able to capture, at least in part, the manner in which humans resolve the weak similarity questions that we asked in our experiments. How, though, can we measure similarity within a network? We address this problem in the next section.

## Similarity in semantic networks

Large-scale semantic models are typically extremely sparse. In the case of networks derived based on word associations, this means that the number of edges connecting any two

nodes (words) is very low. This is less of a problem when dealing with very similar concepts, because they are likely to share some edges despite the overall sparsity of the network. However, sparsity is a serious problem for other concepts. The same problem arises for non-network-based representations like feature overlap, because the number of features shared by weakly related items is very low, if not zero.

Given the problems imposed by sparsity, how can we measure similarity in a semantic network in a sensible way? We consider two different approaches here. The first is the widely used cosine measure of similarity (e.g., Landauer & Dumais, 1997; Steyvers, Shiffrin, & Nelson, 2004), which measures the extent to which two nodes in the graph share the same immediate neighbors. Two nodes that share no neighbors have a similarity of 0, and nodes that are linked to the exact same set of neighbors have similarity 1. Formally, it is defined as follows. Let  $\mathbf{A}$  denote a weighted adjacency matrix, whose  $ij$ -th element  $a_{ij}$  contains a count of the number of times word  $j$  is given as an associate of word  $i$  in a word association task. Each row in  $\mathbf{A}$  is therefore a vector containing the associate frequencies for word  $i$ . The cosine measure of similarity is the angle between these vectors, calculated as follows: because some words can have more associates than others, we normalize each row so that all of these vectors are of length 1. This gives us a new matrix  $\mathbf{G}$ , where  $g_{ij} = a_{ij} / (\sum_j a_{ij}^2)^{1/2}$ , and the matrix of all pairwise similarities is now

$$\mathbf{S} = \mathbf{G}\mathbf{G}^T \quad (1)$$

The key thing to recognize about the cosine measure is that it depends solely on the *local* structure of the graph: the similarities between two words is assessed by looking only at the words to which they are immediately linked.

Our second approach to similarity aims to take into account the overall structure of the entire network graph, and thus to reflect a broader view of the relationship between two nodes. This measure, similar to Leicht, Holme, and Newman (2006), is an example of a "random walk" approach to assessing similarity (see Kemeny & Snell, 1976; Van Dongen, 2000; Griffiths, Steyvers, & Firl, 2007, for related measures). In general terms, the idea is quite similar to the classical notion of spreading activation (e.g. Quillian, 1968). Similarity is thought to be related to the the number and length of the paths through the network that connect two nodes. If there are a lot of short paths that connect two nodes, then it is easy for a random walk through the graph to start at one node and end at the other; these nodes are therefore more similar. Formally, the measure is specified by beginning with the weighted adjacency matrix  $\mathbf{A}$ . This time, however, we normalize the rows so that each one expresses a probability distribution over words. That is, we use the matrix  $\mathbf{P}$  where  $p_{ij} = a_{ij} / \sum_j a_{ij}$ , and then calculate

$$\mathbf{S} = (\mathbf{I} - \alpha\mathbf{P}^{-1}) \quad (2)$$

where  $\mathbf{I}$  is a diagonal identity matrix and the  $\alpha$  parameter governs the extent to which similarity scores are dominated by short paths or by longer paths. A path of length  $r$  is assigned a weight of  $\alpha^r$ , so when  $\alpha < 1$ , longer paths get less weight than shorter ones.<sup>3</sup> Note that under this approach the

<sup>3</sup>As noted by Minkov (2008), this kind of mechanism can help avoid one of the major criticisms of the spreading activation mech-

similarities can be asymmetric (i.e.,  $s_{ij} = s_{ji}$ ). Since our experimental design forces the empirical similarities to be symmetric we use the average of  $\mathbf{S}$  and  $\mathbf{S}^T$  in our evaluations. Interestingly, our approach is very similar to the PageRank measure:  $\mathbf{X} = (\mathbf{I} - \alpha \mathbf{P}^{-1})\mathbf{1}$ . For PageRank it is standard practice to set  $\alpha$  to a fixed value of 0.85 (Page, Brin, Motwani, & Winograd, 1998), where  $\alpha$  is bounded between 0 and 1. Our choice of  $\alpha$  was 0.6 and represents a reasonable trade-off between some degree of decay and a non-trivial contribution of longer paths.<sup>4</sup>

For both measures the similarity indices for each triplet are normalized to sum to 1. This allows the model predictions to be directly comparable to the empirical choice probabilities, which also sum to 1.

## Evaluating the similarity measures

In order to assess whether the semantic network based measures of similarity are capable of capturing the pattern of weak similarities we observed in our experiments, it is first necessary to construct a semantic network. In other words, we must determine the weighted adjacency matrix  $\mathbf{A}$  from which our measures are derived. We constructed this network from a large dataset of word associations consisting of 12,571 cues and over 3 million responses. The data come from a task in which participants were given a short list of cue words and asked to generate three different responses to each single cue (see De Deyne & Storms, 2008b; De Deyne et al., 2011). From this data set we constructed two different weighted directed adjacency matrices. The graph  $\mathbf{A}_1$  only counts the *first* response given by the participant, whereas  $\mathbf{A}_3$  counts all three responses. The graph based on  $\mathbf{A}_1$  is the more conventional approach, and its sparsity is comparable with previous word association studies (Nelson, McEvoy, & Schreiber, 2004). Because it is based on more responses  $\mathbf{A}_3$  is somewhat denser, but in both cases the graphs were quite sparse. The graph  $\mathbf{A}_1$  included 11,969 nodes and only 0.416% of the possible links, whereas  $\mathbf{A}_3$  included 12,420 nodes and 1.176% of possible links.

To evaluate how well the weak similarities from our experiments can be captured using the semantic network models, we calculated the Spearman rank order correlations between the network-derived similarities and the empirical data. The results, summarized in Table 1, demonstrate that both measures of similarity are significantly correlated with the empirical data. As one might expect, the more global measure of similarity (the random walk measure) performs considerably better than the local cosine measure; and the richer network ( $\mathbf{A}_3$ ) tended to produce higher correlations than the network based on less data. Taken together, the general finding is that the more data one uses to define the network, and the more that the similarity measure takes account of the structure in that network, the better one is able to capture human intuitions about weak semantic similarity.<sup>5</sup>

anism, namely the fact that the entire network is quickly activated (e.g. Ratcliff & McKoon, 1994).

<sup>4</sup>Other values of  $\alpha$  were tried as well, but did not substantially change the pattern of results of our experiments

<sup>5</sup>Within the human data from Experiment 1, there are 28 triplets that did not share a single first association in our semantic network, and 72 that did. Because we were concerned that these results might simply be capturing this difference, we re-calculated the correlations

Table 1: Spearman rank order correlations ( $\rho$ ) between the graph-derived similarities and the empirical similarities from both experiments. All correlations are significant at  $p < .001$ , indicated by the double stars. The more global measure of similarity (random walk) consistently outperforms the more local measure (cosine), and that the correlations are stronger for the denser network (i.e.,  $\mathbf{A}_3$ ).

Graph	Cosine		Random walk	
	Exp 1	Exp 2	Exp 1	Exp 2
$\mathbf{A}_1$	.19**	.22**	.48**	.49**
$\mathbf{A}_3$	.38**	.37**	.55**	.57**

For Experiment 2, we can extend the analysis to see if the network measures can account for decision latencies as well. In general, one would expect that more difficult pairs should result in longer decision latencies. For each pair, we calculated the absolute similarity of the strongest pair and compared it with the decision latency of that pair. Restricting our results to the random walk measure of similarity, we found a significant correlation between network-based similarities and decision latencies ( $\rho = -.22$  for the  $\mathbf{A}_1$  network, and  $\rho = -.24$  for the  $\mathbf{A}_3$  network,  $p < .05$  in both cases). This is again consistent with the hypothesis that the semantic network encodes at least some information used to derive weak similarity.

## Discussion

The work in this paper demonstrates that there is substantial agreement between people about the similarity structure of even weakly related items, like HAIL and TEACHER or RAINBOW and TUNAFISH. Moreover, at least some of this agreement can be accounted for by semantic networks constructed from word association data.

The most striking thing about this finding is that there is any agreement about weak similarity at all. In the abstract, there appears to be very little in common between any three items that are randomly thrown together, and it is not an obvious conclusion that people would agree on how they are related. In practice, many people have strong intuitions about any given triplet, just as two of the authors of this paper had strong intuitions about CUP, TEACHER, and HAIL. Two aspects of this are most intriguing. First, there isn't always agreement about these intuitions (just as one author thought TEACHER was the obvious odd one out, and one thought it should be HAIL). Second, as the data from our two experiments show, there is nevertheless substantial agreement (nobody thought CUP should be the odd one out).

The main question we are left with is *why* people should agree on something like this. There is almost certainly no external pressure in the environment to do so; it is difficult to think of any situations in which random unrelated things are thrown together or used, and people must agree with each other about them without communicating explicitly. Rather,

separately for these two subsets of the data. The results did not differ in any substantive way from those reported in Table 1. Interestingly, 27 out of the 28 strongest pairs from these zero-overlap triplets were agreed upon by the human observers more than one would expect by chance. This amount of agreement was similar in Experiment 2, in which 25 of the strongest pairs from 28 triplets were agreed upon more than chance would predict.

such agreement probably stems from commonalities in the shared representations underlying the concepts. But what are those shared representations, and why should they exist at all? It is clear why it would be useful to represent similarities between entities that commonly co-occur, or that are often thought about together – but what benefit is there to building a representation that will probably never be used, and why do people seem to build similar ones?

Part of the answer to these questions may come from our analyses showing that semantic networks built from word associations can account for at least some of the agreement between people. This suggests that perhaps the shared representations measured in our weak similarity task don't occur because they offer some benefit, but rather occur as a by-product of the fact that the mind represents other things. In this case, it is interesting that networks formed from word associations capture some of those other things. We can be somewhat assured that the agreement accounted for by the networks is not the result of trivial or superficial similarities, since denser networks did better and things like frequency and imageability of the words was controlled for. Rather, it may be that these networks capture, at least to some extent, the kind of deep ontological similarities and abstract relationships that drove our intuitions about triples like CUP, TEACHER, and HAIL.

In light of this possibility, there are a number of areas that would be interesting to explore in future work. While our networks did account for a significant amount of the variance in people's weak similarity ratings, a substantial amount remains without explanation. One possibility for this is that our networks, despite being constructed from 12,000 associations, are still almost certainly much sparser and under-specified than people's actual semantic networks. Indeed, we found that the denser network constructed from more associations accounted for the data better. How much improvement is possible with increasingly dense networks and more items and associations? That is, to what extent is a large part of the variance in weak similarity ratings due to the same thing underlying the associations people make in word association tasks? How would this compare to networks constructed in other ways, like co-occurrence in language? How would this change if the networks were constructed in a more robust way, for instance, addressing the sparsity problem by inferring missing links, as in Miller, Griffiths, and Jordan (2009)? Is performance better or worse for different kinds of words, like abstract vs concrete? Work on all of these questions will help us to address the fundamental issue of what kind of semantic representation humans have – and how that representation underlies people's ability to estimate weak similarity.

## Abstract

People automatically chunk ongoing dynamic events into discrete units. This paper investigates whether linguistic structure is a factor in this process. We test the claim that describing an event with a serial verb construction will influence a speaker's conceptual event structure. The grammar of Avatime (a Kwa language spoken in Ghana) requires its speakers to describe some, but not all, placement events using a serial verb construction which also encodes the preceding taking event. We tested Avatime and English speakers' recognition memory for putting and taking events. Avatime speakers were more likely to falsely recognize putting and taking events from episodes associated with take-put serial verb constructions than from episodes associated with other constructions. English speakers showed no difference in false recognitions between episode types. This demonstrates that memory for episodes is related to the type of language used; and, moreover, across languages different conceptual representations are formed for the same physical episode, paralleling habitual linguistic practices.

**Keywords:** Conceptual event units; event segmentation; serial verb constructions; linguistic relativity.

## Introduction

Events occur in a continuous stream with no clear boundaries between them. Despite this continuity, we think and talk about events in terms of discrete and divisible units. Previous research has largely focused on the factors influencing the segmentation of events. This paper examines the question from a complementary perspective: what factors might lead event elements to be grouped together into a single conceptual event unit.

When we perceive ongoing activity, we segment it automatically and unconsciously (Kurby & Zacks, 2008; Zacks et al., 2001a). The conceptual event units thus created are structured hierarchically. Each event unit is made up of smaller units, which in turn combine to form larger units (Zacks, Tversky, & Iyer, 2001b). So, what counts as a single conceptual event unit depends to some extent on which level of granularity we are talking about. The choice of granularity level appears to be made at the point of reporting. Prior to that, people segment events at multiple levels of granularity simultaneously (Zacks, Speer, Swallow, Braver, & Reynolds, 2007).

Previous research shows that event units are determined by at least three main factors. First, the inherent properties

of events, such as points of greater motion, have a large effect on where event boundaries are placed (Newton, Engquist, & Bois, 1977; Zacks, 2004). Second, repeated co-occurrence, particularly in different contexts, encourages event elements to be grouped together, regardless of their inherent properties (Avrahami & Karev, 1994). Finally, the particular event schema that the person engages for an event affects the way they segment it (Zacks et al., 2007); for instance, whether or not a person understood the actor's goal influences the way a participant segments the actor's behavior (Zacks, 2004). The fact that event schemas influence conceptual event structure suggests that language may also play a role here. This paper explores this possibility.

Previous cross-linguistic research on the role of language in event cognition has largely focused on differences in the encoding of manner and path in motion events. The results have been mixed: Some studies have found language effects (e.g., Filipović, 2011; Finkbeiner, Nicol, Greth, & Nakamura, 2002; Kersten et al., 2010), but others have not (e.g., Gennari, Sloman, Malt, & Fitch, 2002; Loucks & Pederson, 2011; Papafragou, Massey, & Gleitman, 2002). More recently, scholars have begun to explore other aspects of language and how they might influence event cognition, particularly with respect to causal actions (e.g., Fausey & Boroditsky, 2011; Wolff, Jeon, & Li, 2009). For example, Wolff et al. (2009) found that the semantic property of whether or not a language allowed an intermediary actor to function as an agent affected both the syntactic and non-linguistic partitioning of events, consistent with the proposal that language may play a role in event segmentation.

In Wolff et al.'s (2009) study both the semantic and the syntactic differences are potential instigators of the non-linguistic event segmentation patterns. The current study narrows in on the potential link between syntactic encoding in particular and the concomitant non-linguistic partitioning of events.

