Setting aside the null effect found by Swallow and Jiang (Experiment 4, 2011), studies involving a specific analysis of recognition performance for target-aligned vs. non-aligned stimuli show recognition for target-aligned stimuli to be either *inhibited* (i.e., recognized significantly below chance levels) or *facilitated*, with a key difference being whether the target stimulus was implicitly or explicitly presented. It is evident that in the present experiment, words were recognized at high levels (78% of the time), and when accounting for target alignment, those synchronized with repetitions were indeed better recognized (a 20% improvement). In fact, when attention was most utilized in the repetition detection task, subsequent performance for the

target-aligned word was best. Recall however, that Tsushima et al. (2008) observed an inhibition for target-aligned, suprathreshold irrelevant stimuli. Although both Tsushima et al. (2008) and the present investigation utilized an above threshold, irrelevant stimuli (written words/ high motion coherence, respectively), it may be that the increased saliency and frequency of presentation of the written words lead to a facilitation rather than an inhibition.

Combined, the present findings and previous research offer insight into how irrelevant information is processed when it is presented simultaneously with an attended target. Under certain circumstances, unattended stimuli can be perceived and affect behavior (see also Dewald et al., 2011; Seitz & Watanabe, 2003; Tsushima et al., 2008). When using a low salience, irrelevant stimulus, there appears to be a relationship between explicit or implicit presentations, fostering either an inhibition (Tsushima et al., 2008), or facilitation (Seitz & Watanabe, 2003) respectively. Regardless of the explicit or implicit nature of the stimuli presentation, synchronization of task-relevant and task-irrelevant signals is crucial to establishing a relationship that will affect perception for task-irrelevant stimuli aligned with task-relevant targets, however, this relationship can be modulated when dividing attention across streams of information (Swallow Jiang, 2010, i.e., a facilitation is observed for explicitly presented stimuli). Most importantly to the present investigation however, when using a high exposure rate to salient, explicitly presented irrelevant stimuli in a limited stimulus set a perceptual window is created in which an “attentional boost” (Swallows & Jiang, 2010) surfaces for stimuli that do not receive direct and focused attention as long as they are presented simultaneously with the relevant target of a separate task.

## Abstract

A novel approach to human conditional reasoning based on the three-valued Łukasiewicz logic is presented. We will demonstrate that the Łukasiewicz logic overcomes problems the so far proposed Fitting logic has in reasoning with the suppression task. While adequately solving the suppression task, the approach gives rise to a number of open questions concerning the use of Łukasiewicz logic, unique fixed points, completion versus weak completion, explanations, negation, and sceptical versus credulous approaches in human reasoning.

**Keywords:** Łukasiewicz logic; computational logic; suppression task; human reasoning.

## Introduction

An interesting study is the *suppression task*, in which Byrne (1989) has shown that graduate students with no previous exposure to formal logic did suppress previously drawn conclusions when additional information became available. Interestingly, in some instances the previously drawn conclusions were valid whereas in other instances the conclusions were invalid with respect to classical two-valued logic. Consider the following example: *If she has an essay to finish then she will study late in the library* and *She has an essay to finish*. Then most subjects (96%) conclude: *She will study late in the library*. If subjects, however, receive an additional conditional: *If the library stays open she will study late in the library* then only 38% of the subjects conclude: *She will study late in the library*. This shows, that, although the conclusion is still correct, the conclusion is suppressed by an additional conditional. This is an excellent example for human capability to draw *non-monotonic* inferences.

Table 1 shows the abbreviations that will be used throughout the paper, whereas Table 2 gives an account of the findings of Byrne (1989). As we are using a formal language, propositions like “She will go to the library” (abbreviated  $L$ ) will be represented by propositional variables like  $l$ , with the intended interpretation that if  $l$  is *true* ( $\top$ ), then “She will go to the library”. Taking a naive propositional approach, we can represent  $A$  by the implication  $e \leftarrow l$ , where the propositional variables  $e$  and  $l$  represent the facts  $E$  and  $L$ , respectively, and so on.

It is straightforward to see that classical two-valued logic cannot model the suppression task adequately: Applying the classical logical consequence operator to some instances of the suppression task (like  $A, C, E$ ) yields qualitatively wrong answers, due to the monotonic nature of the classical logic.

Table 1: The suppression task (Byrne, 1989) and used abbreviations. Subjects received conditionals  $A, B$  or  $C$  and facts  $E, \bar{E}, L$  or  $\bar{L}$  and had to draw inferences.

$A$	<i>If she has an essay to finish then she will study late in the library.</i>
$B$	<i>If she has a textbook to read then she will study late in the library.</i>
$C$	<i>If the library stays open she will study late in the library.</i>
$E$	<i>She has an essay to finish.</i>
$\bar{E}$	<i>She does not have an essay to finish.</i>
$L$	<i>She will study late in the library.</i>
$\bar{L}$	<i>She will not study late in the library.</i>

Table 2: The drawn conclusions in the experiment of Byrne.

Conditional(s)	Fact	Experimental Findings
$A$	$E$	96% of subjects conclude $L$ .
$A, B$	$E$	96% of subjects conclude $L$ .
$A, C$	$E$	38% of subjects conclude $L$ .
$A$	$\bar{E}$	46% of subjects conclude $\bar{L}$ .
$A, B$	$\bar{E}$	4% of subjects conclude $\bar{L}$ .
$A, C$	$\bar{E}$	63% of subjects conclude $\bar{L}$ .
$A$	$L$	53% of subjects conclude $E$ .
$A, B$	$L$	16% of subjects conclude $E$ .
$A, C$	$L$	55% of subjects conclude $E$ .
$A$	$\bar{L}$	69% of subjects conclude $\bar{E}$ .
$A, B$	$\bar{L}$	69% of subjects conclude $\bar{E}$ .
$A, C$	$\bar{L}$	44% of subjects conclude $\bar{E}$ .

Consequently, at least a non-monotonic operator is needed. As argued by Stenning and van Lambalgen (2008)<sup>1</sup> human reasoning should be modeled by, first, reasoning towards an appropriate representation and, second, by reasoning with respect to this representation. As appropriate representation Stenning and van Lambalgen propose logic programs under completion semantics based on the three-valued logic used by Fitting (1985), which itself is based on the three-valued Kleene (1952) logic.

Unfortunately, some technical claims made by Stenning and van Lambalgen (2008) are wrong concerning their second step. Hölldobler and Kencana Ramli (2009b) have shown that the three-valued logic proposed by Fitting is inadequate for the suppression task. Somewhat surprisingly, the suppression task can be adequately modeled if the three-valued

<sup>1</sup>There is an earlier publication (Stenning & van Lambalgen, 2005), but Michiel van Lambalgen advised us to refer to their textbook.

Łukasiewicz (1920) logic is used. The paper gives an account of this finding and discusses a variety of consequences of this new logic and some open questions.

### Adequacy

Computational approaches to explain human reasoning should be *cognitively adequate*. Usually, the concept of adequacy is measured by distinguishing between conceptual and inferential adequacy (Strube, 1996). In our context, a system is *conceptually adequate* if it appropriately represents human knowledge. *Inferential adequacy* measures whether the computations behave similarly to human reasoning. It is common in Cognitive Science to evaluate theories by performing reasoning experiments on subjects. For instance, Knauff (1999) investigates which kind of information humans use when representing and remembering spatial arrangements in Allen’s interval calculus. In Computer Science, one commonly used hypothesis is, that if computational models are biologically plausible then they should also behave similar to the biological brain (Herrmann & Ohl, 2009). However, until now there are no implemented models which easily process computations given a large amounts of data or efficiently deal with incomplete information. These aspects are fundamental for elementary reasoning processes. In this paper, we evaluate the inferential adequacy of our computational logic approach by examining that our approach gives the same answers as subjects in the suppression task experiments.

### A Computational Logic Approach

Stenning and van Lambalgen (2008) have proposed to use logic programs under completion semantics and based on a three-valued logic to model the suppression task. In particular, they suggest that human reasoning is modeled by, first, reasoning towards an appropriate representation or logical form (conceptual adequacy) and, second, reasoning with respect to this representation (inferential adequacy).

In the following we introduce three-valued logics and, in particular, the Łukasiewicz logic. As the chosen representation are logic programs, such programs are introduced next together with their (weak) completion. We adopt the reasoning step towards an appropriate logical form from Stenning and van Lambalgen (2008). Thereafter, we discuss three-valued models for logic programs under the Łukasiewicz semantics and, in particular, the model intersection property which entails the existence of least models. We show that the conclusions drawn with respect to these least models correspond to the findings in (Byrne, 1989) and conclude that the derived logic programs under Łukasiewicz semantics are inferentially adequate for the suppression task.

In order to investigate inferential adequacy we consider the semantic operator associated with logic programs as defined by Stenning and van Lambalgen (2008). For each program  $\mathcal{P}$ , this operator admits a least fixed point, which is equal to the least Łukasiewicz model of  $\mathcal{P}$ . At this point we are able to discuss the technical problems in (Stenning & van Lambalgen, 2008), while showing that they do not occur if we use

Łukasiewicz semantics. Finally, we add abduction to the approach and show that sceptical reasoning is needed in order to model the suppression task adequately.

### Three-Valued Logics

Three-valued logics were introduced by Łukasiewicz (1920). Table 3 gives the truth tables for different three-valued logics. The symbols  $\top$ ,  $\perp$ , and  $\text{U}$  denote *true*, *false*, and *unknown*, respectively. For instance, if  $F$  is mapped to  $\perp$  and  $G$  is mapped to  $\top$  then their conjunction ( $F \wedge G$ ) is mapped to  $\perp$  and their disjunction ( $F \vee G$ ) is mapped to  $\top$ . By introducing

Table 3: The three-valued logics

$F \parallel \bar{F}$	$F \parallel \bar{F}$	$F \parallel \bar{F}$	$\wedge$	$\vee$	$\leftarrow_L$	$\leftrightarrow_L$	$\leftarrow_K$	$\leftrightarrow_S$
$\top \parallel \perp$	$\top \parallel \perp$	$\top \parallel \perp$	$\top$	$\top$	$\top$	$\top$	$\top$	$\top$
$\perp \parallel \top$	$\perp \parallel \top$	$\perp \parallel \top$	$\perp$	$\top$	$\top$	$\perp$	$\top$	$\perp$
$\text{U} \parallel \text{U}$	$\text{U} \parallel \text{U}$	$\text{U} \parallel \text{U}$	$\text{U}$	$\top$	$\top$	$\text{U}$	$\top$	$\perp$
$\perp \parallel \top$	$\perp \parallel \top$	$\perp \parallel \top$	$\perp$	$\top$	$\top$	$\perp$	$\top$	$\perp$
$\perp \parallel \text{U}$	$\perp \parallel \text{U}$	$\perp \parallel \text{U}$	$\perp$	$\top$	$\top$	$\text{U}$	$\top$	$\perp$
$\top \parallel \text{U}$	$\top \parallel \text{U}$	$\top \parallel \text{U}$	$\top$	$\top$	$\top$	$\text{U}$	$\top$	$\perp$
$\text{U} \parallel \perp$	$\text{U} \parallel \perp$	$\text{U} \parallel \perp$	$\perp$	$\top$	$\top$	$\text{U}$	$\top$	$\perp$
$\text{U} \parallel \top$	$\text{U} \parallel \top$	$\text{U} \parallel \top$	$\perp$	$\top$	$\top$	$\text{U}$	$\top$	$\perp$
$\text{U} \parallel \text{U}$	$\text{U} \parallel \text{U}$	$\text{U} \parallel \text{U}$	$\text{U}$	$\top$	$\top$	$\text{U}$	$\top$	$\perp$

a third truth value, there are various options to define the truth tables for the connectives. For example, Kleene (1952) introduced an implication ( $\leftarrow_K$ ), whose truth table is identical to the Łukasiewicz implication ( $\leftarrow_L$ ) except in the cases where precondition and conclusion are both mapped to  $\text{U}$ : In this case, the implication itself is mapped to  $\text{U}$  by Kleene, but to  $\top$  by Łukasiewicz. The set of connectives under Łukasiewicz semantics is  $\{\neg, \wedge, \vee, \leftarrow_L, \leftrightarrow_L\}$ . Kleene also introduced a so-called *strong equivalence*, where the truth value  $\top$  is assigned to  $F \leftrightarrow_S G$  if  $F$  and  $G$  are assigned to identical truth values, and  $\perp$  is assigned otherwise. Fitting (1985) combined the truth tables for  $\neg$ ,  $\vee$ ,  $\wedge$  from Łukasiewicz with the Kleene implication and strong equivalence for investigations within Logic Programming. We will call this combination the *Fitting semantics* where the set of connectives is  $\{\neg, \wedge, \vee, \leftarrow_K, \leftrightarrow_S\}$ <sup>2</sup>. Stenning and van Lambalgen (2008) use Fitting semantics without giving a reason for this particular choice.

### Logic Programs

A *logic program* is a finite set of expressions of the form

$$A \leftarrow B_1 \wedge \dots \wedge B_n, \quad (1)$$

where  $n \geq 1$ ,  $A$  is an atom, and each  $B_i$ ,  $1 \leq i \leq n$ , is either a literal,  $\top$ , or  $\perp$ .  $A$  is called *head* and  $B_1 \wedge \dots \wedge B_n$  is called *body* of the *clause* (1). A clause of the form  $A \leftarrow \top$  is called *positive fact*, whereas a clause of the form  $A \leftarrow \perp$  is called *negative fact*. In the sequel,  $\mathcal{P}$  shall denote a logic program.

Consider the following transformation for a given  $\mathcal{P}$ :

<sup>2</sup>We believe that Fitting had termination analysis of logic programs in his mind when he selected this particular logic.

1. All clauses with the same head  $A \leftarrow Body_1, A \leftarrow Body_2, \dots$  are replaced by  $A \leftarrow Body_1 \vee Body_2 \vee \dots$ .
2. If an atom  $A$  is not the head of any clause in  $\mathcal{P}$  (and, thus, is *undefined* in  $\mathcal{P}$ ) then add  $A \leftarrow \perp$ .
3. All occurrences of  $\leftarrow$  are replaced by  $\leftrightarrow$ .

The resulting set is called *completion* of  $\mathcal{P}$  ( $c\mathcal{P}$ ). If step 2 is omitted, then the resulting set is called *weak completion* of  $\mathcal{P}$  ( $wc\mathcal{P}$ ). Consider  $\mathcal{P} = \{p \leftarrow q\}$ , then  $c\mathcal{P} = \{p \leftrightarrow q, q \leftrightarrow \perp\}$ .  $c\mathcal{P}$  entails that  $p$  and  $q$  are mapped to  $\perp$ . Reasoning with respect to the completion of a logic program is non-monotonic. For instance, if  $\mathcal{P}' = \mathcal{P} \cup \{q \leftarrow \top\}$ , then  $c\mathcal{P}'$  entails that  $p$  and  $q$  are mapped to  $\top$ . The process of weak completion can be associated with the human interpretation of conditionals as biconditionals (Evans, Newstead & Byrne, 1993).

### Reasoning Towards an Appropriate Logical Form

Stenning and van Lambalgen (2008) have argued that the first step in modeling human reasoning is reasoning towards an appropriate logical form. In particular, they argue that conditionals shall not be encoded by implications straight away but rather by licenses for implications. For example, the conditional  $A$  should be encoded by the clause  $l \leftarrow e \wedge \overline{ab}_1$ , where  $ab_1$  is an *abnormality* predicate which expresses that something abnormal is known. In other words,  $l$  holds if  $e$  holds and nothing abnormal is known.

We think that Stenning and van Lambalgen (2008) adequately model the representational part of the suppression task and adopt this reasoning step. Our focus is on the inferential aspect of their approach. In the first two columns of Table 4 the programs obtained for the first six examples of the suppression task are depicted. For instance, in  $\mathcal{P}_{ACE}$  we have that *She will study late in the library* if either *She has an essay to finish* and *Nothing abnormal ( $ab_1$ ) is known* or *She has a textbook to read* and *Nothing abnormal ( $ab_3$ ) is known*. The predicates  $ab_1$ ,  $ab_2$  and  $ab_3$  represent different kinds of abnormality. For instance,  $ab_1$  is true when *The library does not stay open* and  $ab_3$  is true when *She does not have an essay to finish*.

### Three-Valued Models for Logic Programs

A (*three-valued*) *interpretation* is a mapping from a propositional language to the set  $\{\top, \perp, \text{U}\}$  of truth values. It is quite common to represent interpretations by tuples of the form  $\langle I^\top, I^\perp \rangle$ , where  $I^\top$  contains all atoms which are mapped to  $\top$ ,  $I^\perp$  contains all atoms which are mapped to  $\perp$ ,  $I^\top \cap I^\perp = \emptyset$ , and all atoms which occur neither in  $I^\top$  nor in  $I^\perp$  are mapped to  $\text{U}$ . Let  $\mathcal{P}$  be a program and  $I$  an interpretation.  $I$  is a (*three-valued*) *model under Łukasiewicz semantics* for  $\mathcal{P}$  ( $I \models_L \mathcal{P}$ ) if and only if each clause occurring in  $\mathcal{P}$  is mapped to  $\top$  using the truth table depicted in Table 3. Likewise,  $\models_F$  can be defined with respect to the Fitting semantics. For instance, consider  $\mathcal{P} = \{p \leftarrow q\}$ . Then under Łukasiewicz semantics we have three different models  $\langle \{p, q\}, \emptyset \rangle$ ,  $\langle \emptyset, \{p, q\} \rangle$  and  $\langle \emptyset, \emptyset \rangle$ . Under Fitting semantics only the first two interpretations are models, because if  $p$  and  $q$  are mapped to  $\text{U}$  then  $p \leftarrow q \in \mathcal{P}$  is mapped to  $\text{U}$  as well.

Table 4: A summary of the computational logic approach to the suppression task (Part 1).

$\mathcal{P}$	clauses	$wc\mathcal{P}$	$\text{lm}_L wc\mathcal{P}$	Byrne
$\mathcal{P}_{AE}$	$l \leftarrow e \wedge \overline{ab}_1$ $ab_1 \leftarrow \perp$ $e \leftarrow \top$	$l \leftrightarrow e \wedge \overline{ab}_1$ $ab_1 \leftrightarrow \perp$ $e \leftrightarrow \top$	$\langle \{e, l\}, \{ab_1\} \rangle$	96% $L$
$\mathcal{P}_{ABE}$	$l \leftarrow e \wedge \overline{ab}_1$ $l \leftarrow t \wedge \overline{ab}_2$ $ab_1 \leftarrow \perp$ $ab_2 \leftarrow \perp$ $e \leftarrow \top$	$l \leftrightarrow (e \wedge \overline{ab}_1) \vee (t \wedge \overline{ab}_2)$ $ab_1 \leftrightarrow \perp$ $ab_2 \leftrightarrow \perp$ $e \leftrightarrow \top$	$\langle \{e, l\}, \{ab_1, ab_2\} \rangle$	96% $L$
$\mathcal{P}_{ACE}$	$l \leftarrow e \wedge \overline{ab}_1$ $l \leftarrow o \wedge \overline{ab}_3$ $ab_1 \leftarrow \overline{o}$ $ab_3 \leftarrow \overline{e}$ $e \leftarrow \top$	$l \leftrightarrow (e \wedge \overline{ab}_1) \vee (o \wedge \overline{ab}_3)$ $ab_1 \leftrightarrow \overline{o}$ $ab_3 \leftrightarrow \overline{e}$ $e \leftrightarrow \top$	$\langle \{e\}, \{ab_3\} \rangle$	38% $L$
$\mathcal{P}_{A\overline{E}}$	$l \leftarrow e \wedge \overline{ab}_1$ $ab_1 \leftarrow \perp$ $e \leftarrow \perp$	$l \leftrightarrow e \wedge \overline{ab}_1$ $ab_1 \leftrightarrow \perp$ $e \leftrightarrow \perp$	$\langle \emptyset, \{e, l, ab_1\} \rangle$	46% $\overline{L}$
$\mathcal{P}_{AB\overline{E}}$	$l \leftarrow e \wedge \overline{ab}_1$ $l \leftarrow t \wedge \overline{ab}_2$ $ab_1 \leftarrow \perp$ $ab_2 \leftarrow \perp$ $e \leftarrow \perp$	$l \leftrightarrow (e \wedge \overline{ab}_1) \vee (t \wedge \overline{ab}_2)$ $ab_1 \leftrightarrow \perp$ $ab_2 \leftrightarrow \perp$ $e \leftrightarrow \perp$	$\langle \emptyset, \{e, ab_1, ab_2\} \rangle$	4% $\overline{L}$
$\mathcal{P}_{AC\overline{E}}$	$l \leftarrow e \wedge \overline{ab}_1$ $l \leftarrow o \wedge \overline{ab}_3$ $ab_1 \leftarrow \overline{o}$ $ab_3 \leftarrow \overline{e}$ $e \leftarrow \perp$	$l \leftrightarrow (e \wedge \overline{ab}_1) \vee (o \wedge \overline{ab}_3)$ $ab_1 \leftrightarrow \overline{o}$ $ab_3 \leftrightarrow \overline{e}$ $e \leftrightarrow \perp$	$\langle \{ab_3\}, \{e, l\} \rangle$	63% $\overline{L}$

### Reasoning with Respect to Least Models

In order to identify the desired model of a certain program, we reason with respect to their least models. Least models are guaranteed to exist if the model intersection property holds:

$$\begin{aligned} \cap \{I \mid I \models_L \mathcal{P}\} &\models_L \mathcal{P}, \\ \cap \{I \mid I \models_L wc\mathcal{P}\} &\models_L wc\mathcal{P}. \end{aligned}$$

In Hölldobler and Kencana Ramli (2009b) it was shown that the model intersection property holds for (weakly completed) programs under Łukasiewicz semantics. The model intersection property for programs does not hold under Fitting semantics. Consider again  $\mathcal{P} = \{p \leftarrow q\}$ , then both,  $\langle \{p, q\}, \emptyset \rangle$  and  $\langle \emptyset, \{p, q\} \rangle$ , are models for  $\mathcal{P}$ , whereas their intersection  $\langle \emptyset, \emptyset \rangle$  is not a model for  $\mathcal{P}$  under Fitting semantics.

The third column of Table 4 shows the weak completions of the programs encoding the first six examples of the suppression task. Column 4 in Table 4 depicts the corresponding least models where  $\text{lm}_L$  denotes the least model of its argument under Łukasiewicz semantics. The last column shows the results of the suppression task. Specifically we find that

$$\begin{aligned} \text{lm}_L wc\mathcal{P}_{AE} &= \langle \{e, l\}, \{ab_1\} \rangle && \models_L l \\ \text{lm}_L wc\mathcal{P}_{ABE} &= \langle \{e, l\}, \{ab_1, ab_2\} \rangle && \models_L l \\ \text{lm}_L wc\mathcal{P}_{ACE} &= \langle \{e\}, \{ab_3\} \rangle && \not\models_L l \vee \overline{l} \\ \text{lm}_L wc\mathcal{P}_{A\overline{E}} &= \langle \emptyset, \{e, l, ab_1\} \rangle && \models_L \overline{l} \\ \text{lm}_L wc\mathcal{P}_{AB\overline{E}} &= \langle \emptyset, \{e, ab_1, ab_2\} \rangle && \not\models_L l \vee \overline{l} \\ \text{lm}_L wc\mathcal{P}_{AC\overline{E}} &= \langle \{ab_3\}, \{e, l\} \rangle && \models_L \overline{l} \end{aligned}$$

where  $\not\models_L$  means that a given formula cannot be concluded. Our approach coincides with the seemingly favored results of the suppression task and thus appears to be adequate.

### Computing Least Models

In Computational Logic, least models are usually computed as least fixed points of appropriate semantic operators (see, e.g., Apt & Emden, 1982). Stenning and van Lambalgen (2008) devised such an operator for programs discussed herein: Let  $I$  be an interpretation in  $\Phi_P(I) = \langle J^\top, J^\perp \rangle$ , where

$$\begin{aligned} J^\top &= \{A \mid \text{there exists } A \leftarrow \text{body} \in \mathcal{P} \text{ with } I(\text{body}) = \text{true}\}, \\ J^\perp &= \{A \mid \text{there exists } A \leftarrow \text{body} \in \mathcal{P} \text{ and} \\ &\quad \text{for all } A \leftarrow \text{body} \in \mathcal{P} \text{ we find } I(\text{body}) = \text{false}\}. \end{aligned}$$

As shown in Hölldobler and Kencana Ramli (2009b) for any  $\mathcal{P}$ , the least fixed point of  $\Phi_P$  is identical to  $\text{lm}_{3LWC} \mathcal{P}$  and can be computed by iterating  $\Phi_P$  starting with the empty interpretation. The following example shows how the least model of  $\mathcal{P}_{ACE}$  is computed starting with interpretation  $I_0 = \langle \emptyset, \emptyset \rangle$ :

$$\begin{aligned} I_1 &= \Phi_{\mathcal{P}_{ACE}}(I_0) = \langle \{e\}, \emptyset \rangle \\ I_2 &= \Phi_{\mathcal{P}_{ACE}}(I_1) = \langle \{e\}, \{ab_3\} \rangle = \Phi_{\mathcal{P}_{ACE}}(I_2) \end{aligned}$$

where  $I_2$  is the least fixed point of  $\Phi_{\mathcal{P}_{ACE}}$ . This is not a model under Fitting semantics because the clause  $l \leftarrow o \wedge ab_3 \in \mathcal{P}_{ACE}$  is mapped to  $\perp$  and not to  $\top$  such as under Łukasiewicz semantics. This is a counter example for Lemma 4(1.) in Stenning and van Lambalgen (2008) which states that the least fixed point of the  $\Phi_P$  operator under Fitting semantics is the minimal model of  $\mathcal{P}$ . Another statement made by Stenning and van Lambalgen (2008), Lemma 4(3.) states, that all models of  $c\mathcal{P}$  are fixed points of  $\Phi_P$  and every fixed point is a model. Consider the completion of  $\Phi_{\mathcal{P}_{ABE}}$ , then  $t$  is mapped to  $\perp$  and therefore  $l$  is mapped to  $\perp$  as well. However, its least fixed point is  $\langle \emptyset, \{e, ab_1, ab_2\} \rangle$  where  $t$  and  $l$  are undefined. This example also shows that reasoning under Fitting semantics and with respect to the completion of a program is not adequate as only 4% conclude  $\bar{L}$  in this case.

### Unique Fixed Point

As mentioned in the previous subsection, the least fixed point of the operator  $\Phi_P$  can be computed by iterating  $\Phi_P$  starting with the empty interpretation. However, if the operator is a contraction then by the Banach Contraction Theorem (Banach, 1922) the operator has a unique fixed point which can be computed by iterating the operator starting with an arbitrary interpretation. As shown in Hölldobler and Kencana Ramli (2009a),  $\Phi_P$  is a contraction if  $\mathcal{P}$  is acyclic<sup>3</sup>. All programs shown in Table 4 are acyclic.

### Abduction

The second part of the suppression task deals with the affirmation of the consequent and modus tollens. These reasoning

processes can best be described as abductive, that is, a plausible explanation is computed given some observation. Following Kakas, Kowalski, and Toni (1993) we consider an *abductive framework* consisting of a program  $\mathcal{P}$  as knowledge base, a set  $\mathcal{A}$  of abducibles consisting of the (positive and negative) facts for each undefined predicate symbol in  $\mathcal{P}$ ,<sup>4</sup> and the logical consequence relation  $\models_L^{lmwc}$ , where  $\mathcal{P} \models_L^{lmwc} F$  if and only if  $\text{lm}_{3LWC} \mathcal{P}(F) = \top$  for the formula  $F$ . As *observations* we consider literals.

Let  $\langle \mathcal{P}, \mathcal{A}, \models_L^{lmwc} \rangle$  be an abductive framework and  $O$  an observation.  $O$  is *explained* by  $\mathcal{E}$  if and only if  $\mathcal{E} \subseteq \mathcal{A}$ ,  $\mathcal{P} \cup \mathcal{E}$  is satisfiable, and  $\mathcal{P} \cup \mathcal{E} \models_L^{lmwc} O$ . Usually, minimal explanations are preferred. In case there exist several minimal explanations, then two forms of reasoning can be distinguished.  $F$  follows *sceptically* from program  $\mathcal{P}$  and observation  $O$  ( $\mathcal{P}, O \models_s F$ ) if and only if  $O$  can be explained and for all minimal explanations  $\mathcal{E}$  we find  $\mathcal{P} \cup \mathcal{E} \models_L^{lmwc} O$ , whereas  $F$  follows *credulously* from  $\mathcal{P}$  and  $O$  ( $\mathcal{P}, O \models_c F$ ) if and only if there exists a minimal explanation  $\mathcal{E}$  such that  $\mathcal{P} \cup \mathcal{E} \models_L^{lmwc} O$ .<sup>5</sup> For instance, consider the following two programs under sceptical reasoning:

1.  $\mathcal{P}_{AB}$  where  $O = l$ :  $\mathcal{A} = \{e \leftarrow \top, e \leftarrow \perp, t \leftarrow \top, t \leftarrow \perp\}$  and  $\text{lm}_{3LWC} \mathcal{P}_{AB} = \langle \emptyset, \{ab_1, ab_2\} \rangle$ . There are two minimal explanations with either  $\{e \leftarrow \top\}$  and  $\{t \leftarrow \top\}$ . Thus, we cannot conclude whether *She has an essay to finish* or not.
2.  $\mathcal{P}_{AC}$  where  $O = l$ :  $\mathcal{A} = \{e \leftarrow \top, e \leftarrow \perp, o \leftarrow \top, o \leftarrow \perp\}$  and  $\text{lm}_{3LWC} \mathcal{P}_{AC} = \langle \emptyset, \emptyset \rangle$ . There is only one minimal explanation  $\{e \leftarrow \top, o \leftarrow \top\}$  and thus *She has an essay to finish*.

Table 5 depicts the programs, the observations and the minimal explanations for the second part of the suppression task in the second, third, and fourth column, respectively. The second last column shows the least model of the weak completion of the union of the program and the minimal explanation under the Łukasiewicz semantics and the final one shows the results of the suppression task. If we reason sceptically with respect to these least models, then we obtain

$$\begin{array}{ll} \mathcal{P}_A, l \models_s e, & \mathcal{P}_A, \bar{l} \models_s \bar{e}, \\ \mathcal{P}_{AB}, l \not\models_s e, & \mathcal{P}_{AB}, \bar{l} \models_s \bar{e}, \\ \mathcal{P}_{AC}, l \models_s e, & \mathcal{P}_{AC}, \bar{l} \not\models_s \bar{e}, \end{array}$$

which are adequate answers if compared to the seemingly favored results of the suppression task. One should observe that a credulous agent concludes  $e$  from  $\mathcal{P} = \mathcal{P}_{AB}$  and  $O = l$ , which according to Byrne (1989) only 16% of the subjects did.

## Open Questions

### Łukasiewicz Logic

This logic was selected because the technical bugs in Stenning and van Lambalgen (2008) can be solved by switching from Fitting to Łukasiewicz semantics. In particular, the

<sup>3</sup>A program  $\mathcal{P}$  is acyclic if there exists a numbering for all propositional variables such that for all clauses in  $\mathcal{P}$  the value of the head is strictly larger than the value of the literals in the body.

<sup>4</sup>Recall that  $A$  is *undefined* in  $\mathcal{P}$  if and only if  $\mathcal{P}$  does not contain a clause of the form  $A \leftarrow \text{Body}$ .

<sup>5</sup>See (Hölldobler, Philipp, & Wernhard, 2011) for more details.

Table 5: A summary of the computational logic approach to the suppression task (Part 2). The cases  $\mathcal{P} = \mathcal{P}_{AB}, O = l$  and  $\mathcal{P} = \mathcal{P}_{AC}, O = \bar{l}$  have two minimal extensions.

$\mathcal{P}$	clauses	$O$	$\mathcal{E}$	$\text{Im}_{\text{wc}}(\mathcal{P} \cup \mathcal{E})$	Byrne
$\mathcal{P}_A$	$l \leftarrow e \wedge \overline{ab_1}$ $ab_1 \leftarrow \perp$	$l$	$e \leftarrow \top$	$\langle \{e, l\}, \{ab_1\} \rangle$	53% $E$
$\mathcal{P}_{AB}$	$l \leftarrow e \wedge \overline{ab_1}$ $l \leftarrow t \wedge \overline{ab_2}$ $ab_1 \leftarrow \perp$ $ab_2 \leftarrow \perp$	$l$	$e \leftarrow \top$	$\langle \{e, l\}, \{ab_1, ab_2\} \rangle$	16% $E$
			$t \leftarrow \top$	$\langle \{l, t\}, \{ab_1, ab_2\} \rangle$	
$\mathcal{P}_{AC}$	$l \leftarrow e \wedge \overline{ab_1}$ $l \leftarrow o \wedge \overline{ab_3}$ $ab_1 \leftarrow \bar{o}$ $ab_3 \leftarrow \bar{e}$	$l$	$e \leftarrow \top$ $o \leftarrow \top$	$\langle \{e, l, o\}, \{ab_1, ab_3\} \rangle$	55% $E$
$\mathcal{P}_A$	$l \leftarrow e \wedge \overline{ab_1}$ $ab_1 \leftarrow \perp$	$\bar{l}$	$e \leftarrow \perp$	$\langle \emptyset, \{e, l, ab_1\} \rangle$	69% $\bar{E}$
$\mathcal{P}_{AB}$	$l \leftarrow e \wedge \overline{ab_1}$ $l \leftarrow t \wedge \overline{ab_2}$ $ab_1 \leftarrow \perp$ $ab_2 \leftarrow \perp$	$\bar{l}$	$e \leftarrow \perp$ $t \leftarrow \perp$	$\langle \emptyset, \{e, l, t, ab_1, ab_2\} \rangle$	69% $\bar{E}$
$\mathcal{P}_{AC}$	$l \leftarrow e \wedge \overline{ab_1}$ $l \leftarrow o \wedge \overline{ab_3}$ $ab_1 \leftarrow \bar{o}$ $ab_3 \leftarrow \bar{e}$	$\bar{l}$	$e \leftarrow \perp$	$\langle \{ab_3\}, \{e, l\} \rangle$	44% $\bar{E}$
			$o \leftarrow \perp$	$\langle \{ab_1\}, \{l, o\} \rangle$	

model intersection property holds under Łukasiewicz semantics. Hence, for each program  $\mathcal{P}$  a least model does exist which can be computed as least fixed point of the associated semantic operator  $\Phi_{\mathcal{P}}$ . Moreover, a rigorous study has revealed that the suppression task can be adequately modeled under Łukasiewicz semantics, whereas this does not hold for Fitting semantics. Nevertheless, the main question of whether Łukasiewicz logic is adequate for human reasoning is still open. For example, in the Łukasiewicz logic the Deduction Theorem does not hold<sup>6</sup>. Hence, it would be interesting to see how humans deal with the deduction theorem. Can other typical human reasoning problems like the Wason (1968) selection task be adequately modeled under Łukasiewicz semantics?

### Unique Fixed Point

For each program  $\mathcal{P}$  shown in Table 4 the operator  $\Phi_{\mathcal{P}}$  is a contraction. Thus, there is a unique fixed point, which can be computed by iterating  $\Phi_{\mathcal{P}}$  on some initial interpretation. Consequently, if in the suppression task subjects are influenced towards some initial non-empty interpretation, their performance should not differ provided that they have enough time to compute the least fixed point; it should differ, however, if they are interrupted before the least fixed point is computed and asked to reason with respect to the interpretation com-

<sup>6</sup>A logic satisfies the *Deduction Theorem* if for any finite set of formulae  $\Phi = \{\phi_1, \phi_2, \dots, \phi_n\}$  and any formula  $\psi$  the following holds:  $\Phi \models \psi$  if and only if  $\models (\phi_1 \wedge \phi_2 \wedge \dots \wedge \phi_n) \rightarrow \psi$ .

puted so far.

### Completion versus Weak Completion

The program  $\mathcal{P}_{AB\bar{E}}$  served as an example to illustrate that completion is inadequate for the suppression task whereas weak completion is adequate. Likewise, Hölldobler et al. (2011) have shown in a detailed study that the programs mentioned in Table 5 together with their minimal explanations must be weakly completed in order to adequately model the suppression task, whereas completion does not. Are there other human reasoning episodes which support the claim that weak completion is adequate? Even if so, the problem remains to explicitly add negative facts (in the reasoning step towards an appropriate logical form) for those predicates, which should be mapped to  $\perp$  like  $ab_1$  in the program  $\mathcal{P}_{AE}$ .

### Sceptical versus Credulous Reasoning

The case of program  $\mathcal{P} = \mathcal{P}_{AB}$  and observation  $O = l$  in Table 5 shows that agents must reason sceptically in order to adequately model this case. Whereas this is a striking case for sceptical reasoning, the case  $\mathcal{P} = \mathcal{P}_{AC}$  and  $O = \bar{l}$  is less convincing. A sceptical agent will not conclude  $\bar{e}$ , whereas a credulous agent will conclude  $\bar{e}$ . Compared to the corresponding case  $(A, C, \bar{L})$  shown in Table 2, 44% of the subjects conclude  $\bar{E}$ . Unfortunately, Byrne (1989) (and related publications that we are aware of) gives no account of the distribution of the answers given by those subjects who did not conclude  $\bar{E}$ . Hence, at the moment we can argue in favor of a sceptical agent (*the majority of the subjects did not conclude  $\bar{E}$* ), but – given the complete distribution – it may be the case that one can argue in favor of a credulous agent (*there are more subjects concluding  $\bar{E}$  than subjects concluding  $E$  and subjects answering “I don’t know”*).

### Explanations

The approach presented in this paper is based on minimal explanations. Although, there are findings corroborating the human preference of minimal explanations (over non-minimal ones) (Ormerod, Manktelow, & Jones, 1993) – this holds only partially (Johnson-Laird, Girotto, & Legrenzi, 2004). Computational models of abduction typically generate explanations iteratively such that minimal explanations are generated first. How are minimal explanations computed by humans? What happens if there are more than one minimal explanation?