One type of syntactic structure that is particularly interesting for event cognition is serial verb constructions (SVCs). These constructions allow multiple verbs to be placed within a single clause without coordination or subordination (Aikhenvald, 2006; Durie, 1997). The particular syntactic features vary across languages, though there is a shared set of core, prototypical features

(Aikhenvald, 2006; Foley, 2010). Though generally absent in European languages, SVCs are common cross-linguistically. Some languages have a particularly high rate of SVC use and these are called serializing languages. Languages with no SVCs, such as English, are called non-serializing languages.

It has been claimed that SVCs always refer to conceptualizations of a single event (Aikhenvald, 2006; Comrie, 1995). Take the examples below, from Avatime, a Ghana-Togo Mountain language from the Kwa branch of the Niger-Congo language family. The SVC in example (1a) describes what appears to be a single event: a man cutting firewood with the axe he picked up for that purpose. In contrast, the two Avatime simple, single verb clauses in example (1b) describe a less integrated scene of a man picking up an axe (maybe not with the immediate or sole purpose of cutting firewood) and then cutting firewood (not even necessarily with the axe just mentioned).

1. (a) *A-kò kàwɛ-à tsǎ ɪnyɪ-nɛ.*  
3S<sup>1</sup>-take axe-DEF cut firewood-DEF  
'He cut the firewood with the axe.'
- (b) *A-kò kàwɛ-à. A-tsǎ ɪnyɪ-nɛ.*  
3S-take axe-DEF 3S- cut firewood-DEF  
'He took the axe. He cut the firewood.'

While there is a strong feeling among linguists that SVCs should – and do – refer to single conceptual event units (Aikhenvald, 2006; Comrie, 1995; Durie, 1997), the relationship has not been directly tested.

The best evidence for this relationship, to date, comes from a study conducted by Givón (1990, 1991). He tested conceptual event units by investigating the production process. Speakers pause when they are encoding the next unit of speech (Goldman-Eisler, 1968). Givón thus took pauses in speech as an indication of conceptual cohesion: speech that was encoded together, and so between pauses, was taken to refer to single event units. The frequencies of speech internal pauses in different clause types were compared across three languages of Papua New Guinea (Kalam, Tairora and Tok Pisin), which use verb serialization to different degrees. Givón found that pauses were no more frequent within SVCs than they were within simple clauses with a single verb. From this, he concluded that SVCs and simple clauses both refer to single conceptual event units (contra Pawley, 1987). Note that this study only tests chunking at the linguistic level. It does not provide evidence about cognitive event segmentation. To do that, an independent test of conceptual event structure is required.

The present study aims to conduct just such an independent test. It focuses on placement events in the

serializing language Avatime, to test the following two hypotheses: 1) that SVCs correspond to single conceptual events and 2) that differences in linguistic descriptions of events correlate with differences in conceptual event units.

In Avatime, most placement actions, like putting a cup on a table, or a banana in a basket, must be described using both a take verb and a put verb in an SVC<sup>2</sup>, as in example (2). The grammar of the language requires speakers to encode the taking part as well as the placing part of the event, even if the person only saw the placing. Note that it is logically necessary for an object that is being placed to have been taken at some earlier point in time. So, it is not as strange as it may at first appear for a language to require the preceding taking event to also be encoded. The same construction is also used to describe cases when both the taking and placing events are seen. So an alternative interpretation of (2) is: *S/he took the banana and put it in the basket.*

2. *A-kò kòrantì-ɛ kpe ní kàsɔ-yà mè*  
3S-take banana-DEF put LOC basket-DEF inside  
'S/he put the banana into the basket.'

There is a small set of placement events that are described without a take-put SVC. These exceptional events include putting an article of clothing or jewelry on a body part (in its canonical location), and pouring liquids. These are described using either a put verb in a simple clause (3) or a put verb combined with a pouring manner verb in an SVC (4). It is strongly dispreferred to describe such actions using an SVC with a take verb.

3. *A-kpe likùto-lè*  
3S-put hat-DEF  
'S/he put the hat on.'
4. *E-nyi kùni-ò kpe ní kèzi-à mè*  
3S-pour water-DEF put LOC bowl-DEF inside  
'S/he poured the water into the bowl.'

The patterns of placement event descriptions in Avatime, and the claim that SVCs describe single conceptual events, lend themselves to experimental testing. Previous research has shown that people mentally fill in parts of event units that they have not actually seen (Strickland & Keil, 2011). We can build on this finding to test whether Avatime speakers treat take-put episodes as single event units. Specifically, if Avatime speakers see a videoclip showing a

<sup>1</sup> Abbreviations used: 3 '3<sup>rd</sup> person', DEF 'definite', LOC 'locative', S 'singular', ` 'low tone', ^ 'high tone', mid tone is unmarked.

<sup>2</sup> As with many languages with this type of construction, the take verb acts like an object marker and allows the two objects (thing placed, and location where placed) to be expressed (Lord, 1993). However, unlike some languages, in Avatime the take verb still maintains much of its original lexical semantics in these cases. Different take verbs will even be used to mark differences in the type of taking done.

general placement action, which they would describe using a take-put SVC, they should be more likely to falsely recognize a corresponding taking action. In contrast, if Avatime speakers see a videoclip showing a placement action, which they would not describe with a take-put SVC, such as putting on clothing or pouring a liquid, they should not falsely recognize a corresponding taking action.

To control for the possibility that putting events and their corresponding taking events are generally more cohesive than the donning of clothing or pouring of liquids and their corresponding taking events, we tested a control group of English speakers. English speakers describe general placement events with a single put verb which takes the thing moved as the object and the location as a prepositional phrase. For instance, *She put the book on the table*. The pouring of liquids is described using the same structure as general placements, but the verb is specific to pouring. For instance, *He poured water into the glass*. The putting on of clothing and jewelry is described using essentially the same structure but the location is often not expressed. For instance, *She put the necklace on*. There are no cases where the grammar of English requires the corresponding taking event to also be encoded. Hence, English speakers are not predicted to have differences in false recognition rates to these take events.

## Methods

### Participants

Thirty-four native speakers of Avatime, aged 11-16 (mean 14.1 years), were recruited at Vane Junior High School, Ghana. Four Avatime speakers were tested but excluded due to technical difficulties or for consistently answering either yes or no for all items. Thirty-three native speakers of English, aged 11-17 (mean 14.2 years), were recruited in the Blue Mountains and Sydney, NSW, Australia.

All Avatime speakers were fluent in Ewe and English and 11 additionally spoke Twi. One English speaker was also fluent in German, two spoke Spanish, one fluently and the other moderately. Of the remaining English speakers, 9 were completely monolingual and 21 had very limited knowledge of another language (French, German, Italian, Japanese, Korean or Latin).

### Materials

80 paired putting and taking events were filmed in a single location inside the Max Planck Institute, Nijmegen. They were acted out by two Dutch university students, one male and one female. Each videoclip lasted 3-4 seconds.

A paired putting and taking episode showed the same actor removing an object from one location and placing it in another. For instance, in Figure 1(a) a man takes a banana from the shelf and places it on a plate, in Figure 1(b) a woman takes a necklace from a bag and places it on her

neck. Across episodes, the camera angle and position of the actor in the room were kept constant.

Figure 1: Sample frames from the two videoclips (a) ‘man takes banana from shelf’ and ‘man puts banana on plate’; (b) ‘woman takes necklace from bag’, and ‘woman puts necklace on.’

Objects and locations were selected so as to be familiar to both Avatime and English speakers. The source location of the taking event was always different from the goal location of the putting event. Across episodes, the object, locations, position of the actors, and camera angle varied.

Of the 40 episodes, half had general placement events of the type described using take-put SVCs in Avatime, while the other half did not (the donning of clothing and pouring). Descriptions of the items by Avatime participants at the end of the experiment confirmed this distinction: The placement events in the SVC category were described using take-put serial verb constructions 96.2% of the time ( $SD = 1.8$ ). The placement events in the Non-SVC category were described using take-put serial verb constructions 6.5% of the time ( $SD = 1.7$ ). For ease of reference, both the putting and taking events in an episode will be referred to as either SVC or Non-SVC according to the type of putting event.

### Design

The 40 put and take episodes, resulted in 80 individual items, each consisting of a sole put event or take event. The 80 items were divided into two sets: only one part of a put-take episode featured in each set. Pilot testing with Avatime speakers showed that remembering all 40 learning items in one go was too difficult, so testing was divided into two blocks. In each block of a given set, there were 5 SVC put events, 5 Non-SVC put events, 5 SVC take events, and 5 Non-SVC take events. Blocks were counterbalanced across participants. Within each block, items appeared in one of four random orders.

### Procedure

Participants were asked to watch a series of videoclips and to remember them as best they could. They were told that

they would later be shown more videos, some exactly the same as the ones they had seen and some different, and that their task was to tell the experimenter which videoclips were the same and which were not.

Participants watched videoclips one at a time. The videoclips were separated by a black screen lasting 1 second. After the learning phase, there was a 5 minute distraction task unrelated to the experiment. Participants were then tested for their memory of the 20 videoclips they had just seen, plus their 20 unseen counterparts. So, if a participant saw a girl put on a necklace in the learning phase, they now, in the testing phase, also saw the girl taking the necklace out of the bag. Participants indicated whether each event was the same or different to the events they had seen previously. After finishing testing for the first block, participants saw the second block of 20 items and were tested for memory of those as described above.

After completing the memory experiment, participants viewed all the videoclips again and were asked to describe "what the person did".

Avatime instructions were translated by a native Avatime speaker fluent in English in consultation with the experimenter. Instructions and responses were given verbally in the participant's native language. Responses were recorded using an Olympus LS-10 flash recorder with a headset microphone.

Participants were tested individually and the same procedure was used for English and Avatime participants. The whole experiment lasted approximately 45 minutes.

## Results

Responses to seen and new items were analyzed separately using 2 construction-type (SVC or Non-SVC) x 2 event-type (put or take) x 2 language (Avatime or English) x 2 block order (AB or BA) mixed ANOVAs, with construction and event type being within-participant factors, and language and block order between-participant factors. The dependent variable was the number of reported recognitions. Block order was not significant for seen ( $F(1,59) = 0.62, p = 0.43, \eta_p^2 = 0.01$ ) or new items ( $F(1,59) < 0.01, p = 0.94, \eta_p^2 = 0.01$ ), so we collapsed over this factor.

We first tested whether participants were able to correctly recognize the items they had seen. The overall accuracy was 80.7% for Avatime speakers and 83.6% for English speakers. The difference between language groups was not significant,  $F(1, 61) = 0.92, p = 0.34, \eta_p^2 = 0.02$ . There was a main effect of event-type,  $F(1,61) = 9.20, p < 0.01, \eta_p^2 = 0.13$ . Putting events were remembered more accurately ( $M = 8.50$ ) than taking events ( $M = 7.92$ ). There was also a main effect of construction,  $F(1,61) = 9.81, p < 0.01, \eta_p^2 = 0.14$ , and a just significant interaction between construction-type and language  $F(1,61) = 3.94, p = 0.05, \eta_p^2 = 0.06$ . English speakers remembered Non-SVC events more accurately ( $M = 8.73$ ) than SVC events ( $M = 7.99$ ). Avatime speakers showed no difference in recognition between

previously seen SVC events ( $M = 7.98$ ) and Non-SVC events ( $M = 8.15$ ). There were no other interactions.

Our hypothesis concerned false recognitions to previously unseen or new items. It was predicted that there would be a three-way interaction between construction-type, event-type and language. Avatime speakers would have more false recognitions for taking events if the corresponding put event was one that they would describe using a take-put serial verb construction. English speakers should have the same rates of false recognition for SVC and Non-SVC type events. There was no statistically significant 3-way interaction,  $F(1,61) = 0.01, p = 0.92, \eta_p^2 < 0.01$ . However, there was a main effect of language,  $F(1,61) = 14.34, p < 0.01, \eta_p^2 = 0.19$ . Avatime speakers, in general, had more false recognitions ( $M = 2.83$ ) than English speakers ( $M = 1.58$ ). There was also a main effect of construction-type  $F(1,61) = 4.36, p = 0.04, \eta_p^2 = 0.07$ . SVC events had more false recognitions ( $M = 2.37$ ) than Non-SVC events ( $M = 2.04$ ). More interestingly, there was a significant interaction between language and construction-type,  $F(1,61) = 4.36, p = 0.04, \eta_p^2 = 0.07$ , see Figure 2. Avatime speakers had more false recognitions for SVC type events in general ( $M = 3.17$ ) than for Non-SVC type events ( $M = 2.50$ ). English speakers, on the other hand, had the same false recognition rates for SVC ( $M = 1.58$ ) and Non-SVC events ( $M = 1.58$ ). This suggests that Avatime speakers remember events described with SVCs differently to those which are not; and that this effect is not due to properties of the events themselves, since English speakers fail to show a difference across these event types.

Figure 2: Average false recognitions as a function of language and construction type.

Finally, there was an unpredicted interaction between language and event type,  $F(1,61) = 4.51, p = 0.04, \eta_p^2 =$

0.07. Avatime speakers showed more false recognitions for put events ( $M = 3.08$ ) than take events ( $M = 2.58$ ). In contrast, English speakers had slightly more false recognitions for take events ( $M = 1.71$ ) than for put events ( $M = 1.44$ ). There were no other significant interactions.

## Discussion

Avatime speakers, but not English speakers, displayed more false recognitions for put and take events from SVC episodes than from the equivalent events in non-SVC episodes. This is consistent with the suggestion that language may play a role in conceptual event structure. Avatime speakers appear to construct a single conceptual event unit that includes the taking and putting event segments precisely when the putting event is one that they would describe with a take-put SVC.

Our initial prediction was that false recognitions would occur only with the take part of the episode. This was because it is the put event that determines whether or not an SVC is used, and it is this use of the SVC which is predicted to determine whether or not the take action is included in the event unit. For example, picking up a necklace should only be combined with its corresponding putting event if the putting event is something like putting the necklace in a bag, not putting it around your neck. Our results show, however, that Avatime speakers falsely recognize both the take and put parts of the SVC episodes regardless of which part they saw first. This indicates that as soon as both parts have been seen and understood to form an SVC type episode, Avatime speakers join the taking and putting actions together into a single conceptual event unit. Familiarity with either part then spreads to the unit as a whole, resulting in false recognition of the unseen part, be it a putting or a taking action.

These results show a correlation between conceptual event units and linguistic structure, but from these results alone we cannot say whether language influences conceptual structure, conceptual structure influences language, or whether some third factor is involved. There is some ancillary evidence that language may play a causal role here. For example, Trueswell and Papafragou (2010) found that people under high cognitive load directed attention to event elements considered important in their language; while Zacks et al. (2001b) found that there was greater alignment between fine- and coarse-level segmentation when speakers described events while they segmented them, rather than describing them later. To determine whether linguistic encoding is critically involved in this experiment further study would be needed.

The link between SVCs and single conceptual event units has often been suggested as a definitional criterion for SVCs (Aikhenvald, 2006; Comrie, 1995; Durie, 1997). This paper provides the first language external evidence in favor of this often cited relationship. However, SVCs were only compared with sets of separate clauses. To determine

whether or not the link between SVCs and single conceptual event units is useful as a definitional criterion, SVCs should be compared to other types of complex clauses as well. This paper has shown that testing recognition memory is a viable method for investigating the relationship between conceptual event units and syntactic structures.

In addition to the main result discussed above, we found three other effects. 1) Putting events were remembered more accurately than taking events by speakers of both languages. This is in line with predictions based on the asymmetry of sources and goals in motion events (Regier & Zheng, 2007; Papafragou, 2010) and research concerning put and take lexicons (Narasimhan, Kopecka, Bowerman, Gullberg, & Majid, in press; Regier, 1995). 2) Avatime speakers displayed more false recognitions for put events than for take events while English speakers showed the reverse pattern. This is not immediately interpretable and will require further investigation. 3) English speakers remembered both putting and taking events from Non-SVC episodes more accurately than those from SVC episodes. This shows that there may be differences between the episode types which are noticeable by English speakers, even though they do not use SVCs. It seems likely that actions involving clothing as well as pouring actions could be more salient than general taking and putting actions. Although English speakers were sensitive to the distinction between episode types, they nevertheless performed equivalently with respect to memory for new events. So although there may be differences between SVC and Non-SVC episodes these differences alone cannot predict our final results.

## Conclusion

This study provides the first evidence for the often claimed connection between serial verb constructions and single conceptual event units. It demonstrates that event elements grouped together in language are grouped together as conceptual event units: Avatime speakers conceptualize a take-put episode as a single event unit exactly when the placement event is one they would describe with a take-put SVC but not if it is from a Non-SVC. English speakers, on the other hand, do not distinguish the two types of events in their syntax, nor do they demonstrate greater event cohesion for the events described by take-put SVCs in Avatime. Thus, speakers' event conceptualisations parallel the linguistic structures used to describe those events.

## Abstract

The majority of research on emotion and moral decision-making has focused on the intrapersonal effects of emotion. However, witnessing and displaying emotional expressions is also known to play a significant role in the facilitation and coordination of our social interactions. In this work, we hypothesize that interpersonal emotions effect moral appraisals by prioritizing different moral concerns. We investigate the impact of facial displays of discrete emotions, specifically anger and sadness, in a morally charged multi-item negotiation task. The results of our experiment support our hypothesis that moral appraisals can be strongly affected by interpersonal emotional expressions. We show that displays of anger may backfire if one of the parties associates moral significance to the objects of the negotiation, whereas displays of sadness promote higher concession-making. Overall, we argue that emotional expressions can shift moral concerns within a negotiation in ways that can promote cooperation.

**Keywords:** Emotion, Sacred Values, Moral Decision-Making, Negotiations

## Introduction

Recent research into emotion and moral decision-making reveals a consistent pattern. When confronted with possible threats to moral or sacred concerns, people tend to become emotional (e.g. Ginges et al., 2007), uncompromising (e.g. Tetlock, 2003), and act in ways contrary to traditional formalizations of rational self-interest (e.g. Atran, 2010). This article adds a bit of hope to this otherwise gloomy picture. Building on findings from both moral decision-making and the interpersonal effects of emotion, we show how emotion can sometimes foster cooperation rather than conflict. Our findings have potential important implications for negotiation and conflict resolution in sacred domains.

In this article, we build on the social-functional framework of emotions (Keltner & Haidt, 1999; Frijda & Masquita, 1994) which claims that different sociomoral concerns are prioritized based on the distinct emotions that are experienced (Horbeg, Oveis & Keltner, 2011). This theory argues that our perception of the permissibility of actions in moral situations is affected by the emotions experienced, as different emotions heighten the salience of different moral domains. For example, disgust has been linked to violations of purity-sancity (Rozin, et al., 1999), and research shows that experimentally predisposing individuals to disgust increases their tendency to focus on

purity related issues (e.g. sexuality) as opposed to other moral concerns such as justice (e.g. Tapias, Glaser, Keltner, Vasquez & Wickens, 2007). However, the research on emotion-related moral appraisals has been mostly limited to the intrapersonal effects of emotion in decision-making.

In contrast to research on moral decision-making, research on negotiation and conflict resolution has largely emphasized both the intrapersonal as well as interpersonal effects of emotion (Carnevale, 2008; Forgas, 1998). Work on interpersonal aspects of emotion argues that emotional expressions by one party can change how the other party construes and reacts to a situation. The evidence from this line of research suggests that cognitive emotional appraisals are not only antecedents of emotions experienced, but they may also follow from the perception of emotional expressions in others (Lerner, Han, & Keltner, 2007). For example, it has been widely documented that perceiving expressed anger during a course of a negotiation can elicit more concessions compared to other emotions (such as happiness) or no emotions at all (e.g. Van Kleef, De Dreu & Manstead, 2004a, 2004b, 2010; Sinaceur & Tiedens, 2006). These authors argue that anger communicates that a party has high aspirations and that concessions would be required from the other party to reach an agreement. The majority of these findings, however, rely on negotiations only involving issues that might be of interest to people but have no sentimental or moral significance to them (e.g. negotiating over the price of a cellphone and its duration of service). In this article, we build on these findings and show that interpersonal effects of emotion unfold somewhat differently in moral contexts.

Here, we investigate the impact of facial displays of discrete emotions, specifically anger and sadness, in a morally-charged multi-item negotiation task. We hypothesize that perceiving different emotional expressions in others can influence moral cognition by prioritizing different moral domains and shifting interpretive-frames. In other words, our interpretation of a moral issue can be subjected to the emotional expressions conveyed by other individuals involved in the negotiation. Anger is connotated with the prioritization of ethics of autonomy concerned with rights and justice (Rozin, et al., 1999), and sadness is linked to eliciting sympathy and heightening the salience of need, weakness and harm/care (Horbeg, Oveis & Keltner, 2011). We predict that when an object is perceived as a sacred (or protected) value (with intrinsic moral significance) (Tetlock,

2003; Baron & Spranca, 1997), angry or sad facial displays expressed by an opponent will have opposing effects on the behavior of individuals, as these emotions heighten different moral concerns. Recent work in social and cognitive psychology suggests that people with sacred values (SVs) tend to reject tradeoffs with other values (especially with secular ones) and will express anger when considering such tradeoffs (e.g. Tetlock et al. 2000).

We hypothesize that when facing angry opponents, SV participants (those associating moral significance to the item) will show the typical rejection of tradeoffs and concede very little, as their concerns about their sacred values will be amplified by the anger expressed in the other party. In other words, we predict perceiving expressed anger will back-fire for SV participants, that is, will lessen the likelihood of concession. However, when interacting with an opponent who displays sadness, concerns about need and care will become salient, and participants will concede more than SV participants in the anger condition. For non-SV participants we expect to see the known pattern of concession due to perceived anger consistent with findings of Van Kleef and others in non-moral domains (e.g. Van Kleef et al., 2004a, 2004b; Sinaceur & Tiedens, 2006).

We begin by discussing the negotiation task used in this study. Then we explain our hypotheses, and describe our experiments. We close with a discussion of our findings and its implications.

### Sacred-Objects Negotiation Task

It has been argued that research on morally motivated decision-making relies heavily on a “narrow empirical base”, in regards to subject populations as well as the

stimuli used in experiments (Medin & Atran, 2004). The research populations used in these studies mostly consist of undergraduates at major research universities. And the scenarios and the stimuli materials used mainly focus on single-shot trade-offs scenarios where participants are asked about the permissibility of set hypothetical actions (e.g. killing one person instead of five). However, many real-life moral situations unfold over repeated interactions (which can sometimes span years), such as socio-political conflicts involving sacred values (e.g. Israel-Palestine conflict: Ginges et al., 2007; Iran nuclear conflict: Dehghani, et al., 2009, 2010).

In order to overcome some of the above shortcomings, we have recently developed a new web-based multi-round negotiation task involving a participant and an opponent (computer agent), where different objects are placed on a board and the participant and the agent take turns in taking ownership of some of the items and giving away the others (Carnevale et al., 2011) (Figure 1). Participants can move items around the board by grabbing them with a mouse and putting the items either on their own side or on the opponent's side. After each new proposal is extended by the participants, the agent evaluates the offer, expresses an emotional reaction to the offer and decides whether or not to accept the offer or propose a new offer. Participants can express emotional reactions at any point by choosing one the emotional facial displays at the bottom right corner of the screen (Figure 1).

Aspects of this task are easily configurable in order to consider a variety of experiment questions. In the context of this article, all items are initially placed in the middle section of the board and are up for grabs. The negotiation

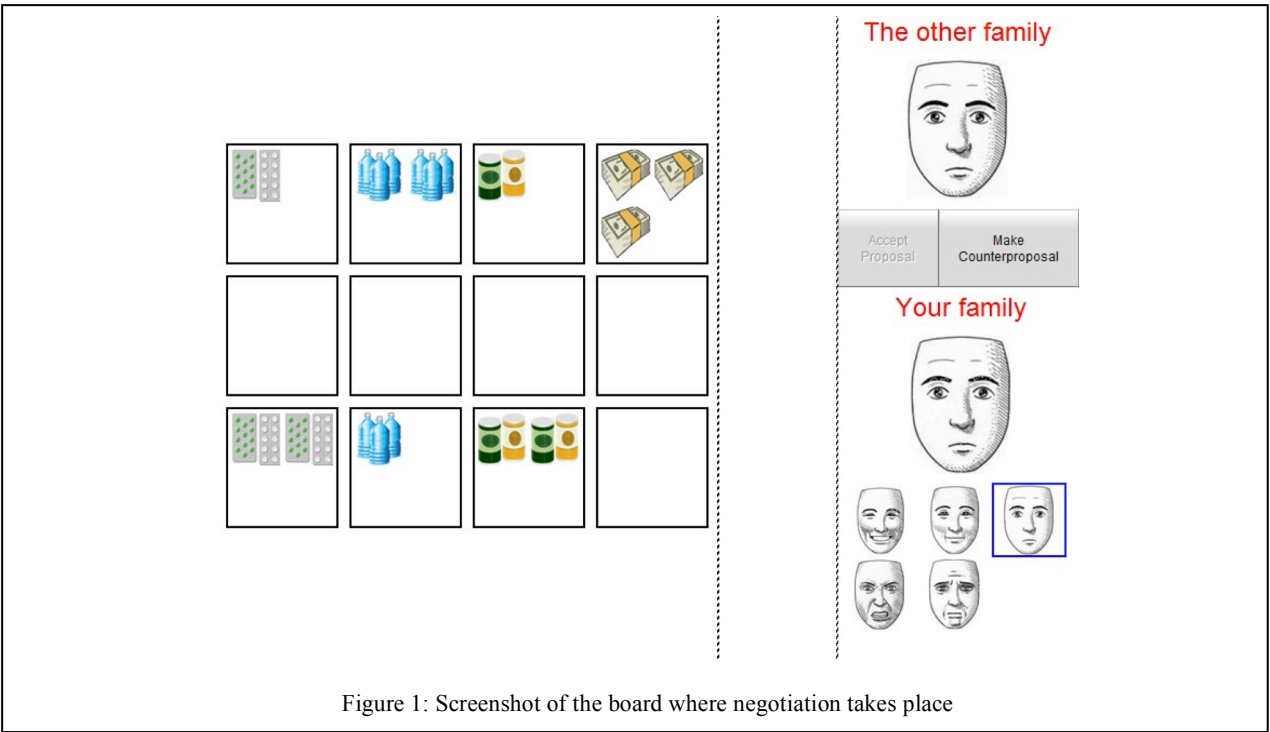

Figure 1: Screenshot of the board where negotiation takes place

consists of 12 rounds with each player taking turns making or receiving offers six times. When a participant makes an offer, the computer opponent decides to accept or reject the offer based on a pre-programmed strategy unknown to the participant. If the opponent decides to reject the offer, it will make a new proposal that the participant can in turn accept or reject.

### Agent Offers

All agents in this study follow the same strategy -- a fixed, non-contingent series of offers that has been designed to simulate resistance to tradeoffs involving sacred values. In pilot testing, most participants perceived this policy to be tough but plausible. There are four different groups of items involved in the negotiations (medicine, water bottles, food cans, money), with three items per group. The negotiation strategy of the agent is as follows ([medicine, water, food, money]): Round 2: [0, 0, 0, 0]; Round 4: [0, 0, 0, 1]; Round 6: [0, 0, 0, 1]; Round 8: [0, 1, 0, 1]; Round 10: [0, 1, 0, 1]; Round 12: [0, 2, 0, 2], where the numbers in the brackets represents how many items in each group the agent chooses to give to the participant. In the decision-making algorithm of the agent, the items are given the following qualitative payoff values: [50, 10, 5, 1]. These payoff values are only used for internal calculations and are not shown to the participants. The agent will accept a participants' offer if it has a higher or equal overall utility than the offer that the agent was about to make. Otherwise, it will reject it and make its next offer.

### Agent Expressions

Agents follow one of two possible facial display policies depending on the condition. The angry agent follows a fixed, non-contingent policy, displaying anger on rounds 2, 6 and 10, and returning to a neutral face after five seconds (i.e., the policy is the same no matter what the participant offered). The sad agent follows the same policy but displays sadness rather than anger. Figure 2 illustrates the expressions. In all other rounds, both agents display a neutral face (Figure 1).

## Experiments

In the following experiment we investigate the interpersonal effects of angry and sad facial displays in the sacred-objects

Imagine the following hypothetical scenario:

There has been an earthquake in the town you live in and many have been injured. All roads to your town have been blocked and as a result aid is coming in very slowly. Because of this every family has to split packages of aid sent using helicopters with another family.

You and the family that have to split the aids with each other, both have babies who have [A: been injured and have developed infections] [B: have caught minor colds]. [A: The only way to control the spread of infection, which if not stopped will become lethal, is to use penicillin] [B: In order to relieve the cold you can give your child acetaminophen]. You are also running low on food, but have enough clean water that would last you for several days. All the shops in the town are closed, so it is uncertain whether you can use the money to purchase goods.

Given the circumstances, you know that no other aid package will be received for another week. The aid packages include medicine including [A: penicillin] [B: acetaminophen], canned food, some money and water bottles.

In the task that follows, you have to negotiate how these items have to be split between your family and the other household. You do not know how much food and water the other family has.