### Negation

In the presented approach positive information is preferred over negative one. Consider, for example, the program  $\mathcal{P} = \{q \leftarrow \top, q \leftarrow \perp\}$ . The least model of  $\text{wc}\mathcal{P}$  is  $\langle \{q\}, \emptyset \rangle$  and, hence, an agent reasoning with respect to this model will conclude  $q$ . Is this consistent with human reasoning? The presented approach could be extended to include integrity constraints like  $\perp \leftarrow q$ . Any model for a program containing such an integrity constraint must map  $q$  to  $\perp$ . Is this adequate for human reasoning? If so, under which conditions shall such

integrity constraints be added within the reasoning step towards an appropriate logical form?

### Connectionist Realization

As shown in (Hölldobler & Kencana Ramli, 2009c), the computation of the least fixed point of the semantic operator  $\Phi_{\mathcal{P}}$  associated with a program  $\mathcal{P}$  can be realized within the core-method (Bader, Hitzler, Hölldobler, & Witzel, 2007). In this connectionist realization,  $\Phi_{\mathcal{P}}$  is computed by a feed-forward network, whose output units are recurrently connected to the input units. Whereas this network is trainable by backpropagation and, thus,  $\Phi_{\mathcal{P}}$  can be learned by experience, there is no evidence whatsoever that backpropagation is biological plausible. The approach can be extended to handle abduction following (Garcez, Gabbay, Ray, & Woods, 2007). However, in this setting, explanations are generated in a fixed, hard-wired sequence, which does not seem to be plausible either.

### Summary

We have presented an adequate computational logic approach for the suppression task. It is based on weakly completed logic programs under Łukasiewicz semantics. Such programs admit least models which can be computed by iterating an appropriate semantic operator. Reasoning is performed with respect to the least models. The approach is extended by sceptical reasoning within an abductive framework. Moreover, it can be realized in a connectionist setting. The approach has been carefully tested against alternatives like completed logic programs, Fitting semantics, and credulous reasoning, but none of these variations was found to be adequate.

# Confidence in Causal Inferences: The Case of Devaluation

Uwe Drewitz (uwe.drewitz@tu-berlin.de)

## Abstract

When people have to make predictions and diagnosis they make use of their causal knowledge. This knowledge refers to two constituting aspects of causality: sufficiency and necessity. In standard theories both aspects are considered as being independent from each other. The present research tests this assumption. In an experiment we examined how peoples confidence in one of both aspects is affected, if they receive negative evidence for the complementary aspect. The presented data show that peoples confidence related to the aspect that has not been challenged by negative evidence decreases under such conditions. This devaluation effect is not predicted by standard theories.

**Keywords:** causal models; causal learning; reasoning under uncertainty; induction

## Introduction

When people make a causal statement like: *A causes B*, they attribute a causal relation. This attribution can be based on various cues to causality (Einhorn and Hogarth, 1986) like spatial and temporal contiguity. However, in many situations people need more information than these. Being repeatedly confronted with a phenomenon, people (can) look for regularities as well. Psychological theories claim, that under such circumstances causal attributions rely on contingency information. Contingency information describe how the occurrence or absence of one event (i.e. event C) goes together with the occurrence or absence of another event (i.e. event E). Based on this information people can determine how likely an effect of interest will occur, given the presence or absence of a putative cause. According to standard psychological theories (e.g. Waldmann & Holyoak, 1992; Waldmann & Hagmayer, 2001; Griffith & Tenenbaum, 2005) people integrate the information about the (co-)occurrence and (co-)absence to either infer a causal relation or estimate it's strength, respectively. Therefore standard psychological theories claim that people base their judgments on all available data for contingency information. This is a reasonable assumption for situations where people do causal judgments. In contrast, in many real-world tasks people do not have to do such integrative judgments. They apply their knowledge to forecast events (i.e.  $E+$  /  $E-$ ) based on given data (i.e.  $C+$  /  $C-$ ). In probability calculus this is captured by conditional probabilities. The prediction of  $E+$  for example can be made based on  $P(E+/C+)$  or  $P(E+/C-)$  (see Fig. 1) depending on whether  $C+$  or  $C-$  is present. These conditional probabilities are independent of each other. Given these facts, standard theories do not predict effects of information integration over all contingency data.

Hence, for a prediction of  $E$  given  $C$ , persons would not integrate over all the four possible pairings of the two events (i.e.  $C$  &  $E$ ). However, we present experimental data that contradict this position.

## Sufficiency and Necessity

Various so called rule-based models (see Allan, 1980) have been proposed in research literature (e.g. Jenkins & Ward, 1965; Cheng & Novick, 1992; Cheng, 1997; White, 2003). They assume that persons rely on frequencies of (co-) occurrence and (co-) absence of two events (i.e.  $C$  &  $E$ ). The four cells in the contingency table in Figure 1 represent their four possible pairings. With respect to these two events, every observation can be assigned to one pairing and as such, to one cell of the contingency table. Every observation gives either positive or negative evidence to one of both aspects of causality: *sufficiency* and *necessity*. Positive evidence can be understood as strengthening an aspect (either sufficiency or necessity). Comparably, negative evidence weakens an aspect. Sufficiency and necessity are complementary building blocks of causality (e.g. Mill, 1869). An event  $C$  is recognized as *sufficient* to produce another event  $E$ , if the latter always follows the occurrence of the former. The same event  $C$  is considered as *necessary* to bring forth the event  $E$ , if its absence of  $C$  is always accompanied by the absence of  $E$ .

		$E$		
		+	-	
$C$	+	$a$	$b$	<i>sufficiency</i> $P(E+/C+) = a / (a+b)$
	-	$c$	$d$	<i>necessity</i> $P(E+/C-) = c / (c+d)$

Figure 1. 2x2 contingency table (+ indicates presence, - indicates absence).

Moreover, sufficiency and necessity are statistically independent of each other. Whereas the *sufficiency* of a putative cause for an effect depends on the frequencies in the cells  $a$  and  $b$ , the *necessity* is determined by the frequencies in the cells  $c$  and  $d$  (see Fig.1). Two different, statistically independent conditional probabilities capture these facts (see Fig.1): the probability of the presence of  $E$  given the presence of  $C$ ,  $P(E+/C+)$ , and the probability of

the presence of E given the absence of C,  $P(E+/C-)$ . These probabilities are complementary in the sense of causality. People are willing to attribute a causal relation between two events if both aspects are met. This idea goes back to John Stuart Mill (1869) who claimed that causal knowledge does not arise from the repeated observation of the sequence of two events only. Instead people also acknowledge what happens if a putative cause *fails* to appear. From this perspective, causes can be characterized in terms of *sufficiency* and *necessity* and both of these aspects have to be satisfied. Every observation that belongs to the pairing of cell a gives positive evidence to the *sufficiency* of the putative cause C for E, the effect of interest. Just as all observations that belong to the pairing of cell d give evidence to the *necessity* of C for E.

How do the described facts fall into the scope of standard theories of causal learning (see introduction)? These theories describe how people come up with a judgment, when they are requested to rate the strength of a causal relation in a causal attribution task. In such tasks people base their judgments on both aspects (sufficiency and necessity), which means that they consider all four frequencies that can be presented in contingency information (see Figure 1). Of course, people do integrative judgments in real-world tasks. But very often they have to make predictions based on given data. In turn, as soon as people can rely for example on the presence or absence of C, i.e. on C+ or C-, their prediction is related to only one of both aspects. For example, given the presence or absence of C (C+ or C-), people act differently as if they were asked to rate the strength of the relation between C and E. Let us assume people have seen numerous pairings where one event C precedes another event E (frequency in cell a). Based on these observations people will predict E+ (presence of E) given C+ (presence of C). In such a case, there is no need to integrate the information about C- (absence of C), which is captured by the frequencies in cells c and d. On the other hand, if C- (absence of C) precedes E- (absence of E), which is represented by the frequency in cell d, people might use this information to predict that E will not occur given the absence of C. In that case information with respect to C+ (cells a and b) can be ignored. Consequently, given the independence of both aspects, neither positive nor negative evidence related to one of the aspects should affect inferences related to the complementary aspect. In contrast, we claim that such an effect exists. We tested this hypothesis based on the representation of causal knowledge, which is introduced in the next section.

### Mental Causal Models

Several ways have been proposed to represent causal knowledge. For example Thüring and Jungermann (1992) suggest that people acquire mental models of causation in terms of conditional rules (e.g. If C+ then E+.). The conditional rules of a model reflect the characteristics of sufficiency and necessity of a causal relationship. This is in

line with the conception of causes as sufficient and necessary conditions for their effects. As shown by Thüring, Drewitz and Urbas (2006) these conditional rules can be obtained by mere induction. In the case of the model of unique causation (see Table 1), which states that "C causes E", the event C is framed as a sufficient as well as a necessary condition for the event E. This is captured by the rules R1 and R2 in Table 1. When a situation calls for a causal inference, the available data (for instance C+ or C-) are matched with the rules (R1 and R2) and the required information is deduced.

Table 1: Model of unique causation.

Model statement: "C causes E"

R1:  $C+ \rightarrow E+$

R2:  $C- \rightarrow E-$

The importance of rules like R1 and R2 lies in the savings they provide. Rules save costs such as time, attention or memory capacity. However, to get all the benefit rules entail, they have to be linked into higher-order knowledge, like models. Let us have a look on both our rules R1 and R2. Neither R1 nor R2 tell us whether there is a causal relation between C and E, or not. Only when they are linked together one possesses this knowledge. We call the linking of rules the construction of a mental model. In this sense the statement "C causes E" is knowledge acquired by building the model, not by having the two rules R1 and R2 only. That also means that as soon as the rules are linked into a model, there is more than there was before. Or, in other words: The whole is more than the sum of its parts. Assuming that our considerations are right, we can ask the following question: If the whole - the mental model - is questioned because one of its parts fails, is there an effect on the other parts as well? In terms of the model of unique causation (see. Tab. 1): When people observe that one rule fails to predict the outcome, is there an effect on how they use the complementary other rule?

### Causal Inferences under Uncertainty

Before we have a closer look on this question we want to make clear what known effects the failure of rule has. Depending on how successful the application of a rule was in the past, people will place more or less confidence into their predictions deduced from that rule. Let's think, for example, of a person that has rather limited causal knowledge as expressed by the model of unique causation. Whenever this person faces a situation where C+ is present, she will apply R1 and predict E+. Vice versa she will predict E- if C- is present, based on R2. As long as E+ goes always together with C+ all her predictions deduced from R1 are confirmed. Hence, her faith in R1 and therefore the confidence she places in her predictions should be high. The same holds for R2 and the related predictions as long as E- goes always together with C-. However, that will change as soon as it turns out that a rule is wrong. If people have build

up incomplete or incorrect rules they will come up with wrong inferences in the course of events. Let's assume that in truth  $C+$  in conjunction with another event  $X+$  may be sufficient for  $E+$  instead of  $C+$  alone. In such a case people will observe  $E-$  subsequent to  $C+$  whenever  $X$  is absent ( $X-$ ). An observation like this will impair the *sufficiency* of  $C$  for  $E$ . Moreover, such an observation will *discredit* the rule  $R1$ . In general, every prediction that is not confirmed but contradicted by a subsequent observation *discredits* the rule it is derived from. Consequently, as long as a person cannot expand her model, she will loose confidence in the respective rule. All a person can do in such an uncertain situation is to reduce the confidence she places in her predictions based on that rule. Hence, the question we raised at the end of the last section remains unanswered. But now, we can reformulate and ask more specifically: Is the effect of the reduction of confidence always limited to the rule that was discredited?

### Discrediting and Devaluating Causal Rules

To start with let us return to contingency information. Figure 1 shows a contingency table for the model of unique causation. A person's observations that fall into cell a provide evidence for the reliability of rule  $R1$ , while observations that fall into cell 'd' provide evidence for the reliability of  $R2$  (see Table 1). On the other hand, all observations made in cell b discredit  $R1$ , while all observations made in cell c discredit  $R2$ . Therefore, the first row of the table provides information about the sufficiency of the cause and the second row about its necessity. As depicted in Figure 1 a cause is only *completely* sufficient, if observations are made in cell a, but not in cell b, and it is only *completely* necessary, if observations are made in cell d, but not in cell c. Only in these cases, the conditional probabilities are at their optimum with respect to a causal relation between  $C$  and  $E$ . From this point of view, the optimum of  $P(E+/C+)$  equals one and equals zero for  $P(E+/C-)$ . Additionally, an increase or decrease of  $P(E+/C+)$  does not affect  $P(E+/C-)$  and vice versa. What does this mean from a psychological perspective? The first implication is consistent with the mechanism of *discrediting* a rule. When the sufficiency or necessity is weakened, the certainty of inferences based on the respective rule should decrease. For instance, if an observation of  $C+$  together with  $E-$  (see cell b in Fig.1) is made, the aspect of sufficiency of  $C$  for  $E$  is weakened. Subsequently, inferences based on  $R1$  go along with a reduced certainty. The second implication touches the central issue of this paper. It illustrates our assumption of devaluation. We assume that negative evidence for one aspect of causality will be reflected by increased uncertainty about the complementary aspect of causality. For instance, if  $R1$  is discredited by negative evidence (observations that fall into cell b), confidence in  $R2$  decreases as well. We call this the effect of devaluation. Table 2 shows which observation discredits and devaluates the rules of the model of unique causation.

So far, we have described the consequences of positive evidence that strengthens a rule and the consequences of negative evidence that weakens a rule in terms of discrediting and devaluation. This leads to three hypotheses:

1. **Strengthening:** Observations that fall into cell a and d of the contingency tables provide positive evidence for the respective rules of the models and should increase the confidence in inferences drawn from these rules.
2. **Discrediting:** Observations that fall into cell b and cell c provide negative evidence and *discredit* the rules as shown in table 2. In all these cases, the confidence in inferences drawn from the rules should get reduced.
3. **Devaluation:** Observations that fall into cell b and cell c should *devalue* the complementary rules as shown in table 2. Again, the confidence in inferences from the affected rules should decrease.

The following experiment serves to test these hypotheses.

Table 2: Discrediting and devaluating causal rules.

Rule	Observation	Discrediting of	Devaluation of
$R1: C+ \rightarrow E+$	$C+, E-$	$R1$	$R2$
$R2: C- \rightarrow E-$	$C-, E+$	$R2$	$R1$

### Experiment

In our study, participants had to acquire causal knowledge about a simulated technical system based on inductive learning. Over the course of the experiment, positive as well as negative evidence was presented to investigate the consequences of discrediting and devaluation.

#### Method

**Participants.** Sixty graduate and undergraduate students at the Berlin Institute of Technology were recruited for the experiment. All of them were paid for their participation.

**Material.** Figure 2 shows the schematic screen layout of the simulated system that was presented to the participants. It was introduced as an electrical system of a power plant. The system was built up from four subsystems that were responsible for two output systems. Information about the state of these subsystems was displayed on four dials (for top boxes in Fig.2). Each dial represented the state of one subsystem, which was either DOWN ( $C+$ ) or UP ( $C-$ ), or unknown because its dial was switched off. Only one subsystem was causally relevant and served as cause  $C$  for the outcome of the relevant output system (either  $E+$  or  $E-$ ). The other three subsystems were irrelevant for the task. One of them was unused (the dial was switched off) while the other two were used as distractors to give the system a more diversified appearance. In the lower half of the screen, the displays for the output systems were shown. In some of the trials participants had to predict the outcome of only one of them and in the remaining trials they had to predict the outcome of both. If only the outcome of one system had to be predicted, the display of the other output system was not shown. Whereas one output system ( $E$ ) was relevant for the

experiment the other was used to make the task more realistic.

Figure 2. Screen layout (schematic) and sequence of one trial of the experiment.

Below the display of each output system two buttons were shown for the prediction of the outcome. One button served the prediction of MALFUNCTION (E+) and the other one the prediction of working operation (OK) (E-). Clicking on one of them was necessary to make the prediction. Finally, below these buttons a slider was presented that could be adjusted to rate the confidence of the judgments. The lowest confidence (0%) was set in the middle of the slider. Subjects were instructed to place the slider on the very right to indicate full confidence (100%) that E- will occur, and on the very left to mark full confidence (100%) for E+.

**Procedure.** The participants' task was to predict the outcomes (E+ or E-) of the output system(s). To solve this task, they had to understand the underlying causal relation between the subsystems and the output systems. In each trial, they were shown the layout of the device as presented in Figure 2. First, subjects had to check the operation of the subsystems. Then, based on the information, which was shown on the dials, they were requested to predict the state of the output system(s) by clicking on the respective buttons (OK or MALFUNCTION). Finally, they rated their confidence for each prediction by adjusting the respective slider(s). After participants finished their prediction and confidence rating, they had to click on a 'send' button and subsequently received feedback that showed the actual outcome(s). The experiment consisted of thirty-three trials. These trials were split up in a *reinforcement phase* and a *test phase*. Figure 3 depicts the experimental procedure schematically. Note that the frequencies in the cells of the contingency tables in Figure 3 (b) are summed up for both phases. In the reinforcement phase, which consisted of twenty-six trials, participants received information that enabled them to acquire a model of unique causation with two rules (R1 & R2, see Table 2). This was accomplished by providing positive evidence for R1 (eight trials, see Fig.3) and R2 (eight trials, see Fig.3). Additionally, there were two distractor trials in which information about an irrelevant subsystem was shown only. In the remaining eight trials participants had to predict only the outcome of the second output system that was irrelevant for the test of

the hypothesis. After the twenty-six trials of the reinforcement phase the test phase started that consisted of seven trials. In four of these seven trials, negative evidence for one of the two rules (R1 or R2) was presented. The negative evidence always opposed the rule reinforced in the last trial of the reinforcement phase. In these trials people had to predict the outcome of the relevant output system (E) only. Another two trials were used as distractor trials presenting information about one of the irrelevant subsystems. In the seventh and last trial of the test phase the post-measure for the relevant test was recorded. Therefore data were presented that matched the same rule as in the last trial of the reinforcement phase (see Fig.3).

**Independent and dependent variables.** Since the model of unique causation consisted of two rules, both were used to investigate the issues of discrediting and devaluation. For this purpose, the sample of sixty participants was split into two groups of thirty participants each. One group received negative evidence about R1, the other half about R2.

Figure 3. Experimental procedure (schematic). Reinforcement phase and test phase were presented in sequence.

Values are exemplary for one of the two experimental groups. Contingency table in (a) displays frequencies for reinforcement phase. The trial of the pre-measure also was the eighth presentation of (C-, E-), which is updated in (b). The contingency table in (b) displays summed frequencies for reinforcement phase and test phase.

To investigate the strengthening of rules, the amount of *positive evidence* ranged from one to eight trials (see Fig. 3a, positive evidence) for each rule (R1 & R2). To test the impact of discrediting, the amount of *negative evidence* ranged from one trial to four trials (see Fig.3b, negative evidence) for each rule (R1 & R2). The factor measurement with the factor levels *pre* and *post* served the investigation of devaluation as described in the procedure (see Fig.3). Throughout the experiment, confidence ratings of inferences

predicting the states of the relevant output system were used as dependent variable.

## Results

For statistical analysis, we computed three ANOVAs with repeated measures, one for each effect. Additional to the significance of effects we report effect sizes after Cohen (1988). Cohen (1988) defines small effects from  $0.10 < f < 0.25$ , medium effects from  $0.25 < f < 0.40$  and large effects from  $f > 0.40$ . The effect of *strengthening* was analyzed with a one-factorial ANOVA with repeated measures for each rule. We used the number of occurrences of positive evidence (1-8) as independent variable. Strengthening greatly affected subjects confidence ratings for R1 ( $F(7,413)=57.12$ ,  $p<0.01$ ,  $f=0.98$ ) as well as R2,  $F(7,413)=46.83$ ,  $p<0.01$ ,  $f=0.89$ . Figure 4 shows the effects of strengthening on subjective confidence for both rules. As depicted, subjects' confidence in their prediction of the state of the output system strongly increases over time.

Figure 4. Effect of positive evidence on confidence ratings, depending on the number of trials. Error bars represent standard error.

For *discrediting* rules 1 and 2 (R1 & R2), the four trials with *negative evidence* were run to weaken subjects' confidence in their predictions. Since rule one was discredited for half the subjects and rule two was discredited for the other half, rule became a factor in the analysis. Therefore a 2x2 ANOVA with repeated measurement was calculated in which the *rules* of the model (R1 and R2) served as between subjects factor and *negative evidence* (trials 1-4) was a within subjects factor. We found a significant large main effect of *negative evidence* ( $F(3,174)=18.19$ ,  $p<0.01$ ,  $f=0.56$ ), but no effect of *rules* ( $F(1,58)=0.03$ ,  $p=0.95$ ,  $f=0.00$ ) nor an interaction effect ( $F(3,174)=1.96$ ,  $p=0.12$ ,  $f=0.18$ ). Figure 5 visualizes the results. To investigate the effect of *devaluating* a rule (Fig. 6), it seems necessary to highlight how we achieved the data for this computation. For all subjects rule 1 and rule 2 were strengthened. The last trial of the strengthening phase for each rule (trial 8) served as pre-measure. However, only for half of the subjects rule 1 was discredited. If these subjects' confidence for the

prediction of rule two (post-measure) was lower after discrediting rule one, devaluation took place. Reversely, for the other half of the sample rule 2 was discredited. Hence, if subjects' confidence for rule 1 (post-measurement) also decreases, devaluation worked as well.

Figure 5: Effect of negative evidence on confidence ratings. Error bars represent standard error.

Figure 6: Effect of devaluation on confidence ratings for both rules. Error bars represent standard error.

A 2x2 ANOVA was calculated over the between subjects factor *rule* (either R1 or R2 was discredited) and the within subjects factor *measurement* (pre- and post-measure). This analysis revealed a medium main effect of *rule* ( $F(1,58)=4.47$ ,  $p=0.03$ ,  $f=0.28$ ) and a large main effect of *measurement* ( $F(1,58)=42.66$ ,  $p<0.01$ ,  $f=0.85$ ). Additionally, we observed a medium significant interaction,  $F(1,58)=5.58$ ,  $p=0.02$ ,  $f=0.31$ . Figure 6 visualizes these effects.

## Discussion

In the present paper we tested three. First, we assumed that positive evidence strengthens subjects' confidence for predictions they derived from a set of rules that was acquired in the course of an experiment. Empirical evidence supported that hypothesis. At the end of the strengthening

phase peoples' confidence was close to 100%. Second, we expected a decrease in participants' confidence in their causal inferences if negative evidence discredited the respective rules. This hypothesis was empirically confirmed as well. Finally, hypothesis three claimed, that negative evidence for one aspect of causality results in decreased confidence in the complementary aspect as well. Empirical findings clearly supported this assumption. This result opposes a normative view that would require people to base their predictions solely on the given facts. For example, given C- subjects should predict E- with high confidence. In contrast, despite their correct prediction of E- (in case of C-) participants confidence decreased with respect to the critical test in the post-measure. This effect emphasizes the idea that humans do not consider sufficiency and necessity as independent of each other. Instead, once people have acquired causal knowledge, they take evidence for both aspects into account. They do so, even if the predictions they make are solely based on one of them. Hence, we conclude that people mentally construct causal models that relate sufficiency and necessity. These models can be seen as a whole. If one part or aspect of such a model proves to be wrong, subjects lose their confidence for the complementary part as well. Existing models of causal learning and reasoning aim to explain integrative judgments. Hence people are required to integrate information over all four cells of the contingency table. Thus, they always have to consider both aspects of causality. Therefore these models do not fit to the conditions of the experimental task. Nevertheless, assuming that subjects frame the task in our experiment as to judge the strength of the relation of C and E, the Power PC model (Cheng, 1997) would predict a confidence level of 66% for the post-measure. This is within the range of our results. Hence, if subjects are asked to make predictions in a causal learning paradigm, they reframe the task to judge the strength of a causal relation of two events. According to Griffith and Tenenbaum (2005) parts of the experimental task can be described as causal structure learning. From this point of view presenting negative evidence for one aspect would favor a different causal structure (compound causation or alternative causation respectively). Hence, it might be that peoples' post-measure judgments reflect their preference for the new structure compared to the previous one. Alternatively the post-measure judgments might reflect participants' uncertainty regarding the new structure. Again, these alternative explanations require people to integrate over all contingency information. In contrast to these alternative explanations there are models of inductive causal learning that are based on cognitive architectures and that emphasize the role of declarative memory (Drewitz & Thüring, 2009; Drewitz & Brandenburg, 2012). These models account for peoples' judgments and their confidence ratings given positive as well as negative evidence. They provide a possible explanation for peoples' performance in inductive learning based on memory processes. Additionally they do not assume that people reframe the experimental task from

prediction to integrative judgments. To discriminate between these explanations, future research should focus on the replication of the devaluation effect for more complex causal models and different dependent variables like reaction times and pupil dilation. If we can replicate the effect we also might be able to differentiate between possible alternative explanations.

## Abstract

Playing an instrument is a physical skill learned through observation, repetition and rehearsal. Students of orchestral instruments seek one-to-one tuition from expert musicians. However as they become more accomplished, the number of suitable tutors becomes more concentrated, especially for less common instruments. Often a tutor-student relationship develops over several years and temporary separation due to overseas performing, auditioning and teaching commitments is problematic. Some music education organisations use video conferencing as a solution to these problems, however it has long been recognised that interaction mediated by video conferencing is not analogous to a co-present experience. In this paper, ethnographic video analysis is used to study the interactions in co-present and separated instrumental music lessons. We find that the musical score represents more than a physical embodiment of the music - it plays an important role in coordinating activity and interaction. In video mediated lessons a single physical score can no longer be shared and interaction is changed as a result.

**Keywords:** video conference; interaction; ethnography.

## Introduction

A recognised method for learning to play an orchestral musical instrument is through regular one-to-one lessons with an experienced tutor. Playing an instrument is a physical practice requiring dextrous manipulation of a complex tool. Marchand (2010) proposes that the interpretation, understanding, and realisation of practice is based in motor cognition. As the student watches the tutor, visually processed signals are paired with observed actions, gestures, and postures. These may be co-ordinated with verbal instruction and commands from the tutor. However learning a musical instrument cannot be achieved purely by verbal description or observation, students learn a practice by 'doing'. Through observation followed by repetition and rehearsal, with iterative feedback from the tutor, the student develops motor and kinaesthetic cognition of how to play their instrument. This is a collaborative process, involving the co-ordination of understanding (Clark & Brennan, 1991).

At an undergraduate level of study, music students seek professionally recognised performers as tutors and their choice of where to study could be influenced by resident tutors and professors at an institute. The number of qualified professional tutors in any particular field is finite, but becomes more limited the more accomplished a student becomes, especially for less common instruments. Once a teaching relationship has been established, musicians tour

and travel frequently, so temporary separation of tutor and student can occur at critical times, such as prior to an important audition or performance. One solution to these problems is video conferencing. This is popular in geographically remote areas such as Australia (Lancaster, 2007) but is also part of urban mainstream conservatoires such as The Manhattan School of Music in New York. However interaction when video is the medium of communication is not analogous to the co-present experience. The belief at the inception of video conferencing that technology which replicated face-to-face interaction, simply at a distance, would enhance communication, contained a fundamental misunderstanding about how people interact when working collaboratively to achieve a task (Whittaker, 2003; Edigo, 1988; Hollan & Stornetta, 1992). Heath et al (1997) found that the visual focus of collaborative work is likely to be aligned to the focal point of the activity, such as a document or object, rather than face-to-face.

Existing research concerning separated musicians has focused on collaborative performance, the impact of latency and delays and tools to enable distributed ensembles to perform, improvise and compose (Chew et al., 2004; Sarkar & Vercoe, 2007; Hamilton, Iyer, Chafe, & Wang, 2008; Barbosa, 2003; Bryan-Kinns & Healey, 2006). However the activity taking place during music tuition is not the same as performance due to the educational frame of reference.

## The Use of Shared Space

Individuals in shared space coordinate their actions through spatial awareness, peripheral monitoring of non-verbal signals and the ability to joint reference; where gaze and gesture around a shared point coordinates the attention of participants (Whittaker, 2003). They use their position relative to each other to create mutually recognised shared space. Kendon (1990) describes how two or more people can organise themselves to create and sustain a shared space, called 'o-space', to maintain a common focus of attention. He goes on to describe sustained clusters and patterns as formations, an 'F formation' being where participants have equal, direct and exclusive access to their o-space. When two people are performing a collaborative task through the medium of video, they no longer have a concept of negotiated mutual distance (Sellen, 1992) and they cannot easily manage their position relative to each other or objects in their environment, there-

Figure 1: The layout for video lessons.

fore participants cannot use formations to create an o-space. Gestures and gaze are also shown to be less efficient in video mediated communication (Heath & Luff, 1991b). There is a body of work investigating the importance of gestures and non-verbal communication to teaching (Roth, 2001), to performing musicians (Vines, Wanderley, Krumhansl, Nuzzo, & Levitin, 2004; Wanderley, Vines, Middleton, McKay, & Hatch, 2005; Broughton & Stevens, 2009) and even specifically to instrumental music tuition (Kurkul, 2007; West & L. Rostvall, 2003). In this paper we analyse the interactions of co-present musicians in a learning environment and compare them to the interactions seen when student and tutor interact through the medium of video.

## Methodology

Ethnography requires a researcher to participate in people's daily lives, watching what happens, listening to what is said and gathering data to understand the issues emerging (Hammersley & Atkinson, 2007). It can offer fine-grained, detailed qualitative insight into how users interact with technology (Whittaker, 2003) and is often used as a tool to assess HCI and CSCW systems, for example the studies by Heath et al (1997; 1991a; 2005). It is the only way to study embodied social practice as it naturally occurs, rather than in conditions created by the researcher.

**Co-present Studies** We observed co-present music lessons taking place at the educational establishments where the students would normally have their weekly lessons. Three thirty-minute lessons were observed and filmed, two clarinet lessons and a trumpet lesson. The students observed were preparing for Grade 7 or 8 exams<sup>1</sup>. A researcher was present since it was not possible to know in advance how much the participants would move around the room, necessitating repositioning of the camera (see researcher position R1 and R2 in Fig-

ure 2), however the researcher took no part in the lessons. The footage was analysed using ELAN and a detailed transcript produced for each class.

**Video Mediated Studies** The video conference data was obtained from a study run by British Telecom Research and Development<sup>2</sup> to evaluate a video conference prototype, designed specifically to support instrumental music tuition. We were invited to observe tests which involved students and visiting tutors at Aldeburgh Music in Suffolk. Six one-hour lessons using the prototype were observed and filmed over three days, including harp, cello, violin, oboe and french horn. The tutors had a photocopy of the student's music, or their own editions of the score to be worked on. Some of the tutors had previous experience of teaching via video conference and some of the student-tutor pairings had worked together previously. A researcher observed from the tutor room, there already being an observer from the prototype team in the student room. Video footage was obtained from both rooms (see camera positions in Figure 1) and analysed synchronously.

## Results and Discussion

Professional musicians interviewed as part of this work believed latency to be the biggest barrier to teaching via video conference, as the delay makes it very difficult to play together (Chew et al., 2004). However analysis of the three co-present lessons showed that synchronous activity (singing or playing together, accompanied playing, the tutor conducting) made up only 11 percent of the lesson on average. This activity was used largely to resolve specific rhythmic problems. Where video conference is used to manage temporary separation of a student-tutor pair, many normal lesson activities can still take place, synchronous tools being saved for the next co-present lesson. The impact of the medium on interaction seemed to be a more significant problem as this affected

<sup>1</sup>Grade 8 from a recognised exam board such as the Associated Board of the Royal Schools of Music is often an entry requirement for music performance undergraduate degrees

<sup>2</sup>As part of the EU FP7 project Together Anywhere Together Anytime ("TA2") <http://www.ta2-project.eu/Pages/overview.html>

all lesson activities.

### Co-present Lesson Interactions

The rooms where lessons took place were small, the space constrained by the piano and the music stand. Nonetheless, in each case, tutors used their position relative to the student and the music stand to communicate their intention to act. This led to the establishment of specific zones within the space, which both participants could be seen to observe. To illustrate this we present vignettes illustrating examples of the use of these zones.

Figure 2: The work zone and listening zone.

**The Work Zone** The music stand became the focal point of a side-by-side F-formation (Kendon, 1990) as participants shared the student's score, the o-space created between them being designated as a 'work zone' (Figure 2). In one example, towards the end of the lesson the student and tutor briefly relax into social conversation. The student moves back slightly and moves her upper body to face the tutor, rather than the music (position S2 Figure 2). The tutor moves her upper body to face the student, the stand no longer the focus of their o-space. The student rubs her shoulder and moves about, relaxing her muscles (Figure 3). The tutor then puts her left hand on the music stand, between two short utterances, whilst still maintaining eye contact with the student. In this way the tutor holds both the stand and the student, triangulating her position (Healey & Battersby, 2009) as she begins the transition back to the work zone. Finally, the tutor turns her head back towards the music stand, pulling her body round, facing back into the work zone (Figure 4). The student also turns back to the stand (position S1 Figure 2), and swings her clarinet up towards her face, having understood the signal that they are going to go back to work.

Figure 3: Moving out of the work zone.

Figure 4: The tutor signals 'back to work'.

**The Listening Zone** In each case, the tutor defined a listening zone (for example T1 in Figure 2). When the tutor occupied this zone, the student understood that they could play without immediate interruption as the tutor wanted to hear a longer section. The tutor also defined a listening position within the listening zone, for example one tutor stood with feet slightly apart, hands loosely folded in front of her body, shoulders relaxed; attending to, but not bidding for, the floor.

**Transitions Between the Zones** When a tutor wanted to give detailed feedback on a passage, they moved forward into the work zone (position T2 Figure 2). When they stepped backwards into the listening zone again, the student understood that the specific topic of detailed work was finished and they should play a longer passage again, for the tutor to listen to and assess.

The transition from listening position to interruption could be sudden or more gradual. In some cases, the first indication that a tutor had diagnosed a problem from their listening position was when they lifted their gaze from the score to look at the student's face or instrument. Sometimes the student had already looked up, aware of their error, to see if it had been detected. In other cases the student demonstrated peripheral awareness; looking up in response to the tutor's movement, returning their gaze, and sometimes even stopping playing. The intent to make a more significant interruption could be indicated in advance by the tutor leaning into the piano to pick up a pencil whilst still in the listening zone, signalling intention to write on the score; or picking up their own instrument, indicating that they wished to demonstrate something the student had played incorrectly.

The duration of the tutor's planned interruption was indicated through the extent of her movement into the work zone.

When the tutor intended only a brief interruption she leaned forward into the work zone, without moving her feet, and pointed to the score whilst giving feedback. Then leaned back into her 'home position' having used body torsion to indicate a temporary movement into the work zone, the lower body remaining in the listening zone or 'base position' (Schegloff, 1998).

### **Control of Musical Turns**

When a student is playing, they are emotionally engaged with their performance and concentrating on the score. However the tutor frequently interrupts to provide immediate feedback on an identified problem. Frequent, unexpected interruptions could become frustrating, however student-tutor pairs managed interruptions in order to reduce the impact. In a music lesson, where a verbal utterance is often followed by a musical response, it is reasonable to assume that a musical phrase is analogous to a conversational turn and we should therefore be able to see the characteristics of turn management (Sacks, Schegloff, & Jefferson, 1974) such as transition-relevant places for a new turn, back-channelling (Moran, 2011), turn breakdown and repair.

We could see evidence of musical turn management whilst the student was playing. Musicians have been shown to have awareness of anticipation of other musician's intentions with respect to musical structure (Moran, 2011) and the position between two adjacent musical phrases or ideas was observed to be preferred by the tutor as a transition-relevant place to interrupt. Even if a change in the tutor's posture indicated that they had diagnosed a problem earlier in a phrase, they would often wait for the long note at the end of the phrase before initiating interruption of the student's performance. This provided an ideal opportunity for the tutor to speak, whilst the student had a natural point to finish, before moving on to the next musical idea.

The transition from verbal instruction, to visual observation, to motor cognition (Marchand, 2010) was observed. After verbally explaining a point, in some cases the clarinet tutor then demonstrated it for the student on her own instrument. The student was asked to imitate. If the tutor was not satisfied with the performance she played the phrase again, exaggerating the aspect not yet corrected. The alternating musical turns increased in intensity, the student's technique converging over time with that of the tutor's. In one example a student impatiently copied the tutor's demonstration, starting to play before she had finished demonstrating. The tutor did not detect any noticeable improvement and musically admonished him, interrupting his performance and playing it again herself, taking back the turn.

### **The Shared Score**

The score played a much greater role in the lesson than a physical embodiment of the music, also providing a shared reference to coordinate joint attention (Whittaker, 2003). In co-present lessons the participants shared a score, usually that which belonged to the student, and both pointed to parts of the

score as they spoke as a convenient way to reference without having to mention bar numbers specifically. Tutors gestured over the score as they talked, linking their comments to specific notes and putting phrases into context of the whole piece. For example, in one lesson the tutor pointed to the music 32 times, half of the instances for navigation purposes such as "from here" and half to reference feedback against musical notation.

Direct eye contact was shared for less than 5 percent of the time, and was made up of brief glances (for example one lesson contained 112 instances of shared gaze, the average duration being less than one second). More often both looked at the score, even when in conversation together, whilst exhibiting a high level of peripheral awareness. For example, when one student performed for the tutor and stumbled over a note, the tutor immediately moved in towards the score with her pencil, starting to speak. However the student interrupted before her pencil reached the score saying "change my right?", his gaze not having moved from the music. The tutor stopped moving, looked up at him nodding and said "you read my mind, yeah" then moved back to her listening position.

Whilst the students had all made pencil annotations on their music outside of the lesson, such as marking fingerings, phrase marks, accents and breathing; during the lesson it was the tutor who annotated the score. For example the clarinet tutor used the character 'O', writing it on specific notes to indicate the 'open throat' required to control tone in some registers or 'X' to signify a particular spacing of fingers on the keys. Through annotation, the student's score built into a permanent and cumulative record of the learning imparted by the tutor; a record of how they had developed.

### **Video Mediated Lesson Interactions**

In the video mediated lessons, students demonstrated awareness of their need to monitor both their music and the tutor at the same time, by initially positioning themselves directly in front of their screen so that they could see both the tutor, and their music, without significantly moving their head. However the score and music stand obstructed the main camera view (Figure 5) and in all cases tutors asked the students to turn around so that they could see their hands on the instrument. The students were then turned between 45 and 90 degrees away from their screen (position S in Figure 1) and no longer had peripheral awareness of the tutor when performing.

### **The Divided Score**

Now that the student's gaze was divided between their score and the screen, there was a dramatic impact on turn control. With a separate music stand and score in each room, a shared work zone could no longer be established, and the tutor could not create a listening zone, removing communication through spatiality. Whilst some tutors still adopted a listening position (for example one tutor formally placed her folded hands in her lap - see Figure 6) they now used exaggerated gestures such as a raised arm or a wave to indicate when they

Figure 5: The score obstructs the camera view.

wanted the student to stop playing, and when these were also unseen, resorted to a vocal request. This was sometimes not heard by the student who was absorbed in their playing and not facing the video conference system speakers, and the tutor had to raise their voice. Even when they were able to rapidly switch their attention, students missed cues through looking in the wrong place at the wrong time. From their perspective, they were continually being stopped unexpectedly by a raised voice, requiring a significant twist of their upper body to see the screen (Figure 7) and this quickly led to frustration.

Figure 6: Tutor's gaze divided between screen and score.

Tutors also struggled with dividing their gaze between the screen and the score (Figure 6). Often they would discuss a phrase looking down at their score, as the student looked at their own separate score. Neither party could monitor their video screen at the same time. Previously the tutor could use peripheral awareness of the student's gaze as evidence of continued attention and the student could use indicative gestures to confirm their understanding of the feedback and its relation to the score (Clark & Brennan, 1991). Navigation became problematic as a result, requiring detailed reference to page and bar numbers to establish precisely where in the score feedback related to, or for the tutor to establish where they would like the student to play from. For example, as shown in the following extract of dialogue.

*Tutor:* that wasn't quite right, let's try it again...  
 [the student starts to play]  
*Tutor:* ...from the beginning of the bar.  
 [student stops, looks up]

*Student:* from the, sorry? From the?  
*Tutor:* from the beginning of the bar.  
 [the tutor starts playing the phrase that she wants to hear, the student is looking hesitant]  
*Tutor:* can you play it from the beginning of the bar and stop on the B and the E?  
*Student:* OK [with instrument raised to playing position]  
*Tutor:* Do you see where I mean?  
 [the student looks at the music intensely, wiggling her fingers on the fret board]  
*Student:* "uh hum" [hesitantly]

The tutor could no longer directly annotate the student's score and it was noted that, in comparison to the co-present lessons, notes and annotations were not frequently made by either participant. One tutor made reference to a student's annotations where they were available on their photocopy of the student's music, confirming their value.

Figure 7: The student must switch gaze from score to screen.

## Conclusions and Further Work

Ethnographic analysis of co-present lessons provided a useful framework to assess the effectiveness of video mediated communication to teach a practice based skill. The importance of the shared score to lesson interaction was evidenced by problems managing interaction such as turn control when participants were separated and could no longer share the same physical representation of the music.

A further study is planned where the instrument class will be confined to woodwind (for example clarinet or oboe) and an additional camera will be placed behind the participants to capture gesturing over the score in more detail. The score will be photographed and the annotations discussed with participants during post-observation interviews. Technological solutions to the problem of interaction lost through the divided score will be suggested. These are likely to involve an interactive visual layer over a digitised representation of the physical score, which shows the separated participants where each person is gesturing on the music. Ideally both participants should be able to mark their layer in a way which allows the student to take an annotated copy away, and return with it for the next lesson. There should be a way for the tutor to communicate intent to interrupt the student's performance through visualisation of gestures on the music. In this way

some of the functions of the shared score can be introduced to the separated lesson.

## Acknowledgments

The author would like to thank Doug Williams at British Telecom Research and Technology Future Content Group; Jonathan Reekie, Bill Lloyd and Marie Bennell at Aldeburgh Music; Ruth Aldred at Manchester Grammar School and Nicola Baigent at Trinity School of Music. Thank you to all of the students and tutors who kindly allowed their lessons to be filmed and the reviewers for their helpful feedback. The Media and Arts Technology programme is supported by an EPSRC Doctoral Training Centre EP/G03723X/1. Arts Council England supported Aldeburgh Music's purchase of equipment.

# Increased Vigilance in Monitoring Others' Mental States During Deception

Nicholas D. Duran (nduran2@ucmerced.edu)

Rick Dale (rdale@ucmerced.edu)

Cognitive and Information Sciences, The University of California, Merced, Merced, CA, 95343

## Abstract

Communicating false information during social interactions places unique cognitive demands on the speaker. One such demand is the increased need to track what another knows to avoid introducing contradictory information. The present study examines the minimal conditions required for vigilant mental state monitoring by using a game-like task that required participants to respond to virtual partners' questions with true or false information. In this task, there were no explicit demands to engage in mental state monitoring. We found increased response times when the answers potentially violated a partner's belief states - but only if participants believed their partner to be an actual cognitive agent. These effects were also shown to be additive to the simple demands in suppressing a truth bias while responding falsely. We argue that participants exert greater cognitive effort as an automatic response elicited by being situated in an interactive, deceptive context.

**Keywords:** deception; belief monitoring; self; other

## Introduction

In this paper, we examine the underlying cognitive processes that are involved in deceptive responding during a real-time social interaction. We propose two primary processes: 1) the inhibition of a prepotent truth response while responding falsely, and 2) the need to track the knowledge of the person to whom one is falsely responding. Both of these processes are commonly associated with executive control and working memory, and thus are hypothesized to involve considerable cognitive costs. Previous studies on deceptive behavior have examined these processes in isolation. In this paper, we show the integrated effects of each process in a single task. Moreover, we provide evidence that when participants merely know that they may have to convey false information, even when the risk of detection is negligible, it is sufficient to induce vigilant tracking of the knowledge of the false information's recipient. However, as an important caveat, this effect only occurs when a person takes an *intentional stance* toward another (Dennett, 1987). As we argue below, such tracking is likely an adaptive response that ensures false or true information conveyed throughout an interaction remains consistent, thereby minimizing the risk of detection.

## Background

Human interaction often involves the exchange of deceptive information. Although these fabrications are mostly innocuous, as in lying to boost one's own credentials or to protect another's feelings, they are routinely introduced into conversations (DePaulo & Kashy, 1998). Nevertheless, the risk of detection when communicating false information is always present. To minimize this risk, plausibility must be maintained, and as such, sophisticated cognitive control processes are likely recruited. A primary need is the suppression

of a truth bias while responding falsely (Duran, Dale, & McNamara, 2010), as well as a need to remember what information is false and maintain this falsity as the ostensible truth in the mind of another (Sip, Roepstorff, McGregor, & Frith, 2008). A number of neuroimaging and reaction time studies have explored truth suppression, showing increased executive function processes involving the inhibition of predominant responses and the resistance to interference (see Spence et al., 2004, for a review).

Much less is known, however, about the processes underlying real-time deception in social interactions. Some work has focused on the recipients of deception and their beliefs about the hidden motivations of their partners (e.g. Schul, Mayo, & Burnstein, 2004). Conversely, others have looked at those doing the deception and have found evidence for active monitoring of their partners' suspicion, purportedly for the purpose of manipulating others' beliefs about their own goals and intentions (Bhatt, Lohrenz, Camerer, & Montague, 2010; Carrion, Keenan, & Sebanz, 2010). In these studies, the modeling of another's mental state consists of the impressions that the other is likely to form. Participants are given opportunities to mislead a partner about the true nature of some privileged knowledge, as a poker player does when bluffing about the cards in their hand. Successful participants are those that strategically fend off another's suspicion with well-timed true responses. These true responses, construed as "deceptive truth," are believed to result from mental state monitoring, and invoke neural regions of cognitive effort similar to that associated with various theory of mind tasks. Beyond considerations about the general impressions or motivations another might possess, deception likely involves the specific content one believes another to believe about events and objects in the world following the deceptive act.

We explore this aspect of mental state monitoring in deceptive interaction; specifically, the need to encode and maintain the factual content of what another might know. This is particularly difficult during an extended interaction where new information is introduced and must be integrated into deceiver's knowledge of another's supposed knowledge. If one is to give another false information about their whereabouts, such as saying they were not at the local Sears on Saturday, the deceiver needs to maintain this model of events for the other, and apply it consistently downstream in the conversation to avoid saying "yes" to a question like, "Were you shopping on Saturday?" From this example, implications that might be drawn from the earlier presented false information also need to be maintained by the deceiver, such as knowing that being at Sears implies shopping. Such a model of others' belief states is likely an adaptive evolutionary response that minimizes the risk of detection (Premack, 2007), but one that

also enacts considerable cognitive costs that combines with those associated with truth suppression (a process that can occur regardless of an audience). To evaluate both these processes in an integrated manner, we turn to a novel *guessing game* task.

The basic structure of this task involves a partner attempting to guess the identity of an object of which another partner is solely aware. This task is similar to the game of “Twenty Questions,” where a “questioner” tries to guess a person, place, or thing by asking yes or no questions. After the allotted number of questions have been asked, the questioner must wager a guess. This task presents a situation where the mental state of another (i.e., the questioner) incrementally converges on what another has in mind (i.e., “answerer”). Although the uninformed questioner is making explicit attempts to converge, the same does not necessarily hold for the partner who is answering yes or no. That is, to succeed in this task, the answerer does not need to track the evolving image emerging in the questioner’s mind. However, in our version of the Twenty Questions game, the answerer is told that there is the possibility of having to give the questioner false information. This simple instructional manipulation is hypothesized to elicit increased vigilance in tracking the mental state of the questioner, largely because the answerer now has to maintain the veracity of what the other believes. Important to the task set-up, there are no explicit instructions for monitoring another’s mental state, nor does it affect the success of completing the task.

Mechanisms involved in such a situation are likely automatic and triggered in response to particular contexts (German, Niehaus, Roarty, Giesbrecht, & Miller, 2004) - one of which, as we argue, is the communication of false information. However, merely being situated in a context that requires transmission of false information is not sufficient. The participant must also take an intentional stance toward their partner, a partner who is thought to have their own set of beliefs, desires, and knowledge states. In other words, participants must consider their partners as having minds worth tracking (Gallagher, Jack, Roepstorff, & Frith, 2002). One test of this claim is to compare participants (i.e., answerers) who believe their partner to be real versus a computer simulation, while holding all other features of the interaction equivalent. Accordingly, on critical trials all participants should find the false responses more challenging than the truth (due to suppression of a truth bias); however, for those who take an intentional stance, they will experience added difficulty because they will also be violating knowledge their partner possesses.

In what follows, we describe in greater detail the method used to assess other-directed mental state monitoring during deception. We then report the findings from two experiments that incorporate crowdsourcing techniques. We end with a brief discussion of the findings and limitations.

## Mental State Monitoring in a Guessing Game

### Initial Set-up

The current task was implemented as an online, Flash-based game that makes use of key features in Amazon Mechanical Turk (AMT). AMT is a crowdsourcing platform that allows participants (i.e., “Workers”) to sign up to complete tasks posted by other users (i.e., “Requesters”). There are many advantages of using crowdsourcing techniques (see Munro et al., 2010, for a review), with one notable advantage being the ability to create an illusion of connectivity, whereby simulated, recorded partners can act as convincing interactive partners (Duran, Dale, & Kreuz, 2011). To achieve this illusion in this study, participants were recruited under the pretext of examining “how people solve problems while receiving misleading information.” They were then told that the task involved beta software that allows us, the Requesters, to connect two Mechanical Turk Workers, but with software that only allows a one-way transmission of audio. The participant’s partner (a recorded simulation of a male’s voice) was always designated as the role of questioner and was the one who would transmit audio. A series of validity checks were then presented that highlighted the connection, such as a “connection screen” where participants ostensibly waited for the software to locate and connect them to their partner, and an “introduction screen” where the recorded partner introduced himself and provided a secret codeword for the participant to enter, ostensibly verifying to the recorded partner that they were “connected” to a real person. As described further below, checks were used to ensure participants believed this sham connection.

### Basic Game Structure

In the initial instructions, participants were provided a demonstration of how the task was structured (see Figure 1 for a flow diagram). First, participants were told that they would be presented with one of two objects (an alarm clock or a red apple) that only they could see. Their partner would then ask a yes or no question to attempt to guess the identity of the object, and once the question was asked, they would trigger a “GO” button that would appear at the bottom-center position of the participant’s screen. When the participant clicked this button, a response screen would appear with “YES” and “NO” response buttons positioned in the top-right and top-left corners. On this screen, a prompt to respond with a “TRUTH” or “LIE” also appeared in the middle of the screen.<sup>1</sup> Thus, if the partner had asked, “Is it a person?,” the participant had to navigate their computer mouse from the bottom of the screen to the “YES” response button. The response was then transmitted to the partner and a short pause was introduced to allow the partner to “formulate” another question before the next trial began.

<sup>1</sup>The use of a “LIE” response prompt has been used in previous research to approximate deceptive behavior and has been shown to invoke similar physiological and neurological reactions as unsolicited deception. However, we acknowledge that this is still an approximation of deceptive behavior, which we address in Study 2.

Figure 1: Flow of interaction in experimental task. In (1), after initial instructions, a typical trial begins by presentation of the to-be-guessed object. The partner then asks a question about the identity of the object; (2) After the question is asked, “GO” appears and participants click to respond; (3) and (4) Participants are given a prompt to respond truthfully or falsely, and do so by clicking “YES” or “NO” boxes; (5) Response is “sent” to partner.

### Monitoring and Contradicting Given Information

Two rounds of the guessing game were played, counterbalanced across the object to be guessed (clock or apple). In each round, the partner asked 5 questions before they made a guess.<sup>2</sup> There were 16 variations of each question set for each object, with each set randomly selected for each participant. In both rounds, participants were prompted to answer truthfully for the first three questions, but for the 4th or 5th questions, they were prompted to respond falsely. These falsification questions presented a situation where participants might violate their partner’s possible belief states. What this means is that by the 4th or 5th questions, the partner has eliminated numerous options of what the object might be, allowing a greater possibility for some objects, like an alarm clock, to be mentally represented. If participants take into consideration this reduced mental set of their partner, a response that denies the possibility of an alarm clock acts to contradict what the partner was increasingly likely to believe. This type of *general* violation constituted one round of the guessing game.

In another round, a *specific* violation was presented. In the corresponding scenario, the question being falsified contradicted information explicitly given earlier in the informational exchange. For example, if an early question like, “Can it be used on a daily basis?,” is initially confirmed by the participant as being true, the participant can infer that their partner believes that the unknown object is “common.” When a later-occurring question such as, “Is it fairly common?,” must then be falsified, the participant is now violating the more

specific belief their partner was inferred to have. An example sequence of questions is given in Table 1. These two types of violation, general and specific, were presented to the participant across the two rounds, in counterbalanced order.

<i>Question Sequence</i>	<i>Expected Response</i>	<i>Prompt</i>
1. Is it a person?	No	True
<b>2. Did someone invent it?</b>	<b>No</b>	<b>True</b>
3. Do people eat it?	Yes	True
4. Does it grow underground?	No	True
<b>5. It is a man-made product?</b>	<b>Yes</b>	<b>False</b>

Table 1: Sample questions asked by simulated partner who is attempting to “guess” an apple. The later-occurring Question 5, in which participants are prompted to falsify, contradicts specific information given earlier in Question 2. Questions were also counterbalanced for whether critical trials required a “yes” or “no” response.

### Establishing Intentional Stance

To examine the incurred processing costs of violating the mental state of another, we compared participants who believed that they were interacting with a real partner versus those who did not. Participants who did not believe they were interacting with a real person were hypothesized to be less likely to attribute mental states to the simulated partner, and

<sup>2</sup>Limited to 5 questions to avoid memory interference or decay that would have likely resulted from 20 questions.

thus should not experience the associated processing costs on the critical false trials. The only costs these participants should experience is that attributable to the suppression of a truth bias when responding falsely. To identify participants who did or did not believe they were interacting with a real partner, we asked two critical follow-up questions at the end of the task. The first probed whether the participant would give a small monetary bonus (paid by us, the Requesters) to their partner for the quality of questions asked. The rationale for including this question is that a participant who suspects that their partner is a mere recording is unlikely to give a reward. The second question was more direct, and asked participants to rate on a scale from 1 to 7 the degree to which they thought they were connected to a real person. Participants who would give a reward, and were on the upper end of the scale for their belief that they were interacting with a real person, were considered those who would take an intentional stance.

## Experiment 1

We collected data from 104 participants. One subject was excluded for answering two of the 10 questions incorrectly. We also removed excessively long trials that were over 8000 ms (0.73% of data), and from this truncated set, we removed trials that were more than three SDs (855 ms) above the mean response time (2308 ms). This resulted in a loss of 2.48% of the data. Forty-eight participants also self-selected into a group who believed that their partner was real, with the remaining participants believing that their partner was not real.

## Results

A mixed effects ANOVA was used to compare the difference in response times for the two groups of self-selected participants, with a within-subjects factor of whether a trial required a true or false prompt<sup>3</sup>.<sup>4</sup> Subject was entered as a random effect. The analysis was conducted using the lmer package in the R statistical software. In this package,  $p$ -values are computed with 10,000 Monte Carlo Markov Chain simulations, using lmer's pvals.fnc function (Baayen, Davidson, & Bates, 2008). We report these  $p$  values and the unstandardized effect estimates for the main effects and interactions.

The results indicate a main effect for participant type (those who believe vs. not believe),  $B = 342$  ms,  $p = .003$ ; as well as for prompt type (false vs. true),  $B = 481$  ms,  $p < .001$ . There was also an interaction between participant and prompt type,  $B = 277$  ms,  $p = .05$ . In follow-up tests to examine this interaction, it appears that for both believers and non-believers,

<sup>3</sup>Because of the smaller number of false critical trials compared to true trials, and because the false trials always occurred near the end of the interaction, we only analyzed the true trials that occurred immediately before the presentation of the false prompt trials. The inclusion of all true trials does not radically alter the reported findings, as the response pattern in the data remains consistent. However, by doing so, the significant interaction is now only marginally significant ( $p = .10$ ).

<sup>4</sup>The comparison between the false prompts that draw on general and specific belief violations showed no statistically significant differences, and thus are combined into one condition.

the false response critical trials showed greater response latencies than true response latencies: believers,  $B = 622$  ms,  $p < .001$ ; and non-believers,  $B = 345$  ms,  $p = .003$ . This effect corresponds to the greater cognitive difficulty associated with suppressing a false response. Moreover, the magnitude of the false response time latencies for believers was much greater than those who did not believe,  $B = 500$  ms,  $p < .001$  (see Figure 2). This finding suggests that believers noticed a contradiction forced by the false prompt that the non-believers did not. The likely reason is that believers had an active model of the other's mental state and experienced greater cognitive effort in consulting and ultimately violating this knowledge.

Figure 2: Overall, the response time latencies are much higher for false (lie) responses compared to true responses, with the greatest response latencies for participants who believed their partner to be real. There are no significant differences across true responses.

## Experiment 2

In Experiment 1, participants appear to use true knowledge provided earlier *upstream* in an interaction to influence later *downstream* responses. As a further test, we examined whether participants encode and consistently maintain false information that is provided upstream. The set-up of this task is such that participants should respond falsely to a later-trial critical question to verify the accuracy of earlier presented false information. To do so, participants are allowed to freely respond without prompts. We hypothesize that participants who believe they are interacting with a real partner will be more likely to choose to respond falsely. In other words, they are more likely to respond falsely *again* to preserve the consistency of their partner's beliefs (because of false information they presented upstream). This response will enact similar cognitive demands as evidenced in Experiment 1.

## Modified Method

Participants first provided their partner with a particular belief about the to-be-guessed object early in the interaction.

This is done by prompting the participant to respond falsely on the second question asked by their partner. Later, downstream in the questioning (on the critical fourth question in the questioning sequence), participants are allowed to choose whether to respond falsely or tell the truth. In one round of the guessing game, the downstream question is related to the earlier false information, and thus if a participant is monitoring what the other knows, and wants to stay consistent with the false depiction of the object, they will voluntarily respond falsely (see Table 2 for a sample sequence of questions). By consulting and acting on the knowledge state of the other, we expect this to incur a processing cost. As a type of control, in a second round of the guessing game, the downstream question is unrelated to the earlier false information, and thus there is no explicit need to consult what the other knows on the critical question. Thus, the differences in the *information related* round should no longer be present in this *information unrelated* round.

Question Sequence	Expected Response	Prompt
1. Is it a thing	Yes	True
2. Can you easily pick it up?	No	False
3. Is it found in people's homes?	Yes	True
4. Can it be moved?	?	--
5. Is it something people might use on a daily basis	?	--

Table 2: Sample question set asked by simulated partner who is attempting to “guess” an alarm clock. The downstream Question 4, which requires a free response, relates to information falsified in Question 2. There are 8 variations of question sets for each object (total of 16).

## Results

One hundred and seventy-six participants supplied data via Mechanical Turk. Five participants were removed for answering two or more of the 10 question incorrectly, and an additional 16 were removed for failing to provide at least one false response in the final unprompted questions. Outlier trials, those trials that exceeded 3 SDs above the mean were also removed. Furthermore, based on follow-up questions, 80 participants were self-selected as those who believed they were interacting with a real partner, 71 believed they were interacting with a simulation, and four participants’ beliefs were undetermined. Thus, 151 participants provided data where their false and true responses could be evaluated.

The main analysis specifically targets the round in the guessing game where there was an opportunity to maintain the false information introduced earlier in the question sequence (i.e., “information related” round; see Figure 3a). By freely answering false on the fourth (critical) question in the

sequence, the false belief state of the questioner is maintained. We hypothesized that this process requires greater processing time because the deceiver must consult what the other knows, recognizing that to respond true would elicit a contradiction. Importantly, such behavior is likely to occur only when a participant believes they are interacting with a real partner. We found evidence for this hypothesis in a simple t-test evaluating the critical false response trials between participants who did or did not believe they were interacting with a real partner,  $t(76) = 2.20$ ,  $p = .03$  (Figure 3a).

It should also be noted that the false response trials in the above analysis represented responses from 41 of the 80 participants who could be classified as believers. This number is fewer than expected given the hypothesis of increased vigilance in maintaining the partner’s belief states. However, when participants who believed they were interacting with a real partner did answer truthfully (thereby contradicting a partner’s mental state), these response times were the second highest of all trial groups (Figure 3a). These elevated scores suggest that participants are aware, at some level, that they are violating their partner’s mental state. This is supported by a significant main effect in a mixed effects ANOVA for participant type (belief vs. not belief), showing that participants who believed they were interacting with another, despite answering truthfully or falsely, had increased response times compared to those who did not believe,  $B = 621$  ms,  $p = .02$ .

Finally, as hypothesized for the round in the guessing game where the upstream information was unrelated to the downstream information, no differences were found between participants who did or did not believe they were interacting with a real partner (see Figure 3b)

## General Discussion

Across two experiments we examined response behavior in a context where participants had to transmit false information to another. We found evidence that participants experience greater cognitive effort in suppressing a truth bias; and furthermore, show evidence of increased effort when they are confronted with a response that violates or potentially violates the mental state of another (as measured by response latencies). For the latter, we argued this increased effort results from an active, or vigilant, monitoring of what another believes. Participants appear to do so as long as they think they are interacting with a “mindful” agent, and also do so despite instructions that have no explicit requirement to consider others’ mental states.

A limitation in this study, found in Experiment 2, is that participants who believed their partner to be real did not overwhelmingly choose to maintain the false information provided upstream in the interaction. One reason is that being detected as providing contradictory information carried little consequence, thus there was little motivation to choose a false response. Other research also suggests strong individual differences in whether participants consider their partners’ sus-

Figure 3: In (a), response times for participants who answered falsely on the critical free response questions is highest for those who believed they were interacting with a real partner versus those who did not believe. There are no differences for true responses. In (b), the control with unrelated information downstream showed no significant effects.

picion in low risk interactions (Bhatt et al., 2010). Despite this limitation, those participants who did think they were interacting with another, and who responded falsely, were the only group to be influenced by the contradictory information in the information stream.

In sum, we explored how truth biases and social factors are jointly involved in simulated “deceptive acts.” While we grant that these are basic cognitive experiments that can only loosely approximate naturalistic contexts, we would argue that the approach opens new avenues of investigation. The underlying *cognitive mechanisms* of deception are still being sought. By employing basic cognitive experimentation in simple but controllable tasks, we could gain a more systematic understanding of the mechanisms underlying deceptive acts. These experiments are a step in that direction.

## Abstract

In this paper, we present the AbsMatcher system for schema matching which uses a graph based approach. The primary contribution of this paper is the development of new types of relationships for generating graph edges and the effectiveness of integrating schemas using those graphs. AbsMatcher creates a graph of related attributes within a schema, mines similarity between attributes in different schemas, and then combines all information using the ABSURDIST graph matching algorithm. The attribute-to-attribute relationships this paper focuses on are semantic in nature and have few requirements for format or structure. These relationships sources provide a baseline which can be improved upon with relationships specific to formats, such as XML or a relational database. Simulations demonstrate how the use of automatically mined graphs of within-schema relationships, when combined with cross-schema pair-wise similarity, can result in matching accuracy not attainable by either source of information on its own.

**Keywords:** Data integration; graph matching; ABSURDIST; semantic relatedness.

## Introduction

Data integration has application to a wide variety of fields from e-commerce to bioinformatics. One of data integration's subtopics is the attribute matching problem which finds mappings between attributes in source and target data sets. This paper presents the AbsMatcher framework which concentrates on one-to-one attribute matches as an initial effort, leaving complex n-to-one matches to future work. AbsMatcher finds matching results based on graphs of within-schema attribute relationships and cross-schema comparisons of attribute similarity. The focus of in this paper is the process and relationships used to create a within-schema graph for each data set.

The AbsMatcher framework has two distinct phases. The first is a mining phase which produces a graph for each data set where edges relate within-schema attributes and an aggregated matrix of cross-schema attribute similarities measures. We refer to these graphs as internal information, because a graph only contains information relating attributes within the same schema. Information which is aggregated into the cross-schema matrix is referred to as external information because it involves a comparison between

attributes in different schemas to determine how semantically similar they are.

Secondly, AbsMatcher's matching phase uses the ABSURDIST (Feng, Goldstone, & Menkov, 2004; Goldstone & Rogosky, 2002) algorithm to combine mined information and determine match correspondences using an iteratively converging global optimization algorithm. ABSURDIST was originally developed to translate between conceptual systems in a psychologically plausible manner. Additionally, ABSURDIST has a weighting ratio to determine the balance of influence on the outcome of internal and external information. Though we focus on specific sources of internal and external information in this paper both AbsMatcher and ABSURDIST were designed in a way so that additional sources could easily be added.

In a graph based approach to schema matching the matching process uses graph matching to determine mappings between attributes/nodes based on the similarity of their sets of relationships/edges. Edges of graphs are labeled with different relationship types, which represent different forms of information. Relationship types can broadly be divided into structural relationships which are based on how attributes are organized in a data set and semantic relationships which are based on meaning of the information associated with an attribute. An example of a structural relationship is a parent/child relationship between nested attributes from an XML data set. An example of a semantic relationship is a general/specific relationship for the concepts represented by two attributes. These examples highlight that one of the challenges in how to create graphs is that what relationships can be used is tied to the format of a data set and the available (meta)data.

Previous systems (Aumüller, Do, Massmann, & Rham, 2005; Giunchiglia & Shvaiko, 2003; Melnik, Garcia-Molina, & Rahm, 2002) address the problem of how to create graphs by only using metadata which can be intuitively translated to graph form. As a result, the graphs created by these translations predominately represent the structural design of a data set. Though structural relationships can be useful, their disadvantage is that factors such as missing metadata, differing metadata formats, or different database designers can remove these structural relationships' usefulness.

This paper presents a set of relationships which can be used as general practice but more importantly are still applicable when metadata is limited or datasets with differing formats are being integrated. Of particular contribution are Yahoo semantic relatedness relationships which leverage Yahoo query results to measure the semantic relatedness of attributes' names. Yahoo relationships are an improvement over the use of tools like Wordnet because of their ability to handle attribute names that have abbreviations, words unique to a domain, and/or multi-term phrases. All three of these factors commonly occur in data sets. Together, Yahoo relationships and the other relationships we present offer tools to use when structural metadata is absent or of no benefit.

We use the terms AbsMatcher and ABSURDIST throughout this work. AbsMatcher is the overall system which formulates graphs after mining internal information and aggregates mined sources of external similarity. ABSURDIST refers specifically to the matching phase which iteratively combines internal and external information to determine a set of correspondences.

### ABSURDIST Background

ABSURDIST was developed to solve the general problem of translating between two conceptual systems. We adapt this approach to data integration by treating attributes as concepts to be matched. A complete discussion of ABSURDIST and how information factors into the iterative process can be found in Goldstone and Rogosky (2002). Information in ABSURDIST is classified as internal (within-schema) or external (cross-schema). External information provides the ability to input cross-schema similarity into the ABSURDIST algorithm. Different external sources are aggregated into an NxM matrix of values between 0 and 1, where N and M are the sizes of the schemas to be matched. The dividing line between internal and external is that internal information is relationships between attributes in the same schema, whereas external similarity is a comparison between attributes in two separate schemas.

ABSURDIST iteratively updates correspondences using internal and external information until reaching a stable point, terminates, and selects the final matches. ABSURDIST as an error minimization algorithm selects the set of matches that result in the least total link error. This section discusses the conceptual motivations of ABSURDIST and leaves specific examples of internal and external information for later sections.

#### Internal Information as Graphs

Internal information in ABSURDIST represents intra-system information about how nodes in each conceptual system relate to other nodes in the same system. Internal information for a system is independent of the system with which it is being aligned. For each schema, ABSURDIST takes internal information as input in the form of: information on relationship types, node types, node

information, and a graph of relationships. Internal information factors into the  $R$  and  $I$  terms of Equation 1. A node in a conceptual system must have a unique identifier and a categorical type. If only one type exists then the effects of node types become irrelevant. Relationships in ABSURDIST represent a conceptual association between intra-system nodes creating a generalized interpretation of structure. A relationship type has a categorical label and is defined as being either directed or undirected. Relationships are instantiated as edges, which collectively form a graph of continuously valued weighted edges. If the same weight is used for every edge, these weights become irrelevant.

#### Iterative Algorithm

ABSURDIST is an iterative algorithm which updates an NxM matrix of correspondences where N and M refer to the number of attributes in the source schema,  $A$ , and target schema,  $B$ , respectively. Each cell in the correspondence matrix,  $C_t(A_q, B_r)$ , represents how strong a match is at iteration step  $t$  for attribute  $q$  in schema  $A$  and attribute  $r$  in schema  $B$ . The algorithm terminates when the matrix has converged or a maximum number of iterations is reached. For each iteration, ABSURDIST updates each  $C_t(A_q, B_r)$  by a net input defined by

$$N(A_q, B_r) = \alpha E(A_q, B_r) + \beta R(A_q, B_r) - \chi I(A_q, B_r)$$

#### Equation 1. Correspondence Update Equation

Equation 1 shows how internal ( $R$  and  $I$ ) and external ( $E$ ) information combine to update the correspondence from attribute  $q$  in schema  $A$  to attribute  $r$  in schema  $B$ . The  $E$  term represents similarity based on external information, the  $R$  term represents similarity based on internal information, and the  $I$  term uses internal information to inhibit incorrect correspondences. As a global optimization algorithm, both  $R$  and  $I$  take into account the state of the system at each iteration  $t$ .  $\alpha$ ,  $\beta$ , and  $\chi$  are weights that control the influence of forms of information, where  $\alpha$  and  $\beta$  are set as a ratio to each other and  $\chi$  is set independently of the others. For example, when  $\alpha$  is one and  $\beta$  is zero only external information is used to find correspondences.

#### Related Research

A number of surveys have been done which cover the different aspects of the schema matching problem (Shvaiko & Euzenat, 2005). One of the established approaches to schema matching is to use candidate matchers to generate candidate matches which are aggregated into a final set. Graph-based systems, including AbsMatcher, have multiple modules to generate edges in the graph, multiple modules to generate the equivalent of external information, and then use a graph matching algorithm to generate correspondences based on graphs. It is possible that correspondences generated using a graph matching algorithm could be used as a candidate matcher in a system. Cupid (Madhavan, Bernstein, & Rahm, 2001), and Similarity Flooding (Melnik, Garcia-Molina, & Rahm, 2002) systems all use

graph matching to accomplish schema matching. COMA++ (Aumuellner et al., 2005) is a generalized framework for schema matching which was used in the Similarity Flooding system to combine the results from graph matching with non-graph-oriented candidate matchers. The difference between AbsMatcher and these previous systems is the generality of AbsMatcher and generating graphs based on semantics instead of data model metadata.

Previous graph-based schema matchers construct graphs based on the metadata for the data model. These systems have modules specifically built for translating different data models -- such as relational databases, XML, ontologies, or conceptual hierarchies -- into a graph form. This approach makes the graphs generated dependent on the thoroughness of the data set creator, and completely different graphs will be generated even when the same data set is stored in different data models. The advantage of these systems is that they leverage the effort of data set creators. For example considerable effort is generally put into the design phase of a relational database. Examples of using metadata would be creating a relationship between parent and child XML attributes or the fact that an attribute is a primary key in a relational database. The disadvantage of basing graphs on metadata is that derived relationships often have more to do with how data is stored and less about semantic relationships. The goal of the information sources we present in this paper is that they can be used regardless the data model and still generate semantic relationships.

The Semantic Matching (Giunchiglia & Shvaiko, 2003) system provides the closest comparison to AbsMatcher. It creates a graph based on metadata and a limited number of semantic relationships. Semantic Matching uses electronic thesauri in order to create overlap, mismatch, and general/specific relationships. The one issue with electronic thesauri is that they only work with words in their index and are unable to handle abbreviations or phrases which are often used to name attributes. AbsMatcher shares the same motivation as Semantic Matching, but uses the web to create semantic relatedness relationships and mines the data sets for statistical relatedness relationships. Additionally, ABSURDIST was designed with a general idea of relationships, which makes adding new forms of internal relationships a simple process.

We mine semantic relatedness using Yahoo query results (Bollegala et al., 2007) and Information Dependencies (Dalkilic & Robertson, 2000), however, neither has been used for schema matching.

## Mining ABSURDIST Graphs

The focus of this paper is on the process and relationships types used to create within-schema graphs. The unifying characteristic for all of the relationships we present is that they are not specific to a data model nor represent structural information. We present two categories of relationships; ones which use the entropy of the data and the second which uses Yahoo query results based on attribute names to measure semantic relatedness.

Mining an ABSURDIST graph is a two-stage process. The first is mining edges of the desired relationship type and the second is filtering out noisy edges. Filtering is done by using thresholds to eliminate mined edges whose values are not statistically significant enough to represent something beyond noise. For brevity's sake we limit the discussion of filtering to describing what the threshold checks for each relationship type.

## Entropy Relations

Entropy-based relationships use an information theoretic approach to look at the information content of attributes based on their data. The goal is to look for patterns which defy statistical trends and therefore are more likely to represent user intended relationships. We use the Information Dependency (InD) measure (Dalkilic & Robertson, 2000), which is based on Shannon's Entropy, to look at the information content of attributes. Entropy relationships require at least a sample of the data. The discussion of Entropy relationships includes approximate attribute entropy relationships, data set key relationships, and approximate functional dependencies.

Attribute entropy relationships measure the degree to which attributes resemble keys, which have a different value in each record in the data set for the attribute, or constants, which have the same value in each record in the data set for the attribute. An attribute being close to a key or constant is a unique statistical property which is a result of how data is created, e.g. an ISBN is purposefully defined as a key. Attributes in other data sets that are semantically similar are likely to also have similar statistical properties, so when keys or constants occur they are strong indicators of a likely match. In Table 1, *PersonName* is an example of a key and *Gender* is an example of an attribute that is almost a constant. Attribute Entropy relationships are filtered based on their entropy values and only kept when those values are either above (approximate key) or below (approximate constant) defined thresholds.

Data set keys are sets of attributes that together have a unique set of values for the data set and therefore form a key. Data set key relationships are created between pairs of attributes that together are close to forming, or do form, a data set key, but neither attribute is a key on its own. An example from Table 1 is that by combining *Address* and *Gender* a unique set of values exists for every row. The above example would result in an edge *PairKey*(*Address*, *Gender*) to be created in the graph. A data set key relationship creates undirected edges between attributes and uses the entropy value as the weight. Data set approximate key relationships are filtered using a threshold which defines how close to a primary key the attribute set must be.

The last Entropy relationship type uses Approximate Functional Dependencies (AFDs). AFDs are probabilistic rules,  $X \rightarrow Y$ , which measure the ability of values for a left hand side (LHS) attribute set to determine values of the right hand side (RHS) attribute set. The closer an AFD's measured value is to 1 the better the LHS is at predicting the

RHS. AbsMatcher’s use of AFDs as an information source for schema matching presents a novel application for AFDs. We use AFDs which have a single attribute LHS and a single attribute RHS in creating dependency relationships. By only using single attributes on each side the search space is reduced from  $2^{N+M}$  to  $N \times M$ . Though Functional Dependencies (FDs), which AFDs extend, have been used in schema matching, this is to our knowledge the first use of AFDs. Filtering dependency relationships uses a threshold which parameterizes the number of standard deviations that an AFD’s value must be away from the average value of all AFDs with the same LHS or RHS.