The negotiation is done in a sequence of alternating offers. You will make the first offer. The other negotiator may or may not accept your offer. If it does not accept it, that is, if it rejects your offer, it will send you a new offer. You can either accept or reject its offer. If you accept it, you will get to keep the items that you did not give them. If you reject their offer, you can make another offer and submit it to them. If after 12 rounds there is no agreement, the negotiation will end in no agreement. In this case, you both will only receive one of each item and the rest will be given away.

Try to get as many items as you can.

Figure 3: Participants were presented either with scenario A (deadly-infection) or scenario B (minor-cold)

task discussed in the previous section. Similar to other negative emotions, both anger and sadness serve as calls for adjustment of behavior (Van Kleef et al., 2004). Anger, which is the most common emotion in conflict situations, signals potential confrontation (Allred, 1999) and is related to the ethics of autonomy concerned with rights and justice (Rozin et al., 1999). On the other hand, the hypothesized communicative function of sadness, especially when combined with tears, is to elicit sympathy, signal appeasement, indicate a social need for help and to prioritize the salience of need, harm and care (Shariff & Tracy, 2011; Hasson, 2009; Tiedens, 2001; Horbeg, Oveis & Keltner, 2011). As discussed previously, we hypothesize that perceiving different emotional facial displays in others would prioritize different moral domains and affect moral decision-making. Therefore, we expect that the participants' moral appraisals would be influenced by the angry or sad emotional expressions displayed by the agent during the negotiation. We specifically predict that participants who view an object of the negotiation as a sacred value would show the typical rejection of tradeoffs seen in SV

participants (e.g. Tetlock et al. 2000) but only when they interact with the agent displaying anger. On the other hand, SV participants interacting with the sad agent would concede significantly higher than SV participants interacting with the angry agent. Moreover, the backfiring effect of anger should only be seen for participants who perceive the negotiation object as sacred.

### Participants

Two hundred and fourteen American Amazon-Turk workers (age: 33.71, gender: 56% female) were paid \$1 each to participate in our study. On average it took each worker 6 minutes and 16 seconds to complete our task.

### Design

The study employed a between subject 2 X 2 X 2 full factorial design, where the first factor was agent's expressed emotion (anger/sadness), the second factor was the experimental scenario (deadly-infection scenario/minor-cold scenario, Figure 2), and the last factor was whether or not participants held a SV for the medicine package. After reading one of the two scenarios described in Figure 3, we assessed participants' values regarding the medicine package using Baron and Spranca's (1997) measure. In accordance with this measure we asked our participants: "How do you feel about giving up the medicine package?", and they were provided the following four choices to choose from:

a. I think this definitely needs to happen.

b. I do not object to this.

c. This is acceptable only if the benefits of trading the medicine are great enough.

d. This shouldn't be done no matter how great the benefits are.

Participants who answered “d” were categorized as holding a SV for the medicine package. Participants then played the Sacred-Objects task as described in the last section.

### Results

Participants who dropped out of the negotiation before Round 4 (made only one or two offers and were exposed to the emotional displays of the agent only once) were excluded from the analysis ( $N = 21$ ). From the participants who read the deadly-infection scenario, 62.77% ( $N = 59$ ) perceived the medicine package as a sacred value, compared to 44.44% ( $N = 44$ ) in the minor-cold scenario ( $\chi^2(1, N = 193) = 5.7884, p = 0.0161$ ). However, the scenario manipulation did not have an effect on the course of the negotiation and there was no difference in participants' responses and offers between the two scenarios. Therefore, for the rest of the analysis we combine the data from the two scenarios into one condition.

We examined demands for the items through the course of the negotiation (Figure 4). As predicted, SV participants conceded less on medicine than Non-SV participants throughout the negotiation (Demand 1:  $t(191) = 2.8485, p = 0.0292$ ; Demand 2:  $t(191) = 5.1783, p < 0.0001$ ; Demand 3:

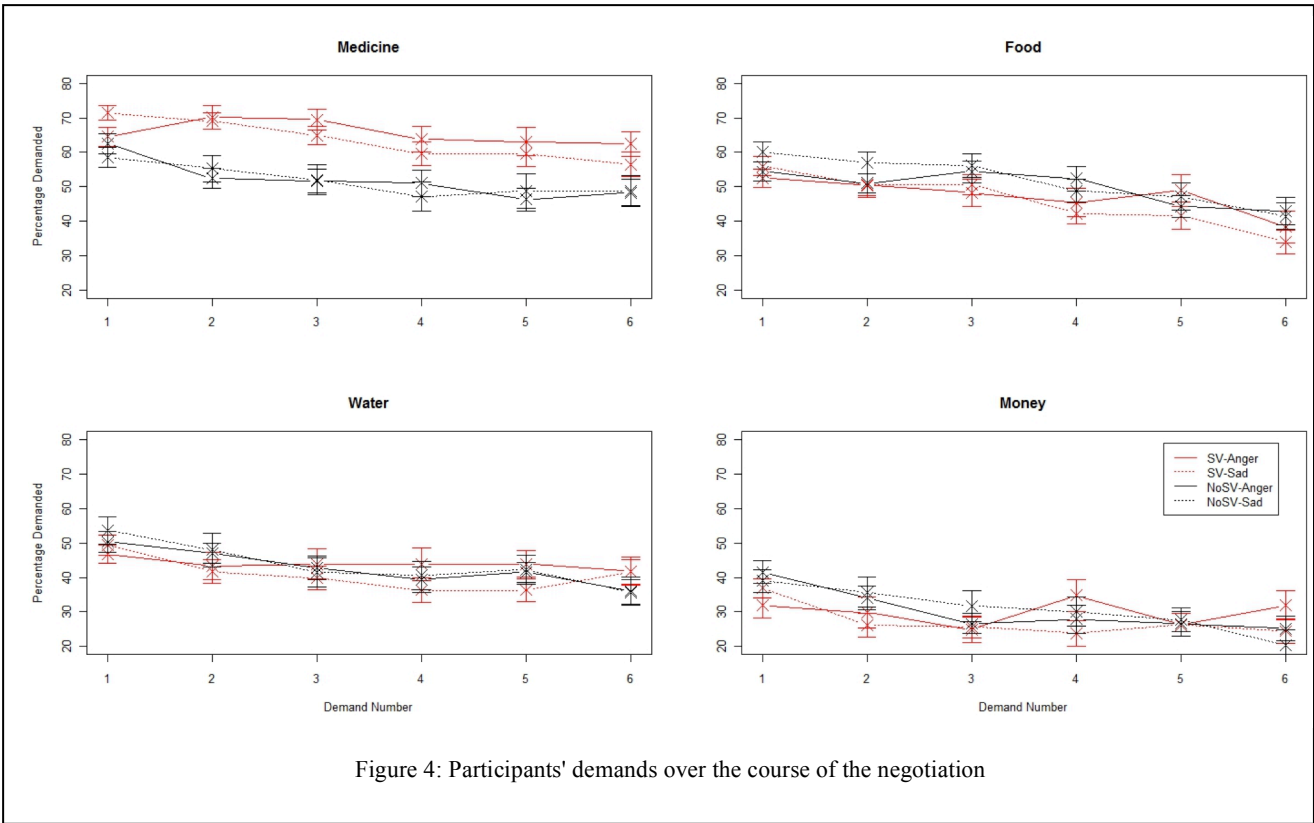

Figure 4: Participants' demands over the course of the negotiation

$t(191) = 4.5055, p < 0.0001$ ; Demand 4:  $t(191) = 3.2353, p = 0.0086$ ; Demand 5:  $t(186) = 3.7789, p = 0.0013$ ; Demand 6:  $t(185) = 2.8966, p = 0.0254$ ;  $p$ -values have been adjusted for multiple comparisons using Bonferroni correction). Corresponding effects were not obtained for the non-sacred objects (water bottles, food cans, money). Repeated measures ANOVA with Greenhouse-Geisser correction, with proposal round number as the within-subjects factor, and SV/NoSV and displayed-emotion as between-subjects factors, determined an overall main effect of time ( $p < 0.001$ ) for all the four objects, and an interaction between time, SV/NoSV and agent's emotion for medicine ( $F(4.585, 839.99) = 2.082, p = 0.053$ ). Again, corresponding effects were not obtained for the non-sacred objects.

To further analyze the differences in concession rates between the groups for different items, we used demand difference (number of packages in the first offer deducted from last offer) for medicine as a dependent variable in a 2 X 2 ANOVA where the first factor was the displayed emotional reaction (sadness/anger) and the second factor was the presence or absence of sacred values. For medicine, there was a significant interaction between SV and the agent's displayed emotion ( $F(1,189) = 4.7615, p = 0.0303$ ) (Figure 5). As predicted, SV participants who interacted with the sad agent conceded significantly higher than SV participants who interacted with the angry agent ( $t(101) = 2.3809, p = 0.0191$ ). Interestingly, SV participants who interacted with the angry agent conceded much less on medicine than Non-SV participants interacting with the same agent ( $t(94) = 2.1191, p = 0.0367$ ).

Given that the trends of negotiation for the rest the objects were similar, we combined them into a single group called non-sacred objects. A 2 X 2 ANOVA (SV/NoSV X AngryAgent/SadAgent) with average demand difference for non-sacred objects as the dependent variable, revealed a significant main effect of SV/NoSV, where SV participants conceded less ( $F(1,189) = 3.8550, p = 0.0511$ ), and a main effect of agent's emotion, where displayed sadness induced more concession ( $F(1,189) = 3.8915, p = 0.0499$ ). There was no interaction between SV and Agent's emotion for the non-sacred objects.

We also analyzed the participants' expressed emotion throughout the length of the negotiation. A planned comparison revealed that the difference in expressed anger between SV participants who interacted with the angry agent and non-SV participants interacting with the same agent was marginal ( $t(86) = 1.2613, p = 0.1053$ , one-tailed). Also, another planned comparison showed that SV participants who interacted with the agent that displayed sad facial expressions, expressed more sadness than SV participants who interacted with the angry agent ( $t(93) = 1.6826, p = 0.0479$ , one-tailed).

## Discussion

Our experiment shows that there was an overall concession over time for all items. However, for the medicine package, the amount of concession made by participants depended on

Figure 5: Demand difference for medicine as a function of Agents' emotional expressions and Sacred Value (SV)

whether they viewed the item as sacred and the agent's displayed emotion. As predicted, SV participants who interacted with the agent that displayed anger made significantly smaller concessions compared to SV participants who interacted with the sad agent. This finding supports our hypothesis that not only are moral concerns prioritized based on experienced intrapersonal emotions (Horbeg, Oveis & Keltner, 2011), but interpersonal emotions also affect moral appraisals by heightening different moral concerns. Specifically, we had predicted that witnessing sad facial displays would affect the decision-making of SV participants, by heightening the salience of need, weakness and harm/care (Horbeg, Oveis & Keltner, 2011). On the other hand, SV participants interacting with the angry agent showed the typical rejection of tradeoffs, as witnessing anger expressions amplified their concerns about their sacred values. Interestingly, consistent with findings of Van Kleef and others in non-moral domains (e.g. Van Kleef et al., 2004a, 2004b; Sinaceur & Tiedens, 2006), anger expressions for non-SV participants resulted in higher concession rates.

Overall, the contribution of our work is two-fold. First, our result emphasizes that moral appraisals can be strongly affected by interpersonal emotional expressions of other parties. Second, we showed that expressing anger may not be the best strategy to achieve higher concession rates in negotiation. Our result demonstrates that displays of anger may backfire if one of the parties associates moral significance to the objects of the negotiation. Displaying sadness was found to be a far more effective strategy to elicit concessions from the other party.

Sacred values play important roles in many cultural and political conflicts (e.g. Ginges et al., 2007; Dehghani et al., 2009, 2010). In this work we argued that moral concerns can be shifted within a negotiation in ways that promote cooperation and concession-making. One real-world implication of our research is that in negotiation involving sacred values, displaying anger and aggression might backfire, in the sense that it will result in conflicts to escalate and anger to reciprocate. However, non-aggressive and non-confrontational signals may result in better outcomes and larger concessions in these circumstances.

## Abstract

Language plays a crucial role in the formation and categorization of one's ethnic identity. Recent work on linguistic accent emphasizes the role of accent in person perception and social categorization, demonstrating that accent serves as a meaningful ethnic category indicator. In this paper, we examine whether accent can be used to implement socio-cultural markers. We investigate whether the accent of a virtual character, as a marker for culture, can cause cultural frame-shifts in individuals. We report an experiment, performed among bicultural and monocultural individuals, in which we test the above hypothesis. Our results show that accent can have a socio-cultural effect on people's cognition.

**Keywords:** accent, culture, frame-switching, biculturalism

## Introduction

There is a substantial amount of research focusing on the influence of language on human cognition. Language, at its core, is a cognitive tool that helps us construct shared meanings, categorize our knowledge, and thus piece together the various associative networks of collective experiences to form our perception of the world around us. According to the Whorfian hypothesis (Whorf, 1956), the grammar of a language and the manner in which the language is processed can provide a glance into the implicit organization of knowledge in that culture. This inherent influence is reflected in the belief that the grammatical structure of a language shapes our interactions due to the speakers inherent exposure to certain observations and mental representations, otherwise known as the principle of linguistic relativity (Chiu, Leung, & Kwan, 2007).

The results from previous studies with bilingual participants support the use of language as a means of activating associated cultural constructs. For instance, Chinese bilinguals randomly assigned to respond in Chinese reported more collective self-statements in open-ended self-descriptions, lower self-esteem, and more agreement with Chinese cultural views (Ross, Xun, & Wilson, 2002). These qualities are in line with traits commonly associated with Eastern collectivist cultures. The findings also suggest that cultural identities may be stored in separate knowledge structures and activated by the associated language. Marian and Neisser (2000) examined the retrieval of autobiographical memories in bicultural individuals and found that memories become more accessible when the language used at retrieval matched the language used at encoding. In other words, Russian-English bilinguals were able to remember more events from the Russian-speaking period of their lives when they responded in Rus-

sian and more experiences from the English-speaking period of their lives when they responded in English.

In their meta-analysis of cross-cultural studies of self-enhancement, Heine and Hamamura (2007) point out the limitations and confounds in existing research regarding whether language can independently prime a cultural mindframe. Lee, Oyserman, and Bond (2010) attended to these shortcomings in their study by exploring the effect of experimentally manipulated language use on value endorsements and self-descriptions. By unobtrusively manipulating language as a prime, they found that bilingual participants randomly assigned to use English reported significantly more self-enhancing social comparative judgements than those using Chinese. In addition, English users demonstrated more social distancing after under-performance and standardized their failure in the context of the behavior of their peers in order to protect their positive self-regard. This is in line with the expected behavior of someone from an individualist culture and touches on the work done by Tesser (2000) and Kwan et al. (2004) regarding the mechanisms employed to protect, augment, or maintain self-esteem. The above findings also support the claim that societies are socialized for both individual and collective mindsets, but responses are dependent on the cultural mindset salient at the moment of self-reflection (Lee et al., 2010).