Table 1. A sample data set of people

PersonName	Address	Gender
Santa Claus	100 North Pole	Male
Mrs. Claus	100 North Pole	Female
Jeremy Engle	215 Lindley Hall	Male
Rob Goldstone	338 Psychology	Male

### Semantic Relationships

The premise behind using semantic relatedness is to create a relationship between attributes that are thematically related. A trivial example of this would be attributes for the first and last name of a person. If the respective attribute labels are “first” and “last” then a graph edge is created between these attributes based on the thematic association of these labels.

$$WebJaccard(P,Q) = \begin{cases} 0, & H(P \cap Q) < c \\ \frac{H(P \cap Q)}{H(P) + H(Q) - H(P \cap Q)}, & H(P \cap Q) \geq c \end{cases}$$

### Equation 2. WebJaccard Using Yahoo! Query Hits

One of the common tools for mining semantic relatedness is using WordNet (Fellbaum, 1998). Semantic relationships are found for two words according to their common membership in sets of synonyms, or synsets. Though WordNet has a large dictionary, the tools that rely on it fail when one of the two words is not in the dictionary. There are two common scenarios which increase the likelihood of WordNet failing. The first is that data sets commonly have domain specific terms that are less likely to be in a general dictionary like WordNet. The second problem is that data sets commonly have attribute names that are multiple words and/or use abbreviations. The tools making use of WordNet are not capable of handling either of these cases. In order to overcome these issues, we use tools that query the World Wide Web instead of WordNet.

We use the WWW as a source of information and adapt existing information retrieval measures to use the number of results from queries to compute similarity. Our semantic relatedness relationships are based on work by Bollegala et al. (2007) which queried Google and used the number of query results in computing existing similarity measures, however they only tested its use on single words.

The first step in mining semantic relatedness relationships is to tokenize attribute names. Attribute names are tokenized on occurrences of underscores and capital letters to create a multi-term query. Though not sophisticated these simple rules provide a best effort for creating multi-term queries. The relatedness of two attributes is then found using the WebJaccard measure as expressed in Equation 2, where  $P$  and  $Q$  are the multi-term queries for each attribute name. When available we also include the data set name as a query term to provide sense disambiguation. We use Yahoo as a source for querying because of the open availability of their search API. Yahoo semantic relatedness relationships are filtered to include edges only when the WebJaccard value is above a threshold.

### Mining the External Similarity Matrix

We use existing sources of external information, and therefore only discuss them briefly. External information directly compares attributes in the source and target schemas to look for similar attributes. While mining external similarity both attribute names and values from the data are used. We tested basic sources of external information to investigate the effects of combining internal and external information. Two sources of external similarity were prototyped and tested.

The first source of external similarity is string edit distance, which is a lexical comparison of attribute names. String edit distance represents a method for finding matches that are “low hanging fruit.” We use the jSimlib (<https://jsimlib.dev.java.net/>) library that normalizes string edit distance by the sum of the length of the two strings.

The second source of external similarity is cosine similarity, which is commonly used to compare the similarity of two free text documents. The similarity of the two documents is computed as the cosine value between the term frequency vectors for each document. For attribute-to-attribute schema matching, when the attributes contain text we treat them as documents and create term frequency vectors. The Lucene (<http://lucene.apache.org/java/docs/index.html>) framework was used to calculate the cosine similarity.

We tested three groups of data sets that vary in domain and size which come from the Illinois Semantic Integration Archive (ISIA) at <http://pages.cs.wisc.edu/~anhai/wisc-si-archive/>. The Courses data sets have listings of classes from four different universities, data sets sizes range from twelve to sixteen attributes. The second group of data sets is the Real Estate I (REI) data sets, which includes the homeseekers, nky, windermere, and yahoo data sets. Three of the data sets have sizes in the mid-thirties and the final one is in the sixties. The third group of data sets is the Real Estate Core (REC) data sets. REC data sets are the same as the REI data sets, but only include attributes that have a match in one of the other data sets. This reduced the number of attributes in the data sets to the low twenties, except one having twenty-eight attributes. The REC group is used to test the effects on matching performance when attributes with no matches are removed.

## Validation Experiments

The goals in evaluating AbsMatcher are to look at the performance of internal information by itself and whether the combination of internal and external information provides better cumulative performance. WebJaccard and Entropy internal relationships are meant to provide a baseline ability for schema matching so performance is judged first by whether consistent evidence of an ability to find matches, and second by looking for evidence that combining internal and external information is better than only external information. Finding evidence of these two points would indicate matches being found which internal information can uniquely contribute to finding. Performance is measured using recall. Many schema matching systems provide statistical matches, as opposed to absolute matching, so we present recall for correct matches made and for the correct match being one of the top 3 best matches. This more liberal scoring criterion provides information on whether AbsMatcher has partial information that could be leveraged by future improvements to the algorithm or information sources. Precision is not included because currently AbsMatcher returns a match for each attribute in the smaller of the two schemas. This means that the number of matches returned for a pair of schemas will remain constant no matter what other parameters change. This point is discussed further in future work.

For the initial tests, we first explored schema matching using only the previously described internal relationships, in three combinations. The Entropy combination includes attribute entropy, data set key, and dependency relationships. The WebJaccard results consist of semantic relatedness relationships based on Yahoo results. Finally, the “All” combination includes both Entropy and WebJaccard relationships.

We first look at the extent to which schemas can be matched using only the mined graphs for the two data sets. When using only this limited source of information a high level of performance cannot be expected. However, this limitation is useful in making an initial judgment of whether mined graphs contain useful information. For each group of data sets we select the best performing parameters and present the results in Figure 1 for all three combinations of internal relationships and all three groups of data sets.

Figure 1. Data sets by types of internal relationships

The first result to examine is AbsMatcher’s ability to find correct matches. Though the results in Figure 1 are relatively low in the context of overall performance of schema matching systems, the more appropriate context is as a source of matches which would be used in a broader system. In this context WebJaccard and Entropy relationships do show consistent ability to find at least some matches. The performance of the top 3 correspondences improves over just correct matches indicating that AbsMatcher can provide supporting evidence which would affirm or discredit correspondences from other candidate matchers. As seen in Figure 1 the top 3 correspondences can provide useful results on a third to half of all matches. The top 3 matches can be useful when considering that the weights of correspondences in the top 3 can often be very close.

The second result to examine is what sources or combinations of sources of internal relationships are the most effective. Neither the Entropy nor WebJaccard relationships were consistently the best between the different data set groups. Though neither was consistently the best, the positive result is that when combined in *All*, performance improved or matched the performance of the best performing source of internal relationships. The fact that adding sources of internal relationships does not degrade performance strengthens the potential that when other existing forms of internal relationships are added, performance could be improved.

For the second set of tests, we combined both internal and external sources of information. For some matches the information which best indicates the correct match is derived by comparing an attribute from each data set. In ABSURDIST this means the use of external information that is combined with internal information using Equation 1. In Equation 1 there are two weighting coefficients,  $\alpha$  and  $\beta$ , which determine the balance between external and internal information. The  $\alpha:\beta$  ratio represents the comparative weights of external:internal information. We tested AbsMatcher with different ratios, where each represented a different balance between external and internal information. Figure 2 presents results for a representative three of those ratios. The 0:1 data point represents using only internal information, which corresponds with the results in Figure 1. The 1:0 data point represents only using external information. The 3:1 data point tested the effort to combine the use of internal and external information. The goal in this evaluation is to determine whether combining internal and external information has a benefit over just using external similarity.

Figure 2 provides evidence that combining internal and external information can for some data sets provide better results than either one in isolation. Though the improvement for Courses and REC data sets is small the fact that it occurs for both supports the claim that internal structure can improve matching performance. It must be remembered that the results for Courses and REC represent the average performance across twelve different pairs of

data sets matched. The ability of internal structure to find correct matches and the additional beneficial effect that it can have when combined with external similarity indicates that internal structure is to some extent finding both unique and useful information for schema matching.

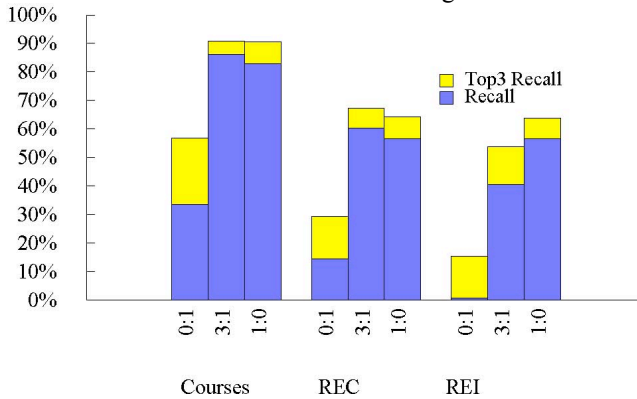

Figure 2. Data Sets by Ext:Int Ratio

The REI data sets do not benefit from internal information. This could in part be due to the fact that REI alignments leave more attributes unmatched. The REC data sets are versions of the REI data sets where attributes with no matches removed. They average 15.5 correct matches between a pair of data sets, meaning that on average half of the attributes in a data set for REI are not being matched, yet information is still mined for them. Courses and REC have a different scale yet both show similar trends in the ability to find correct matches. The only difference between REC and REI data sets is the existence of unmatched attributes, so the difference in performance can be unambiguously attributed to this. This indicates that information which indicates invalid matches could be an important feature to add to AbsMatcher.

## Conclusions

The goal in developing AbsMatcher was to create a schema matching system that used a graph based approach, but was not reliant on a specific data model as a source of information. To this end, we propose Entropy and WebJaccard relationships which can be used even when more descriptive metadata, such as XML or metadata from a relational database, is unavailable. Additionally, these relationships emphasize non-structural relationships in an effort to create graphs which are more conceptual in nature. We then tested these graphs using the ABSURDIST graph matching system. ABSURDIST is ideally suited because of its ability to accept graphs with a wide variety of forms (weighted, unweighted, directed, undirected, labeled, and unlabeled) and ABSURDIST was designed specifically with the idea of combining internal and external information together.

The goals in testing AbsMatcher were to look at whether Entropy and WebJaccard relationships are useful for schema matching on their own and whether they have benefits when

combined with external similarity. Experiments demonstrated that to varying extents the tested relationships are able to accomplish both of the goals. The results presented in this paper were aggregated over multiple individual experiments. The additive benefit of our sources of internal structure is important because it argues that internal structure holds unique information for finding correspondences.

These results were based on aggregating results from a number of matching pairs. It is important to note that there were outliers on both the positive and negative side. This is a common problem in schema matching, where sources of information perform well in certain scenarios and poorly in others. It is this point which motivated the approach of aggregating many disparate measures of similarity. This leads to the idea that by adding new information sources into AbsMatcher we can improve even beyond the baselines presented in this work.

## Abstract

Language games are tools to model some aspects of the social aspects of language and communication. Our approach aims to cover the ground between the elementary naming game and the complex models for social use, for the growth of possibly redundant community and personal lexicons. It uses weighted lists of words for the personal lexicon, probabilistic choice as a selection mechanism and lateral inhibition as the weight update scheme. The results demonstrate that the model is a generalization of the elementary naming game, and it provides a good picture of how big a lexicon agents use for the task, how this size can be controlled using the model parameters and a possible way of explaining how synonymy is kept under control.

**Keywords:** emergence; stochastic naming game; synonymy; language game; semiotic dynamics

## Introduction

Language is a social phenomenon. Although there are uses to language that are not social, and there are modes of social interaction other than language use, a very clear and salient function of language is collaboration and communication among individuals in a population. However, computational studies on language until mid-90s had been more focused on modelling the individual capacities in language acquisition and performance, and did not provide much insight into what language might look like from the viewpoint of a population of language users.

A new generation of research addresses this problem by investigating language as it is produced, used and propagated in a community of language users. A fruitful approach has been to see language as a complex adaptive system. What this basically implies is that only at the population level can we adequately characterize language use, and only by taking into account that language is constantly reshaped by its users. How an individual uses language and how the population generally uses language can and do affect one another. In short, the claim is that some features of language do not stem directly from linguistic or cognitive capacity but from a society of interacting agents. One such feature is the lexicon and its emergence as a common vocabulary of a community.

This new branch of research proved to be quite fertile and produced a large body of work. One path of this research is exemplified by Kirby, who approaches language as “the result of an interaction between three complex adaptive systems that operate on different timescales: the timescale of biological evolution (phylogeny), the timescale of individual learning (ontogeny) and the timescale of language change (glotogeny)” (Kirby, 2002).

Another avenue is that of Steels, who also sees language as a complex adaptive system (Steels, 2000). His work started as an investigation of semiotic dynamics in simple language games played among artificial autonomous agents, and eventually led to an elaborate construction grammar formalism called Fluid Construction Grammar (FCG) for simulating a population of language users who bootstrap their own language (Steels & De Beule, 2006).

Steels’s original models were kept elementary to make them easier to analyze. FCG, however, is quite comprehensive. We feel that there is much to be discovered at various levels of complexity, from the trivial, original “naming games” to the full-blown grammatical complexity of FCG. For example, one feature, the negotiation for names of objects, remains simple: if two agents agree on a name, they agree to adopt that one and discard the alternatives, therefore their lexicons are nonredundant if and when convergence arises. Since complex adaptive systems are very unpredictable in terms of how things might change if we change the structure of interactions, we think it is important that we explore much of the degrees of freedom as we can, trying to characterize the emerging structures and phenomena at each level of complexity added.

In that spirit this paper presents an investigation of a naming game among artificial agents with a slightly more complex, weight-based lexicon scheme rather than the original, and a consequent probabilistic word selection scheme. Our focus here is on the tension between lexicon growth and synonymy in the population. The paper first describes the original naming game. Our extension is described next. Our experiments and results are then presented.

## The Original Naming Game

The naming game focuses on vocabulary formation and agreement in a population. The agents try to bootstrap a vocabulary of (proper) nouns that they associate with the objects they try to name (De Vylder & Tuyls, 2006). It is assumed that the agents already know how to send and receive signals, and possess the motivation to do so. It is further assumed that the objects are uniquely identifiable by all agents, so feature sets as in the discrimination game are not employed.<sup>1</sup> The final assumption is that the agents have an independent channel of communication (such as pointing) through which they can reveal their word-object pairings to each other.

<sup>1</sup>Note that it is perfectly possible to combine the two games, as done by Steels (2003).

Formally, the game involves a set of objects  $O = \{o_1, \dots, o_m\}$ , and a set of agents  $A = \{\alpha_1, \dots, \alpha_n\}$ . Each agent  $\alpha_j$  possesses a lexicon  $L_{\alpha_j} = \{E_{\alpha_j,1}, \dots, E_{\alpha_j,k}\}$  where  $k \leq m$ , and each entry in the lexicon consists of a list of words associated with the object  $o_i$ ,  $E_{\alpha_j,i} = \{w_{i,1}, \dots, w_{i,q}\}$ . All agents also possess a function that maps from the global set of objects to the agent's repertoire of words ( $\phi_a : O \mapsto E_{\alpha_j}$ ).<sup>2</sup> Therefore, an agent is characterized only by its lexicon. A game consists of these steps:

1. Two agents are chosen, one as the hearer ( $\alpha_h$ ) and one as the speaker ( $\alpha_s$ ).
2. The speaker chooses an object ( $o_i$ ) to refer to, and points to it (i.e. makes his choice explicit without using the system we try to bootstrap)
3. The speaker chooses a word in the lexicon for the object ( $\phi(o_i)$ ), or creates one if necessary.
4. The hearer tries to decode the word into the object being referred to ( $w_{k,j} \in E_{h,k}$ ), and uses the independent channel to signal this to the other (e.g. points to it).
5. The speaker agent assesses if the response complies with its lexicon, and makes the hearer aware of this assessment. Agents update their lexicons accordingly.<sup>3</sup>
6. If all agents have identical lexicons, the game stops.

Each game results in success ( $\exists w_{i,n} \mid w_{i,n} = \phi_s(o_i); w_{i,n} \in E_{h,k}$ ) or failure ( $\nexists w_{i,n} \mid w_{i,n} = \phi_s(o_i); w_{i,n} \in E_{h,k}$ ). Upon success, both agents purge their entries for that object of all but the successful word. Otherwise, the hearer adds the new word to its entry of the object, or creates one if necessary. There is no intermediary between a word exchange being successful and a word dominating an agent's lexical inventory for an object; it operates on an all-or-nothing basis.

## The Stochastic Naming Game

The current proposal has four key differences from the original model:

1. **Lexical entries:** The lexical entries in the original model are simple lists of words. The proposed model implements lexical entries as *weighted* lists of words, updated upon interactions. This allows a graded behaviour in which words are preferred, and constitutes a more realistic situation in which convergence should be achieved, compared to plain lists.

More formally, for each agent  $\alpha_i$ , an additional value function  $\theta_{\alpha_i}$  is added to retrieve the weight:

$$\theta_{\alpha_i} : w_{k,q} \mapsto \mathbb{R}$$

<sup>2</sup>The function  $\phi_a$  returns  $E_a$  which is a list of *all* the words used for an object from the perspective on agent  $a$ , and not the most successful word.

<sup>3</sup>Note that this assessment does not require global knowledge; it is a local decision determined solely by agent's lexicon and its assessment of the interaction with another agent.

Basically, this is just a lookup for the weight associated with the word in an agent's lexicon. By adding this, the characterization of an agent is a tuple of the lexicon and  $\alpha_i$ , instead of only the lexicon as in the original game:

$$\alpha_i : \langle L_{\alpha_i}, \theta_{\alpha_i} \rangle$$

2. **Word selection:** The word selection scheme in the original model simply picks a word from the set of words present in the lexicon. It does not specify how to pick the word. Although there are some suggestions for schemes that optimize convergence (Baronchelli, Dall'Asta, Barrat, & Loreto, 2005), there is no set practice. The proposed model has a specific scheme that makes a weighted, probabilistic choice of the word to use at each round. This introduces a number of advantages. First, it introduces some noise by not guaranteeing the leading word to be chosen at every round. Some level of noise is often beneficial to convergence in dynamical systems. Second, it is a more realistic scheme, especially when top words have similar scores. Third, it makes the system more fault tolerant by minimizing the impact of successful rounds caused by words that are ultimately going to fail and of unsuccessful rounds caused by words that are ultimately going to succeed.

Formally, the function  $\phi_{\alpha_i}$  is changed to return a word by a weighted random choice. To this end, we first define a probability distribution  $P$  where:

$$P(w_{k,q}) = \frac{\theta_{\alpha_i}(w_{k,q})}{\sum_y \theta_{\alpha_i}(w_{k,y})} \quad (1)$$

Subsequently, the word  $\phi_{\alpha_i}$ 's returns can be characterized as a random variable  $X$  with distribution  $P$ .

$$\phi_{\alpha_i}(o_k) = X \quad (2)$$

for which:

$$X \sim P; X \in E_{\alpha_i,k} \quad (3)$$

3. **Parameters:** As a consequence of the update scheme, there are more parameters in this version of the game than the original one. In particular, three  $\delta$ -values ( $\delta_{\text{success}}$ ,  $\delta_{\text{failure}}$  and  $\delta_{\text{inhibition}}$ ) are added for use in updating the lexicon, whose precise roles are elaborated in the following paragraphs. Additionally, two  $\theta$ -values ( $\theta_{\text{max}}$  and  $\theta_{\text{min}}$ ) are added as the maximum and minimum values for any score in the lexicon.
4. **Update scheme:** The agents in the proposed model no longer discard the competing synonyms (i.e. the other words in the lexical entry) upon a successful interaction. Instead, the agents update the weights of their lexical entries for the object upon every interaction.

A function  $\omega$  is added to each agent which returns a new, updated weight function after an interaction:

$$\omega : \theta_{\alpha_i} \mapsto \theta'_{\alpha_i}$$

This function  $\omega$  adds or subtracts from scores some predefined  $\delta_{\text{success}}$ ,  $\delta_{\text{failure}}$  and  $\delta_{\text{inhibition}}$ , based on lateral inhibition (Lenaerts, Jansen, Tuyls, & De Vylder, 2005). Upon a successful interaction with word  $w_{k,p}$ , this function returns a new function  $\theta'_{\alpha_i}$  and optionally modifies the lexicon of the agent. The modification is that if the resulting score for a word is less than a predefined value  $\theta_{\min}$ , that word is removed from the lexical item for that object. Also, there is a set limit  $\theta_{\max}$  on how large the weight may grow, at which point no weight is added. More formally,  $\omega$  returns the following upon success:

$$\theta'_{\alpha_i}(w_{k,q}) = \begin{cases} \min(\theta_{\alpha_i}(w_{k,q}) + \delta_{\text{success}}, \theta_{\max}) & \text{if } q = p \\ \theta_{\alpha_i}(w_{k,q}) - \delta_{\text{inhibition}} & \text{if } q \neq p \end{cases} \quad (4)$$

where

$$\omega(\theta_{\alpha_i})(w_{k,q}) = \theta'_{\alpha_i}(w_{k,q}) \quad (5)$$

and the following upon failure:

$$\theta'_{\alpha_i}(w_{k,q}) = \begin{cases} \theta_{\alpha_i}(w_{k,q}) - \delta_{\text{failure}} & \text{if } q = p \end{cases} \quad (6)$$

where

$$\omega(\theta_{\alpha_i})(w_{k,q}) = \theta'_{\alpha_i}(w_{k,q}) \quad (7)$$

It then modifies the lexicon as follows:

$$L'_a = (L_a / E_{\alpha_i,k}) \cup E'_{\alpha_i,k} \quad (8)$$

where

$$E'_{\alpha_i,k} = \{w | \theta'_{\alpha_i}(w) \geq \theta_{\min}; \forall w \in E_{\alpha_i,k}\} \quad (9)$$

With this scheme, it is possible to mimick the original model of Steels by using  $\delta_{\text{success}}$ ,  $\delta_{\text{failure}}$  and  $\delta_{\text{inhibition}}$ , values of 10.0, 0.0, 10.0 respectively. Informally, this makes sure that success always maximizes the weight of a word and always eliminates other synonyms, and that failure does not have an impact on the weights. This, in effect, is the behaviour of the original model.

## Methodology

Each parameter set, that is, a tuple of  $(\delta_{\text{success}}, \delta_{\text{failure}}, \delta_{\text{inhibition}})$  was considered a unique case, and the simulation was run 50 times for each case, using 50 agents and 2 objects.<sup>4</sup> The model is considered to have reached convergence when there is 100% success over a success window of 100 rounds or when it reaches the limit for number of rounds,

<sup>4</sup>Originally, up to 5 objects were going to be tested but as far as we could tell from the pilots, this did not provide any interesting insights that 2 objects did not provide for our intentions. Since more objects dramatically increased the simulation time and analysis, the simulations were run using just 2 objects.

which is chosen as 500,000 for this study. This is the product of the number of agents and the number of objects, making it very likely that all agents will have taken part in at least one interaction regarding each object, making the success window more meaningful. Also, note that our concept of “convergence” is different from what is used in the literature. It does not mean that all lexicons are identical, it simply means that all lexicons are “similar enough” for the intended purpose, “similar enough” defined as above. This way, it is possible to see if synonyms can exist at the point where the success of any given communication is almost certain.

The model was run with various  $\delta$  parameters. The method of choosing them was fixing a set of ratios in the form  $\delta_{\text{failure}}:\delta_{\text{success}}$  and  $\delta_{\text{inhibition}}:\delta_{\text{failure}}$ , and then producing the actual  $\delta$  values by choosing a value for  $\delta_{\text{success}}$  and calculating the rest using that chosen value.

There were five values for  $\delta_{\text{success}}$  denoted by the set  $\{1.0, 3.0, 5.0, 8.0, 10.0\}$ . For the ratio  $\delta_{\text{failure}}:\delta_{\text{success}}$ , the ratios picked were  $0.0:1.0$ ,  $0.5:1.0$ ,  $1.0:1.0$ ,  $1.5:1.0$  and  $2.0:1.0$ . The ratios used for  $\delta_{\text{inhibition}}:\delta_{\text{failure}}$  were  $0.0:1.0$ ,  $0.5:1.0$ ,  $1.0:1.0$  and  $1.5:1.0$ . If both  $\delta_{\text{failure}}$  and  $\delta_{\text{inhibition}}$  are 0.0 for a case, it is not possible to calculate  $\delta_{\text{inhibition}}$  from the ratio, so for those cases  $\delta_{\text{inhibition}}$  was set to  $\delta_{\min}$  to provide some negative feedback to the model so that it can converge.

The cases in which  $\delta_{\text{inhibition}} > 1.25 \times \delta_{\text{failure}}$  are excluded since this corresponds to the vicinity of the original model and our aim is at exploring different areas of the parameter space. Only the case represented by the tuple (10.0, 0.0, 10.0) is included for comparison since it exactly corresponds to the behaviour of the original model.

The values  $\delta_{\max}$  and  $\delta_{\min}$  were fixed at 10.0 and 0.1, respectively.

## Results

The results make it clear that choosing the original model parameters is not the only viable option for our model. In fact, of the total of 70 parameter sets, only 16 performed worse than the original model parameters in terms of time of convergence.

In the following, we will present the results on how model parameters interact. We are not going to present all the results because of space considerations. The analysis will be made both in terms of time of convergence, relative convergence rate and lexicon size. Relative convergence rate is defined as the time it takes for the system to converge once the average size of the lexicons are maximized (this time point of maximum lexicon size is represented as  $t_{\max}$  in the simulation). Time of convergence is the total number of rounds from the start of the simulation to converge. Lexicon size is the total number of words in an agent’s lexicon.

The results confirm that  $\delta_{\text{inhibition}}$  functions as a way to shrink the lexicon to have a greater relative convergence rate, that is, to reduce the time it takes for the convergence to be reached once  $t_{\max}$  is reached. The functions of  $\delta_{\text{success}}$  and  $\delta_{\text{failure}}$  are straightforward as positive and negative feedback,

respectively.

### Interaction of $\delta_{\text{success}}$ and $\delta_{\text{failure}}$

The interaction of  $\delta_{\text{success}}$  and  $\delta_{\text{failure}}$  is easier to explain. These are directly counteracting forces, and therefore if  $\delta_{\text{failure}}$  is greater than  $\delta_{\text{success}}$ , the system fails to converge save a few exceptional cases. This is not surprising since the system, especially before  $t_{\text{max}}$ , mostly learns by failing the exchanges therefore learning new words. If the impact of failure is higher than that of success, then it becomes really difficult to disseminate some words to all agents so that later they can converge to that word. Basically, they all get discarded before their commonality causes them to become successful across many interactions.

This effect is further compounded by non-zero  $\delta_{\text{inhibition}}$  values, which, upon occasional initial success, acts effectively as a failure penalty for all non-successful words, further decreasing the number of common words. However, there are a few cases where models with  $\delta_{\text{success}} \leq \delta_{\text{failure}}$  actually converge to a common vocabulary. In a closer look, there are two conditions under which convergence occurs. One is when all  $\delta$  values are quite small, so that success can accumulate to save at least a couple of alternatives for a word from being discarded. In contrast, larger values mean that one or two failures guarantee discarding of a word, and the number of successes have little impact on this since the scores stop increasing once they hit the upper limit of  $\theta_{\text{max}}$ . In other words, small  $\delta$  values give the agents some room to keep a greater amount of interaction history, and therefore they become better at evolving their lexicon in tandem with the population trends.

The other case is where  $\delta_{\text{inhibition}} = 0$ . This leaves only  $\delta_{\text{success}}$  and  $\delta_{\text{failure}}$  to battle each other, and occasionally leaves room for convergence unless  $\delta_{\text{failure}} < 1.25 \times \delta_{\text{success}}$  or  $\delta_{\text{failure}} > 0.75 \times \theta_{\text{max}}$ . This is equivalent to saying that  $\delta_{\text{failure}}$  should leave room for at least two failures until a previously successful word is discarded, i.e. the word is not discarded right away upon failure. Since there is no other mechanism to decrease the weights, this allows some dissemination with a bit of luck.

### Interplay of $\delta_{\text{failure}}$ and $\delta_{\text{inhibition}}$

The key to the relationship between  $\delta_{\text{failure}}$  and  $\delta_{\text{inhibition}}$  is that they can replace one another with slightly different effects.  $\delta_{\text{inhibition}}$  is a stronger form of  $\delta_{\text{failure}}$  which affects not only one but almost all (save the successful one for the round) words associated with an object each round. In fact, this is why the original model, with the parameter set (10.0,0.0,10.0), can function without  $\delta_{\text{failure}}$ .

This great impact of  $\delta_{\text{inhibition}}$  effectively shrinks the lexicon, and this makes the  $t_{\text{max}}$  smaller but also reduces the relative convergence rate. The reason is that at  $t_{\text{max}}$  there are less alternatives that the system may converge to for an object. This means that any perturbation in the system, such as an interaction where the speaker agent prefers a not-to-be-successful word, needs to be counteracted so that the sys-

tem returns to moving towards the word it originally had been converging to.

In contrast, a big lexicon at  $t_{\text{max}}$  means there are many alternatives, and a disturbance need not be fully counteracted; the system might just converge to another word-object pairing that is salient in the population. Accordingly, our results show that a relatively large  $\delta_{\text{failure}}$  combined with a small  $\delta_{\text{inhibition}}$  produces the fastest convergences, with a large lexicon at  $t_{\text{max}}$  since  $\delta_{\text{inhibition}}$  does not get a chance to shrink the lexicons as much. After that, applications of  $\delta_{\text{inhibition}}$  mostly help convergence to the pairings that will ultimately dominate.

### Lexicon Size

Lexicon size can be used as an indicator of game dynamics. Since it is not a parameter but a quantity that manifests itself during the game, it is difficult to test. Nonetheless, there are some clear tendencies that are important.

Figure 1: A log-log plot of time of convergence versus average lexicon size for all convergent parameter sets.

The first such tendency is between the time of convergence and average lexicon size at  $t_{\text{max}}$ . It turns out that there is a direct proportion between the logarithm of average lexicon size and the logarithm of the time of convergence. Roughly, this means the bigger the lexicon size at  $t_{\text{max}}$ , the longer the convergence takes. This indicates that the time of convergence and relative convergence rate are not necessarily correlated. Although parameter sets that produce bigger lexicons converge fast after  $t_{\text{max}}$ , they also take longer to put together (i.e. to reach  $t_{\text{max}}$ ) and therefore do not necessarily represent the sets that allow convergence in the minimum number of rounds.

The second tendency is best represented by a plot of rounds (i.e. the time series) versus average lexicon size (see Figure 2). The plots fork into two fairly distinct groups, and all of the plots with bigger lexicon size belong to parameter sets in

Figure 2: A log-log plot of time of convergence versus average lexicon size for all convergent parameter sets.

which  $\delta_{\text{inhibition}} \leq 0.1$ . This demonstrates that  $\delta_{\text{inhibition}}$  has the function of shrinking the lexicon. In the figure, it is apparent that for all cases, there is a peak (whose position in time we call  $t_{\text{max}}$ ) after which convergence is achieved (which is also a finding encountered in the original naming game literature). For very small values of  $\delta_{\text{inhibition}}$ , this peak is more or less identical to the time point at which convergence is achieved. In other words,  $\delta_{\text{inhibition}}$  shrunk the lexicon so little that the system converged with a larger average lexicon size. In other words, on average, at least some of the objects have more than one alternative word associated with them although the success rate climbed to 100% over a window of 100 rounds. This may hold an insight into how synonymy may be controlled in human languages.<sup>5</sup> In our model, synonymy does not necessarily hinder mutual communication. In more complex models, if they have analogous tendencies at all, it might be beneficial for large populations to be able to communicate very successfully without a full agreement on which object is referred to by which word.

This also suggests that memory requirement for this task is not necessarily determined by the amount of memory available to the agents but by the type of learning a population adopts (or is born with), and the fact that the task is undertaken by a population. Even if they had very big memory capacities (i.e. more than they need to use), part of this capacity would be redundant because of the decay in weights of the unsuccessful or non-successful words would get them discarded from the lexicon.<sup>6</sup> However, parameter sets with small  $\delta_{\text{inhibition}}$  (similar to those in the top partition of Figure

<sup>5</sup>Of course, these are results from a single study with very strict and narrow boundaries in terms of what it deems possible “language”; hence the verb *inspiration* instead of *insight*.

<sup>6</sup>Non-successful words are those whose weights are decremented not because they failed, as unsuccessful words’ are, but because some other word succeeded and  $\delta_{\text{inhibition}}$  was nonzero.

2) can conceivably make use of more memory than available here. This indicates that  $\delta_{\text{inhibition}}$  is a way of controlling the memory use of the population for the task.

## Conclusion

We believe that this line of research is quite relevant to cognitive science and to study of linguistics in general. Although the communicative capacities of our agents are very limited in that they do not contain any capabilities for syntax, discourse etc., our results are somewhat reminiscent of Elman’s work on importance of starting with a small working memory in language acquisition (1993). Our model shows that using a reasonable  $\delta_{\text{inhibition}}$  actually facilitates learning although it does reduce the amount of memory used for the task. In our model, it is not even about the availability of more memory; the memory simply does not need to be larger.

This would not make sense for learning static knowledge where having as many samples as possible at any point in time is the goal. But such a finding is arguably not as surprising for learning population-generated knowledge which may change from one point in time to the other. The memory constraint comes not from the learners but from the nature of what is learned, how it changes and the relationship between the learners and what is learned. The constraint is not on any given specific lexicon but on the “lexicon of the population”. In other words, this effect does not really stem from the agents themselves but from the fact that what they are trying to agree on is malleable by this very process of negotiation.

It also confirms the previous findings in the semiotic dynamics literature that the sudden popularity of a word upon coinage is an illusion. The conclusion from this literature, including this study, is that there are often many competing synonyms for the same concept, and, after a word hits a popularity threshold, the system falls into a spiral of making the most popular word even more popular. This is even true in a model such as ours where there is a net negative feedback,  $\delta_{\text{failure}}$ , and varying ratios of the strength of other mechanisms of pressure, unlike other models in the literature. There are grey areas where words are neither in disuse nor popular, and they need not become either unused or popular for convergence to occur.

Finally, these simulations can give us an idea about controlling synonymy. Our model does not necessarily have much pressure towards eliminating synonymy; it just works by looking at how successful communications are. The only pressure on synonymy is controlled by  $\delta_{\text{inhibition}}$ . Such inhibition effectively means that success of one word for an object is the failure of others for that same object. However, unlike simpler models in the literature, synonymy can be preserved while still achieving very high communicative success, though only when using low  $\delta_{\text{inhibition}}$  values and with the side effect of having a larger vocabulary to hold the synonyms. The fact that the model also converges with multiple synonyms for an object both when  $\delta_{\text{inhibition}} \neq 0$  and  $\delta_{\text{inhibition}} = 0$  demonstrates that this ability to maintain syn-

onymy is not about the existence but the magnitude of the pressure towards no synonymy, as exerted by  $\delta_{\text{inhibition}}$ .

The main lesson to learn from this is that synonyms are eliminated only if they seriously hinder communicative success, and they are eliminated more or less globally when they do. It would be more feasible to use synonyms if the agents had contextual cues as humans do to constrain the search space, but synonymy can be preserved even without this additional information. If the ambiguity they bring is manageable within the task we are trying to achieve with our language (and these models demonstrate that there really exist such tasks), they need not be eliminated. This is analogous to the difference between colloquial text and legislation in terms of ambiguity, which arguably has something to do with what the population of language users intend to use the language for. What we are trying to achieve in such tasks is not necessarily identical lexicons but communicative success, and what this means has to be defined on a per-case basis.

Figure 2 shows that we pay the price for synonymy if we let it loose: it causes either late convergence or no convergence. The natural equivalent of these results are open to discussion. Our suggestion is that they seem to indicate keeping it low among a community while not completely eliminating it seems to be a way of balancing expressivity and communicative success. If either aspect begins to dominate, it will be equivalent to widespread synonymy and no synonymy, respectively. The conclusion that these may be counteracting forces are shown by synonym's relation to number of iterations, rather than assumed cognitively.

# Learning Unattested Languages

Sara Finley (finleys@elmhurst.edu)

Department of Psychology, Elmhurst College  
Elmhurst, IL, 60126, USA

## Abstract

This paper demonstrates the role of morphological alternations in learning novel phonotactic patterns. In an artificial grammar learning task, adult learners were exposed to a phonotactic pattern in which the first and last consonant agreed in voicing. Long-distance phonotactics encoded as strictly piecewise languages suggest that first-last phonotactic patterns should be unattested in natural language. However, recent theories of morphologically induced phonological patterns predict that long-distance agreement between the first and last consonant of a word can occur when the agreement is induced as a morphological alternation. The results of two experiments support the prediction that first-last harmony patterns are more easily learned when morphological cues to the pattern are present. Participants only learned the first-last pattern when presented as a morphological alternation.

**Keywords:** statistical learning, phonotactics, morphology.

## Introduction

One of the major goals of generative linguistics is to explain the nature of language in terms of computational constraints on the cognitive capacity for human languages. Computational models of phonotactic patterns work to understand the restrictions that underlie the set of patterns that are possible in natural language and the set of patterns that are not possible. Recent work has argued that phonotactic patterns, defined as constraints on the co-occurrence of different sounds within a word, are subject to a very specific set of computational constraints (Heinz, 2007, 2011a, 2011b). In particular, it has been demonstrated that long-distance phonotactic patterns derived from consonant harmony can be simulated using strictly piecewise languages (Heinz, 2010; Heinz & Rogers, 2010; Rogers et al., 2010), a subset of regular languages.

Computational models of phonotactic patterns raise three important questions for a theory of the cognitive science of language. First, is there a correlation between the patterns that are learnable and the patterns that can be generated by computational models? There is a prediction that any long-distance consonant agreement pattern that does not fall within the set of strictly piecewise languages should not be learnable. Second, do computational models of phonotactic patterns capture the intricacies of generative models of phonological representations? If morphological and syntactic constructions require more complex computational machinery to generate, then there is a question of whether patterns at the interface between phonology and morphology, and phonology and syntax are subject to the same computational constraints as purely phonotactic patterns (Heinz & Idsardi, 2011). Third, is there a way to

reconcile apparent exceptions to general tendencies linguistic typology? Linguistic tendencies are typically proposed as opposed to universals because almost any ‘universal’ has exceptions (Evans & Levinson, 2009).

These questions are particularly salient for a specific, hypothetical phonotactic pattern: first-last agreement (Lai, 2012). For the purposes of this paper, a first-last agreement pattern is any phonotactic pattern in which the first and last segment in a word must agree in terms of some phonological feature. For example, a first-last consonant voicing pattern requires that the first and the last consonant in a word share the same value for the feature [Voice]. In such a pattern, the word [boteg] would be a possible word because the first consonant ([b]) and the last consonant ([g]) are voiced, even though the medial consonant ([t]) is voiceless. However, \*[boget] would not be a possible word because the first consonant ([b]) is voiced and the final consonant ([t]) is voiceless.

First-last patterns are said to be unattested in natural language (Lai, 2012). One possible explanation for the failure to find a true case of first-last agreement is that such patterns can not be generated with a strictly piecewise grammar (Heinz & Rogers, 2010). If long-distance phonotactic patterns must be generated with a strictly piecewise grammar, patterns that fall outside of the cognitive constraints on phonological patterns may not be learnable.

While purely phonotactic first-last patterns have not been described in natural languages, there are some possible cases of first-last agreement patterns when morphology is considered. A morphologically controlled phonological alternation is any sound pattern that occurs only in the presence of a specific morphological environment. For example, the alternation between /o/ and /e/ in ‘goose’ vs. ‘geese’ is induced by the alternation between singular and plural. Such morphologically controlled patterns may manifest as a first-last agreement pattern. For example, in Lokaa, a Benue-Congo language spoken in Nigeria, the future tense is marked with a low tone on the final syllable and a prefix containing a low tone (e.g., [nà-à-fúkà] ‘you will gather’). In this case, the first and last vowels of a word must agree in tone, but only in the future tense. (Iwara, Akinlabi, & Truckenbrodt, 2003). Finley (2009) accounts for this morphological alternation using morpheme-specific constraints that target specific edges of the word. Finley’s analysis suggests that morphologically controlled patterns, also referred to as ‘featural affixation’, are subject to different constraints than purely phonotactic patterns. The possibility that featural affixation can target the first and last element of a word leads to the prediction that long-distance

patterns that cannot be generated with a strictly piecewise model of phonotactics may be generated at the interface between phonology and morphology.

There are three reasons to believe that phonotactic patterns and morphologically controlled phonological patterns are subject to different representational and learning constraints. First, as discussed above, the typological restrictions on morphologically controlled patterns tends to be more open than the restrictions placed on phonotactic patterns (Finley, 2009). Second, infants appear to learn phonotactic patterns earlier than morphologically controlled phonological patterns (Jusczyk, Friederici, Wessels, Svenkerund, & Jusczyk, 1993). Third, Lai (2012) demonstrated that adult learners are worse at learning a first-last consonant agreement pattern than a typical consonant harmony pattern that targeted all relevant segments of the word.

The problem with understanding the difference between morphological and phonotactic patterns in terms of representation and typology is that there are reasons why the typology of phonotactic constraints may be different from the typology of morphologically controlled phonological patterns. For example, the lack of existence of a first-last phonotactic agreement pattern may reflect constraints on phonotactic representations, or it could simply reflect an accidental gap. In addition, phonotactic patterns may be learned faster than morphologically controlled phonological patterns because phonotactic patterns apply to a large range of words, while morphologically controlled patterns only apply to specific morphological environments. In this case, the infant must learn both the phonological pattern, but also the morphological environment.

One possible way to understand the relationship between typological and computational constraints on long-distance phonotactic patterns is to explore the existence of learning biases for long-distance patterns. Previous research suggests that first-last phonotactic agreement patterns may not be learnable (Lai, 2012). While Onnis, Monahan, Richmond, and Chater (2005) showed learning of first-last phonotactics, this pattern was based on syllables, rather than features, and therefore may be subject to different constraints. However, there is a question of whether adults may be able to learn first-last agreement patterns if they are presented as a morphologically controlled phonological alternation. In an artificial grammar learning task, it is possible to compare learners with the same language backgrounds (American English) with two languages that are minimally different (phonotactic first-last agreement vs. morphologically controlled first-last agreement). If morphologically controlled patterns are subject to different constraints on learning and representation, one should expect that in the case of first-last agreement patterns, morphologically controlled patterns should be easier to learn than a phonotactic agreement pattern. This prediction is particularly interesting because it goes against the general findings that phonotactic patterns are learned before morphological patterns. In an artificial grammar learning

paradigm, adult participants were exposed to a first-last agreement pattern that was induced either as a morphological alternation or as a phonotactic pattern. Participants who were exposed to the pattern as a phonotactic pattern did not differ significantly from chance or control participants. This is similar to Lai's (2012) results, which showed that an unattested first-last agreement pattern is less easily learnable than a version of an attested consonant harmony pattern. However in the study reported here, participants were exposed only to the first-last agreement pattern, either presented as a phonotactic constraints or as part of a morphological alternation.

## Experiment 1

### Participants

All participants were adult native speakers of English with no previous exposure to a language involving first-last agreement or consonant harmony. Forty-six University of Rochester undergraduate students and affiliates and were paid \$10 for their participation. Two additional participants were from the Elmhurst College Psychology Department Human Subject Pool, and were given extra course credit for their participation.

### Design

Participants were trained on a first-last voicing agreement pattern via auditory exposure. In this pattern, the first and the last consonants of every word agreed in voicing. All words were of the form CVCVC, where C refers to stop consonants drawn from the set /p, t, k, b, d, g/, and V refers to vowels drawn from the set /i, e, o, u, a/. The first and last consonants were either both voiced /b, d, g/ or both voiceless /p, t, k/, with no restriction on the voicing of the medial consonant.

Participants in the Morphological Training condition were exposed to 24 pairs of CVCVC items (repeated five times each) in which the first CVCVC item contained voiceless stops in the first and last positions and the second item contained voiced consonants in the first and last positions (e.g., /kidat gidad/ and /topak dopag/). Participants in the Morphological Training condition were told that they were listening to a novel language, and that they would hear pairs of words, the first of which was a 'singular' form and the second of which was a 'plural' form. The use of 'singular' and 'plural' labels was designed to create the effect of a morphologically controlled alternation. Because adult English speakers are familiar with the distinction between singular and plural, it was assumed that participants recognized that the pairs of items were morphologically related. There was no other semantic information accompanying the training items.

Participants in the Phonotactic Training condition were exposed to the same 48 words that were presented to the participants in the Morphological Training condition, and were told that they would be listening to words from a novel language. There were two main differences between the

Morphological Training condition and the Phonotactic Training condition, reflecting the two main differences between phonotactic and morphologically controlled phonological patterns. First, participants in the Phonotactic training condition were given no semantic information about the items. Second, items in the Phonotactic Training condition were not presented as pairs of items, but as single words presented in a random order.

The medial consonant varied between voiced and voiceless such that half of the items showed voicing agreement for all consonants, and the other half of exposure items showed voicing agreement only between the first and last consonant. In addition, the distribution of consonants was even, such that each consonant appeared in an equal number of items in both final and initial positions. One third of training items contained identical consonants in both first and last positions. Examples of the training stimuli can be found in Table 1.

Table 1: Example Training Items.

Voiceless	Voiced
<b>kidat</b>	<b>gidad</b>
<b>topak</b>	<b>dopag</b>
<b>pibot</b>	<b>bibod</b>

In the Morphological Training condition, all ‘singular’ words had voiceless consonants in first and last positions, and all ‘plural’ words had voiced consonants in the first and last positions. There are two reasons why this design was chosen (as opposed to adding a suffix that alternated depending on the quality of the first consonant, as in /kida-kidat, dopa-dopad/). First, the present design allows the Morphological Training and the Phonotactic Training conditions to use the exact same set of training items, as opposed to two different sets for each condition. Second, the voiceless-voiced alternation mirrors the morphological harmony patterns described in Finley (2009). For example, Kanembu shows an alternation in which the incomplete form are all [–ATR], while the complete forms are all [+ATR] (Akinlabi, 1996).

Following exposure, all participants were given a two-alternative forced choice test. This test was designed to probe whether participants had learned the agreement pattern. All participants received the same set of 40 test items that contained ten Old Items (items heard in the training set), ten New Items (items not heard in the training set), and 20 filler items that contained the voiceless alternation.

All test items were of the form CVCVC in which the ‘correct’ (harmonic) item contained a voiced consonant in the first and the last position of the word, and the ‘incorrect’ (disharmonic) item contained a voiced segment in the first position and a voiceless consonant in the final position. Examples of test items can be found in Table 2, below.

Participants in both training conditions were given identical instructions for how to complete the test phase.

Participants were told that they would hear two words. One word was from the language they had just heard, and the other word was not from the language they had just heard; if they believed the first word was from the language, they were instructed to press the ‘a’ key; if they believed the second word was from they language, they were instructed to press the ‘l’ key. Participants did not hear pairs of words in the test phase.

Table 2: Example Test Items.

Old Items	
Harmonic	Disharmonic
<b>gidad</b>	<b>gidat</b>
<b>dopag</b>	<b>dopak</b>
New Items	
Harmonic	Disharmonic
<b>bikad</b>	<b>bikat</b>
<b>depod</b>	<b>depot</b>
<b>gutub</b>	<b>gutup</b>

A female native speaker of English produced the spoken materials that were used in the experiment, and had no knowledge of the design or purpose of the experiment. The speaker produced all sounds in a sound-attenuated booth. All bi-syllabic stimuli were produced with stress on the first syllable, but instructions were given to the speaker to pronounce all vowels (as English vowels in unstressed position tend to be reduced). All stimuli items were normalized for intensity (set at 70dB) using Praat (Boersma & Weenink, 2005).

All phases of the experiment were run in Psyscope X (Cohen, MacWhinney, Flatt, & Provost, 1993). Participants were given both written and verbal instructions. The entire experiment took approximately 20 minutes.

### Results

Proportion of correct responses (i.e., choosing the item that contained a voiced stop in the first and last position) for all conditions are given in Figure 1. Responses were compared via a 2x2 mixed design ANOVA. There was a significant effect of Training,  $F(1, 34) = 4.24, p < 0.05$ , in that participants in the Morphological Training condition (mean = 0.63,  $CI \pm 0.084$ ) selected the harmonic option more often than participants in the Phonotactic Training condition (mean = 0.51,  $CI \pm 0.085$ ). There was no effect of Test Item,  $F < 1$ , and no significant interaction,  $F(1, 34) = 2.30, p = 0.14$ .

Responses to Old and New items were compared to 50% chance via Bonferroni corrected one-sample t-tests. There was a significant effect in the Morphological Training condition for both Old Items, with a mean of 0.64,  $CI \pm 0.11, t(17) = 2.75, p < 0.05$ , and New Items, with a mean of 0.62,  $CI \pm 0.083, t(17) = 2.99, p < 0.01$ . This suggests that participants in the Morphological Training condition learned the harmony pattern at a level greater than chance. There

was no significant differences in the Phonotactic Training condition for either Old Items, with a mean of 0.47,  $CI \pm 0.12$ ,  $t(17) = -0.49$ ,  $p = 0.63$ , or New Items, with a mean of 0.54,  $CI \pm 0.082$ ,  $t(17) = 1.14$ ,  $p = 0.27$ . This suggests that participants in the Phonotactic Training condition failed to learn the harmony pattern at a level greater than chance.

Figure 1: Results.

It is important to note that the success of the participants in the Morphological Training condition was not limited to correct items that were fully harmonic. Participants in the Morphological Training condition selected the correct item 64%, of the time when the medial item was voiceless and the first and last item was voiced (e.g., /beteg/),  $CI \pm 0.11$ ,  $t(17) = 2.86$ ,  $p = 0.011$  (because of the small number of items, Old and New items were combined in this analysis, with a mean of 67% for Old items and 59% for New Items). This analysis rules out the possibility that participants only learned a harmony pattern that required all consonants to share the same feature for voicing.

There was a high amount of individual variation in the present experiment. Three of 18 participants in the Morphological Training condition showed a mean below 50%, while nine of the 18 in participants in the Phonotactic training condition showed a mean lower than 50%. The fact that so many participants in the Phonotactic Training condition scored below chance suggests that these participants were not attending to the relevant aspects of the stimuli. These participants may have simply been ‘guessing’ incorrectly more often than correctly, or they may have inferred a pattern that was not actually present in the data.

The results of the present experiment support the hypothesis that a first-last agreement pattern is more easily learnable as a morphologically controlled phonological alternation than as a phonotactic pattern. Participants in the Morphological Training condition responded correctly to harmonic items at a level greater than chance, and significantly outperformed participants in the Phonotactic Training condition, who failed to learn the first-last agreement pattern.

There were two major differences between the Morphological Training condition and the Phonotactic

Training condition. First, participants in the Morphological Training condition received information about the morphological status of the items in the training (singular-plural pairs). Phonotactic patterns are not morphologically restricted, and morphological information is therefore irrelevant to the phonotactic pattern. Second, the training items in the Morphological Training condition were presented as pairs of words, voiceless followed by voiced. This reflects the fact that morphologically controlled phonological alternations are typically described in terms of an alternation. While both pieces of information are necessary to differentiate between phonotactic patterns and morphologically controlled alternations, it is unclear whether the unattested phonotactic first-last agreement pattern might be learnable if words were simply presented as pairs of words that differed in voicing. Presentation of items as pairs of words may highlight the regularities present in the word, regardless of the morphological status of the pairs of words. Experiment 2 tests whether adult English speakers are able to learn the unattested phonotactic first-last alternation if the items are presented in pairs of voiceless-voiced ‘alternations’ without morphological information.

## Experiment 2

### Participants

All participants were adult native speakers of English with no previous exposure to consonant harmony. All 18 participants were Elmhurst College undergraduate students, recruited from the Elmhurst College Psychology Department Human Subject Pool, and were given extra course credit for their participation.

### Design

Participants in Experiment 2 were given the same exposure items as participants in the Morphological Training condition in Experiment 1. Participants were exposed to 24 pairs of items that reflected an alternation between CVCVC words in which the first and last consonants agreed in voicing; the first word of each pair contained voiceless stops, and the second word of each pair contained the corresponding voiced stops. Unlike Experiment 1, participants in Experiment 2 were not given any information about the morphological status of the pairs of items. Participants were simply told that they would be listening to words from a novel language. They were not told that the items were presented in pairs. Participants in Experiment 2 received the same test items as participants in Experiment 1.

### Results

Proportion of correct responses (i.e., choosing the item that contained the voiced stops in first and last position) were recorded, and are present in Figure 1, above.

Responses to Old and New items were compared to 50% chance via Bonferroni corrected one-sample t-tests. There was no significant effect for Old Items, with a mean of 0.57,

$CI \pm 0.11$ ,  $t(17) = 1.27$ ,  $p = 0.22$ . There was, however, a marginal difference for New Items, with a mean of 0.60,  $CI \pm 0.093$ ,  $t(17) = 2.26$ ,  $p = 0.074$ . These results suggest that participants in Experiment 2 did not reach full criterion for learning, but did show some evidence of learning beyond the chance level.

In addition, a 2x3 ANOVA was performed comparing results for Experiment 1 with results for Experiment 2. There was a marginal effect of Training,  $F(2, 51) = 2.21$ ,  $p = 0.080$ , no effect of Test Item,  $F < 1$ , and no significant interaction  $F(1, 51) = 1.10$ ,  $p = .34$ . Pairwise comparisons revealed no significant differences between Experiment 2, with a mean of 0.58,  $CI \pm 0.084$ , and the Phonotactic Training condition of Experiment 1,  $p = 0.21$ , or the Morphological Training condition of Experiment 1,  $p = 0.42$ . These lack of significant differences suggest that participants in Experiment 2 performed at a level intermediate between that of the Phonotactic Training condition and that of the Morphological Training condition in Experiment 1.

There are potentially many reasons why participants in Experiment 2 did not perform significantly different than either the Morphological Training condition or the Phonotactic Training condition. First, it is possible that some of the learners imposed morphological structure on the pairs of words. In informal debriefing, several participants noted that they had analyzed the pairs of words as being related ‘like singular and plural’. If some learners naturally impose morphological structure on alternating pairs of words, it would suggest that learners use morphological cues when they have the potential to be helpful. Second, it is possible that the presence of cues to a morphologically controlled phonological pattern (alternations and morphological information) provide the best learning environment for the most people. If only one of the cues is present, learning will be intermediate between having both cues and no cues at all. Third, it is possible that the high degree of individual differences across both experiments made finding a significant effect difficult. Of the 18 participants in Experiment 2, five showed means lower than 50%. These individual differences may have been compounded the additional factors that lead to an intermediate result for Experiment 2. Fourth, the lack of a difference may simply reflect a floor effect. It may be difficult to show substantial differences between training conditions, due to the fact that learning in the Morphological Training condition of Experiment 1 was significant, but not highly robust.

## Discussion

The present study explored the role of alternations and morphological information in learning phonotactic patterns. First-last agreement patterns, which fall outside of the strictly piecewise grammars, are predicted to be unlearnable (Heinz 2010; Lai, 2012). However, linguistic analyses that demonstrate the possibility of a morphologically controlled alternation that targets the first and last segments of a word

(Finley, 2009), along with the existence of morphologically controlled first-last agreement patterns, leads to the prediction that morphologically controlled phonological patterns may not be subject to the same constraints on learning and representation as purely phonotactic patterns. This prediction was tested using an artificial grammar learning paradigm in which adult native English speakers were exposed to an artificial first-last agreement pattern that was either presented as a morphological alternation or as a phonotactic alternation. Participants failed to learn the phonotactic pattern, but successfully learned the morphologically controlled phonological alternation. This result suggests that unattested phonotactic patterns may be possible given the right morphological cues.

The results of the present experiment have important consequences for theories of typological linguistic universals. One of the major issues with proposing a linguistic universal is that it is very difficult to interpret potential counter-examples, or a lack of counterexamples (Evans & Levinson, 2009). For example, if there are no cases of first-last agreement patterns in natural language, is it because of a cognitive restriction or because of an accidental gap? In the case of first-last agreement patterns, potential counter-examples can often be ‘explained-away’ in terms of morphological restrictions. Using an artificial grammar learning paradigm, it is possible to tease apart issues of the source of a typological restriction (Nevins, 2009). First, if two patterns that are minimally different except for a predicted restriction on language, there is a clear prediction that one pattern will be learned more easily than the other. For example, Finley (in press) compared learning between minimally different vowel harmony languages. One language had typologically (and phonetically) salient mid vowels as the source for harmony, while the other language had typologically (and phonetically) less salient high vowels. Participants who were exposed to the typologically salient cues were able to learn the harmony pattern, while participants who were exposed to the less salient cues failed to learn the pattern. Second, it may be possible to find explanations for potential counterexamples to proposed linguistic universals. Additional social and cognitive cues may support learning a pattern that falls outside a predicted learning space. Artificial grammar learning experiments provide a mechanism to control for these factors. In the present study, it was demonstrated that the proposed restriction that strictly piecewise languages patterns form part of the cognitive constraints on phonological grammars may not hold in the case of morphologically controlled alternations.

Jusczyk and colleagues (1993) suggest that infants may learn phonotactic patterns faster than morphological ones. This appears to be at odds with the results of the present study, in which the morphologically controlled pattern was learned with greater ease than the phonotactic pattern. There are two possible explanations for this difference. First, the present study addressed phonotactic patterns that are outside of the range of naturally occurring attested phonological

patterns. Thus, it may be possible that phonotactic patterns are easier to learn than morphologically controlled alternations, but only when the phonotactic pattern falls within the set of strictly piecewise languages. Second, the artificial nature of the present study may have provided a shortcut to learning. Participants were told that they were hearing morphological alternations. In a natural learning situation, the learner has to discover both the morphological component to the pattern as well as the phonological component. Infants may be better at learning phonotactic constraints simply because there is less information to attend to. Adults in a language learning task can use morphology as a cue to learning in a way not possible in infant language learning.

The present study leaves open the question of why morphologically controlled phonological alternations might allow for a larger range of possible languages than phonotactic patterns. One possibility is that morphology provides additional cues to learning that may not be possible when learning a purely phonotactic pattern. This falls in line with theories that predict that metalinguistic cues such as social factors and communicative intent play an important role in the typology of language and language learning. Another possibility is that the computational power of morphological and syntactic processes exceeds that of purely phonotactic patterns. Thus, patterns at the interface of phonology and morphology/syntax may thus fall outside of the computational power of purely phonological patterns (Heinz & Idsardi, 2011). If this is the case, there is a question of how to integrate phonotactic patterns at the interface between morphology and syntax.

This issue has important implications for computational models. If morphologically controlled phonological patterns are governed by a different set of constraints than phonotactic patterns, there is a question of how to incorporate both into a computational model of language and language learning. The ultimate goal of linguistics is to provide a model of language that explains the mechanisms that underlie the processes that are found (and are not found) in natural language that is both cognitively plausible and computationally elegant. Understanding the factors that learnability of various types of phonological patterns will ultimately lead to an understanding of the cognitive capacity for language.

# Systemic Expertise: Instructing Non-Artists on Depicting Human Figures in 3-D

Nick V. Flor

Virtual World Research Lab  
Anderson School of Management  
University of New Mexico  
nickflor@unm.edu

## Abstract

I use the theoretical framework of distributed cognition to develop a repeatable procedure that non-artists can follow to model 3-D human figures—manikins—on a computer, which are sufficient for prototyping. The approach was not to train artists to be expert human figure modelers, but rather to derive a distribution of abilities across person and computer such that the system of person-in-interaction-with-technology exhibited expertise. These abilities were discovered through an analysis of two equivalent functional systems: figure modeling on a computer and figure drawing on paper. I report a test of the procedure on a group of non-artists, which yielded a high success rate. This research contributes to our understanding of applying distributed cognition to the design of instructional procedures, and to our understanding of the sciences of the artificial.

**Keywords:** distributed cognition; science of the artificial; 3-D human figure modeling; virtual worlds.

## Introduction

Drawing the human figure on paper is a difficult task, as anyone who has picked up a pencil and tried to draw a figure can attest. Modeling the human figure on a computer is also a difficult task, since it either starts with a drawing of a human figure (Oliverio, 2007; Patnode, 2008; Russo, 2006), or it requires detailed knowledge of surface anatomy (de la Flor & Mongeon, 2010; Ratner, 2009; Spencer, 2010). Moreover, one must learn how to operate a complex 3-D software package.

The general problem is that of representing an imagined human figure in some medium, which requires a complex skillset typically acquired through years of practice. For this reason when there is a task that requires either human or human-like figures, such as an animated movie or a video game, one hires artists who are experts in figure modeling.

The specific research question explored in this paper is as follows: is it possible to design a replicable procedure that *non-artists* can learn in a short amount of time for modeling human figures on a computer? This research contributes to our understanding of distributed cognition (Hutchins, 1995), and the sciences of the artificial (Simon, 1996).

The answer to this question has practical implications as well. We live in a highly networked, digital ecosystem where almost every mobile device, notebook, or desktop computer has a graphics processor capable of displaying 3-d models. There is significant opportunity for designing scientific and educational applications that make use of this capability such as virtual worlds (Bainbridge, 2007; see Figure 1). There are also many individuals that have business and information systems backgrounds that would

like to develop applications that take advantage of these 3-D capabilities, but lack the skills in figure modeling. Certainly one could always hire an artist, but knowing how to model figures in 3-D and to model objects generally, allows one to more quickly explore the spaces of virtual world prototypes and possible 3-D representations. Artists can still be utilized later in the process to add finishing aesthetics.

Figure 1. Virtual UNM Campus Developed by the Author on a Mobile Device—Human Figure in the Center

Hutchins (1995, p. 155), provided a guiding framework for answering this research question when he wrote:

*“...a good deal of the expertise in the system is in the artifacts, (both the external implements and the internal strategies)—not in the sense that the artifacts are themselves intelligent or external agents, or because the act of getting into coordination with the artifacts constitutes an expert performance by the person; rather, the system of person-in-interaction-with-technology exhibits expertise. These tools permit the people using them to do the tasks that need to be done while doing the kinds of things the people are good at: recognizing patterns; modeling simple dynamics of the world, and manipulating objects in the environment” (p. 155).*

In the context of this framework the research question becomes not can we make a non-artist into an expert figure modeler, but rather can we design a system of external implements and internal strategies, such that the system of person-in-interaction-with-technology exhibits expert figure modeling skills?

## The Processes of Human Figure Modeling and Human Figure Drawing

The task of modeling a human figure on a computer consists of a person (the modeler) and the computer running the 3-D modeling software. The challenge is to discover a distribution of abilities across person and computer, which allow a non-artist to model a human figure in a short amount of time.

A comprehensive cognitive ethnography of the process of modeling and drawing the human figure is beyond the scope of this paper. Instead, I describe the general processes and key representations that occur during modeling, based on my experience building 3-D virtual worlds, as well as working with and observing professional Hollywood modelers, animators, and visual FX personnel, as a faculty member and director of the University of New Mexico’s interdisciplinary film & digital media program.

### The Process of Human Figure Modeling

The process most commonly used in industry to model human figures is commonly referred to as *character modeling with reference pictures*, although I use the term “3-D tracing” because it is analogous to the technique of placing see-through paper over a photograph and creating a drawing by tracing. The method can be seen in a variety of books including, Guindon (2007, pp. 15-83), Ingrassia (2009, pp. 269-288), Oliverio (2007, pp. 47-323), Patnode (2008, pp. 133-207), and Russo, (2006, pp. 83-152). The general process is as follows (see Figure 2 for depictions of the steps):

- 1.The modeler first obtains reference pictures. In the movie and videogaming industries, these reference pictures are typically drawn by a concept artist in the art department. The concept artist either draws the pictures on paper then scans them into an electronic format, or uses a paint program to draws them directly into an electronic format. The reference pictures depict front and side views of the character to be modeled, with features lined up in both photos including the top of the head, the waistline, and the bottom of the feet.
- 2.The reference pictures are then imported into a modeling program. The pictures are placed at right angles to one another, and centered.
- 3.The modeler adds a simple box to the workspace so that it overlaps the torso in both the front and the side reference-picture views.
- 4.Finally, the modeler molds the box to the reference drawings—extruding limbs, adding edge loops, and moving vertices so that the edges of the model line up with the edges in the reference pictures. Figure 3 details the molding process.

Figure 2. Figure Modeling with Reference Pictures, viz., 3-D Tracing. A modeler (1) obtains front and side pictures of a human figure; (2) imports them into a 3-D modeling program; (3) adds a basic box that covers the torso; (4) molds the box to the pictures.

Figure 3. Molding to Reference Images—a time-intensive activity where an artist molds a box or a plane to images, by aligning vertices to landmarks on front and side pictures. In this example, a plane is molded to a face, but the same actions apply to molding a box to a body. The pictures are scaffolds that are removed after modeling is completed.

**Abilities and Issues for Non-Artists.** For a non-artist to successfully perform the figure modeling process, the main abilities he or she must acquire are to draw the human figure in front and side views (step 1), and to align vertices to landmarks in front and side views (step 4). As mentioned, figure drawing is a difficult skill to learn. Moreover, the alignment process is time consuming. For this reason, figure modeling with reference pictures is not a suitable method for the non-artist.

There is no research that analyzes these abilities and sheds light on developing a new figure modeling process for non-artists. However, an analysis of the figure drawing process reveals abilities that are helpful for developing a new figure modeling process via a redistribution of those abilities across person and computer.

### The Process of Human Figure Drawing

The output of figure drawing is both an input to the figure modeling process (step 1 in Figure 2), and is also an equivalent functional system to figure modeling. It is equivalent because both figure drawing and figure modeling result in a representation of the human figure. The difference is the medium—paper in the case of figure drawing, and a computer in the case of figure modeling.

Observations of artists reveal that the drawing of a human figure on paper results from at least three distinct kinds of representations layered on top of one another (refer to Figure 4). These observations are corroborated by information in drawing instructional books (Hampton, 2009, pp. 54-55; Lee & Buscema, 1978, pp. 70-71; Loomis, 1943, pp. 43-45; Reed, 1984, p. 38).

- 1.The first representation the artist creates is a rough sketch of the figure that depicts broadly the action of the body and limbs. Examples of rough figure sketches include *stick figures*, which use lines to represent the body and limbs; and *gestures*, which are drawings that are completed quickly, in several minutes or less, that are sufficient for a viewer to understand the meaning of the action depicted.

2. The artist then layers a representations consisting of geometric primitives based on spheres, cubes, and cylinders over the rough sketch in order to give the figure both mass and depth (Hampton, 2009, p. 54; Hogarth, 1996, p. 8; Lee & Buscema, 1978, p. 21; Ozawa, 1999; Reed, 1984, pp. 22,24,26). These primitives serve an important function which is known in the psychological literature as scaffolding (Wood, Bruner, & Ross, 1976). As one artist put it: “Square boxes ... are necessary for proper depiction of the human form as well. Picture the 3-dimensional human body and think of it in terms of boxes... Once you become accustomed to drawing, there will be no need to draw the boxes, but you should always keep them in mind to make certain you think in three dimensions.” (Ozawa, 2005, p. 15)
3. Finally the artist layers representations of muscles, clothing, and shadows over the geometric primitives in order to add realistic detail to the figure. It should be noted that this last representation varied among artists, with some listing it as one representation and others breaking it into as many as three separate representations. Moreover, these are not the only representations that an artist can layer next. For example, if the publisher allows colors, the artist layers color over the detailed figure drawing. However, I list this as one representation—detail—because the general consensus was to layer various kinds of detail over the second representation of the figure-as-geometric primitives.

		
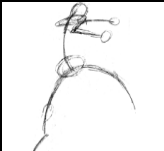

Representation 1: Rough action sketch	Repr. 2: Mass via shapes	Repr. 3: Detail, which can include muscles, clothing and shading

Figure 4. Figure Drawing as a Sequence of Layering Three Representations (figures adapted from Lee & Buscema, 1978)

The artist’s use of these intermediate representations is a good example of the principle of cognitive effort conservation in a distributed cognitive system. Without using these intermediate representations an artist would have to imagine a fully-detailed figure mentally and then draw it. This kind of imagining is a computationally-intensive process for skills like perspective. Instead, when using intermediate representations, an artist can work on different aspects of the figure in smaller more manageable steps, which then serves as a kind of guiding framework for adding more complexity in subsequent representations. In particular, the rough sketch allows the artist to focus on depicting the meaning of the pose. Once complete, this rough sketch serves as a framework for the piecemeal addition of body masses with depth using simple boxes, cylinders, and other geometric shapes, which are easier for

the artist to draw in perspective than actual body parts. Once the figure with mass and depth is completed, the basic geometric shapes serve as a framework for the piecemeal placement of muscles, clothing, and lighting details. In this manner the use of intermediate representations changes the task from a detailed thinking then drawing task, into an easier and incremental looking and drawing task.

**Abilities for Non-Artists.** The observable representations are produced by specific abilities, which in the case of figure drawing on paper are located mainly in the head of the artist and that take many years of practice to develop. According to Loomis (1943), the fundamental abilities required for human figure drawing include “proportion, anatomy, perspective, value, color, and knowledge of mediums and materials.” Briefly, an artist uses *proportion* ability to draw body parts in the proper, aesthetically pleasing, sizes relative to one another (Repr. 1). Ability in *anatomy* is used to detail the surface of the body as influenced by the underlying skeletal and muscular structures (Repr. 3). *Perspective* ability allows the artist to draw the body parts from different observation points and with *foreshortening* (Repr. 2), where body parts that are closer to an observer appear bigger than those parts that are further away. It is important to note that foreshortening is the single most difficult ability for drawing figures (Hogarth, 1996, p. back cover). *Value* skill is used to apply the appearance of light and shading to the figure (see last image in Repr. 3). *Impact* is the ability to draw figures in poses that are visually interesting (Repr. 1; Lee & Buscema, 1978, p. 60). Finally, knowledge of mediums and materials is an operational skill—the ability to use paper and pencil or other media and instruments for drawing. Figure 5 depicts the abilities needed for figure drawing on paper.

Figure 5. A Visual Depiction of the Abilities for Figure Drawing.

## Redistributing Abilities, Manikins & Satisficing

All the abilities for drawing a human figure on paper, with the exception of proportion, are difficult or time-intensive for an individual to learn.

However, when modeling a human figure on a computer one can have the computer perform most of the difficult abilities, including rendering the figure with the proper perspective, with the proper shading (value), and with color.

The problem of learning anatomy remains, but one can satisfice and remove anatomical detail as a goal, yet still

produce human-like figures that are useful for virtual world prototyping. This is not without precedence in figure drawing or animation. Both artists (Loomis, 1943) and animators (Williams, 2001) emphasize the use of manikins (similar to Figure 6), devoid of anatomical detail, for prototyping poses or movements. Detail is added only after the poses and movements have been worked out.

When anatomical ability is removed as a requirement, a non-artist need only learn proportion and impact to model human-like figures on a computer. Like in drawing and animation, detail can always be added later to a manikin. Figure 6 depicts a distribution of abilities suitable for a novice to model 3-D figures on a computer, and where the computer does the more difficult representational abilities.

Figure 6. A visual depiction of the distribution of abilities needed to model figures for *prototyping* purposes. Abilities in parentheses are added abilities that are not part of the figure drawing skill set (not covered in this paper)

### A Procedure for 3-D Figure Modeling

The redistribution of abilities as depicted in Figure 6, changes the task of modeling a human figure, from drawing and molding boxes to reference pictures (see Figure 2), to the easier task of creating body parts in proportion. The values for the following procedure were derived from the body proportions specified by (Hamm, 1963).

*3-D modeling* is an activity where an individual creates representations of real or imagined things—that appear to have width, height, and depth—using a special kind of computer program known as modeling software. Popular examples of modeling software include Maya and 3ds Max, both by Autodesk Corporation. The representations are known as models, and the person that creates them is referred to as a modeler.

There are two basic ways to model, using polygons or using curves. This instruction covers polygon modeling—the most popular kind of modeling for games and virtual worlds. Using polygon modeling, the modeler starts with a basic object — e.g., a cube, sphere, or pyramid with a certain *width x height x depth* and with a certain number of faces — much like a sculptor starts with a lump of clay. The modeler then molds this source object into a target object using the operations of moving, cutting, extruding, wedging, merging, deleting, and mirroring, which are applied to the object’s vertices, edges, and faces.

### Part 1. Creating the Body

To create a body (Figure 7): (1) Create a cube that is 1x2.5x1 units with 2x5x2 faces; (2) Wedge the top back face 45 degrees, yielding an arm face; (3) Move the outer-bottommost edges .1 units in the x direction yielding a leg face; (4) Extrude the arm face 2.5 units, tapered by .1 units; (5) Extrude the leg face 2 units yielding a thigh; (6) Move the thigh face’s inner-bottommost edge +.1 units in the x-direction; (7) Extrude the thigh face 2 units, tapered by .1 units, yielding a calf; (8) Move the middle back vertices to a z-value of zero and merge the overlapping vertices, yielding a back wedge; (9) Mirror to see what the completed body will look like; (10) Save file.

Figure 7. Modeling the Body (see text for explanation)

### Part 2. Creating the Hand

To create a hand (refer to Figure 8): (1) Create a cube .5x.125x.5 with 2x1x4 faces; (2) Wedge the thumb face 30 degrees; (3) Inset the stubs .01; (4) Extrude the fingers .5 with 3 divisions; (5) Extrude the thumb .25, then .125; (6) Move back the pointer and ring finger .0625 and move the pinky back 0.125; (7) Move the pinky joint edges back -.0625 and the middle finger joint edges up .0625; (8) Remove the back edges and vertices; (9) Move in the wrist edges inwards by .1; (10) Save file.

Figure 8. Modeling the Hand (see text for explanation)

### Part 3. Creating the Feet

To create a foot (Figure 9): (1) Create a cube that is .5x.25x1, with 1x2x2 faces; (2) Merge the toe vertices down; (3) Move the ankle sides in by .1, and the front ankle by .2; (4) Extend the toes by 1.25; (5) Save file.

Figure 9. Modeling the Foot (see text for explanation)

## Part 4. Creating the Head

To create a head (refer to Figure 10), simply create a cube that is .7x1x1 with 2x3x3 faces, then save the file. The head can be shaped after it is attached to the body in part 5.

Figure 10. Modeling the Head (see text for explanation)

## Part 5. Combining the Pieces

The final step is to merge all the pieces into one (refer to Figure 11). After saving all the separate body parts: (1) Import the half-body; (2) Import the foot; (3) Snap foot to leg; (4) Merge objects & vertices; (5) Import hand; (6) Snap hand to upper limb; (7) Merge objects and vertices; (8) Mirror to get the right side of the body; (9) Attach the head; (10) Smooth figure if desired; (11) Save.

Figure 11. Attaching the Body Parts (see text for explanation)

The resulting manikin is suitable for inserting into a game for prototyping purposes, or one can take the time to further shape and texture the manikin to look more realistic (see Figure 11, last image).

## Method for Testing the Procedure

### Participants

Forty-three students participated in this study. The students came from MGMT 330—Fundamentals of Virtual Business Programming, and none of them had any experience with figure drawing or 3D modeling prior to taking the course, which was a required course for junior and senior level students majoring in management of information systems.

### Apparatus

For hardware, students used their personal laptops or desktop computers to run the 3-D modeling software. The software used was Maya 2010, which the students downloaded for free from the Autodesk.com website as part of Autodesk's free software program for students and faculty. All 43 students reported successfully loading Maya onto their personal computers. The University's online instructional system, WebCT, held a link to YouTube tutorial videos made by the instructor on the topic of modeling 3D characters and this video was made available to all students.