This literature demonstrates the cognitive implications of experimentally manipulating language as a prime to prompt a shift in an individuals cultural mindset. The findings from these studies support the use of language as a marker for culture, however, in this paper we aim tease apart the specific aspects of language that act as cultural markers, e.g., by manipulating accents. Ethnolinguistic identity theory indicates that language plays a crucial role in the formation and categorization of one's ethnic identity (Giles, Bourhis, & Taylor, 1977). Rakič, Steffens, and Mummendey (2011a) compared the strength of vocal accents compared to facial visual appearance as indicators for ethnic categorization. They found that not only did accent serve as a meaningful ethnic category indicator, but participants also overlooked visual stimuli, such as facial features typically associated with a culture, in the presence of this more meaningful auditory information (Rakič et al., 2011a). In other words, sociopsychological processes were a more salient tool in determining memorability than objective stimulus features. In a later study, they examined the effect of accent workplace context. Job applicants with a standard German accent were compared to those with

nonstandard regional accents to test for biases influenced by the auditory information. Rakič, Steffens, and Mummendey (2011b) found that speakers with a standard German accent were perceived as more competent and more hireable than regional accent speakers. In addition, speakers with a Bavarian accent and the standard German accent were perceived as having higher socio-intellectual status than the remaining speakers. These results bolster the role of linguistic accent in person perception and social categorization.

In this paper, we examine whether accent can be used as a marker for culture by evoking cultural *frame-switching* (Hong, Morris, Chiu, & Benet-Martinez, 2000) in bicultural individuals. Cultural frame-switching refers to the idea that interpretive frames, in individuals who have internalized two cultural identities, can shift due to situational cues (Benet-Martinez, Leu, Lee, & Morris, 2002). For example, Hong et al. (Hong et al., 2000) prime Chinese-Americans with American, Chinese or neutral iconic images and demonstrate that participants in the Chinese prime condition interpreted the next task with more of a Chinese interpretive lens (focused more on external attributions) than those in the American or control conditions. On the other hand, participants in the American prime condition projected more American cultural values by focusing on individual attributions for the same task. A plausible explanation for frame-switching is that multi-cultural individuals have different norms and culturally specific systems of meaning (D'Andrade, 1984), which are activated depending on the context and the social environment. Hence, activation of different cultural interpretive frames can result in varied constraints on the individual's psychophysical behaviors.

The shift in the interpretive frames can be especially notable if there are significant differences in normative behavior between an individuals two cultures. There is growing evidence in the social sciences that culturally normative behaviors vary across cultures (see Henrich, Heine, & Norenzayan, 2010 for a review). In other words, behaviors that are considered typical in one culture may be considered abnormal in another. The variability of culturally normative behaviors and cognitions have been noted in different aspects of human behavior. Related to this work, researchers have shown cultural differences in morally motivated decision-making by identifying moral domains that are present (or salient) in some cultures but not in others (Shweder, Much, Mahapatra, & Park, 1997; Haidt, Koller, & Dias, 1993). Domains such as respect for authority and the saliency of the distinction between purity and impurity are some that have been identified in helping people characterize certain situations as morally tinged within one cultural group but not another. In this work, we carefully control for non-verbal behavior and manipulate only accent of spoken English, in order to experimentally evoke frame-switching and measure its effect on the participants' perception and cognition. Based on the previous literature, we predict individuals interacting with a counterpart having a culturally congruent accent will use moral frames specific to that

culture. Our method differs from studies that use language as a prime in the sense that in our experiment participants only listen and do not generate language explicitly.

## Embodied Conversational Agents

Virtual agents, particularly when rendered as embodied conversational characters, are capable of providing a compelling multimedia platform that serves as an effective interface for research purposes, educational applications or entertainment. Embodied conversational agents (ECAs) make it possible to manipulate external features such as visual appearance, speech type, and contextual graphical environments. This ability makes ECAs a convenient platform to isolate unique cultural characteristics and realize them through simulation. Along with enhanced experimental control, ease of manipulations, consistency and controlled measurements (Loomis, Blascovich, & Beall, 1999), these features make ECAs useful and reliable tools for studying cultural cognitions. For example, we can objectively pinpoint certain social and behavioral characteristics that are relevant to specific cultures and implement them using virtual agent technology. There have been a small number of studies investigating how culturally congruent virtual agent characteristics can affect users' cognition. In an effort to examine the interaction between culture and ECA design in the domain of education, Rader, Echelbarger, and Cassell (2011) developed virtual peers that matched the dialect of children speaking African-American English and asked the children to complete a bridge building exercise. The children alternated playing the role of student and teacher as they explained the building process. Rader et al. found that students who tend to speak more dialected English did so less when they played the role of a teacher. This work suggests that the virtual peer and culturally congruent context, coupled with the role switch, influenced students to speak mainstream English, which is shown to be related to higher student achievement. In another line of work, Yin, Bickmore, and Cortes (2010) report that individuals who process information using peripheral cues perceived an agent tailored to their own culture as more persuasive and trustworthy.

## Experiment

In this paper, we experimentally model frame-switching among bicultural individuals using the accent of an ECA and measure if their preference for certain moral acts are affected by this manipulation. Our hypothesis is that the accent of a virtual agent should affect people's perception of the culture of the agent. If this is true, then a virtual human that has an accent that is congruent with a participant's culture will elicit use of the congruent cultural frame. In order to test our hypothesis, we designed an experiment in which we control for non-verbal behavior of an ECA while manipulating only its accent. We recruited Iranian-American and American (US majority culture) participants and had them read a story which included Iranian and US cultural values and customs. The participants were then asked to summarize the story and answer a few questions about the material.

## Participants

Fifty-two Americans (mean age = 40) and Fourteen Iranian-Americans (Iranians living in Southern California for more than 5 years) (mean age = 34.61) participated in this study. The participants were recruited using craigslist.com and snowball sampling, which consisted of asking subjects to refer other subjects for the study. Each subject received \$25 at the end of the experiment for participating. The participants were not aware that they were participating in a culture study. Each participant completed the task in individual experimental sessions.

## Design

The study employed a between subject 2 X 2 full factorial design. The first factor is the culture of the participants (American or Iranian-American). The second factor is the agent's accent, which was either a standard American English or Iranian English accent, spoken by the virtual agent.

## Stimuli

The participants were first asked to read a short story (Figure 2) about a student named Anthony who was asked to go to dinner at this classmate's (Shawn) house. After arriving in Shawn's house, Anthony comes to the conclusion that Shawn's parents were not expecting a guest for dinner. Anthony complements Shawn's dad about an art piece in the house, and Shawn's dad insists that Anthony should take the picture. Finally, Anthony's friend picks him up from Shawn's house before dinner was served. The story included a balanced number of American and Iranian cultural products (e.g. proverbs), values, and events that could be tied to the celebration of Iranian New Year and to Saint Patrick's day<sup>1</sup>. None of these idea units were explicitly labeled with their cultural referent (there was no explicit reference to St. Patrick's day as such) and the idea units were interleaved so as to minimize memory distortions due to recency or primacy. After reading the story, participants interacted with an ECA.

## Rapport Agent

The agent used in this experiment, Utah (Hartholt, Gratch, Weiss, & Team, 2009) (Figure 1), is designed to establish rapport with human participants by providing contingent feedback while a user is speaking. To produce feedback, the agent first detects and analyzes in real-time the human speakers' audiovisual features, which are silence, head nod, eye-gaze (looking at the agent or not) and smile. The audio feature detector extracts intensity from the raw signal every 100ms using Praat<sup>2</sup>. With the intensity information, it outputs a binary feature, speech or silence, every 100ms. The visual feature detector<sup>3</sup> tracks the position of the face, the facial feature points, the direction of eye gaze and the smile level. With this information, it outputs visual features indicating whether the

Figure 1: The ECA used in our Experiments

human is nodding or not, looking away or not, and smiling or not. Based on the perceived audiovisual features, the response model (Huang, Morency, & Gratch, 2011) decides, in real-time, the most appropriate responses, such as head nod and smile. These different styles of animations are first converted into Behavior Markup Language (BML) (Kopp et al., 2006) and then sent to an action scheduler, which keeps track of the duration of each animation. If the current animation has not been completed, the new animation will be ignored. The BMLs are passed to Smartbody (Thiebaux & Marsella, 2007), a virtual human animation system designed to seamlessly blend animations and procedural behaviors. Finally, the byproducts of Smartbody are rendered by a commercial game engine, Gamebryo<sup>4</sup>, and displayed to users. For the experiment, the voice of the ECA was prerecorded using the voice of the second author, whom is familiar with both Iranian and American cultures. The second author did not participate in recruiting nor in running the experiments.

## Procedure

After participants finished reading the story, the virtual agent greeted them, explained an overview of the research center and asked them to verbally summarize the story they had just read. Next, they filled out a questionnaire about the appropriateness of certain actions and intentions of the characters within the story. They were specifically asked the following two questions: 1. Was it appropriate for Anthony to leave before dinner? 2. Do you think Shawn's parents really wanted to give the picture to him? Our hypothesis predicts that participants should use culturally congruent frames to interpret and answer these moral questions. The Iranian cultural frame suggests that it is not appropriate to refuse someone's generosity and hospitality. If cultural frame-shifting does indeed take place for Iranians-Americans when interacting with the culturally congruent agent, then they should say it is inappropriate for Anthony to leave dinner early. For the second

<sup>4</sup><http://www.gamebryo.com>

... My classmate Shawn, who I'm not really good friends with and don't know too well, invited me to a bonfire at the beach. I told him that I was hungry and needed to get something to eat before going to the beach. He was going to his parent's house for dinner and invited me over. I don't know him well, so I initially refused his offer. But he kept on insisting that it's the beginning of Spring and I should go and have dinner with his family. On the way to his house, Shawn asked why I was wearing almost all green. I thought it was a strange question as a lot of students were wearing green that day...

I went over to his house and met his dad at the living room. I thought to myself that the apple doesn't fall far from the tree. Upon seeing his father, Shawn introduced me to him, saying this is my good friend Anthony. He seemed surprised by my presence. Now I wasn't sure if they were expecting a guest for dinner. Then Shawn's mother came to the living room. I had met her before. She used to work in the registrar of the school. I said hi to her and she greeted me back saying that it looked like water had gone under my skin...

... I didn't understand why they were asking me to stay for dinner, because I think they didn't have any dinner prepared.

... I saw a very small art piece on the wall of their hallway. It was a picture of some Chinese looking guys playing with a ball on horses. I told his dad that this is a lovely picture. He thanked me and told me that I could take it. I first thought he was kidding, but he seemed serious and told me that he wants me to take it. Shawn's mother also said that it will look better in my house and I should take it. Given that they were insisting so much, and the piece didn't look expensive I took it and thanked them for it.

... Shawn's parents told Shawn that they had to wait for another hour and a half to serve dinner because some family friends had just called and were coming to visit them for the first day of spring. Given that I had plans to go watch the game and couldn't wait that long, I got up thanked them for the picture and salad, and had my friend pick me up. Shawn and his parents insisted that I should wait and have dinner with them. But my friend was already there to pick me up...

Figure 2: Excerpt from the story read by participants

question, the Iranian frame could interpret the event as an instance of Iranian hospitality, especially when it comes to sharing their cultural artifacts (in this case Persian miniature). Next, participants were asked several questions about different emotions of the characters in the story. Lastly, to check the effectiveness of our manipulation, participants answered the following two questions in a random order: 3. Did the agent have more of an American accent or Middle-Eastern accent? 4. Did the agent appear more Western or more Middle-Eastern? Each question was answered on a 6-point scale (1 = No he did not, 6 = Yes he did; 1 = Not at all appropriate, 6 = Completely appropriate; 1 = Very much American, 6 = Very much Middle-Eastern; 1 = Very much Western, 6 = Very much Middle-Eastern).

## Results

For both manipulation check questions, we used the responses to questions 3 and 4 as dependent variables in a 2 X 2 ANOVA, where the first factor was the culture of the participants (American or Iranian-American) and the second factor was the accent of the agent (American or Iranian). There was a main effect of agents' accent for both questions (appearance:  $F(1, 62) = 11.038, p = 0.0015$ ; accent:  $F(1, 62) = 68.1434, p < 0.001$ ). The agent with an Iranian accent was viewed to not only have a more Middle-Eastern accent but also appeared more Middle-Eastern. Also, there was a main effect of culture for the appearance question ( $F(1, 62) = 4.276, p = 0.0428$ ) where Americans ranked the agent as more Middle-Eastern looking than did the Iranian-Americans. The responses to the first question were used as the dependent variable in a 2 X 2 ANOVA, with similar factors as above. There was a significant interaction between the two factors ( $F(1,62) = 4.3649, p = 0.0408$ ). A planned comparison revealed that Iranian-American participants who interacted with the agent with an American accent viewed Anthony leaving before dinner as more appropriate than the Iranian-Americans who interacted with the agent with an Ira-

nian accent (Welch Two Sample one-tailed t-test:  $t(10.596) = 10.596, p = 0.0512$ )<sup>5</sup> (Figure 3). However, this difference did not reach significance for Americans ( $t(49.48) = 1.4179, p = 0.1625$ ).

Next, using the responses to the second question as the dependent variable, we ran the same 2 X 2 ANOVA. There was a main effect of culture ( $F(1, 62) = 9.5759, p = 0.0029$ ), where Iranian-Americans ranked this question lower than Americans. There was an interaction between culture and accent of the agent ( $F(1, 62) = 9.5759, p = 0.0029$ ), where Iranians who interacted with the American accent agent indicated that Shawn's parents didn't want to give the picture to Anthony compared to those in the Iranian accent condition (Welch Two Sample t-test:  $t(9.008) = 3.1186, p = 0.0123$ ). However this difference did not reach significance for Americans ( $t(49.983) = -1.2908, p = 0.2027$ ).

There were also interactions between culture and agent's accent for Anthony's feeling of happiness ( $F(1, 62) = 5.0474, p = 0.0282$ ) and satisfaction ( $F(1, 62) = 12.7468, p < 0.001$ ). For happiness, Iranian-Americans interacting with the agent with an Iranian accent rated Anthony's happiness higher than those Iranian-Americans who interacted with an American accented agent ( $t(11.725) = 2.4057, p = 0.0336$ ), and vice versa for American participants ( $t(49.408) = -2.2325, p = 0.0301$ ). The same significant trend held for Anthony's satisfaction (Iranian-Americans:  $t(11.855) = 3.2666, p = 0.0068$ ; Americans:  $t(48.815) = -3.543, p < 0.001$ ). Similarly, there was a two-way interaction between culture and accent for Shawn's parents' satisfaction ( $F(1, 62) = 7.0429, p = 0.0101$ ) and the effect also approached significance for Shawn's satisfaction ( $F(1, 62) = 3.0044, p = 0.0880$ ). Similar to the emotions reported above, participants ranked the satisfaction of Shawn's parents and Shawn higher when the accent

<sup>5</sup> A power test revealed that if we had the same number of Iranian-American participants as American participants, with probability of 99.15% a two-tailed test with the means of the above sample would have reached significance.

Figure 3: Interaction between culture and accent of the agent

of the agent matched their own accent (Shawn's parents': Iranian-Americans:  $t(10.121) = 3.6028$ ,  $p = 0.0047$ ; Americans:  $t(49.362) = -1.4053$ ,  $p = 0.1662$ , Shawn's: Iranian-Americans:  $t(5.953) = 0.7476$ ,  $p = n.s.$ ; Americans:  $t(49.054) = -2.2229$ ,  $p = 0.0309$ ).

## Discussion

This study provides evidence of how spoken accent can make a socio-cultural effect on people's cognition. In a fully factorial design, Iranian-Americans who interacted with a virtual agent that spoke Middle Eastern accented English were more likely to use a congruent cultural frame to interpret a morally charged scenario. The compelling aspect of this effect is that the accented virtual agent's visual appearance was identical across experimental conditions and the only manipulation was the agent's accent. Although simple effects were not significant for the Americans, the trends were in the correct direction. The trends could be due to the fact that most of the American participants recruited in this study have a multicultural background (33% African-American, 14% Latino).

To our surprise, our manipulation also affected people's evaluations of the emotions of the characters in the story. We speculate that this effect might be due to the fact that participants who interacted with an agent whose accent matched their own attributed intentions and goals that are congruent to their own cultural mindset to the characters and, as a result, appraised the situation for the characters more positively. Therefore, when Iranian-Americans interacted with the ECA that had an Iranian accent, they appraised the intentions and goals of the characters to be more in line with the Iranian culture, hence they evaluated the situation more positively, compared to Iranian-Americans who interacted with the American accented ECA.

We acknowledge the low number of Iranian-Americans

participants in our study. However, we would like to note that the probability of replication of a result is dependent on p-levels but not affected by sample size (e.g. Killeen, 2005).

In summary, contributions of this work are two-fold. First, the study adds to the literature in cross-cultural psychology by showing that just spoken language accent can induce cultural frame shifts. Second, this work makes a methodological contribution to the field of human-computer interaction and experimental psychology. Our results also have implications for teaching cross-cultural fluency and competency.

## Abstract

Using a structural priming paradigm, the details of sentence production model have been investigated substantially, specifically the processes in grammatical encoding level. Many studies provide evidence that the function assignment stage and the constituent assembly stage are processed separately in grammatical encoding. However, it is less known whether these two stages interact with each other during the processes, and if so, how the processes are executed. In this study, we report three structural priming experiments in Japanese, in which function assignment and word order were manipulated independently and simultaneously in order to examine the processes at two stages directly. Our results revealed that priming effects patterns were different depending on whether the effects occur at function assignment stage or at constituent assembly stage. Based on the current findings, implications for the recent models of sentence production are discussed, from the perspective of the grammatical function assignment and word order determination.

**Keywords:** Structural Priming; Sentence Production; Active/Passive sentence

## Introduction

People can express thoughts by conveying them through language. Speakers can often express their meaning in several ways by using different linguistic expressions. For example, a transitive event in which a dog is chasing a cat can be expressed by an active sentence (the dog is chasing the cat) as well as by a passive sentence (the cat is being chased by the dog). How do speakers put words together, and choose a syntactic structure? Many decisions must be made during the production process. How these decisions are made and how these decisions generate a linguistic expression, especially how the grammatical function roles and word order are determined during the processing are the central issues of sentence production.

Current models of sentence production widely assume that language production has three levels: message encoding level, grammatical encoding level, and a phonological and phonetic encoding level (e.g., Bock and Levelt, 1994, Ferreira and Slevc, 2007). Grammatical function assignment

and word order are assumed to be determined during the grammatical encoding level, in which speakers encode the preverbal message into a grammatically well-formed linguistic message. The grammatical encoding level is comprised of two separate encoding stages: the function assignment stage in which thematic roles such as agent and patient are assigned to grammatical functions and the constituent assembly stage in which word order is processed. For example, the choice of active/passive alternations is assumed to take place in the function assignment stage, in which the agent role is mapped to the subject and the patient role to the non-subject in the active voice, and the opposite mapping takes place in the passive voice. However word order is assumed to be left unspecified at this point. In the subsequent stage, the constituent assembly stage, word order is processed, such as in the case of the canonical/scrambled word order alternations in Japanese.

In contrast several studies have provided empirical evidence that suggests function assignment and word order are computed simultaneously (Bernolet, Hartsuiker, & Pickering, 2007; Branigan, Pickering, & Tanaka, 2008). Most production models assume that these two stages in the grammatical encoding level are computed separately, (e.g., Hartsuiker & Westenberg, 2000; Vigliocco & Nicol, 1998). Therefore, there is still controversy about whether grammatical functions and word order are encoded separately in different stages. Furthermore, less is known about how these two stages are computed during the production processes, that is whether or not these two stages interact with each other and if so, how the processes are executed.

A structural priming paradigm has often been used to investigate the details of the production model. Structural priming is known as the speaker's tendency to reuse syntactic structures that they have recently produced or comprehended (Bock, 1986). Using a picture description task, Bock (1986) found that after repeating a prime sentence participants were more likely to describe a subsequent target picture with the structure that they had just repeated in the prime sentence. For example, more

passive sentences were produced after passive primes than after active primes. Since previous studies have shown that structural priming is sensitive to syntactic/structure factors between the prime and target pairs (e.g., Bock, 1989, Bock & Loebell, 1990), the structural priming paradigm has been used to investigate the details of the processes in the grammatical encoding level specifically. However empirical evidence supporting the two separate stages model and the one stage model both come from research using the structural priming paradigm (e.g., the separate stages model: Hartsuiker & Westenberg, 2000; Shin & Christianson, 2009; the one stage model: Bernolet, Hartsuiker & Pickering, 2007; Tanka, 2007).

In this study, we investigated whether the function assignment stage and the constituent assembly stage are independent of each other in the grammatical encoding level. Moreover we aimed to investigate the details of how the function assignment stage and the constituent assembly stage are computed during the production processes, that is whether the processes of grammatical function assignment and word order determination interact with each other and if so, how the processes are executed.

In order to answer these questions we used Japanese and conducted three structural priming experiments. The relatively free word order of Japanese allowed us to manipulate function assignment and word order independently. In Japanese, besides mapping a thematic role to the subject (active/passive sentence), one can choose to place the subject at the first position before the non-subject in the sentence, namely, canonical word order (SOV word order), or after the non-subject, in scrambled word order (OSV word order). This word-order variation in Japanese allows us to manipulate the grammatical functions independent of overlap in the word order between prime and target pairs and enable us to investigate the function assignment stage and the constituent assembly stage separately.

If the two stages are computed simultaneously, we would expect to see structural priming effects only when both function assignment and word order match between the prime and the target pairs. If the function assignment stage and the constituent assembly stage are independent of each other, we would expect to see structural priming effects when only one function assignment or word order is shared between the prime and the target pairs (i.e., OSV-passive and SOV-passive pairs; OSV-passive and OSV-active pairs). Moreover, if the processes of two stages interact with each other, we would expect to find structural priming effects between the prime and target pairs interacted with grammatical function assignment and word order determination process.

In Experiment 1, we examined whether the pure structural priming effects of active and passive sentences in Japanese can be observed when conceptual factors were controlled. In Experiment 2, we looked at whether priming effects can be found when function assignment is matched between prime-target pairs, even without sharing the word order, like OSV-

passives and SOV-passives pairs. In Experiment 3, we manipulated function assignment and word order independently and simultaneously in order to look at whether the priming effects can be observed across the two stages.

## Experiment 1

In Experiment 1, we examined structural priming effects of active and passive sentences in Japanese. If the locus of the voice priming effects occurs at the function assignment stage, i.e. the assignment of the subject to agent role in active sentences or patient role in passive sentences, we expect to observe priming effects.

## Method

**Participants** Twenty students, all native speakers of Japanese at Hiroshima University participated in the experiment (13 females and 7 males, the mean age was 22.1 years). Participants were paid 500 yen for their participation. Throughout the experiment, a female native speaker of Japanese acted as the confederate.

**Materials** The prime was either an active or a passive sentence: (1) active prime and (2) passive prime. A target picture (Figure 1) was presented immediately after the prime. Two sets of 80 items were created: a confederate set and a participant set. The confederate set consisted of 80 sentences (20 prime and 60 filler sentences), and the participant set consisted of 80 simple black and white line drawings (20 target and 60 filler pictures). In addition, we prepared two sets of 36 simple black and white line drawings for a picture recognition task.

soccer player-NOM fans-OBL cheer-PASSIVE  
“The soccer player is being cheered by the fans.”

Figure 1: Example of a target picture. A girl chasing a boy.

To ensure that the observed effects are purely structural in nature, conceptual factors such as event type, animacy of NPs, and viewpoint shifts were carefully controlled in the prime/target pairs. That is, our experimental items only involved human entities for both agent and patient, minimizing the bias of conceptual accessibility. The event type between primes and targets was paired among positive, negative or neutral types, in order to eliminate the possibility that the event similarity facilitates the use of same viewpoint between the prime/target pairs.

**Procedure** We adopted a confederate-participant dialogue-style setting (Branigan, Pickering & Cleland, 2000). Participants were told that the study was investigating how people communicate to each other. Participants were asked to describe pictures in turn with the confederate. The experiment always began with the confederate's description. The confederate pretended to describe the picture even though the prime sentence was visually presented on screen. Next, participants were asked to repeat the prime sentence loudly, while memorizing and creating a mental image of the picture. Then, participants described the target picture on the screen and the confederate repeated the description and pretended to memorize it. The experiment consisted of three blocks, and after each block, participants and the confederate were asked to complete a picture recognition task in which a set of pictures was presented. Participants and the confederate were asked to decide whether these pictures matched the description given by the partner during the block.

## Results and Discussion

Priming effects were observed even after conceptual factors being strictly controlled (Figure 2). The results showed that, more passive sentences were produced after passive primes (11.5%) than active primes (1.5%), indicating a clear priming effect ( $F_1(1,19)=10.94, p<.001$ ;  $F_2(1,19)=17.36, p<.001$ ).

Figure 2: Percentages of passives in each condition.

After participants heard passive primes (i.e., assign the sentence subject to patient role) from the confederate, they tended to use passive sentences more often than after they heard active primes (i.e., assign the sentence subject to agent role). Because the conceptual factors between prime and target pairs have been carefully controlled in Experiment 1, the priming effects are most likely due to the processes in the function assignment stage.

However, there is an alternative explanation to the priming effects in Experiment 1. The passive primes and the produced passive sentences shared the same patient-agent thematic role order, but the active primes and the produced passive sentences do not. Since previous studies have demonstrated that the thematic role order did affect the priming effects (e.g., Chang, Bock, & Goldberg, 2003), it is possible that the locus of the priming effect occurs outside the function assignment stage. In experiment 2 we addressed these concerns.

## Experiment 2

In Experiment 2, we looked at whether priming effects can be found when function assignment is matched between prime-target pairs, even without sharing the word order, like OSV-passives and SOV-passives pairs. If function assignment and word order are computed simultaneously, the effects observed in Experiment 1 are expected to disappear in Experiment 2. In contrast, if function assignment is responsible for the priming effects, and it can be processed separately from word order, then we expected to observe the priming effects again.

## Method

**Participants** Twenty students, all native speakers of Japanese, at Hiroshima University participated in the experiment (11 females and 9 males, the mean age was 22.8 years). Participants were paid 500 yen for their participation. Throughout the experiment, a female native speaker of Japanese acted as the confederate.

**Materials** The materials were similar to those in Experiment 1, except we changed the word order of the subject and non-subject (oblique object) in the passive prime as in (3). This time the agent-patient order in active primes and passive primes was controlled.

- (3) sapootaa-ni sakkaa sensyu-ga ooen-sare-teiru.  
fans-OBL soccer player-NOM cheer-PASSIVE  
“The soccer player is being cheered by the fans.”

**Procedure** The procedure was identical to Experiment 1.

## Results and Discussion

The voice priming effects observed in Experiment 1 was replicated (Figure 3). Participants produced more passive sentences after passive primes (6%) than active primes (2%). The main effect of prime type was marginally significant in the participant analysis and significant in the analysis on items ( $F_1(1,19)=3.43, p=.08$ ;  $F_2(1,19)=4.63, p<.05$ ). Participants showed a tendency to reuse a passive sentence after passive primes, even though function assignment only was shared between the passive primes and the produced passive targets, and the thematic order was also unmatched, priming effects were found again. Thus the results from

Figure 3: Percentages of passives in each condition.

Figure 4: Percentages of OSVs in each condition.

Experiment 2 suggest that the voice priming effects in Experiment 2 are due to the processes in the function assignment stage.

In addition to the voice priming effects, we discovered another interesting finding. Participants produced more scrambled sentences (scrambled active sentences: OSV-active) after passive primes (OSV word order, 14.5%) than after active primes (SOV word order, 6.5%) (Figure 4). Analyses revealed a main effect of word order priming effect was marginally significant in the participant analysis and significant in the analysis on items (SOV-active) ( $F_1(1,19)=3.94, p=.06$ ;  $F_2(1,19)=11.50, p<.005$ ), meaning that more OSV-active were produced after the scrambled passive primes (OSV-passive) than canonical active primes.

The word order priming effects that were found between OSV-passive and OSV-active suggest that the word order determination processes occurred in the constituent assembly stage (place the subject before or after the non-subject) and could be primed separately from the function

assignment stage (assign an agent role to subject or non-subject NPs).

Results from the Experiment 1 and Experiment 2 strongly support that the function assignment stage and the constituent assembly stage are independent of each other in the grammatical encoding level, and the grammatical function roles and word order are determined separately during the processes.

However, since we did not manipulate the conditions in active voice systematically, whether the word order priming effects across voice between OSV-passive and OSV-active pairs in Experiment 2 reflected purely word order priming effects is unknown. Moreover whether function assignment and word order determination processes interacted with each other and if so how the processes are computed is left unknown. We examine these questions in Experiment 3.