## Procedure

Students were given a lecture on how to model 3D figures based on the procedure described previously. They were then given an assignment where they had a week both to create a personalized robot avatar and to animate a walk cycle for the robot avatar (see Figure 12 for the written instructions). Note: I used the term "robot" instead of manikin since students were more familiar with the former.

- Based on the Professor's Robot as taught in class:
1. Model a robot body in Maya (filename: body.mb).
  2. Model a robot head in Maya (filename: head.mb).
  3. Model a robot hand in Maya (filename: hand.mb).
  4. Model a robot foot in Maya (filename: foot.mb).
  5. Personalize your robot body parts.
  6. Merge all the body parts to yield a robot avatar.
  7. Animate a walk cycle for your robot avatar (filename: robot.mb).
  8. Export your walking robot avatar as an fbx file (filename: robot.fbx).

Figure 12. Written Instructions Given to Students

Students received the lecture through YouTube videos that were embedded in the University's online instructional delivery system, WebCT. The total time for the video lectures was approximately one hour. MGMT 330 was a purely online course with no face-to-face component.

## Results

There were 43 students in MGMT330. Of these 43 students, 33 turned in a robot, while 10 students did not turn in a robot. Of the 10 students that did not turn in a robot, 7 did not turn in any assignments at all during the semester. Of the 33 students that turned in a robot, 3 did not save their files properly and only turned in an animated skeleton. However, when their work was checked in person, they indeed modeled a robot correctly. If you removed, the 7 students that did not show up to class, then 91.6% of the students successfully followed the procedure for modeling a robot. Figure 13 depicts the robots created by the students.

Figure 13. Figures Created by the Management Students

## Discussion and Conclusion

The research in this paper presents a repeatable procedure I developed for modeling human figures in 3-D based on a distributed cognition analysis, which can be used to create characters for prototype virtual worlds in academia and industry. Unlike teaching someone how to draw human figures on paper, teaching a person how to model human figures on a computer can be done reliably and in a relatively short amount of time—at least for sophomore-level college students and beyond.

While both drawing and modeling are instances of the general activity of representing human figures in some medium, the specific tools & media change the distribution of abilities needed by the artist. When the tool is a computer running the modeling software, many of the abilities that are difficult and time-consuming for a person to master such as drawing objects in the proper perspective on paper, get distributed to the computer.

While a procedure for quickly modeling character for virtual worlds and games is valuable, equally important is the approach used to design this instructional procedure. Having to design instruction outside of one's expertise is not limited to instructors in academia, but is an activity that both managers and employees may have to engage in especially in a project with new employees using new tools. While instructional procedures are not always written down, they are important to create nonetheless. In situations, where one must design instruction outside of one's expertise, the distributed cognition theoretical framework suggests that it is possible to:

1. Find a reference system of activity that is equivalent in terms of its output to the target system. In the current study, figure drawing on paper was equivalent to figure modeling on a computer. Both activities are known as functional systems in the distributed cognition framework.

2. Analyze observable representations in the reference system, to determine the fundamental abilities needed to produce the result in the reference system. In this study, the fundamental abilities included proportion, impact, perspective, value, and anatomy.

3. Decide on a new distribution of abilities based on: (a) the goal of the larger system that the target system is part of—or the intended use of the output of the target system; (b) the capabilities of the technology in the target system; and guided by (c) the principle of effort conservation. For figure modeling, abilities like proportion and impact were kept with the person, whereas abilities like perspective and value were distributed to the computer.

What are the limitations of this procedure? Consider that there were two fortunate consequences of my analysis: (1) the abilities that remained after I applied the procedure, i.e., proportion and impact, were easy for a non-expert to master; and (2) the abilities distributed to the computer, such as perspective, foreshortening, and shading (value)—abilities that are difficult for an artist to master when drawing figures on paper—were already implemented by the software.

If after ability distribution, the difficult abilities are not already implemented in the software, someone will have to implement their functionality. And if the remaining abilities are difficult for people to master, then designing an instructional procedure may not be an option.

However, instructors at least have another option to consider in designing their pedagogy. Furthermore, this procedure gives instructors the potential to create novel and possibly innovative forms of instructional material, which provide students the ability to create artifacts that were previously only possible by experts.

### Abstract

Task-cuing paradigms are typically taken to explore control of task-set. However, they can be construed as requiring not selection of a task-set, just retrieval of a cue+stimulus-->response (CSR) mapping. In this paper we considered performance in a task-cuing paradigm in which participants saw a color cue that indicated whether they should classify a digit as odd/even or high/low using one of two responses. Half the participants were instructed in terms of tasks (Task group) whilst the others were required to learn the CSR mappings without mention of tasks (CSR group). Predicted performance under CSR conditions was modeled using an APECS connectionist network. Both the model and CSR group produced small switch costs, mostly due to incongruent stimuli, and large congruency effects that reduced with practice. In contrast, the Task group produced a larger switch-cost and a smaller, stable congruency effect.

### Introduction

We often think of our behaviour as being governed by both higher-level cognitive control processes and lower-level associative processes (McLaren, Green & Mackintosh, 1994). Typically these processes are thought to operate simultaneously but with a degree of independence. This paper takes a task-cuing paradigm, typically taken as measuring the higher level cognitive control processes involved in changing between tasks (Monsell, 2003), and asks if the performance typically seen could instead be accounted for by lower level associative processes. This paradigm has been used widely to measure control processes in areas as diverse as aging (Mayr, 2001) and schizophrenia (Meiran, 2000) It is also commonly included in brain training packages as a way to improve your ability to multitask and pay attention. Given such widespread use, it is important to assess if the paradigm actually measures control processes at all; it has been argued that it does not (Logan and Bundesen, 2003; Schneider and Logan, 2005).

The response contingencies in many task-cuing experiments can be construed without any reference to tasks. This paper examines what happens when participants approach such an experiment without knowledge of the task-sets. Data and simulation suggest that they can learn the statistical structure of the experiment through the use of

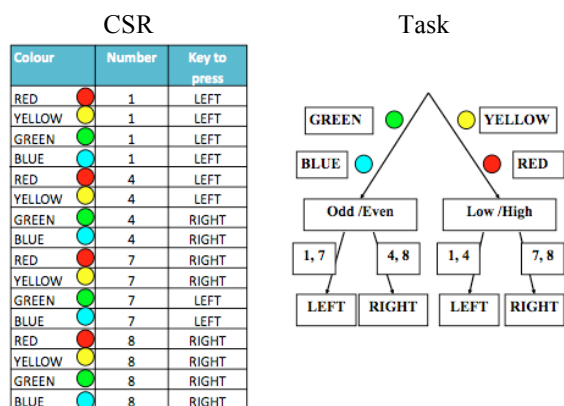

Figure 1 on the left shows the way in which the experiment was presented in the CSR condition and on the right in the Task condition.

associative learning mechanisms, but their performance differs from that of participants construing the situation as one requiring task-selection and switching.

To clarify this, let us consider the task-cuing paradigm that we used. Under standard instructions in this paradigm participants are told, for example, that if the background circle is blue or green then they should classify the digit they then see as odd/even, where odd requires a response with the left key and even with the right. However, if the background circle is red or yellow they should classify the digit as higher/lower than 5, with a right response for high, and a left response for low. This is the "task-set" construal of what is required, as illustrated on the right of Figure 1. Yet participants do not need knowledge of these tasks to know how to respond, as the color and the number combination is completely predictive of the required response, e.g. a 4 on yellow will always require a left response. Hence, especially with small stimulus set, it is entirely possible for participants in a task cuing experiment not to use the task-sets at all, in which case the experiment is not measuring task-based control processes.

In the experiment reported here we compare a group who are explicitly instructed to use the task-sets with one that has no knowledge of the underlying task-set structure. In order to examine whether, and in what ways, performance differs

between the two conditions we will consider three of the common effects found within the task-switching literature: the switch cost, the reduction in the switch cost with time to prepare (RISC effect) and the congruency effect (Monsell, 2003, Kiesel et al, 2011).

It is typically found that when participants change from performing one task to performing another task there is a switch cost; participants are generally slower and less accurate on a task-switch trial than a task-repeat trial. Participants are also able to reduce this switch cost when they are given more time to prepare the task set, i.e. when there is a longer time between the cue (colored circle), which indicates the task-set, appearing and the stimulus (number) appearing the switch cost declines. Explanations of these effects have appealed to task set inertia (Allport, Styles & Hsieh 1994) —conflict due to residual activation of the previous task set - and/or the need to perform a task set reconfiguration process (Rogers & Monsell, 1995) which reduces conflict if performed before the stimulus appears. But, according to the compound-cuing model of Logan and colleagues (Logan & Bundesen, 2003; Schneider & Logan, 2005) participants simply retrieve the response associated with the combination of cue and stimulus, so these effects cannot be taken as hallmarks of control.

In the task-cuing experiment already described, the responses for the two tasks are mapped onto the same keys, i.e. the left key represents odd and high, whilst the right key represents even and low. Hence for some numbers the response is always the same regardless of the task cued, e.g. 1 always requires a left response; these are called *congruent* stimuli. For other numbers the response changes with the task cued, e.g. 4 requires a left response if the task is high/low but a right response if the task is odd/even; these are *incongruent* stimuli. Typically, it is found that participants are faster and more accurate for congruent than incongruent stimuli. As with the switch cost and reduction in switch cost (RISC) effect there have been both task-set based and non-task-set based explanations of this congruency effect. Some researchers have argued that the congruency effect is due to response conflict from the currently irrelevant task-set (Kiesel et al, 2011). Other researchers have argued that it is caused by associative interference, as the incongruent stimuli are linked to both responses whilst the congruent stimuli are only linked to one (Kiesel, Wendt & Peters, 2007).

In this experiment we asked whether the switch cost, the RISC effect and the congruency effect depend on how the participants construe the experiment, i.e. whether in terms of tasks or cue + stimulus to response (CSR) mappings.

In addition to considering these standard task switching effects we also considered the effect of introducing novel stimuli (cf. Rogers & Monsell, 1995). This is particularly relevant for assaying the difference between switching among stimulus-classification task rules versus applying a single set of learned CSR rules. For participants using tasks there should be little impact of introducing new stimuli. There might be a slight novelty effect, but they should be

able to treat the new stimuli in the same way as the old, continuing to apply the same classification rules. However, participants with no knowledge of the task-sets have no way of knowing how to respond to the novel numbers; they should be reduced to learning how to respond by trial and error, and one would expect performance on the new numbers to be dramatically worse than performance on the old numbers.

### Modeling

As summarized above there is plenty of evidence to suggest how participants typically perform in a task-cuing paradigm with knowledge of the tasks (Monsell, 2003, Kiesel et al, 2010). In order to attempt to predict how participants would perform in the task-cuing experiment described above without knowledge of the task-sets we simulated performance using an associative model. The mappings for the congruent stimuli are shown in outline in Table 1. It is immediately evident that they should be easily captured by an associative model, as the stimuli in isolation predict the correct response.

		Cues (Color)			
		W (blue)	X (green)	Y (red)	Z (yellow)
Stimuli (Digit)	<b>A (1)</b>	<b>L</b>	<b>L</b>	<b>L</b>	<b>L</b>
	B (3)	L	L	L	L
	C (6)	R	R	R	R
	<b>D (8)</b>	<b>R</b>	<b>R</b>	<b>R</b>	<b>R</b>

*Table 1 The associative structure of the congruent trials. L indicates a left R a right response. Boldface rows indicate example initially trained stimuli; the others introduced later*

The incongruent stimuli, shown in Table 2, are more of a challenge for an associative model. There is evidence from rabbits (Saavedra, 1975) and humans (Livesey et al, 2011) that, although these stimuli are harder to learn than the congruent stimuli, they can be learned. However, a single layer error-correcting model, e.g. Rescorla-Wagner (1972) would be unable to learn this structure.

		Cues (Color)			
		W (blue)	X (green)	Y (red)	Z (yellow)
Stimuli (Digit)	E (2)	R	R	L	L
	<b>F (4)</b>	<b>R</b>	<b>R</b>	<b>L</b>	<b>L</b>
	<b>G (7)</b>	<b>L</b>	<b>L</b>	<b>R</b>	<b>R</b>
	H (9)	L	L	R	R

*Table 2 shows the associative structure of the incongruent trials using the conventions employed in Table 1.*

In addition to the difference in performance on incongruent and congruent trials, one might also expect effects of cue equivalence (Honey & Ward-Robinson, 2002; Hodder, George, Kilcross & Honey, 2003). These studies

trained rats or humans (respectively) with the same contingencies as the incongruent trials. They found that cues that indicated the same outcome from stimuli became equivalent e.g. here W and X would become equivalent as would Y and Z, in that there would be a greater degree of generalization between W and X than W and Y. Honey and Ward-Robinson (2002) found that a modified connectionist model was able to account for their data by allowing the same hidden unit to carry the mappings for equivalent cues. We used a model from the same class as their chosen model. The model is known as APECS (McLaren, 1994, 2011; LePelley & McLaren, 2001) and has a good record in modeling human learning and memory. APECS has the basic characteristics of a back-propagation network (Rumelhart, Hinton and Williams, 1986), i.e. it is a standard feedforward error correcting system with input, hidden and output layers that has been modified in two key ways:

**Learning algorithm and rates** The APECS learning algorithm allows the learning rates to change in an adaptive manner. On each trial, the hidden unit with the largest error receives a higher learning rate than the other hidden units. This effectively means that one (or a few) hidden unit(s) is (are) selected to carry each mapping from input to output.

**Bias** The APECS group of models also includes an adaptive bias whose learning rate is varied to prevent catastrophic interference to old learning occurring when new information is learnt (McCloskey and Cohen, 1989). The adaptive bias lowers the chances of the same hidden unit being used by a different mapping and hence prevents the previous learning being over-written.

### Modeling Method

**Sequencing** As in the experiment below, one third of trials were "switch" trials (defined with respect to the task-set representation). The cue changed color on every trial, and either of two colors signaled each task. The number of times a given stimulus appeared in a given task on a repeat or switch trial was constrained. There were 14 blocks of 49 trials in total. For the first 10 blocks only 4 stimuli were possible, whilst for the last 4 blocks 8 stimuli were possible.

**Representation and Architecture** The 4 cues and 8 digit stimuli were represented discretely with one input unit coding for each. The responses were also represented discretely, and the model was trained to 0.9 for the correct response and 0.5 for the wrong one. It was trained to auto-associate the input with the output, with certain output units active only if a specific input unit was active. The network had three layers: 16 input units, 14 hidden units and 18 output units.

**Learning parameters** The fast learning rate was set to 0.8 whilst the slow learning rate for the unselected units was 0.0005. For the bias the learning rate for selected hidden units was 0.5 and for others was 0.005.

**Output** The output of the model was assessed by subtracting the difference between the actual activations of the two response output units (desired response – undesired response) from the target difference (0.4). On this measure larger scores mean worse performance.

### Modeling Results

Figure 2 shows the performance of the model plotted as the difference between the desired output difference (0.9–0.5) and the actual output difference – hence 0.4 represents no learning whilst 0 represents perfect learning. The points are plotted by block pair, congruency, switch and new stimuli. Darker lines represent incongruent stimuli (IC) with diamonds representing the originally trained stimuli and triangles the transfer stimuli (New). Lighter lines represent congruent stimuli, with squares representing the originally trained stimuli and circles the transfer stimuli (New). Dotted lines represent switch trials (Sw) and solid lines repeat trials (Rep).

The results were analyzed across block pairs 2–5 (as block pair 1 was a practice block) using an ANOVA with the factors, block pair, congruency, and switch.

**Task switches** There was a small but significant effect of "task switch"; the model's performance was worse on switch than repeat trials (switch: 0.075, repeat: 0.055),  $F(1,31)=49.5$ ,  $p<0.001$  — see Figure 2.

**Congruency** There was a large and significant effect of congruency; the model's performance was worse on incongruent than congruent trials (congruent: 0.095, incongruent: 0.035),  $F(1,31)=168.5$ ,  $p<0.001$ .

**Switch by congruency.** The switch cost was significantly larger for incongruent trials (0.04) than the congruent trials (–0.002),  $F(1,30)=10.4$ ,  $p<0.01$ .

**Acquisition effects.** Overall performance reliably improved from block pair 2 to 5 (Figure 2),  $F(3, 93)=44.3$ ,  $p<0.001$ . The two-way interaction between block pair and congruency was significant  $F(3, 93)=43.3$ ,  $p<0.001$ . This interaction can be seen in Figure 2 which shows the congruent stimuli being learnt quickly whilst the incongruent stimuli take longer to learn.

**Transfer to new stimuli** The effect of transfer was analyzed by comparing the performance on the newly introduced stimuli with that on the old stimuli in block pairs 6 and 7. As expected, the model found the novel stimuli

(0.189) much harder than the previous stimuli (0.089),  $F(1,31)=509$ ,  $p<0.001$ .

### Modeling Discussion

The model predicts a large congruency effect which varies over blocks, a small switch cost which is only present in the incongruent trials and a significant disadvantage for newly introduced stimuli. This gives a clear indication what we might expect from participants if they were performing on an associative basis. It is also different from the typical task-cuing results where the switch cost is usually larger than the congruency effect. We now consider the empirical data obtained from participants trained on this task under Task or CSR instructions.

### Behavioral Method

**Participants** The participants were 35 psychology undergraduates (mean age = 20.3 years, 7 males) at the University of Exeter. Participants took part for course credit and a bonus payment, which was contingent on their performance (average payment £2.04, range £1.50-£2.50).

**Stimuli** The task cues were circles ( $6.7^\circ$  of visual angle), filled with: blue (RGB: 0, 0, 255), red (RGB: 255, 0, 0), green (RGB: 0, 255, 0) or yellow (RGB: 255, 255, 0); in the center of the cue, the digit stimulus was then displayed in 60-pt Courier bold font ( $1.3^\circ$  of visual angle). The two sets of digits used were 1,4,7,8 and 2,3,6,9 – these sets were used as on average the values are the same distance from 5 (the criterion value for 'high'/'low'). An iMac was used to display the stimuli using Matlab 2008a with Psychtoolbox.

**Design and procedure** The sequencing was constrained in the same way as for the model, with the addition of a variable CSI that was alternated by blocks to give a long CSI of 1200 ms and a short CSI of 100 ms. For the first block pair, participants were given a piece of paper with correct responses in the format of the relevant Task or CSR diagram (as in Figure 1); in addition participants in the Task condition were given standard task-set instructions verbally and on-screen, whereas participants in the CSR condition were directed to learn cue+stimulus  $\rightarrow$  response mappings on the basis of trial by trial feedback.

After 5 block pairs the second set of four stimuli was introduced in addition to the set already in use. No mention of the new numbers was made prior to their appearance. Participants were debriefed using a structured questionnaire, and replaced if their reported strategy differed from that instructed, i.e. if they induced the tasks in the CSR group, or failed to use the tasks as instructed in the Tasks group. Two participants in the Task group (who did not mention using tasks) and one participant in the CSR group (who induced one of the tasks) were replaced in this way.

### Behavioral Results

The results were analyzed using an ANOVA as for the model, with the additional between-subjects variable of instructions and within subjects variable of CSI.

**Task switches and instruction.** There was a much larger switch cost in the Task group (160 ms) than in the CSR group (18.6ms),  $F(1,30)=16.0$ ,  $p<0.001$  — see Figure 3. The switch costs were reliable for the Task group,  $F(1,15) =$

22.4,  $p<0.001$ , and nearly reliable for the CSR group,  $F(1,15) = 3.24$ ,  $p=0.092$ . For errors, there was a near reliable interaction between instruction group and task switch/repeat,  $F(1,30)=3.13$ ,  $p=0.087$ : the switch cost for the Task group was a reliable 2.9%,  $F(1,15)= 11.9$ ,  $p<0.01$ , and for the CSR group 1.2%, also reliable,  $F(1,15)=5.46$ ,  $p<0.05$ .

**Preparation and instruction.** As Figure 3 shows, preparation reduced the RT switch cost in the Task group from 213 ms (4.5%) in the short-CSI blocks to 107 ms (1.4%) in the long CSI blocks, this was significant in the RTs,  $F(1,15)=6.23$ ,  $p<0.05$  and nearly so in the errors,  $F(1,15)=3.96$ ,  $p=0.065$ . There was no such effect in the CSR group, for whom the switch cost was 16 ms (0.9%) in the short-CSI blocks and 21 ms (1.5%) in the long-CSI blocks  $F<1$ . The interaction was reliable in the RTs,  $F(1,30)= 5.67$ ,  $p<0.05$  and nearly significant in the errors,  $F(1,30)=3.91$ ,  $p=0.057$ . Participants in the Task condition also showed a general preparation effect, whereby if only the task-repeat trials are considered they were faster with a long-CSI (611ms) than with a short-CSI (853ms),  $F(1,15) = 63.8$ ,  $p<0.001$ . For the same contrast the CSR group was slightly, but not reliably, slower in the long-CSI (776ms) than at the short-CSI (745ms) condition,  $F(1,15) = 2.55$ .

**Congruency and instruction.** RT and error rate showed (Figure 3) a much larger effect of congruency in the CSR group (346 ms, 7.4%) than in the Task group (91 ms, 6.1%); the interaction was highly reliable for RTs,  $F(1,30)=23.9$ ,  $p<0.001$ , but not for error rate,  $F<1$ . In separate analyses, the congruency effect was reliable for both the Task group,  $F(1, 15) = 6.26$ ,  $p<0.05$ , for RTs, and  $F(1,15)=33.8$ ,  $p<0.001$ , for errors, and the CSR group,  $F(1,15) = 84.5$ ,  $p<0.001$ , for RT, and  $F(1,15)=11.3$ ,  $p<0.01$ , for errors.

**Switch by congruency.** In agreement with the model the switch cost was larger for incongruent trials for the CSR group (30ms, 2%) than congruent trials (7ms, 0.4%). Similarly for the Task group the switch cost was larger for incongruent trials (161ms, 4.8%) than congruent trials (69ms, 1.1%). There was an overall significant interaction between task switch and congruency in the errors,  $F(1,30)= 10.4$ ,  $p<0.01$ , but not in the RTs. This effect did not differ between the two experimental conditions in the error data or RTs.

**Acquisition.** Overall performance improved from block pair 2 to 5 (Figure 4), and this was reliable in RTs and errors,  $F(2.7,79.6)=43.3$ ,  $p<0.001$ ,  $F(2.7, 79.6)=4.60$ ,  $p<0.05$ . The three-way interaction between block pair, congruency and instructions was significant in the RTs only,  $F(2.7, 79.6)= 7.35$ ,  $p<0.01$  and marginally so in the errors,  $F(2.7, 79.6), 2.23$ ,  $p=0.095$ . Separate analyses revealed a highly significant block pair by congruency interaction in the CSR condition, RT:  $F(2.3,34.6)= 9.40$ ,  $p<0.001$ , errors:  $F(2.3,34.6)=6.94$ ,  $p<0.05$ , but not in the Task group,  $F<1$ . This interaction can be seen in Figure 4 which shows the congruent trials being learnt quickly by the CSR group whilst the incongruent trials took longer to learn, a pattern similar to the predictions made by the model.

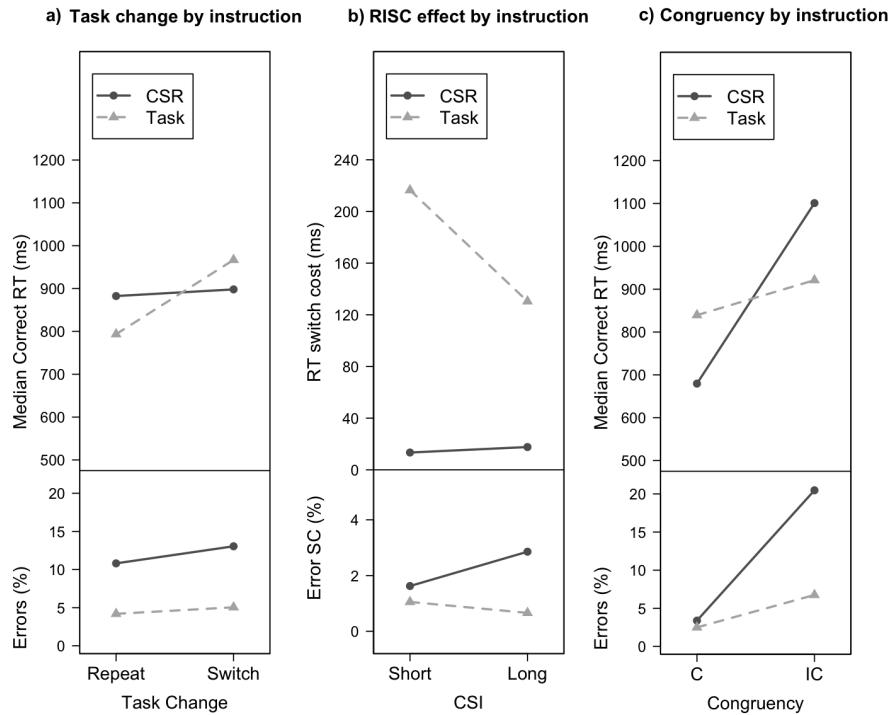

Figure 3 shows switch cost reductions in switch cost and the congruency effect, for the Task and CSR groups.

**Introduction of new stimuli.** Figure 4 also illustrates that the two groups were differentially affected by the introduction of novel stimuli at block pair 6. The new stimuli seem to be accommodated with ease by the Task group, but for the CSR group they clearly cause problems, especially incongruent stimuli. As for the model, the effect of new stimuli was analyzed by comparing the performance on the novel stimuli with that on the old. As expected, the CSR group was more affected by the introduction of new stimuli; their RT (error rate) was much larger for the new stimuli 1201 ms (21.7%) than the old stimuli 946 ms (4.1%), whereas in the Task group performance on the new stimuli, at 780ms (7.5%) was more equivalent to that of the old stimuli, 731 ms (4.8%). This difference was supported by a significant interaction in both the RTs,  $F(1,25)=23.8$ ,  $p<0.001$  and errors,  $F(1,30)=37.7$ .

### Discussion

There was a clear difference in the performance of the two groups. The Task group exhibited a large switch cost, which was substantially reduced by the opportunity to prepare. In contrast, the CSR group had a smaller switch cost, which derived largely from the incongruent stimuli and was unaffected by CSI. The CSR group had a much larger congruency effect, which was modulated with practice because congruent stimuli were learnt much faster than incongruent stimuli. In contrast the Task group exhibited a smaller congruency effect which was much more stable over practice.

These differences in the performance of participants with

and without knowledge of the task-sets suggest that there is merit in theories of performance in task-cuing paradigms that appeal to task-set. However, given that participants who had no knowledge of the tasks showed significant "switch costs" and congruency effects also indicates that these phenomena are not *per se* indices of top-down control of task-set (as Logan & Bundesen, 2003, have also argued, for different reasons). Hence, part of the switch cost seen in the Tasks group might have the same source as for the CSR group, and the congruency effect in the Task group might be an ameliorated version of that seen in the CSR group, with top down task-set control helping to shield against associative interference (Dreisbach & Haider, 2009). However, the marked differences in performance between the groups — the much larger switch cost and its reduction with preparation in the Tasks group, and the much larger congruency effects in the CSR group — clearly suggested a qualitative difference in processing strategy between them. The effects of practice and transfer, with the CSR group's rapid learning of the congruent stimuli and difficulty with the transfer test contrasting with the relatively stable switch costs over practice, and good transfer for the Tasks group, also pointed to a substantial difference in processing strategy between groups, and highlights one of the advantages of a task-set strategy — the ability to generalize to novel cases.

Moreover, the data of the CSR group seem in agreement with the behavior of an associative learning network. All of the effects predicted by the model were present in the CSR

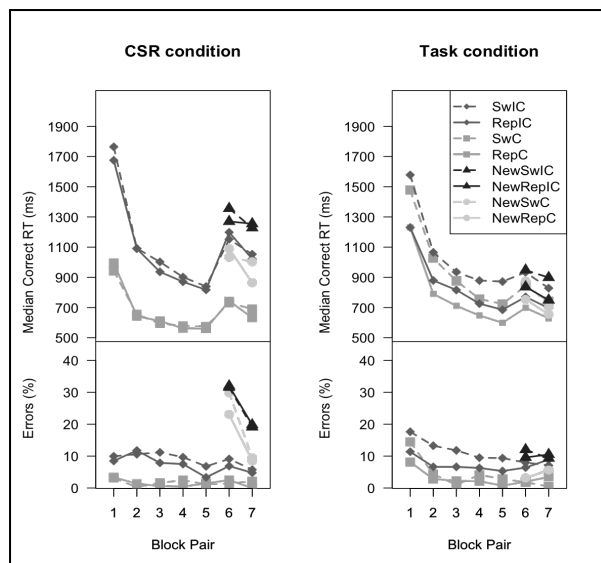

Figure 4 shows the performance over block pairs in the same way as Figure 2.

group: a large congruency effect and its modulation by practice, a modest "switch cost" due mostly to the incongruent stimuli, and a marked disadvantage in coping with new stimuli. This is certainly consistent with the suggestion that this group's performance was dependent on associative learning. We conclude that there is evidence to suggest that when participants perform in a task-cuing paradigm without knowledge of the tasks, they produce a distinctive pattern of results which is in line with the predictions of an associative model. If one is interested in using task-cuing to measure control processes, it may be wise to check for use of a CSR strategy, and to use conditions (e.g. larger stimulus sets) that discourage it.

## Abstract

This study investigated the relation between word surprisal and pupil dilation during reading. Participants' eye movements and pupil size were recorded while they read single sentences. Surprisal values for each word in the sentence stimuli were estimated by both a recurrent neural network and a phrase-structure grammar. Higher surprisal corresponded to longer word-reading time, and this effect was stronger when surprisal values were estimated by the neural network. In addition, there was an early, positive effect of surprisal on pupil size, from about 250 ms before word fixation until 100 ms after fixation. This early effect, which was only significant for the network-based surprisal estimates, is suggestive of a preparation-based account of surprisal.

**Keywords:** Reading; Eye tracking; Pupillometry; Sentence comprehension; Surprisal; Recurrent neural network; Phrase-structure grammar

## Introduction

Language comprehension is mostly incremental: When listening to or reading a sentence, each word is immediately integrated with information from the sentence so far (e.g., Just, Carpenter, & Woolley, 1982). It has been argued that the amount of cognitive effort required to process a given word can be quantified by its *surprisal* (Hale, 2001; Levy, 2008), an information-theoretic measure of the extent to which the word's occurrence was unexpected. Formally, if  $w_{1..t}$  denotes the sentence's first  $t$  words, the surprisal of the following word is:  $\text{surprisal}(w_{t+1}) = -\log P(w_{t+1}|w_{1..t})$ . These values can be estimated by any language model that assigns probabilities to word sequences.

The relationship between surprisal and cognitive load (i.e., relative difficulty in processing) has indeed been observed in reading studies: Words with higher surprisal values take longer to read, which accounts for several phenomena in sentence comprehension, such as garden-path effects (Brouwer, Fitz, & Hoeks, 2010) and anti-locality effects (Levy, 2008). More generally, reading times at each word in sentences or texts have been shown to correlate with surprisal (e.g., Boston, Hale, Patil, Kliegl, & Vasishth, 2008; Demberg & Keller, 2008; Fernandez Monsalve, Frank, & Vigliocco, 2012; Frank & Bod, 2011; Smith & Levy, 2008).

Here, we investigate an alternative empirical index of cognitive load; one that can be measured continuously and with precise time-resolution: pupil size. By analyzing how and

when effects of word surprisal appear in pupillometry data, we are able to use a physiological measure to investigate the fine-grained time course of sentence-comprehension processes.

A large number of studies, using a variety of tasks, have looked at the relationship between cognitive load and pupil dilation (for a recent overview, see Laeng, Sirois, & Gredebäck, 2012). Although these studies differ in how cognitive load is operationalized, increased cognitive load is invariably found to result in larger pupil size. In a non-linguistic context, Preuschoff, 't Hart, and Einhäuser (2011) showed that pupil size (and therefore, presumably, cognitive load) increases when a stimulus is less expected. They had participants perform a simple gambling task and found that experiencing surprise causes pupil dilation: Pupil size correlated not with the gambling outcome itself but with its unexpectedness.

Whether unexpectedness of words in sentences also results in pupil dilation is still an open question. In fact, there has been only very little pupillometry research in psycholinguistics. Engelhardt, Ferreira, and Patsenko (2010) found that a mismatch between syntactic and prosodic structure of auditorily presented sentences results in larger pupil size compared to a condition in which the two structures matched. In another sentence-listening study, Piquado, Isaacowitz, and Wingfield (2010) found a pupil response to both syntactic complexity and sentence length. To the best of our knowledge, there exists only two published studies in which pupillometry is applied during sentence reading: Raisig, Hagendorf, and Van der Meer (2012) presented participants with written descriptions of simple events in everyday activities and found increased pupil dilation when the order of presentation was incongruent with the actual temporal order of the described activities. Just and Carpenter (1993) compared object- and subject-relative clauses and found increased reading times and pupil dilation on the object-relatives, which have long been known to be more difficult to process (Hakes, Evans, & Brannon, 1976). Moreover, the occurrence of a semantically implausible word resulted in increased pupil size compared to a plausible-word condition.

Here, we did not compare particular sentence pairs but, instead, investigate the general relation between word surprisal

and pupil size, looking for effects on each word within a large set of visually-presented sentences. The goals of this study were to explore pupillometry as a methodology for investigating sentence-comprehension processes during reading; to uncover the time-course of surprisal effects; and to assess the suitability of two very different model types for surprisal estimation: recurrent neural networks (RNNs) and phrase-structure grammars (PSGs). We found a very early, positive effect of surprisal on pupil size, which was only significant for the surprisal values generated by the RNN. These findings suggest that surprisal effects are caused by a process of word prediction rather than word integration.

## Method

### Eye tracking and pupillometry

**Materials** The self-paced reading study by Fernandez Monsalve et al. (2012) and Frank (2012) used 361 sentence stimuli, semi-randomly selected from three novels published on [www.free-online-novels.com](http://www.free-online-novels.com). Two hundred and five of these sentences (comprising 1931 word tokens) could fit on a single line of the display and were therefore used in the current eye-tracking experiment. Of those 205 sentences, 110 had a corresponding yes/no comprehension question to ensure that subjects were reading for meaning.

**Participants** Seventeen monolingual, native English speakers were recruited from the University College London subject pool. One participant was excluded due to technical issues, leaving 16 participants (11 women, mean age 27.6) with analyzable data.

**Procedure** Subjects were seated 50 cm from the monitor with their chin on a chin rest. Both eyes were tracked using a head-mounted eye-tracker (SR Research, EyeLink II). Individual sentences were presented in 18-point Courier font, left-aligned on the display. Each sentence was preceded by a left-aligned fixation cross that was presented for 800 ms. Gaze direction and pupil area were sampled at a rate of 500 Hz.

After initial calibration (nine fixation points) and five practice trials, subjects were invited to ask clarification questions and the experiment began. Another calibration check was performed after the practice items and then again after every 35 trials (the final set had only 30 trials), at which time subjects took a self-paced break (total 205 trials, six sets). Additionally, drift correction on a single centrally located fixation point was performed at the start of each trial. Responses were recorded using a mouse (center button to continue after finishing a sentence; right and left buttons to respond 'yes' or 'no', respectively, to comprehension questions). The entire experiment (with instructions and calibration) took approximately 50 minutes to complete. The order of trial presentation was randomized throughout.

### Surprisal estimation

For each word in the experimental sentences, surprisal values were generated by the same set of probabilistic language

models as used by Fernandez Monsalve et al. (2012). All models were trained on 702,412 sentences (comprising 7.6 million word tokens; 7,754 word types) from the written-text part of the British National Corpus.

**Recurrent neural network** Although RNNs are often used for learning the statistics of language, they are nearly always applied to artificial toy languages. Training such models on a large, English-language corpus, as we do here, requires something more advanced than the standard Simple Recurrent Network (SRN; Elman, 1990). The solution was to first encode each word as a distributed vector and train the network on sequences of those word representations. More precisely, network training was divided into three distinct stages (see also Fernandez Monsalve et al., 2012; Frank, 2012):

1. A co-occurrence matrix  $\mathbf{P} = (p_{ij})$  was constructed, where each  $p_{ij}$  is the (smoothed) probability that word types  $i$  and  $j$  occur adjacently in the training data. These values were then transformed into  $q_{ij} = \log p_{ij} - \log(\sum_k p_{ik} \sum_k p_{kj})$ . The 400 columns of  $\mathbf{Q}$  with highest variance were selected, and formed the 400-dimensional vectors for each of the 7,754 word types. This representational space captures the paradigmatic relations between words (e.g., words of the same syntactic category tend to receive similar representations), which boosts generalization to untrained input.
2. The 702,412 training sentences, in the form of word-vector sequences, were given as input to an SRN that learned to predict the vector representation of the upcoming word  $w_{t+1}$  after each sentence-so-far  $w_{1...t}$ . The SRN used standard backpropagation and received the complete training corpus five times.
3. A two-layer feedforward network with 200 hidden units learned to 'decode' the SRN's output vectors into localist representations, that is, into 7,754-dimensional vectors where each element corresponds to a word type. It received the training data two times and, like the SRN, used standard backpropagation for connection-weight update. Its output units have softmax activation functions, so each output vector forms a probability distribution over word types.

The complete model, combining these three stages, generates estimates of the probabilities  $P(w_{t+1}|w_{1...t})$  for all word types, from which the surprisal of the actual next word follows directly. These surprisal values were obtained at ten intervals during training of the decoder network, resulting in ten sets of surprisal estimates (by an increasingly well-trained model) each of which was analyzed independently.

**Phrase-structure grammar** Grammars are usually not induced from 'flat' word sequences but require complete syntactic tree structures as training material. It was therefore necessary to first obtain such structures by parsing the training sentences. This was done by the Stanford Parser (version 1.6.7; Klein & Manning, 2003). The resulting collection of tree structures served as the PSG training corpus.

In a standard probabilistic context-free grammar, the probability of a production rule is conditioned on the rule’s left-hand side. For example, the rule ‘NP  $\rightarrow$  Det N’ would be associated with the probability that a phrase consists of a determiner (Det) followed by a noun (N), given that it is a noun phrase (NP). A grammar’s structural sensitivity can be increased by also conditioning on other parts of the tree structure, for example, by estimating the probability of ‘Det N’ given that the current phrase is an NP that belongs to a verb phrase. In this manner, many different grammars, with different structural sensitivities, can be induced from the same set of training data. Here, we applied Roark’s (2001) grammar-induction algorithm to obtain eight different grammars (see also Fernandez Monsalve et al., 2012; Frank & Bod, 2011). Next, an incremental parser (Roark, 2001) processed the experimental sentences. At each word, it computed the probabilities of possible syntactic structures<sup>1</sup> (under each of the eight grammars) given the sentence-so-far  $w_{1..t}$ . The sum of those probabilities equals  $P(w_{1..t})$ , and surprisal values follow because  $-\log P(w_{t+1}|w_{1..t}) = \log P(w_{1..t}) - \log P(w_{1..t+1})$ . That is, for each word we obtain eight grammar-based surprisal values, in addition to the ten RNN-based surprisals discussed above.

## Results

All participants displayed adequate comprehension by answering at least 80% of the comprehension questions correctly. We excluded from consideration the first and last word of each sentence, clitics, words attached to a comma, the first fixated word, and non-fixated words. Further, data corresponding to fixations outside the sentence presentation region, as well as regressions (i.e., fixations to words earlier in a sentence after a fixation on a later word) were discarded.

### Word-reading time

**Analysis** As a measure of word-reading time, we took total fixation time on a word before fixation on any other word (i.e., the first-pass reading time, or gaze duration; av. 231 ms, s.d. 116 ms). A mixed-effects regression model was fitted to this dependent variable (14,304 data points), using as predictor variables: sentence presentation order (both linear and quadratic factors), word position in sentence (linear and quadratic), word length, log of word frequency, and log of forward transitional probability (i.e., the word’s probability given the previous word). Also, all significant two-way interactions were included,<sup>2</sup> as were all significant random slopes of main effects.<sup>3</sup>

The effect size of surprisal is defined as the decrease in regression model deviance when surprisal is included as an

<sup>1</sup>The least probable structures were ignored to make this computation feasible.

<sup>2</sup>These were determined by first including all two-way interactions and then removing the least significant ones until all  $|t| > 2$ .

<sup>3</sup>These were a by-item slope of sentence order and by-subject slopes of all factors except forward probability and quadratic sentence order.

Figure 1: Effect of surprisal (as estimated by either RNN or PSG) on gaze durations as a function of linguistic accuracy (average  $\log P(w_{t+1}|w_{1..t})$ ). Plotted are the estimated  $\chi^2$ -statistics (where negative values denote effects in the negative direction) and best fitting second-degree polynomials. The dashed lines at  $\chi^2 = \pm 3.84$  denote the level beyond which  $p < .05$ .

additional predictor. This quantity is the  $\chi^2$ -statistic of a log-likelihood test for the significance of surprisal. Effect size can be contrasted with ‘linguistic accuracy’: the extent to which the model has learned the statistical patterns of the language. Linguistic accuracy is quantified as the average of  $\log P(w_{t+1}|w_{1..t})$  estimated over the experimental sentences, weighted by the number of times  $w_{t+1}$  occurs in the analysis.

**Surprisal effect** Figure 1 plots the size and direction of the surprisal effect as a function of linguistic accuracy. As expected, all the statistically significant effects are in the positive direction: More surprising words take longer to read. Moreover, models that capture the statistics of the language more accurately also account for more variance in reading time.

Surprisal as estimated by the RNN model (after sufficient training) shows stronger effects than does PSG-based surprisal. We compared the RNN and PSG that showed the strongest effects by testing whether one set of surprisal estimates had an effect over and above the other. The RNN’s surprisals did have an additional effect over the PSG’s ( $\chi^2 = 7.6$ ;  $p < .01$ ) but the reverse was not the case ( $\chi^2 = 1.93$ ;  $p > .15$ ). That is, the grammar does not yield surprisal values that explain any unique variance in reading times.

### Pupil size

**Analysis** As the eyes move across the screen, the angle between the eye gaze and camera changes, affecting the observed pupil size. This was corrected for by fitting a second-degree polynomial to the measured pupil sizes during saccades as a function of the horizontal gaze direction. Correction was performed for each presentation block (i.e., between recalibrations), participant, and individual eye (left or right).

The fitted values then served as a baseline of pupil size at each horizontal location on the display. If both eyes were successfully tracked, pupil size was averaged over the two. For each subject and sentence separately, pupil sizes were then rescaled to a percentage of the average over the sentence.

The effect of word surprisal on pupil size was analyzed at every 2 ms sample (i.e., the sampling rate of the eye-tracker), from 500 ms before the first fixation on a word, up to 1000 ms after that fixation. If any pupil size during that 1500 ms time window was below 70% or above 130%, the data for those 1500 ms were discarded.

When we analyzed reading times, a baseline regression model was fitted to the gaze durations. In the case of pupil sizes, however, it is not possible to fit just one baseline model because the values of the dependent variable differ across samples. Alternatively, a different model could be fitted to each sample but that would make it impossible to track the surprisal effect over time. Therefore, the same, simplified baseline model is used for all samples. It contained the main effects from the reading-time analysis, except that the factor ‘word position’ was replaced by the fixated letter’s position in the sentence (both linear and quadratic factors). Letter position allows us to take into account differences in luminosity across the display, which can affect pupil dilation. In addition, because samples of pupil dilation are taken up to 500 ms before fixation on the current word, the length, log frequency and log forward probability of the *previous* word are also included. As before, the effect size of surprisal was defined as the decrease in regression model deviance due to surprisal. Surprisal estimates were taken from the RNN and PSG model that explain the most variance in gaze duration.

**Surprisal effect** Figure 2 shows how strongly a word’s surprisal affects pupil size, time-locked to the moment of first fixation on that word. There is a positive relation between surprisal and pupil size, which arises very early, even before fixation (i.e., parafoveally).

Considering that the effect of a word’s surprisal arises before fixation on that word, it makes sense to discard cases in which the previous word was not fixated. Specifically, it is unlikely that enough information about a word can be obtained if it is still more than one word ahead. Indeed, as shown in Figure 3, the effect of surprisal remains as strong even when we only take into account cases in which there is a fixation on the previous word (in spite of a 30.3% reduction in the amount of data).

**Entropy effect** Alternatively, the early effect of surprisal could be due to readers’ uncertainty about the upcoming word.<sup>4</sup> If uncertainty about  $w_{t+1}$  correlates positively with its surprisal, and being in a state of increased uncertainty causes the pupils to dilate, then the apparent effect of surprisal may actually be an effect of uncertainty. Such an effect can appear during processing of  $w_t$ , without any information about the

upcoming word  $w_{t+1}$ .

We investigated this possibility by estimating how much uncertainty about  $w_{t+1}$  a reader may experience after processing  $w_{1...t}$ . In information theory, uncertainty about the value of a random variable is quantified by its *entropy*. In the context of incremental sentence comprehension, the uncertainty about  $w_{t+1}$  is defined as:

$$H(w_{t+1}) = - \sum_{w_{t+1}} P(w_{t+1}|w_{1...t}) \log P(w_{t+1}|w_{1...t}).$$

The entropy  $H(w_{t+1})$  is based on the probability distribution  $P(w_{t+1}|w_{1...t})$ , which is exactly the output of the RNN model. Note that, unlike the word’s surprisal, the entropy over  $w_{t+1}$  does not require knowledge of the actual upcoming word  $w_{t+1}$ . Crucially,  $H(w_{t+1})$  equals the expected value of surprisal( $w_{t+1}$ ) so the two values correlate positively ( $r = .38$  in our data set). A positive effect on pupil dilation of uncertainty about  $w_{t+1}$  could therefore be misinterpreted as an effect of the surprisal of  $w_{t+1}$ . However, as Figure 4 shows, the relation between entropy (as estimated by the RNN) and pupil size is (if anything) negative. Consequently, the effect of surprisal in Figure 3 is not an entropy effect in disguise.

## Discussion

Our reading-time results corroborate earlier findings: More surprising words take longer to read; this effect grows stronger as surprisal values are estimated by linguistically more accurate models; and RNN-based surprisals account for more variance than do grammar-based estimates. Like Frank and Bod (2011), we found no additional effect of the grammar-based surprisals. However, applying the same surprisal estimates to data from a self-paced reading study, Fernandez Monsalve et al. (2012) did find an additional effect of the PSG’s surprisals, possibly because their data set was almost ten times larger than our current set.

Importantly, predictions by computational models of language have never before been applied to the analysis of pupil-lometric data. Hence, the effect of word surprisal on pupil size had not yet been demonstrated. This effect confirms that surprisal is indeed a cognitively relevant measure of processing load, and not merely of processing *time*.

Two explanations have been proposed for the relation between word surprisal and cognitive load: According to Levy (2008), integrating a new word into the interpretation of the sentence so far comes down to updating a probability distribution over all possible sentence interpretations. He proves that the extent of this update, expressed as the Kullback-Leibler divergence from the old distribution to the new, equals the word’s surprisal. Alternatively, Smith and Levy (2008) argue that the surprisal effect is due to the reader’s processing system being more prepared for more expected words. Under that account, we may expect surprisal effects to occur sooner than if they result from integration of the new word with the current sentence interpretation. Therefore, the very early, pre-fixation effect we found here seems most compatible with Smith and Levy’s preparation account.

<sup>4</sup>We would like to thank an anonymous reviewer for this suggestion.

Figure 2: Effect of surprisal on pupil size over time.

Figure 3: Effect of surprisal on pupil size over time, taking only cases where the previous word was fixated.

Figure 4: Effect of entropy (uncertainty about the upcoming word) on pupil size over time.

The early occurrence of a surprisal effect may also explain why only the RNN predicted pupil size. Presumably, RNNs simulate early, predictive processing whereas applying a PSG (i.e., parsing) generates syntactic structure and therefore models later ‘integrative’ processing. Hence, an early effect on pupil size that does not depend on integrative processing would only be predicted by RNNs and not by PSGs.

## Conclusion

A word’s surprisal has a very early effect on pupil size during reading: At about 250 ms *before* the word is fixated, its surprisal is a significant predictor of the reader’s pupil size. This suggests that surprisal effects are due to preparation (Smith & Levy, 2008) rather than integration (Levy, 2008). Moreover, it may explain why surprisal estimates by RNNs have a stronger effect than those from PSGs. Perhaps more importantly, however, we have established that pupillometry is a viable paradigm for studying the fine-grained time course of reading processes.

## Acknowledgments

The research presented here was funded by the European Union Seventh Framework Programme (FP7/2007-2013) under grant number 253803, and by a grant from the Economic and Social Research Council of Great Britain (RES-620-28-6001) awarded to the Deafness Cognition and Language Research Centre. We are grateful to Naima Ansari for her assistance with data collection.

## Abstract

Distributional models of semantics are a popular way of capturing the similarity between words or concepts. More recently, such models have also been used to generate properties associated with a concept; model-generated properties are typically compared against collections of semantic feature norms. In the present paper, we propose a novel way of testing the plausibility of the properties generated by a distributional model using data from a visual world experiment. We show that model-generated properties, when embedded in a sentential context, bias participants' expectations towards a semantically associated target word in real time. This effect is absent in a neutral context that contains no relevant properties.

**Keywords:** Distributional models of semantics; concepts and properties; context effects; eye movements; visual world.

## Introduction

The representation of semantic concepts has been the subject of an intense debate over the last few decades (Murphy, 2002). An emerging consensus is that the internal structure of a concept can be represented as a set of semantic properties (Garrard, Lambon Ralph, Hodges, & Patterson, 2001; Baroni & Lenci, 2008). These properties can be accessed in the form of semantic feature norms elicited from experimental participants (McRae, Cree, Seidenberg, & McNorgan, 2005). In the computational modeling literature, this idea has been taken up by distributional models of semantics. Such models have traditionally been used to compare the similarity of words or concepts. However, recently, a distributional model has been proposed that is able to generate properties associated with a concept (Baroni, Murphy, Barbu, & Poesio, 2010). These properties are computed based on corpus data, and have been shown to overlap with those generated in feature elicitation experiments. Distributional models can therefore be claimed to provide a cognitively plausible representation of concepts in terms of semantic properties.

In the present paper, we propose a novel way of testing this claim using the visual world paradigm (Tanenhaus, Spivey-Knowlton, Eberhard, & Sedivy, 1995), which allows the study of conceptual processing in real time. We embed the properties generated by Baroni et al.'s model for a given target word into a sentential context. If the model-generated properties are cognitively plausible, then they should bias participants' expectations towards a target word, compared to a competitor word not associated with the properties. As a baseline, we also embed the target and competitor in a neutral context; the contextual expectation effect should be absent in this case.

## Background

The idea of testing the predictions of distributional models using the visual world paradigm goes back to Huettig, Quinlan, McDonald, and Altmann (2006). They were interested in validating the semantic similarity measures generated by two distributional models: Latent Semantic Analysis (LSA; Landauer & Dumais, 1997) and Contextual Similarity (McDonald, 2000). Huettig et al. (2006) demonstrated that the similarity scores generated by both models are significantly correlated with fixation probabilities in a visual world experiment.

Huettig et al. used a list of 26 target/competitor pairs of semantically related but not strongly associated words. In every pair, one of the words corresponded to a target object depicted in a visual scene (the target word); the other one (the competitor word) was semantically related to the depicted object. For every pair of words, a spoken sentence was recorded that contained either the target or the competitor. Huettig et al. focused on the effect of hearing the target vs. the competitor as critical word. For this reason, the context sentences they used were neutral, providing background information that did not bias the participants towards either the target or the competitor. One of their contexts is given in (1) as an example.

- (1) At first, the man laughed loudly, but then he saw the elephant (target)/alligator (competitor) and understood that it was dangerous.

The crucial manipulation in our experiment, however, concerns the context sentence. We run Huettig et al.'s neutral context as a baseline condition, but we add two context conditions: a context containing properties associated with the target, and a context containing properties associated with the competitor. These context sentences were constructed using three properties produced by the distributional model Strudel (Structured Dimension Extraction and Labeling; Baroni et al., 2010). Strudel is a model trained on the lemmatized and part-of-speech tagged version of Ukwac, an English corpus of two billion tokens extracted from the Web (Baroni, Bernardini, Ferraresi, & Zanchetta, 2009).

Strudel shares with other distributional models the assumption that it is possible to represent the meaning of a word in terms of other words that frequently appear in its linguistic context. Unlike traditional distributional approaches, Strudel describes concepts not only in terms of their most frequent

context words, but can also represent a word’s internal structure in terms of semantic properties (e.g., visual features, the functions of an artefact). The output of Strudel is a list of properties linked to the corresponding concept through a pattern describing the relation between the concept and the property. An example is the relation *elephant\_in\_jungle*, in which the concept *elephant* is related to the property *jungle* via the pattern *in*. The set of properties for each concept is computed based on the number of co-occurrences in the corpus, taking into account the number of relevant patterns. The properties that Strudel generates this way are cognitively plausible in the sense that they overlap with human-generated feature norms such as the McRae et al. (2005) norms, as Baroni et al. (2010) demonstrate.

## Experiment

This experiment had two main goals. Firstly, we wanted to test Strudel’s ability to produce semantic properties for concepts. We evaluated this by using the properties to create sentential contexts, which we predict should bias participants towards the target concept. Secondly, we wanted to establish the effect that such contexts have on the processing of the target concept.

Huetting et al. used a neutral context and found that participants are more likely to fixate a target object when they hear its name, but they also show an increased fixation probability for the name of a semantically associated object. We expect this effect to be modulated by context. More specifically, the processing of properties associated with the target should build up an expectation for the target, and as a consequence, there should be more fixations on the target object when the target word is spoken, compared to the neutral context condition. This effect should be attenuated for the competitor, which is distinct from the target, but semantically related (as in Huetting et al.’s design).

## Method

**Materials** The visual world paradigm requires both visual and linguistic stimuli. We used the same visual scenes as Huetting et al. Each scene contained black and white line drawings of the target object and three distractors; the pictures were extracted from the Snodgrass and Vanderwart (1980) collection. Huetting et al. removed phonological competitors and matched the pictures according to naming and image agreement, familiarity, visual complexity, and word frequency of the correspondent noun. Moreover, they tested the visual similarity between pictures. In our experiment, we used the same scenes used in the original experiment: this allowed us to skip the norming process.

We used the same linguistic materials as Huetting et al. for the neutral context condition. We added to this two context conditions: one for the target concept, and one for the competitor. For each of the 52 concepts (26 competitor/target pairs) in the Huetting et al. materials, we extracted from the output of Strudel the first 20 semantic properties

Figure 1: Example scene for the pair elephant (target)/alligator (competitor) in the experiment. The box highlights the target object (not shown to participants).

(nouns, verbs, and adjectives) ordered according to their log-likelihood ratio. We constructed a context sentence for each concept using three of these properties (excluding those associated with words that are part of the same target and competitor pair).

The context sentences had a standard pattern: a temporal subordinate clause introducing the situation followed by the main clause. The target concept is embedded at the end of the main clause and followed by an adverb (which serves as a spill-over region for the analysis). As an example, Figure 1 depicts the scene associated with the pair elephant (target)/alligator (competitor). The sentences associated with this scene are:

- (2) Neutral Context: At first, the man laughed loudly, but then he saw the **elephant** and understood that it was dangerous.
- (3) Target Context: While the man was crossing the *jungle*, he saw a *poacher capturing* an **elephant** ferociously.
- (4) Competitor Context: While the man was crossing the *swamp*, he saw a hippo *attacking* a *gigantic* **elephant** ferociously.

The critical word is given in **bold**; the properties are in *italics*. For every sentence there was also a counterpart that included the competitor word (in this case **alligator**), resulting in six conditions in total.

The quality of the materials was evaluated in two norming studies performed using Amazon Mechanical Turk. In a sentence plausibility judgment task, 33 native English speakers rated the sentences on a scale from 1 (completely implausible) to 7 (completely plausible). The mean rating for the con-

cept in the sentence with the corresponding properties was 5.67 ( $SD = 0.63$ ) and in the opposite sentence, it was 4.70 ( $SD = 1.07$ ); the opposite sentences were created by swapping the critical words across conditions (target for competitor and vice versa). An Anova showed no main effects, but a significant interaction of concept (target or competitor) and sentence (target or competitor) ( $F_1(1, 35) = 27.86, p < .001$ ;  $F_2(1, 32) = 53.81, p < .001$ ).

In a sentence completion task, we removed the critical words from the sentences and asked 21 participants to complete each of the 52 sentences (two groups of 36 sentences) by typing the most plausible noun. After a process of synonym reduction, we counted the number of occurrences for each word. Good sentences had to elicit primarily the nouns they were associated with and only a small percentage of competitor or unrelated words.

The combination of these two norming studies was used to ensure that a given context was sufficiently associated with the target word, and not with the competitor word. Based on the norming data, we excluded eight pairs of concepts: these were cases in which Strudel had produced properties for a different sense of the word than the one in the Huettig et al. materials, as well as cases in which the target sentences were too different from the competitor ones so that the properties could not be plausibly swapped.

The sentence materials were recorded by a native English speaker at a normal speech rate for presentation in the experiment.

**Procedure** The entire experiment included 108 sentences: 18 word pairs (36 words in total) embedded in a neutral context and two biasing contexts. We rotated the position of the four objects on the screen to control for order or position effects. In total we therefore obtained 432 distinct items that we split in 24 lists of 18 items. The distribution of items across lists was based on a Latin square design, ensuring that each list included exactly one word from each target/competitor pair. Twenty-five filler items were added and a random presentation order generated for each list.

Twenty-four native English speakers from the University of Edinburgh were paid five pounds for taking part in the experiment. Each participant saw the items of one of the 24 lists, randomly interspersed with nine yes/no questions about the sentence or the scene. The questions were there to ensure that participants paid attention throughout the experiment.

Participants were seated in front of a 21" multi-scan monitor with a resolution of 1024 x 768 pixels and their eye movements were recorded using an EyeLink II head-mounted eye-tracker with a sampling rate of 500 Hz. Only the dominant eye was tracked. At the beginning of the experiment and after every ten trials, the eye-tracker was recalibrated using a nine-point randomized calibration. Before each trial, drift correction was performed. At the beginning of each trial the scene appeared on the screen, and the sentence began to play at the same time; the scene disappeared after 1500 ms after the end

of the sentence. The experiment was explained using written instructions and preceded by practice trials. The instructions asked participants to listen carefully to the sentences and look wherever they wanted on the screen. The experiment lasted approximately 30 minutes.

## Results and Discussion

**Fixation Probabilities** Our analysis is based on the fixations on the target object compared to the fixations on the three distractor objects on the display. We excluded out-of-screen fixations and blinks from the analysis. Figure 2 plots the probability of fixating the target object across the three context conditions. The neutral context condition used the sentences of Huettig et al.; the target and competitor conditions used the contextually biased sentences produced based on the Strudel properties. In each plot, 0 ms corresponds to the acoustic onset of the critical word; our analysis takes into account the first 1000 ms after this onset. The vertical line shows the average offset of the critical words, with confidence intervals. The horizontal line at .25 indicates the probability of randomly fixating one of the four objects.

An inspection of the plots reveals a broadly similar trend across the three context conditions. The critical words require some time before they are recognized, which means that the fixation probabilities for the target and the competitor words take between 200 and 500 ms before they diverge. After that, we observe an increase in fixations to the target word compared to the competitor. The point of divergence is about 200 ms later in the neutral context; a semantically related context seems to aid the recognition of the critical word and triggers early fixations to the corresponding object. (Bear in mind that the competitor context is also semantically related to the target, as our norming studies showed.)

In the neutral context condition (Figure 2(a)), we observe a steady increase in fixation probability for both the target and the competitor word, which start to diverge at the offset of the critical word (this is presumably the point at which the critical word has been recognized by the participants). From that point on, we see more fixations on the target than on the competitor. This is in line with what Huettig et al. (2006) found: a competitor word triggers fixations to a semantically related target object, but less fixations than the target word corresponding to the target object. Our neutral context condition therefore provides a replication of Huettig et al.'s results. (The original paper also showed that the difference in fixation probability between target and competitor correlates with their semantic similarity, but we will not test this claim.)

In the target context condition (Figure 2(b)), participants had heard a sentence containing properties of the depicted objects. Presumably this enables them to predict the target word with some accuracy (and our sentence completion study confirmed this). As the target is expected (and hence less interesting) at this point, we only observe a small increase of fixation probability for the target compared to the competitor, which starts early, at around 200 ms. This early start is consistent with the fact that participants are able to predict the critical

(a) Fixation probability in a *neutral context* sentence.

(b) Fixation prob. in a sentence associated with the *target* object.

(c) Fixation prob. in a sentence associated with the *competitor* object.

Figure 2: Fixation probabilities on the target object over time for the target (continuous red line) and competitor (dotted blue line) words. The onset of the critical word is at 0 ms. The vertical lines indicate the mean of the offset of the critical word with confidence interval. The horizontal line shows a probability of .25 (random baseline for four objects).

word in this condition based on the context sentence.

In the competitor context condition (Figure 2(c)), participants had heard a context sentence that is not directly associated with the depicted target object, but is instead associated with the semantically related competitor. In this case, hearing the target word (rather than the contextually appropriate competitor word) is unexpected, i.e., it generates interest and

a larger increase in the number of fixations compared to the competitor word. This means that the two conditions diverge more than in the target context condition, and the divergence remains high for the whole period of analysis.

**Inferential Statistics** To statistically analyze the effect of the experimental manipulation on participants' fixations, we adopted the framework of linear mixed effect models (LME, Baayen, Davidson, & Bates, 2008). As suggested by Barr (2008), the dependent variable was the empirical logit of the fixation probability, calculated for each bin as:

$$\text{emplog} = \log \left( \frac{Y + .5}{N - Y + .5} \right)$$

where  $Y$  is the number of fixations on the target object and  $N$  is the total number of fixations in the bin.

Our model included the factor *Word* representing the nature of the critical word, coded as *Competitor* =  $-.5$  and *Target* =  $.5$ . To determine context effects, we included two factors in contrast coding: the factor *Context* coded the difference between the neutral context =  $-.5$  and the biasing context =  $.25$  conditions; the factor *TargetSentence* differentiated the biasing context sentences further by distinguishing *Competitor* =  $-.5$  and *Target* =  $.5$ . We have also included *Region* as a factor that indicates if the bin is in the critical region (coded as  $-.5$ ) or in the region after the offset of the critical word (coded  $.5$ ). Finally, the continuous predictor *Time* was discretized into 10 ms bins (range 1–100).

The random effects we included were *Participant* and *Item*, which were intercepts in the model. We also included random slopes for all the main effects (*Word*, *Context*, *TargetSentence*, *Region*, and *Time*). We used the model selection procedure of Coco and Keller (2012) to find the minimal model that best fits our data. Table 1 gives the coefficients and significance levels for the minimal model; main effects or interactions not listed in this table were not included in the minimal model by the selection procedure.

**Effect of Context** The factor *Context* compares fixation probabilities in the neutral context and in the biasing context, collapsing the competitor and the target context in the biasing context condition. We find a significant, positive main effect of this factor, suggesting that participants make more fixations on the target object in the biasing context condition. This is modulated by a negative interaction *Time:Context*, which indicates that fixation probability increases over time in the neutral context condition. This explains the upwards trend in Figure 2(a), but not in the biasing context conditions (Figures 2(b) and 2(c)).

While there is no general effect of whether the context is the competitor or the target sentence (no main effect of *TargetSentence*), we do find a significant positive interaction *Time:TargetSentence*. This confirms that there is a larger increase in fixations to the target object in the target context compared to the competitor context.

Table 1: Coefficients for the mixed effects model for the data in Figure 2.

Predictor	Coefficient
(Intercept)	-1.15***
Time	0.17*
Context	0.80*
Time:Context	-0.64***
TargetSentence	-0.47
Time:TargetSentence	0.11**
Word	-0.06
Time:Word	0.18***
Region	0.09
Region:Context	-0.41**
Region:TargetSentence	-0.61***
Word:TargetSentence	0.84***
Time:Word:TargetSentence	-0.43***
Region:Context:Word	-0.60***

\*  $p < .05$ , \*\*  $p < .01$ , \*\*\*  $p < .001$

**Effect of Critical Word** While there is no main effect of Word, we find a significant positive interaction Time:Word that indicates that fixations on the target word increase more quickly than fixations on the competitor word. This is not surprising: when participants hear a word that matches the target object on the screen, they fixate this object more frequently (recall that the target object is depicted in all conditions, the competitor object is never on the screen).

**Effect of Region** There is no significant main effect of Region: whether the fixations are in the critical region (between the onset and the offset of the critical word) or in the post-critical region. However, we find a significant negative interaction Region:Context, suggesting that the neutral context sentences receive more fixations in the post-critical region compared to the biasing context sentences. This is compatible with the observation that context facilitates the processing of the critical word, which thus receives fixations earlier in the context condition.

The interaction Region:TargetSentence confirms that in the post-critical region participants fixate the target object more in the competitor context, presumably because it conflicts with their contextual expectations in this case. In the target context, however, contextual expectations and target object match, which means there is no reason to fixate the target object more frequently (compare Figures 2(b) and 2(c)).

**Interaction of Context and Critical Word** The most important interactions with respect to our experimental hypothesis are those involving Context and Word or TargetSentence and Word. These interactions demonstrate

that context has an effect that is specific to the critical word.

We find a significant positive interaction Word:TargetSentence, which demonstrates that the target object receives more fixations when the target word occurs in the target context (rather than in the competitor context). This effect changes over time (significant negative interaction Time:Word:TargetSentence): the increase in fixations in the target word condition is larger in the competitor context than in the target context. For the competitor word, the opposite tendency emerges. This confirms the prediction that an expected critical word (i.e., one matching the context) is less interesting, and thus less likely to be fixated.

Finally, we can report a significant negative interaction Region:Context:Word, suggesting that the effect of Word in the neutral context condition is limited to the post-critical region, while in the biasing condition, it is stronger in the critical region. This corresponds to the observation that the fixation curves for the target and the competitor word diverge earlier for the biasing context conditions (see Figure 2).

## General Discussion

First of all, our results replicate the findings of Huettig et al. (2006). In the neutral context condition, we find that participants fixate the target object both when they hear the critical word, and when they hear the semantically related competitor. While we observe less fixations on the target for the competitor word, Figure 2(a) clearly indicates that it is fixated more than chance (corresponding to a probability of .25).

However, the main purpose of our experiment was to test the ability of a distributional model of semantics to generate properties of concepts that are cognitively plausible. We therefore included two context conditions in our experiment, one in which the context sentence contained properties related to the target word, and one in which it contained properties related to the competitor word. In both cases, the properties were created by Strudel, a model of semantic representation.

When we compared these two biasing context conditions to the neutral context condition, we found two main effects. Firstly, a biasing context facilitates the processing of the critical word. Over time, the context builds up an expectation of the critical word, resulting in less fixations to the target object when it is contextually expected. This effect occurs for both types of biasing contexts, which is in line with the fact that the target and the competitor words were semantically related, which presumably implies that their properties are also semantically related. In the neutral context, in contrast, no expectations can be computed, as participants cannot guess the identity of the target word before its onset. The target object is unexpected and hence more interesting and receives more fixations, but these fixations appear later, once the recognition of the target word is complete.

Our second finding is that a biasing context makes it possible to anticipate the critical word: in a target context, we get more fixations to the target during the target word, com-

pared to the competitor word (Figure 2(b)). In the competitor context, we also initially find more fixations during the competitor word than during the target word. However, the pattern reverses after about 200 ms, presumably because of the match between the target word and the target object on the screen, which overrides the contextual expectation of the competitor word. Fixations for the target word remain high, however, compatible with a violation of contextual expectations (Figure 2(c)).

Both effects provide confirmation for the claim that we started out to prove: distributional models of semantics can generate properties that are cognitively plausible. They are plausible in the sense that they can be used to construct contexts that successfully bias participants towards a word that is compatible with the context. This contrasts with a neutral context, in which differences in fixation probabilities are purely driven by the semantic similarity with the target word. We therefore conclude that models like Strudel are a first step towards modeling linguistic context in a distributional way, which contrasts with the single-word approach that most of the distributional semantics literature has taken so far.

### Acknowledgments

The work reported here was funded by the European Research Council under award number 203427 “Synchronous Linguistic and Visual Processing”. We are grateful to Moreno I. Coco and Christoph Scheepers for their essential support and suggestions and to Desmond Elliott and David Matthews for the help in the production of the linguistic stimuli used during the experiment.

## Abstract

Concepts are typically conceived as context-free knowledge structures. Recently, a different view has emerged according to which subjects produce situation-specific conceptualizations, thereby raising important questions about the level of contextual dependency in conceptual representations. In this paper, we present a feature-norming study in which subjects are asked to generate properties of concepts presented in context. Collected data are analysed to investigate the actual amount of conceptual variation induced by contexts and the effect of context modality.

**Keywords:** Semantic feature norms; property generation; context.

## Concepts and contexts

Both in classical and in post-classical models, concepts have been conceived as substantially context-free knowledge structures. Regardless of the particular theory (e.g. exemplar, prototype, and connectionist), it is generally assumed that concepts result from abstracting critical information about an entity *per se* (such as shape, colour, etc.), leaving behind background situations (i.e. the contexts) in which these entities are experienced. Concepts thus become invariant to different contexts of use. Accordingly, the same representation of an apple is used both when categorizing an entity on a tree, and when categorizing the same entity in a supermarket.

Recently, this view has been overtly criticized. For instance, Yeh and Barsalou (2006) argue that concepts not only contain a large array of situational information about the physical settings, events, and subjective perspectives of agents, but they also produce different conceptualizations in different contexts. For instance, the supermarket situation would activate context-specific information concerning an apple, different from that activated by a different context, such a tree in a garden. These two claims directly follow from the perceptual simulation model adopted by the authors, but more in general they raise important questions about the level of contextual dependency in our conceptual representations. Wu and Barsalou (2009) used a property generation task to investigate the situated nature of concepts, and reported that approximately 26% of the features produced by subjects were indeed situation-related. Subjects generated properties (semantic feature norms) provide interesting evidence about conceptual representations, but one intrinsic limit of the study in Wu and Barsalou (2009) is that stimuli

were presented *out of context*, as it is customary in semantic norming. This way, it becomes impossible to address and test the more specific and crucial issue concerning the relation between concepts and context, that is the actual effect of the context in modulating and biasing conceptual representations.

In this paper, we present a feature-norming study in which subjects are asked to generate properties of concepts presented *in context*. To the best of our knowledge this is the first property generation task with this design. While we do not commit ourselves to any specific model of conceptual representation, collected data allow us to address directly three key issues concerning the effects of different contexts on concepts: i.) the actual amount of conceptual variation induced by contexts, and ii.) the property types that are more subject to contextual variation, and iii.) the effect of the context modality. In particular, we will investigate the effect of both linguistic contexts (i.e. a sentence in which the context noun appears) and extralinguistic contexts (i.e. an image of a situation in which an entity can be experienced).

## Semantic Feature Norms

Nowadays there is a strong consensus on the fact that it is possible to describe the internal structure of a concept in terms of a set of semantic properties (Garrard, Lambon Ralph, Hodges, & Patterson, 2001; Baroni & Lenci, 2008). A traditional way to access and study the structure of conceptual knowledge is the use of semantic features norms. These are lists of properties that participants produce describing and defining a specific concept; moreover they include several measures and statistics calculated according to feature production frequencies.

As suggested by McRae and colleagues (McRae, Cree, Seidenberg, & McNorgan, 2005) these lists do not provide a static and definitive representation of concepts, however, they are the most direct way to study the dynamics associated with the online process that takes place when subjects have to process a specific concept.

Different researchers used these lists to investigate various aspects of human cognition. They have been used to test the psychological validity of cognitive theories (Wu & Barsalou, 2009), and as stimuli for different experiments such as semantic similarity (McRae, Sa, & Seidenberg, 1997) and property verification tasks (Cree, McNorgan, & McRae, 2006).

One of the most widely used norms is the collection of McRae et al. (2005). This is the largest set of semantic properties freely available: it includes properties for 541 living and non-living concepts. Another smaller example is represented by the collection of Vinson and Vigliocco (2008). In this case, the authors extended their analysis to the domain of actions and events. They collected norms for 167 living and non-living objects and for 287 events and actions.

The pros of these collections are relatively straightforward; however they exhibit also different limitations (McRae et al., 2005). The process of collection, normalization and classification is extremely long and expensive. Moreover, the linguistic nature of the task favours the information which is easily verbalized, penalising spatial and temporal relations between entities. During the classification phase, the annotators have to reinterpret the intents of the subjects and cannot always preserve the original information. Finally, as we said above, all existing norms were collected by presenting words in isolation and not associated with a specific context. In this work, we will focus our attention on this last feature.

### Collecting context-sensitive feature norms

The main goal of this work is to describe the collection of semantic feature norms for 8 concrete concepts and to analyse the effects that contextual variability exerts on the number and types of properties produced.<sup>1</sup>

### Design

The collection was performed on-line using a website interface.

**Stimuli** The 8 normed concepts correspond to the following English nouns: *apple*, *banana*, *bear*, *horse*, *bike*, *car*, *hammer*, and *knife*. The nouns were sampled in order to have an equal number of animate and inanimate concepts belonging to the semantic classes traditionally used in these studies, that are fruits, animals, vehicles, and tools.

For each concept, we identified two alternative situations frequently associated with the correspondent object. We downloaded from the Web 16 colour pictures depicting the two contexts for each concept and we downsized them (288\*320 pixels). The pictures do not include the target object unless it is strictly necessary for the correct interpretation of the context (e.g. a showroom without some cars inside would not be identifiable). This way, participants are not biased in their descriptions by a specific instance of the concept appearing in the picture. A native English speaker produced 16 sentences describing the context depicted in the correspondent picture. Unlike the visual contexts, the sentences include the target concept noun (written in capital letters).

For every trial, the target concept noun (in capitals) appears on the top of the screen and is followed by 10 blank lines that participants have to fill in with concept properties. In the case

of the linguistic context, the sentence containing the target word appears instead of the target word. For the visual context, the picture appears on the left of the blank lines. Figure 1 shows the visual and linguistic contexts for *apple*.

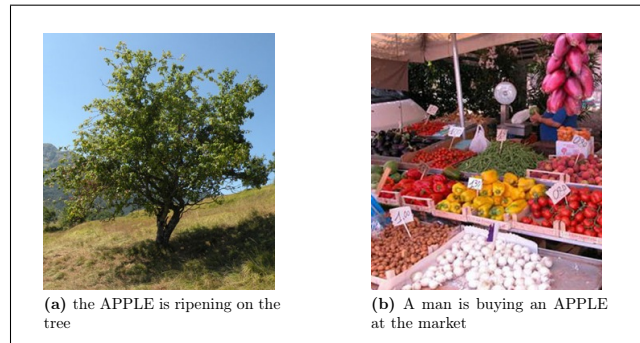

Figure 1: *apple*: visual and linguistic contexts.

**Procedure** The entire experiment included 40 different combinations of the 8 concepts and the 5 different context types (2 visual, 2 linguistics, and 1 no context). 125 lists of 8 items each were created: the distribution of the items across lists was based on a Latin Square design, ensuring that every list comprised only one occurrence of each concept and one of each specific context. Every list included the 8 concepts as follow: one or two out of context, three or four in a visual and linguistic context respectively. The order of the trials was semi-random: all the out of context trials appeared before the linguistic ones and those before the visual ones. In this way, the complexity of the stimulus increased during the experiment.