### Experiment 3

In Experiment 3 we manipulated function assignment and word order independently and simultaneously in order to examine the interaction between two stages directly.

#### Method

**Participants** Thirty-three students, all native speakers of Japanese at Hiroshima University participated in the experiment (25 females and 8 males, the mean age was 21.5 years). Participants were paid 500 yen for their participation. Throughout the experiment, a female and a male native speakers of Japanese acted as the confederate.

**Materials** The prime was either an active or a passive voice sentence with canonical (SOV) or scramble (OSV) word order. (1) SOV-active prime, (2) SOV-passive prime OSV-active prime, and (3) OSV-passive prime were similar to those in Experiment 1 and 2. In addition, we created a (4) OSV-active prime condition. Two sets of 120 items were created: a confederate set and a participant set. The confederate set consisted of 120 sentences (32 prime and 88 filler sentences), and the participant set consisted of 120 simple black and white line drawings (32 target and 88 filler pictures). In addition, we prepared two sets of 60 simple black and white line drawings for a picture recognition task.

- (4) sakkaa sensyu-o      sapootaa-ga      ooensi-teiru.  
 soccer player-ACC      fans-NOM      cheer  
 “The fans are cheering the soccer player.”

**Procedure** The procedure was identical to Experiment 1 and 2.

#### Results and Discussion

Again, the voice priming effects and the word order priming effects were observed.

Figure 5 shows the proportion of SOV-passive sentences in each conditions. The interaction of voice and word order

Figure 5: Percentages of SOV-passives in each condition.

Figure 6: Percentages of OSV-actives in each condition.

was significant in the participant analysis and marginally significant in the analysis on items ( $F_1(1,32)=7.43$ ,  $p<.05$ ;  $F_2(1,31)=3.31$ ,  $p=.08$ ).

Contrasts across SOV word order conditions revealed that more SOV-passive sentences were produced after SOV-passive primes (6%) than after SOV-active primes (1.6%) ( $F_1(1,32)=9.06$ ,  $p<.01$ ;  $F_2(1,31)=7.30$ ,  $p<.05$ ). This pattern of result is identical to those in Experiment 1, which reflected a voice priming effect.

The tendency of difference was also found in active prime conditions – more SOV-passive sentences were produced after OSV-active (4%) than after SOV-active (1.6%) ( $F_1(1,32)=4.73$ ,  $p<.05$ ;  $F_2(1,31)=2.17$ ,  $p=.15$ ). The voice priming effects between OSV-active prime and SOV-passive target suggests that the similarity between these sentence types, although both function assignment and word order were different between the prime/target pairs. Although the conceptual factors were strictly controlled in Experiment 3, this finding suggests the locus of this priming effects might occur outside the grammatical encoding level.

In contrast, the results showed that in OSV-active responses only the main effect of word order was significant ( $F_1(1,32)=7.01$ ,  $p<.05$ ;  $F_2(1,31)=5.28$ ,  $p<.05$ ). More OSV-actives were produced after OSV primes than after SOV primes (Figure 6). This result suggests that after an active voice is selected at function assignment stage, the word order is determined at the constituent assembly stage, and affect by both OSV-active and OSV-passive primes. Again the results showed that word order determination occurs indecently from the function assignment stage.

Taken together, the findings from the voice priming suggest that various factors affect and complicate the processes at function assignment stage (assign an agent role to subject or non-subject NPs). However, the foundlings from the word order priming suggest that the processes at constituent assembly stage are rather straightforward only be influenced by word order determination.

## General Discussion

Three experiments investigated the production processes of the two stages in the grammatical encoding level. In particular, we examined whether the function assignment stage and the constituent assembly stage are processed separately or simultaneously and how the processes are computed.

Using a structural priming paradigm in Experiment 1, we demonstrated that the priming effects of passive voice occur in the function assignment stage, which has a major influence on the choice of active or passive voice, even when the active voice is highly favored. The results from Experiment 2 further confirmed that the priming effects are raised due to the processes in the function assignment stage. Moreover the word order priming effects were found across active and passive voice, which suggested that word order was determined independently of the function assignment stage, in the constituent assembly stage. The results from Experiment 3 further confirmed that the function assignment stage and the constituent assembly stage are computed separately during the production processes. Moreover the pattern of the voice priming effects and the word order priming effects are different according to the stages.

The results from Experiment 3 show the similarity between the OSV-actives and SVO-passives, in this case both function assignment and word order were different between the prime/target pairs. This is consistent with previous studies (e.g., Prat-Sala & Branigan, 2000). Prat-Sala and Branigan (2000) demonstrated that Spanish speakers tend to produce dislocated active sentences (OVS word order) instead of using passive sentences when the patient is more salient than the agent (a language setting which facilitates the production of passives). The authors interpreted that the results suggest that conceptual factors may be associated with variations in word order directly, and the way in which the factors influence is constrained by the syntactic options available within that language.

Prat-Sala and Branigan (2000) suggested the similarity between the dislocated actives and passives when producing an event in which the patient is more salient than the agent (e.g., a sentence emphasis on the patient). In Japanese, both passive sentence and OSV-active are assumed to put emphasis on the patient (Shibatani, 1985, 1990). An explanation of the priming effects found in Experiment 3 between OSV-actives and SVO-passives, might occur outside the grammatical encoding level, that it is due to the similarity between the OSV-active and SOV-passive, which both put emphasis on the patient. For example, after participants heard SOV-passive primes from the confederate, both passive voice and OSV word order were more available than usual at the grammatical encoding level. Although the event type between prime and target pairs were controlled, processing a passive prime might explain the emphasis on the patient roles. If the emphasis of the patient role is persistent between the prime and target pairs, because the active voice was highly favored as conceptual factors were controlled in our study, participants might have chosen an OSV-active over an OSV-passive or SOV-passive, in order to make the patient more salient than the agent. This explanation is consistent with the findings in Bernolet, Hartsuiker, and Pickering (2009), and can be explained by the current model of sentence production which assumes that perspective meaning, a sub-component in the preverbal message level, can affect constituent assembly stage directly. Further studies are needed to examine whether the priming effects between SOV-passive and OSV-active in our study were due to word priming effects or the persistence of emphasis in the patient role. Further studies are needed to examine whether the persistence of emphasis in the patient role can influence the priming effects in the grammatical encoding level.

In conclusion, our findings provide support for a two-stage production model with two separate stages within the grammatical encoding level, namely the function assignment stage and the constituent assembly stage. Moreover, our findings suggest that various factors affect and complicate the processes at the function assignment stage; however, the processes at the constituent assembly stage are rather straightforward by the syntactic options available in that language.

### Acknowledgments

This research was supported by Grant-in-Aid for Scientific Research #20320060 (PI: Hiromu Sakai, Hiroshima University) from the Japan Society for the Promotion of Science. I would like to thank Mikihiro Tanaka, Jeff Pannell, Kyoko Sakamoto, Hiroe Maeda, Kanako Ono and Takuya Kubo for helpful discussions and helping with data collection.

## Abstract

Irrelevant, but overtly presented, stimuli that are temporally aligned with an attended target in a separate task are later inhibited in a recognition task (Dewald, Dumas, & Sinnett, 2011). This is contrary to findings in the perceptual learning literature where facilitation has been observed for later recognition of irrelevant motion stimuli, albeit after extensive exposure rates. Here, we adapted previous work to include higher exposure rates, and subsequently observed a reversal in inhibition in favor of enhanced recognition performance. Participants responded to immediate picture repetitions in a stream of line drawings while ignoring simultaneously presented superimposed words. A surprise test measured recognition for the unattended words. Words that had previously appeared simultaneously with a repeated picture were recognized significantly *more often* than words that had appeared with non-repeating pictures. The findings suggest that the exposure rate and the quantity of irrelevant stimuli can have a significant impact on whether perception is inhibited or facilitated.

## Introduction

Throughout the past decade, researchers have explored how information is processed when it is explicitly or implicitly presented, and the fate of this information when it receives or does not receive direct and focused attention (Dewald, Sinnett, & Dumas, 2011; Mack & Rock, 1998; Rees, Russell, Frith, & Driver, 1999; Seitz & Watanabe, 2003, 2005; Sinnett, Costa, & Soto-Faraco, 2006; Tsushima, Sasaki, & Watanabe, 2006; Tsushima, Seitz, & Watanabe, 2008; Swallow & Jiang, 2010). For instance, several investigations have shown significant perceptual learning enhancements in the absence of focused attention for stimuli that are, in fact, presented below the threshold for visual awareness (i.e., implicitly presented) (Seitz & Watanabe, 2003; 2005; Watanabe, Náñez, & Sasaki, 2001). More recently and contrary to these findings, Tsushima and colleagues (Tsushima et al., 2006; Tsushima et al., 2008) presented evidence suggesting that when the implicit stimulus is made explicit (i.e., observable), a later inhibition is observed. Thus, it would appear that facilitation or inhibition is dependent on whether or not stimulus presentation is sub- or suprathreshold. Furthermore, all of these investigations purport that a synchronous temporal

relationship between the irrelevant stimulus (motion in these investigations) and a separate but attended target in the exposure stage is critical to observing these facilitatory or inhibitory effects in a later recognition task (i.e., the nonsynchronous condition is baseline).

Demonstrating learning enhancements for irrelevant stimuli, Seitz and Watanabe (2003) had participants take part in a series of experiments in which improved motion perception for an irrelevant, subthreshold motion, was postulated to be due to the establishment of a temporal relationship between task-relevant and task-irrelevant stimuli (Seitz & Watanabe, 2003; 2005, see also Watanabe et al., 2001 for a further example using a similar paradigm). Briefly, participants were required to identify a differently colored letter in a rapid serial visual presentation of letters. This primary task was superimposed over an irrelevant background motion stimulus that involved an array of moving dots, of which a small subset moved in coherence. Note that the coherently moving dots (5%) were implicit in nature, demonstrated by chance motion discrimination during pre-testing. While every letter was accompanied with an array of moving dots, the direction of the subthreshold coherent motion was always the same for the target letters of the primary task, while remaining random for non-target letters. The implicit motion synchronized with the presence of the task- target (the different colored letter) was later identified significantly more often than the other motions (i.e. those accompanying non-target letters) in a motion detection task (see, Seitz and Watanabe, 2003). It was hypothesized that when the irrelevant motion and task-target were presented simultaneously during exposure, the learning associated with attention being directed to the detection of the task-relevant features of the task-target would also be applied to the task-irrelevant stimulus of background motion, despite the motion being subthreshold and attention being explicitly directed towards the primary attention-demanding task. Further bolstering this account is the fact that significant improvements in the motion discrimination task were observed only for the motion direction that was paired with the presence of the task-target (i.e., simultaneously presented). However, it is important to recall that the irrelevant stimuli temporally aligned with the presence of the task-target were subthreshold in nature.

Given the differences in perception for subthreshold and suprathreshold information, a logical ensuing question would be to explore what happens when above threshold irrelevant motion stimuli are presented during the exposure stage.

Addressing this very question, Tsushima et al (2008) conducted a similar experiment using explicit rather than implicit motion. Specifically, their experiment included a condition with suprathreshold motions (i.e., 50% coherence) during the primary task (i.e., exposure stage), in addition to a subthreshold motion condition (i.e., 5% coherence). Although one might perhaps expect that higher motion coherence would lead to stronger learning effects (when compared to lower motion coherence signals) due to an arguably strengthened perceptual signal (Britten, Shadlen, Newsome, & Movshon, 1992), the opposite occurred. Facilitation was found only for the subthreshold stimulus levels, while an inhibition was observed for suprathreshold exposure (i.e., explicit presentation). Combined, these findings suggest that strong (overt) target-aligned irrelevant features are subject to attentional inhibition, as the initial task requires attention to be directed to the letter stream. This possibly prevents the strong, but irrelevant, feature from being learned. However, subthreshold motion is not subject to this same inhibitory control, and might therefore be learned and facilitate later perceptual performance.

Other experimental paradigms have utilized different approaches and stimuli to further investigate the way information is processed during dual-task performance. Interestingly, despite the explicit presentation of their stimuli, opposite findings from Tsushima et al (2006) have been observed, with a facilitation for overt stimuli that was presented simultaneously with an attended target from a separate task. For instance, Swallow and Jiang (2010; see also Lin et al., 2010 for a similar example of a paradigm utilizing temporally aligned targets) completed a series of experiments suggesting an “attentional boost” (i.e., facilitation) for simultaneously presented information in a dual-task paradigm, rather than an inhibition as witnessed by Tsushima et al (2006; 2008). In their experiment, participants monitored a stream of pictures of various scenes. A series of distractor items (small black superimposed squares) were simultaneously paired with the presentation of each picture. Participants were required to remember as many of the presented scenes as possible, in addition to monitor the distractor stream for the presence of an “odd-ball” color change (i.e., the presence of a white square rather than a black square). In a subsequent forced choice recognition test for the picture scenes, an enhanced recognition for pictures that had been presented simultaneously with the presence of the target (i.e., the ‘odd-ball’ color change) in the distractor stream was observed (i.e., an attentional boost).

Of particular note to Swallow and Jiang’s (2010) findings is that participants were required to attend to both streams of information simultaneously (encode the pictures as well as detect an “odd ball” target). Recall that in the paradigm utilized by Seitz and Watanabe (2003) as well as

Tsushima et al (2008), participants were instructed to detect a target in one stream (i.e., identify a differently colored letter) while being exposed to the background coherent motion, but not actively attend to the background motion (i.e., the motion was in fact irrelevant at this stage in the experiment). Regardless of these procedural differences, it is important to note that Swallow and Jiang’s (2010) findings are based on the presentation of above threshold stimuli, much like the 50% coherent motion in the Tsushima et al (2008) paradigm. A second important difference is the nature of the stimuli. Swallow and Jiang used pictures (see also Lin et al., 2010) while irrelevant motion was used in the other examples. It is likely that explicitly presented pictures are processed much differently than irrelevant and implicitly presented motion. Combined, the procedural differences between these two paradigms may be a contributing reason as to why a contradictory pattern of results has been observed (i.e., facilitation for Swallow & Jiang, 2010 and inhibition for Tsushima et al., 2008).

Recent work from our laboratory (Dewald et al., 2011) examined the temporal pairing of highly salient and overtly presented task-relevant and task-irrelevant stimuli with an adapted inattention blindness (IB) task (see Rees et al., 1999; Sinnett et al., 2006 for similar examples), requiring participants to monitor a stream of pictures with synchronized superimposed words, and respond to immediate repetitions in the picture stream while ignoring the word stream. Following the picture repetition detection task, participants were administered a surprise recognition test for the (ignored) words that had been superimposed over the pictures during the repetition detection task. Words that had been temporally aligned with the presence of a task-target (i.e., an immediately repeating picture) were subsequently recognized significantly below chance levels (i.e., inhibited), while words that had been temporally aligned with non-targets (i.e., a non repeating picture) were recognized at chance levels. These findings dovetail with the conclusions of Tsushima et al (2006, 2008) and suggest that suprathreshold presented stimuli will be inhibited rather than facilitated if presented simultaneously with an attended target from a separate task.

Critical the experiment presented here, a key component of the paradigm used by Tsushima et al (2006, 2008) and Seitz and Watanabe (2003, 2005) is that the exposure rates of implicit and explicit motion were extremely high, often including multiple days of exposure including thousands of trials. On the other hand, our previous research included a mere 200 total trials lasting approximately 10 minutes. Furthermore, while our research (see also Swallow & Jiang, 2010) paired many different irrelevant stimuli (i.e., words) with the relevant task target (picture repetition), the sub- and superthreshold motion paradigms paired only a single motion direction with all targets in the primary task. This important point is explained further below. The present investigation therefore aims to further extend this research by exploring whether recognition for a highly salient stimulus will in fact be facilitated if presented more

frequently, and without other competing stimuli. That is, it will address the question of whether using a higher frequency of presentation for a salient irrelevant stimulus could in fact modulate the previously observed inhibition and lead to facilitation effects (i.e., akin to the attentional boost effect; see Swallow & Jiang, 2010).

There are a number of possible outcomes in the present investigation. First, based on the conclusions of Seitz and Watanabe (2003), in regards to the temporal pairing of task-relevant stimuli (e.g., immediate picture repetitions) and task-irrelevant stimuli (e.g., superimposed words), it could be predicted that this synchronization will at the least establish a relationship that will affect perception for task-irrelevant stimuli aligned with task-relevant targets. It should be noted however, that studies by Tsushima et al (2006; 2008) as well as Dewald et al. (2011) suggest that if an irrelevant stimuli is explicitly presented (rather than implicitly, as used by Seitz & Watanabe, 2003), the temporal relationship between task-relevant and task-irrelevant stimuli may lead to an inhibited performance in a later recognition task for the irrelevant items. Critical to the question at hand, our previous demonstration used 50 different words rather than a single word (i.e., akin to a single motion; see Dewald et al., 2011). This increased quantity of words could have augmented the salient nature of the stimuli, thereby necessitating that they be ignored in order to complete the primary task of detecting picture repetitions, and consequently lead to inhibitory effects. To better approximate the conditions used by Seitz and Watanabe (2003), in the present experiment we utilize only one high-level irrelevant stimulus (a specific written word) that may lead to an enhanced performance rather than inhibited. This would therefore be analogous to the same unchanging suprathreshold motion always paired with the presence of the task-target in Tsushima et al (2008). We argue that although explicit and suprathreshold in nature, coherent motion detection fails to be processed to the same level as semantic words (see Borst & Egelhaaf, 1989 for a review of visual motion detection). Therefore, it can be predicted that the repeated exposure of a single word that is temporally aligned with an attended target will lead to a later facilitation in recognition for that word when compared to words that were not temporally aligned with an attended target (i.e., similar to the attentional boost, see Swallow & Jiang, 2010). We predict that these results will surface due to a synergy of higher salience for words along with increased exposure levels to the word that is temporally aligned with the presence of a task-target (note, all words were presented in equal frequency).

## Method

**Participants.** Sixteen participants (n=16) were recruited from the University of Hawai'i at Manoa in exchange for course credit. Participants were naïve to the experiment and had normal or corrected to normal vision.

**Materials.** A total of 50 pictures were selected from the Snodgrass and Vanderwart (1980) picture database. The pictures (on average 5 to 10 cm's) were randomly rotated  $\pm 30$  degrees from upright so as to ensure the difficulty of the task in each version of the experiment (see also Rees et al., 1999). Each of these pictures was combined with eight one to two syllable, high frequency English words (average length of 5 letters; range 4-6) selected from the MRC psycholinguistic database (Wilson, 1988). The overall average frequency of the eight selected words was 361 per million, ranging between 135 and 782. The words were displayed in bold, capitalized letters in Arial font at a size of 24 points. Each word was superimposed over a picture and the picture-word stimuli did not exceed 10 cm horizontally or vertically. Care was taken to ensure that picture-word combinations did not have any semantic relationship.

A stream of 960 picture-word concatenated items was created. Repeated pictures acted as the task relevant-targets. The presentation stream was broken into eight blocks of 120 trials in which an immediate picture repetition occurred on average of one out of every eight trials, equating to an average of 15 task-relevant target repetitions per block, for a total of 120 trials of exposure to a task-relevant target (and specific word, see below).

Eight words were selected to be superimposed over the 960 trial picture stream. This was done to parallel the quantity of items and exposure to irrelevant stimuli as well as mimic the dependent measure employed by Watanabe et al. (2001; see also Seitz & Watanabe 2003, 2005). The eight selected words can be thought of as the eight coherent motions. That is, the same single word was always temporally aligned with the presentation of an immediately repeated picture target. All eight words were presented equally. The presentation was pseudorandomized so that on average one out of every eight trials was an immediate picture repetition (and therefore the presentation of the same superimposed task-irrelevant target word). Only one superimposed word was aligned with all of the immediately repeated pictures for each participant. This single word was randomized between the eight words between participants (2 participants per word) so as to control for any possible differences that may have existed regarding particular word saliency.

A surprise recognition test was administered after the completion of the repetition detection task. The test consisted of a total of sixteen words from which half came from the previously viewed visual stream, while the other half consisted of foil words that had never been seen before. The foils were words that had never been used in the exposure stage of the experiment, but were taken from the same database and had an average frequency of 236 per million with a range of 165-399. The eight non-foil (previously seen in the picture repetition task) words were words that were either temporally aligned with the task-relevant target, (i.e., superimposed over the immediate repetition of a picture), or were not temporally aligned with the task-relevant target (i.e., superimposed over non-

immediately repeating pictures). For ease of explaining and reference, words synchronized with task-relevant targets will be referred to as *target-aligned* words and those not aligned with task-relevant targets will be referred to as *non-aligned* words (see also Dewald et al., 2011).

Both the repetition detection and word recognition tasks were randomized and presented by DMDX software (<http://www.u.arizona.edu/jforster/dmdx.htm>) one at a time, written in bold, capitalized letters in Arial font at a size of 24 points, in an identical fashion as they were displayed in the previous stream. The words in the recognition test remained on the screen until a response was made.

## Procedure

Participants were required to attend to the picture stream (i.e., ignore the simultaneously presented superimposed words) and respond to immediate picture repetitions by pressing the ‘G’ key on the keyboard of the computer. Each item in the picture-word presentation was presented for 350 ms with a 150-ms inter-stimulus interval (ISI; blank screen) between each item for a stimulus onset asynchrony (SOA) of 500 ms (see Figure 1). Before the first experimental block, a training block of eight trials was given and repeated until participants were familiar and comfortable with the task.

Figure 1. Each picture–word stimulus was presented for 350 ms and then replaced by a blank screen for 150 ms before the next stimulus. The task is to respond to picture repetitions and ignore the words, for which a surprise recognition test is later given. Note that the *target-aligned* word (in the present case ‘MUSIC’) remains the same across all repetition trials.

Immediately after the repetition detection task, the surprise word recognition test was administered to all participants. Words were displayed individually on the center of the screen in the same size and font as previously presented in the repetition detection task, and remained on the screen until the participant made a response. Participants were instructed to press the “B” key if they had seen the word during the repetition detection task or, instead, the “V” key if they had not seen the word before.

## Results

Overall task performance for word recognition was 78%, which was significantly above chance levels ( $t(15) = 6.58$ ,  $p < .01$ ). In order to address the question at hand, that is, if recognition performance is enhanced for words that had

appeared with a picture repetition, the average correct recognition score for *target-aligned* words (words superimposed over immediately repeated pictures) and *non-aligned* words was compared against chance, and also against each other. In this case, recognition for *target-aligned* (87.5%,  $SE=.85$ ) and *non-aligned* words (68.4%,  $SE=.37$ ) was significantly better than chance ( $t(15) = 10.91$ ,  $p < .001$  and  $t(15) = 4.89$ ,  $p < .001$  respectively). Most importantly, recognition for *target-aligned* words was significantly better than performance for *non-aligned* words ( $t(15) = 2.31$ ,  $p = .03$ ; see Figure 2).

Additionally, the correct rejection of foil words was compared with overall performance for *target-aligned* and *non-aligned* words. No significant differences between recognition for *target-aligned* words and correct rejections surfaced (*target-aligned*: 87.5%,  $SE=.85$  vs.  $CR: 88.6\%$ ,  $SE=.03$ ,  $t(15) = -.07$ ,  $p = .994$ ). There was a significant difference between correctly recognizing *non-aligned* words and correctly rejecting foil words (*non-aligned*: 68.4%,  $SE=.37$  vs.  $CR: 88.6\%$ ,  $SE=.03$ ,  $t(15) = 3.69$ ,  $p < .002$ ). Further demonstrating the overall accuracy of word recognition, there were significantly fewer false alarms (FA) (i.e., incorrectly identifying a foil word as having been present during the picture repetition task), when compared with correct foil rejections ( $FA = 10.4\%$  vs.  $CR = 88.6\%$ ,  $t(15) = 17.08$ ,  $p < .001$ ), *target-aligned* words (87.5%,  $t(15) = 17.65$ ,  $p < .001$ ), and *non-aligned* (68.4%,  $t(15) = 13.79$ ,  $p < .001$ ) words as well as significantly fewer false alarms than to be expected by chance ( $t(15) = 19.11$ ,  $p < .0001$ ).

Lastly, confirming that participants were able to successfully perform the initial repetition task, an analysis was also conducted on the accuracy of the primary task of detecting immediate target repetitions. Overall, participants accurately detected target repetitions (**Hits**: 75%,  $SE=0.20$  vs. **Misses**: 25%,  $SE=0.79$ ,  $t(15) = 11.83$ ,  $p < .001$ ).

Figure 2. Recognition percentages and standard error bars for Target-Aligned (grey bar) and Non-Aligned (black bar) words in the surprise word recognition test after attending to the picture stream.

## Discussion

The present findings extend investigations exploring how above threshold, but unattended information is processed

when it appears simultaneously with an attended target (Dewald et al, 2011; Lin et al, 2010; Seitz & Watanabe, 2003, 2005; Swallow & Jiang, 2010; Tsushima et al., 2006, 2008). Critically, despite all task-irrelevant words being recognized better than chance, words that were temporally aligned with a picture target (i.e., repetition) were recognized at significantly higher rates when compared with words that did not appear with a picture target. Specifically, performance for both the *target-aligned* (88%) and *non-aligned* (68%) words was significantly better than chance, but *target-aligned* words were recognized significantly better than *non-aligned* words. Accordingly, this suggests that, at least in the present case, temporally pairing explicitly presented irrelevant stimuli with relevant target stimuli facilitates subsequent recognition of the irrelevant stimuli.

Performance on the ability to correctly reject foil words further bolsters the notion that target-alignment is critical for enhanced perception. Participants were significantly more accurate at correctly rejecting foil words in the recognition test than they were at correctly identifying *non-aligned* words (88% vs. 68%, respectively), while no significant differences were observed when comparing performance for rejecting foils with accuracy for *target-aligned* words (88% vs. 87%). These data suggest an “attentional boost” (see Swallow & Jiang, 2010) for irrelevant stimuli as long as the stimuli were presented simultaneously with a target in the picture repetition task, despite not receiving direct attention.

The superior recognition of *target-aligned* words is analogous to the enhanced motion detection for coherent motion displays aligned with relevant task-targets observed by Seitz and Watanabe (2003). Interestingly, this enhancement was found only after exposure to implicitly presented motion directions. When explicitly presented (i.e., suprathreshold) an inhibition was observed for motion recognition, rather than a facilitation (see Tsushima et al., 2006; 2008). These findings would seemingly indicate that the enhancement or inhibition of performance is contingent on whether the initial irrelevant but target-aligned stimulus was implicitly or explicitly presented. The present findings fail to support either notion. That is, *facilitation* for target-aligned stimuli was observed, despite all irrelevant stimuli being overtly presented.

Aligning with our result, other recent investigations have observed an “attentional boost” (i.e., facilitation) for simultaneously and overtly presented information in a dual-task paradigm (Lin et al., 2010; Swallow & Jiang, 2010). However, significant procedural differences warrant discussion. Specifically, Swallow and Jiang’s (2010) task (see also, Lin et al, 2010) required participants to attend to both the irrelevant and relevant streams of information, rather than only one stream as done here (see also Seitz & Watanabe, 2003; but see Swallow & Jiang, 2011, discussed below). Thus, the key distinguishing feature between the respective paradigms is whether or not attention was simultaneously directed to both streams of information or if

only a single stream receives attention while the other is ignored.

Addressing the differing approaches, Swallow and Jiang (2011) required to only attend to one stream of information while ignoring the other. In this case, participants were required to direct their attention to the detection of the “odd ball” target only and not required to pay attention to the concurrently presented picture scenes (i.e., the images were now *irrelevant* to the task). A surprise recognition test administered for the pictures (task-irrelevant) revealed that the attentional boost effect did not occur when the background scenes were made task-irrelevant, thereby suggesting that temporal alignment was not sufficient to foster the attentional boost of target-aligned irrelevant stimuli.

This elimination of the attentional boost seemingly contradicts the present findings demonstrating an enhanced performance for the recognition of target-aligned stimuli. A potential explanation for this could be found in the differing amounts of irrelevant stimuli utilized in each respective paradigm. For instance, in Swallow and Jiang’s (2011) experiment over 100 different stimuli (pictures) served as the irrelevant items, while presently there was only one target-aligned stimulus and seven non-aligned items (i.e., analogous to Tsushima et al., 2008). This considerable difference in stimulus set size could be why we observed an attentional boost (despite attention not being directed to both streams). Note, the elimination of the attentional boost effect is actually a null effect when comparing aligned with non-aligned items, therefore it is difficult to make a strong claim regarding these findings.

Further support for the speculation that the quantity of irrelevant items modulates whether the boost is observed or not, comes from previous research conducted by our laboratory (Dewald et al., 2011). In this work, the paradigm was identical to the present (i.e., detect picture repetitions followed by a word recognition test), but an inhibition for target-aligned stimuli was observed. Importantly, the number of irrelevant items (50) was more in line with Swallow and Jiang’s (2011) recent work. Furthermore, as stated before, using semantic words rather than pictures could also be a contributing reason why we continue to see an attentional boost here, despite attending to only one stream of information (pictures).