125 native English speakers recruited online performed the experiment. Each participant saw the 8 items of one of the 125 lists; in this way, every concept and context were seen only once. The experiment started after written instructions of the task and 3 examples. The task required to read the word (or the sentence) at the top of the screen and to produce a maximum of 10 properties per concept describing different aspects of it. The instructions clearly stated that the aim of the experiment was to study how people process the meaning of words; subjects were not instructed to take contextual variability into account. Moreover, we provided a list of possible qualities of the concepts to take into account during the actual experiment: colours (e.g. CHERRY *red*)<sup>2</sup>, tastes (e.g. ICE CREAM *good*), shapes (e.g. BALL *round*), functions (TRAIN *transportation*), typical locations (SHARK *ocean*), emotions (CHRISTMAS *excitement*), evaluations (SOUP *hate*), etc. We did not set a maximum amount of time for a single trial however, on average, the entire experiment lasted about 15 minutes.

<sup>1</sup>The collection is freely available at <http://sesia.humnet.unipi.it/norms>

<sup>2</sup>In this work, we use caps to indicate CONCEPTS and italics to indicate the *properties produced*.

## Post Processing

**Data Codification** After collecting the features, a process of data filtering and normalization was carried out. We identified all the synonym properties and we normalized them to the same feature (e.g., “bike” and “bicycle” were coded as *a bike*). Coordinate or disjunctive features providing more than one piece of information were split into separate tokens. For example, “is red, green or yellow” became *is red, is green, and is yellow*. We removed all the quantifiers (e.g. “can be”, “generally”, “usually”) and other materials not relevant to the analysis (e.g. miscellanea, incoherences, and free associations). Finally, one of the authors coded the resulting properties according to a specific set of patterns (e.g. BEAR *beh\_eats\_honey* codes “to eat honey” as a prototypical behaviour (beh) of bears) and classified them according to the scheme described below.

**Coding Scheme** The properties were classified according to a partially simplified version of the coding scheme proposed by Wu and Barsalou (2009). The scheme includes 24 property types grouped into 4 main categories:

- *Taxonomic properties* (TAX): properties describing taxonomic relations (hypernyms, hyponyms, synonyms, and coordinates).
- *Entity properties* (ENT): properties describing the entity per se (e.g. internal and external properties and elements, prototypical behaviours).
- *Situation properties* (SIT): properties associated with the contextual background (e.g. locations, time, participants, functions).
- *Introspective properties* (INT): properties describing feelings and mental states (e.g. evaluations, contingencies).

## Results

Participants produced 6922 properties in total: 3619 entity properties, 2025 situation properties, 644 introspective properties, and 634 taxonomic properties. Table 1 reports the average number of features (and Standard Error) produced by every subject for each item and grouped by property class and modality. There are no noticeable differences among modalities (visual, linguistic, and no context): this suggests that different contexts are not exerting a significant effect on the number of properties generated. The differences arise analysing the property classes. The properties describing different aspects of the target concept (ENT) are the most frequent (52% of the total). Properties providing contextual information related to the target concept (SIT) are produced the 29% of the time (interestingly, this figure is close to the one reported by Wu and Barsalou (2009)). Properties describing mental states (INT) and taxonomic relations (TAX) are less frequent (around 9%).

Table 1: Average (AVG) and Standard Error (SE) of the number of features produced by each subject for each concept grouped according to broad property class and modality.

## Analysis

**Model** We analysed the data adopting the framework of the linear-mixed effects models with a Poisson linking function (Baayen, Davidson, & Bates, 2008). The dependent variable was the property frequency. Table 2 presents the coefficients and p-values of the mixed model. To investigate the effects exerted by contextual variability we included two factors in contrast coding: the factor *Modality* for the effects of visual (+.5) and linguistic context (-.5), and the factor *Context* for the effects produced in the out-of-context (-.5) and in the in-context (+.25) conditions. We also analysed the effects associated with the type of feature produced: the factor *Property* compared the object related properties such as entity and taxonomic properties (-.25) and the context related properties such as situation and introspective properties (+.25); the factor *ObjectProp* coded the effects of taxonomic (-.5) and entity (+.5) properties; and the factor *SituationProp* the effects of situation (-.5) and introspective (+.5) properties. The random effects were *Subject* and *Concept*, which were intercepts in the model. We also included random slopes for all the main effects (*Modality*, *Context*, *Property*, *ObjectProp*, and *SituationProp*).

Table 2: The coefficients for the linear-mixed effects model.

Predictor	Coefficient	Signif.
(Intercept)	0.66	***
Property	-0.28	
ObjectProp	1.10	***
SituationProp	-0.43	***
Context	0.01	
Modality	0.04	
Context:Property	-0.09	
Context:Object	-0.17	
Context:Situation	-0.06	
Modality:Property	0.14	
Modality:Object	-0.13	
Modality:Situation	-0.29	**

\*  $p < .05$ , \*\*  $p < .01$ , \*\*\*  $p < .001$

**Property Types** The factor `Property` compares the overall mean of entity and taxonomic properties (properties more associated with the object) with the overall mean of situation and introspective properties (properties that are more associated with the context). We find a slightly significant effect ( $p < .1$ ) in favour of the first group of properties: object related properties are produced more frequently than context related properties. The factor `ObjectProp` shows a significant positive main effect for the entity properties compared to the taxonomic ones. The factor `SituationProp` reveals a positive effect for situation properties compared to the introspective ones.

**Context and Modality** As expected, there is no significant main effect for `Context` and `Modality`. We only find a not significant effect associated with the visual context. Participants produced almost the same number of properties independently of the presence and type of contextual information they are exposed to.

**Interactions** The interactions reported in table 2 do not reveal significant effects. The only significant effect is described by the interaction `Modality:SituationProp` where situation properties are positively biased by visual contexts, while introspective properties are more biased by linguistic properties.

### Qualitative Analysis of Feature Types

In this section we present a qualitative analysis of the data to determine the main effects exerted by contextual information on specific property types.

For each concept, we divided the features produced in both contexts from those associated only with a specific context. We did the same procedure for visual and linguistic contexts independently. The aim of this analysis is to determine which property types are more dependent on a specific context (context dependent) and which are produced in both contexts (context independent). We are interested in a general evaluation of this effect without taking into account inter-conceptual variability: for this reason we combined the results obtained for each concept. After a preliminary analysis, we discovered that property types show an almost coherent trend both in a visual and linguistic context. We analysed the effects exerted by the two modalities using a linear model. We did not find a significant difference between visual and linguistic modality as main effect ( $\beta_{Visual} = 3.90, p = 0.94$ ) and also in interaction with the context\_dependent vs context\_independent variable ( $\beta_{Visual:ContextInd} = 4.54, p = 0.88$ ). For that reason, table 3 reports the results from a general point of view, without modality distinction. If there is a difference between the two modalities we will discuss it separately. We report the percentage of context dependent and context independent properties out of the total number of properties of the same type (e.g. the 92% of hypernyms are context independent). We also present in bold the percentage for the entire

class at the end of each group of properties (e.g. the 80% of taxonomic properties are context independent). In brackets there is the number of properties of each type out of the total number of properties in the same class (e.g. the 78% of taxonomic properties are superordinates).

Table 3: Percentage of the features that are context dependent (associated with only one context) and context independent (associated with both contexts).

Property	Dependent	Independent
C-super (.78)	0.08	0.92
C-subord (.19)	0.57	0.43
C-coord (.02)	1	0
C-syn (.02)	0.5	0.5
<b>Taxonomic</b>	<b>0.2</b>	<b>0.8</b>
E-exsurf (.27)	0.15	0.85
E-excomp (.24)	0.12	0.88
E-sys (.21)	0.28	0.72
E-beh (.07)	0.39	0.61
E-incomp (.06)	0.24	0.76

E-mat (.06)	0.07	0.93
E-quant (.02)	0.53	0.47
E-whole (.01)	0.21	0.79
<b>Entity</b>	<b>0.2</b>	<b>0.8</b>
I-cont (.68)	0.62	0.38
I-eval (.30)	0.38	0.62
I-emot (.02)	0.5	0.5
<b>Introspective</b>	<b>0.54</b>	<b>0.46</b>
S-func (.47)	0.25	0.75
S-assoc (.15)	0.58	0.42
S-loc (.15)	0.44	0.56
S-action (.08)	0.33	0.67
S-particip (.08)	0.48	0.52
S-origin (.06)	0.1	0.9
S-time (.01)	0.59	0.41
S-socart (<.01)	1	0
<b>Situation</b>	<b>0.35</b>	<b>0.65</b>

**Taxonomic Properties** Taxonomic properties describe highly stable relations among concepts. As expected, the 80% of these properties are equally produced in different contexts. The hypernyms (C-super, e.g. CAR *a vehicle*) are the 78% of the entire taxonomic class. These properties are represented by a small number of highly frequent feature types (in total only 22 for the visual and linguistic modalities) describing associations strictly language related. Hyponyms (C-subord, e.g. APPLE *Granny Smith*) include a high number of infrequent property types (in total 48 subordinates) and are more context dependent. This can be expected, given that each concept is associated with many hyponyms, which in turn might become differently prominent depending on the context. Co-

ordinates (C-coord, e.g. APPLE *a pear*) and synonyms (C-syn, e.g. CAR *an automobile*) are only a small group of properties.

**Entity properties** The trend of this class is consistent: all the properties describing objects' qualities are not sensitive to contextual variability (the 80% of the total). The only exception is represented by those properties describing frequency or intensity (E-quant, e.g. APPLE *different varieties*); however this group includes a very small number of features and it is valid only for the linguistic modality (65% of context dependent properties).

**Introspective properties** The most substantial group among introspective properties is represented by contingency properties (I-cont, e.g. APPLE *is good with cinnamon*). These properties describe the "common sense knowledge" associated with a specific object in specific conditions. For this reason, it is not surprising to see a strong contextual effect. On the other hand, evaluations about the object (I-eval, e.g. APPLE *is delicious*) are less context dependent: participants have a personal opinion about every object that is unlikely to change in different situations. Emotions (I-emot, e.g. BEAR *is scary*) are very few cases.

**Situation Properties** The behaviour of this group of data is more various, given also the high heterogeneity of the properties in this class. Some properties are intrinsically related to an entity, and, therefore, less variable across situations: for instance, typical functions (S-func, e.g. CAR *used for transportation*), actions (S-action, e.g. APPLE *used by cooking*), origins (S-origin, e.g. APPLE *grows on trees*) and locations (S-loc, e.g. BANANA *grows in tropical climates*). Instead, other property types are more context-related, and, therefore, subject to stronger cross-situation variation, such as associations (S-assoc, e.g. CAR *associated with speed*). Participants (S-particip, e.g. BANANA *eaten by monkeys*) are almost equally present in both sets.

### Analysis of Feature Density

The last analysis we carry on compares the distribution of specific features in terms of feature density: how many subjects produce the same feature for the same stimulus. We analysed the features divided into the context dependent and context independent sets. In the context dependent set the 85% of specific properties are produced by only one person, the 11% by two different subjects. The remaining 4% is shared by properties produced from 3 to 10 people. On the other hand, in the context independent set we have the 21% of features produced only by 2 subjects (the minimum value for having an overlap). The maximum number of subjects that produced the same feature is 47 (KNIFE *is sharp*).

## General Discussion

The experiment described in this work was aimed to test the effects exerted by contextual variability on the production of semantic properties by human beings. We gave both quantitative and qualitative evidence of these effects. Neither modality nor context variability has significant effects on the number of features produced. People list almost the same number of properties in different contexts. However, these properties are not equally distributed and the differences among them are statistically significant. As already emerged in the literature, subjects produce more entity properties than taxonomic ones and more situated properties than introspective ones. It is interesting to note that merging together the properties more object related (entity and taxonomic) and the properties more context related (introspective and situation) the difference decreases considerably with only a slightly significant effect in favour of the first group. This suggests that people are including in their dynamic representation of concepts both information describing the object *per se* but also almost the same amount of background information. To gather more evidence, we performed also a qualitative analysis. In this case, we extracted from the collection only the properties produced in context and we identified those occurring with both contexts and those associated with only one. The results are straightforward for the taxonomic and entity properties: almost the 80% of all the properties classified in this way are produced in both contexts. We assist to an opposite effect when we move to the introspective properties. More complex is the dynamic of situation properties: some of them are more related to the object, some others to the context.

These results suggest that the context sensitivity of concepts is strongly limited to certain property types. A possible explanation can be found in Barsalou (1982). In this work, the author suggests the existence of two different kinds of properties: *context independent properties* strictly associated with the object *per se*, and *context dependent properties* associated with the specific context in which the word appears. Our data point in the same direction. It is possible to identify a large group of "core" properties that are not biased by contextual variability (in particular entity and taxonomic properties, as expected) and a smaller group of more dynamic properties produced less frequently and only associated with specific contexts (introspective properties, and partially situation properties).

## Acknowledgements

The experiment was funded by the Computational Linguistics Lab (University of Pisa) and the European Research Council under award number 203427 "Synchronous Linguistic and Visual Processing". We thank Larry Barsalou, Marco Baroni, Frank Keller and Moreno I. Coco for their help and suggestions.

# Learning transfer in small group coordination

Seth Frey (sethfrey@indiana.edu)

Cognitive Science, 1101 E. 10th St., rm. 290B  
Bloomington, IN 47401 USA

## Abstract

This work tests the adaptation of groups from two generalizations of the multiple-player stag hunt to a difficult third version, the notorious weakest-link game. The two training conditions either encouraged or discouraged the development of stable subgroups. Theories of modularization predict that stable subgroups will facilitate coordination in larger groups by helping them “scale up.” However, internal structure may also cause “overfitting,” or adaptation to only spurious features of training. In this experiment, experience with internal structure prevented coordination at larger scales, while experience in environments that discourage internal structure led to performance at least as high as in the control environments. I offer the analogy from individual learning transfer, that distracting details from superficially-similar domains may transfer and interfere with coordination. This work has implications for the development and adaptability of small coordinating groups. In particular, it demonstrates that coordination is not a monolith, and experience with one sense may impair performance under others.

**Keywords:** stag hunt; learning transfer; n-player games; coordination games; group structure.

## Introduction

Adaptability and transfer have been a focus of group research since its inception (Bavelas, 1950; Guetzkow & Simon, 1955). The research in “endogenous” groups applies modern experimental methods and game theoretic approaches to understanding adaptability and learning during group formation.

Traditional group experiments impose groups by design, and they use careful matching procedures and information conditions to minimize interaction and reputation effects, and to maintain the independence of individual reasoners. Investigations of *endogenous* group formation encourage interactions and attend to the processes of group formation within an experiment. Endogenous group experiments permit the study of internal (often “network”) structure. In groups, *internal structure* describes the heterogeneous but systematic pattern of coordinated behavior between subgroups. Internal structure can be measured by observing the behavior of group members over time. As the demands on a group change, these internal patterns should also change. For large networks, group structures can be compared along innumerable dimensions, but for the small groups featured in this study it is possible to meaningfully quantify structure with fewer variables.

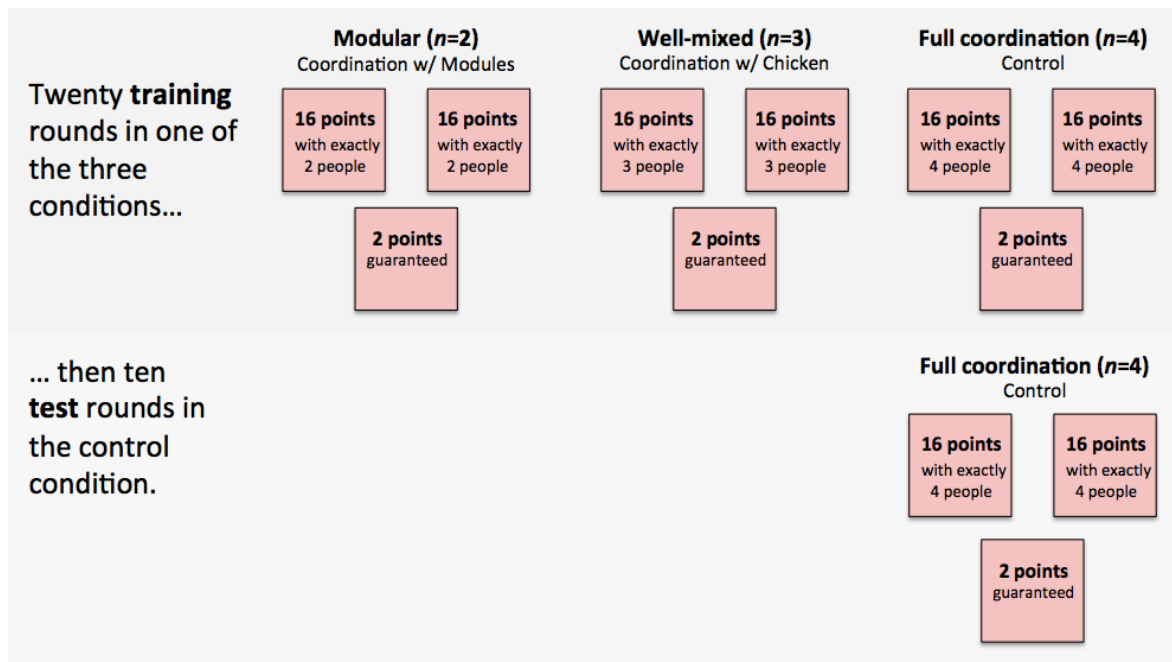

Ahn, Isaac, & Salmon (2008) documented segregation processes as a result of reputation formation and individual choice. Camerer and Weber elicited unprecedented

coordination in the weakest-link game by starting with successful groups of two and “growing” them slowly up to the standard 7-person case (Camerer & Weber, 2008). Their work shows that coordination can be attained if the learning process occurs in parallel with the group formation process. Across a diversity of paradigms, many other experiments have found conditions in which the internal structure created by local information improves group-level outcomes (Ahn, Esarey, & Scholz, 2009; Goldstone, Roberts, Mason, & Gureckis, 2010; Kearns, Suri, & Montfort, 2006; Mullen, Johnson, & Salas, 1991; Mason, Jones, & Goldstone, 2008).

There is also conflicting evidence that internal structure interferes with coordination among endogenous groups. Weber & Camerer (2003), complementing their “slow growth” result above, showed that combining two successful medium-sized groups can induce coordination failure in the large merged group. Rick, Weber, & Camerer (2006) hypothesized that decentralization would promote adaptability. After their result failed to materialize, they reframed the experiment in terms of learning transfer (Rick, Weber, & Camerer, 2007). Frey & Goldstone (2010) show the simultaneous emergence of internal structure and coordination failure in a multiple-player stag hunt. Participants in groups of many sizes could coordinate on equilibria that required larger quora for larger payoffs. Despite many trials and large groups, coordination failure was common, and the successes were most typical for the smallest subgroups of pairs and triplets, despite the much larger rewards available with more concentrated groups. There is no theory to reconcile the conflicting effects of group formation on individual outcomes.

This experiment explores whether internal structure will help or hinder groups in coordinating at larger scales. The complex experimental designs and large networked groups of most endogenous group experiments make it difficult to carefully distinguish hypotheses. I introduce a 4-player coordination game that elicits three types of coordination, depending on the value of an experimentally manipulated parameter. An experiment with only four players can be represented as a very small network. The design focuses on learning transfer from each of three coordination games.

Learning transfer is a growing area of behavioral game theory. Studies suggest that experiences of cooperation or coordination can transfer across very different types of games (Stahl, 2000; Devetag, 2005). In the most ambitious study, Woolley, Chabris, Pentland, & Hashmi (2010) give evidence for a general Collective

**Figure: Structure of the game, and design of the experiment**

Groups of four picked from three choices over thirty rounds of a Stag Hunt game, moving from twenty training rounds to ten identical test rounds. Two of the three choices (the top two) required coordination with exactly  $n$  other group members for 16 points (Stag), and the remaining choice guaranteed 2 *secure* points (Hare).

Intelligence factor by which certain groups seem to transfer easily across many unrelated collective tasks. But the processes of individual learning and transfer are complex, and we cannot cherry-pick concepts from the individual-level without acknowledging this complexity. For example, one individual-level phenomenon that complicates the idea of general intelligence is *negative transfer*, a type of learning transfer. In cases of negative transfer, a superficial similarity between two tasks will induce transfer of spurious concepts that actually hinder performance (Gagne, Baker, & Foster, 1950; Day & Goldstone, 2012). For example, tennis and badminton are superficially similar sports, but skills developed in one should not necessarily transfer to the other; Some tennis techniques, like maintaining firm wrists, will not improve performance in badminton. Negative transfer complicates general intelligence factors by introducing order effects, and generally by raising questions about what it means for two tasks to be similar or distant.

With the right design, a failure of internal structure to improve large-scale coordination implies negative transfer. Groups in this environment did in fact show negative transfer from their experience of a seemingly congruent coordination game. The consequence is that transfer is better from a less similar game—one that discouraged the slow, modular development of large-scale coordination.

## Method

Participants played a novel multiple player generalization of the stag hunt, a classic two-player game. This paradigm was designed to explore the relationship between a group's internal patterns of behavior and their ability to coordinate at larger scales.

In the prototypical stag hunt, two players choose blindly to either hunt *Hare* or *Stag*. Hare offer little meat but can be caught without another's assistance. Stag reward both hunters with more food per person, but they cannot be successfully hunted by an individual alone. A decision to hunt hare instead of stag reflects an aversion to risk, because a lone stag hunter gets nothing while hare hunters are guaranteed a small but secure reward. The stag hunt captures many of the general incentives and pressures behind coordination, and the properties of agents in the stag hunt are well documented, both theoretically and empirically (Harsanyi & Selten, 1988; Camerer, 2003; Skyrms, 2004). However, upon expanding to multiple players, the number of generalizations explodes, and most extant research is in simulation.

In the multiple player stag hunt reported here—the *structured stag hunt*—players have three choices: they may hunt hare alone for a small payoff (2 points) or they may hunt either of two stag for a larger payoff (16 points). Group size in this game is fixed at four players.

The payoff structure of the two stag strategies depends on parameter  $n$ , which may equal 2, 3, or 4. At

$n=4$ , the *Full coordination* condition, players who select one of the Stag strategies receive the large payoff only if all 4 players select it (See Figure). At this equilibrium, four hunters have successfully coordinated to hunt one of two large stag. At  $n=4$ , there are three pure strategy Nash equilibria, corresponding to the decision of all four players to all choose one of the three strategies. Previous work suggests that, as the game is iterated, players will settle into one of these three pure strategy equilibria (Camerer & Weber, 2007). The game also has many mixed-strategy equilibria—at all parameterizations—but I will attend only to the more salient pure equilibria. The Full coordination condition functioned as a control baseline condition for comparison with the other two conditions.

For  $n=3$ , the *Well-mixed* condition, only 3 players may hunt stag in order to receive a payoff. If all four players chose the same Stag strategy, then they each receive 0 points. In this condition, the proverbial stag has plenty of meat for three people, but is, perhaps, very likely to be startled by the stirrings of a larger crowd. At  $n=3$ , the structured stag hunt resembles the game of Chicken, in which the most profitable strategy for individual players gives the lowest payoff if all players select it.

Both theory and experiment suggest that coordination will be unstable in this condition of the game (Bornstein, Budescu, & Zamir, 1997). There are nine pure-strategy Nash equilibria in the Well-mixed condition but, unlike the other two conditions, there is no equilibrium in which all four players receive the largest payoff. Because the only symmetric equilibria involve selecting randomly from a distribution over the three strategies (mixed strategies), experience in the Well-mixed condition should select against the development of stable internal structure.

Finally, in the *Modular* condition, when  $n=2$ , an internal group structure becomes possible. When  $n=2$  the same penalties apply if more than 2 players select the same stag strategy—players earn nothing. However, the  $n=2$  condition is special because it is possible to split four players evenly between the two Stag such that all four players receive the higher payoff. The condition is called Modular because it requires division into two subgroups. With social learning, experience in the Modular condition should promote the development of an internal group structure. Based on results from previous work (Frey & Goldstone, 2010), my prediction is that groups in the Modular condition will naturally stratify between the two stag strategies over time. Whether this facilitated transfer to the Full coordination condition was an open question.

In all three conditions, Pareto dominance fails to select between the two pure equilibria involving Stag strategies, and there is an equilibrium selection problem on top of the traditional problem of selecting between Hare and a single Stag. The complexity of introducing two Stag was necessary to create the three nearly identical conditions.

## Experiment

These three versions of the structured stag hunt provide the basic ingredients for distinguishing between two competing theories of how a group's internal structure influences its ability to coordinate.

Participants played the structured stag hunt in three conditions: a Full control condition and the Modular and Well-mixed conditions.

Participants played thirty rounds of the game. In all three conditions, the last ten rounds functioned to *test* performance in the Full coordination version of the game. In the control condition, the first 20 *training* rounds were also played with  $n=4$ . In the Well-mixed condition, groups played these first twenty rounds at  $n=3$ . In the Modular condition, groups played the first twenty rounds at  $n=2$ .

## Subjects and procedure

52 psychology undergraduates played the game in 13 groups of four. Experiments were conducted over networked computers concealed in separate cubicles. Complete instructions were read aloud before participants were given the opportunity to review them individually. After the first round, participants saw their group's previous round's choices before the next round began. However, participant icons were made identical to make it more difficult to use reputation to form internal structure. Experimental sessions lasted just under five minutes on average, with about 10 seconds per round. Participants were paid a small bonus of 1¢ per point, and mean earnings were \$1.25, or \$15.00 an hour. The experiment was always run in the free time after other collective behavior experiments.

## Measures

The main dependent variable in this experiment is the number of test rounds, out of ten, for which groups settled on one of the pure equilibria containing the Stag strategy. If internal group structure can improve higher-level coordination, then Modular groups will coordinate more successfully in test trials than the Well-mixed groups.

Other dependent variables were influenced by condition and number of rounds, including *group clustering* and *group internal structure*, *payoff*, *opting out*, and *fixation*.

*Group clustering* and *internal structure* were measured as the mean and standard deviation of the distances between participants. In each round, two participants shared distance 0 if they had made the same choice, and 1 otherwise. Summed over all rounds, two participants have distance 30 if they never selected the same choice, and distance 0 if they always selected the same choice. Using pairwise distances between group members, the structure of the group can be represented as a fully connected distance network. If the mean of these distances is low, participants are tending toward clustering on the same choice. For small groups, the standard deviation of distance is equivalent to closeness centrality (Frey & Goldstone, 2010), a measure of relational structure in networks. If the standard deviation is high, participants tend

Dependent measures	Grand Mean	Full ( <i>n</i> =4; control)			Well-mixed ( <i>n</i> =3)			Modular ( <i>n</i> =2)		
		Train	change	Test	Train	change	Test	Train	change	Test
Performance	1.92	0.25		3	<b>3.5 *</b>	↑	4.25	1.25		0
Group distance	3.56	3.8	↓	1.0	3.81	↓	2.25	<b>4.6 *</b>		<b>4.25 *</b>
Group structure	2.82	3	↓	0.92	2.9	↓	2.25	<b>3.48 *</b>		<b>3.41 *</b>
Payoff	4.19	1.6		5.9	<b>4.8 *</b>		7.2	<b>5.56 *</b>		0.712
Opting out [0,1]	0.09	0.15		0.14	<b>0.074 *</b>		0.045	<b>0.045 *</b>		0.089
Fixation [0.33,1]	0.7	0.66	↑	0.93	0.71	↑	0.79	0.57	↑	0.72

**Table: Summary measures of group performance**

Distance is reported instead of clustering. Distance and clustering are inversely related.

**bold\*** reports a significant effect ( $p < 0.01$ ). In a “Train” column, comparison is with respect to training in the control condition. In a “Test” column, comparison is with respect to tests in the control condition.

Arrows report significant effect directions of experience, within a condition, from Train to Test ( $p < 0.01$ ). All regressions report statistics distributed on  $F(5,30)$ .

*Italics* in upper right Test columns represent one significant post-hoc test between Modular and Well-mixed test performance.

to be close to some group members and distant from others. By this definition, a modular arrangement of two groups of two will register as having the highest internal structure.

*Payoff* was the mean number of points per participant. *Opting out* was measured as the percentage of secure Hare choices, out of thirty. *Fixation* measured pure strategy play, the phenomenon of choosing the same strategy repeatedly. Fixation was defined as the maximum value in a participant’s observed distribution of choices. By this, pure-strategy play will register a maximum fixation of 1.0, and random mixed-strategy play will register the minimum value of 0.33.

## Results

Two separate ANOVAs were used to compare the three conditions in the training trials separately from in the test trials. These analyses encoded three dummy variables, one for each condition. Additionally, a multiple regression tested the effects of experience within each condition. The adjusted  $R^2$  of the regression over performance was 71%, and the model was significant ( $F(6,30)=11.2$ ,  $p < 0.01$ ). To maintain the independence of observations, these analyses were conducted at the group-level. Means and significance values are summarized in the Table.

Looking first at the 20 training trials of the control condition, it is clear that Full coordination is difficult. Participants successfully coordinated on Stag in an average of 0.5 of the 20 training rounds. Groups performed much better during training in the Well-mixed condition, coordinating successfully on a Stag in 7 of the 20 training rounds (and significantly more often than groups in the Full coordination condition;  $F(1,21)=24$ ,  $p < 0.01$ ).

During training in the Modular condition, participants settled upon the stable configuration (two subgroups of two) in only 2.5 of the 20 training rounds. This was not significantly higher than control. However, partial solutions were more common, with 21 instances (out of a possible 40, or two per round), of exactly two subjects successfully coordinating on a Stag.

Performance in the control condition increased (non-significantly) from 0.5/20 to 2.75/10 during the final ten test rounds. The first ten rounds of the Full condition may be understood as an alternative baseline, corresponding to an entirely untrained experience of the game. Across all sessions of the Full coordination condition, no groups successfully coordinated on Stag in the first ten rounds of training. Variance in performance was much higher in this condition than in the other two; Groups in the control condition tended either to converge stably on coordination success (10/10 test trials) or coordination failure (0/10 test trials), with little behavior in between these extremes.

Groups trained in Well-mixed trials showed improvement upon advancing to the test trials ( $t(32)=3.16$ ,  $p < 0.01$ ). Mean performance on test was 4.25 out of 10 rounds. This was not significantly different than the test performance of the control group. However, a t-test showed that after training in the Well-mixed condition, groups exhibited better test performance than Modular groups ( $t(3)=-5.67$ ,  $p=0.010$ ), even though the Well-mixed game is less similar to the Full coordination game.

Across all test rounds of all groups in the Modular condition, no group successfully coordinated on Stag during test (0/20). Groups in the Modular condition did not show significantly different performance between training and test trials.

Group clustering, group internal structure, payoff, opting out, and fixation were modeled in the same manner as performance, with a linear model to establish the effects of increasing experience in the game, and separate ANOVAs for train and test trials to establish differences between the three conditions. These dependents were also modeled at the group level. Though many of these results may not become motivated until the discussion, means and significance values are summarized in the Table.

Groups exhibited significant internal structure. In the Well-mixed and Full coordination conditions, experience in the game (number of rounds played) predicted increased clustering ( $t(32)=-5.86$ ;  $t(32)=-7.6$ , respectively—both

$p < 0.01$ ) and decreased internal structure ( $t(32) = -3.95$ ;  $t(32) = -5.95$ , both  $p < 0.01$ ). Clustering and structure did not change for Modular groups, and during test trials, only Modular groups showed less clustering and more internal structure than control groups ( $F(1,33) = 6.22$ ,  $p < 0.01$ ;  $F(1,33) = 6.76$ ,  $p < 0.01$ ).

Payoffs in the training rounds were significantly higher in both the Modular and Well-mixed conditions than in the Full coordination condition ( $F(1,21) = 14.9$ ,  $p < 0.01$ ;  $F(1,21) = 20.5$ ,  $p < 0.01$ ). These differences did not persist between the test trials, and the change between train and test trials was not significant in the regression.

Opting out (choosing the secure payoff) showed the same pattern as payoffs. Opting out was significantly below control during the training of both Modular and Well-mixed groups ( $F(1,21) = 13.2$ ;  $F(1,21) = 12.7$ , both  $p < 0.01$ ), but these changes did not persist in test and were not reflected in the model of experience. Over all trials and conditions, only 9% of choices were to the assured payoff.

Over all subjects, mean fixation was 70%; the most common strategy selected by a given subject was selected for 70% of the rounds. Fixation increased with experience in all three conditions, but did not differ significantly across conditions (Control:  $t(32) = 6.06$ ,  $p < 0.01$ ; Well-mixed:  $t(32) = 4.83$ ,  $p < 0.01$ ; Modular:  $t(32) = 2.99$ ,  $p < 0.01$ ).

## Discussion

In the Full coordination control condition, groups face a more complex version of the already-difficult weakest-link game (Van Huyck, Battalio, & Beil, 1990). They performed moderately well in the test trials.

In the Well-mixed condition, groups showed moderate performance solving the  $n=3$  coordination problem, and their performance on test was at least as good as that of groups trained in the control condition. Data support the prediction that these groups would not form modules or other manifestations of an internal structure, or at least not to the degree exhibited by groups in the Modular condition.

For groups trained in the Modular condition, there was a stable efficient outcome for two subgroups of two whereby all four players receive the largest payoff. Evidence supports the prediction that this environment promotes the emergence of stable subgroups; groups in the Modular condition did in fact exhibit high internal structure consistent with a modular group structure. However, while groups in this condition earned more during training than other groups, they were unable to settle consistently upon two groups of two simultaneously. Modular groups were also unable to use their experience within a structured group to coordinate upon stag during the test rounds.

Why did groups with internal structure test worse than groups without internal structure? I will reject a few possibilities. The first is that subgroups of two are small, while subgroups of three are almost as large as subgroups

of four. Previous work has shown that incremental growth can aid coordination at higher scales (Camerer & Weber, 2008) while larger growth spurts can hinder it (Weber & Camerer, 2003). However, this perspective ignores that fact that coordination in all three conditions is coordination among four people. The structure of the Well-mixed condition, which creates conditions like those in the game of Chicken, makes successful coordination more than a matter of finding three willing risk-takers; it also involves coordinating with a fourth who will forgo the greatest payoff. Perhaps subjects in the structure condition learned to randomize. This would be consistent with the moderately efficient mixed strategies that exist in this condition. But mixed strategies are even more efficient in the well-mixed condition, which should have elicited randomized behavior most effectively. Subjects in the structure conditions could not have fixated too intently on specific strategies because fixation was not higher than in the other conditions. Poor performance can also not have been due to Modular groups opting out and selecting Hare; opting out was also not significantly higher than in any other condition during test, and it did not change with experience.

One more possible explanation is that internal structure itself caused the coordination failure at higher levels. The measures of group structure indicate that participants in the Modular condition overcame the difficulties of positively identifying each other and managed to form groups with internal structure. The structures that the Modular condition selected for were congruent with the demands of Stag in the Full coordination condition; subgroups need only merge into one larger group. However, the experience of stable subgroups seems to have transferred negatively to the Full coordination trials.

## Conclusion

This work looks at the interaction of individual reasoning processes as group members interact and learn to coordinate. Some previous work suggests that building up small coordinating subgroups will aid growth to full-scale coordination. This work supports competing claims, that the spontaneous emergence of local stable patterns of coordination may interfere with large-scale coordination. While groups without stable internal structure performed as well as control groups, groups that adapted to match the modular structure of their problem found that this structure interfered with full-scale coordination in the test environment. While groups are certainly adaptive in an important sense, adaptability is not a universal, or even well defined property of group behavior. Similarly, not all experiences of coordination and cooperation are the same, and experience with one type of coordination can impair performance in others.

## Abstract

In a society, a proportion of the individuals can benefit from creativity without being creative themselves by copying the creators. This paper uses an agent-based model of cultural evolution to investigate how society is affected by different levels of individual creativity. We performed a time series analysis of the mean fitness of ideas across the artificial society varying both the percentage of creators,  $C$ , and how creative they are,  $p$  using two discounting methods. Both analyses revealed a valley in the adaptive landscape, indicating a tradeoff between  $C$  and  $p$ . The results suggest that excess creativity at the individual level can be detrimental at the level of the society because creators invest in unproven ideas at the expense of propagating proven ideas.

**Keywords:** adaptive landscape; agent-based model; creativity; cultural evolution; discounting; EVOC; imitation; individual differences; time series analysis

## Introduction

Our capacity for self-expression, problem solving, and making aesthetically pleasing artifacts, all stem from our creative abilities. Psychologists have almost universally converged on the definition of creativity proposed by Guilford over sixty years ago at his annual address to the American Psychological Association (Moran, 2011). Guilford defined creativity in terms of two criteria: originality or novelty, and appropriateness or adaptiveness, *i.e.*, relevance to the task at hand. Individuals vary from not particularly creative to highly creative. Not only are humans individually creative, but we build on each other's ideas such that over centuries, art, science, and technology, as well as customs and folk knowledge, can be said to evolve (Cavalli-Sforza & Feldman, 1981; Gabora, 1996; A. Mesoudi & Laland, 2006; A. Whiten & Stringer, 2011). Creativity has long been associated with personal fulfillment (May, 1975; Rogers, 1959), self-actualization (Maslow, 1959), and maintaining a competitive edge in the marketplace, and it is often assumed that more creativity is necessarily better.

However, there are significant drawbacks to creativity (D. H. Crompton & Runco, 2010; Ludwig, 1995). Generating creative ideas is time consuming, and a creative solution to one problem often generates other problems, or has unexpected negative side effects that may only become apparent after much effort has been invested. Creative people often reinvent the wheel, and may be more likely to bend rules,

break laws, and provoke social unrest (Sternberg & Lubart, 1995; Sulloway, 1996). They are more prone to affective disorders such as depression and bipolar disorder, and have a higher incidence of schizophrenic tendencies, than other segments of the population (Andreasson, 1987; Flaherty, 2005; Goodwin & Jamieson, 1990).

Given these negative aspects of creativity, it is perhaps just as well that, in a group of interacting individuals, not all of them need be particularly creative for the benefits of creativity to be felt throughout a social group. The rest can reap the rewards of the creator's ideas by simply copying, using, or admiring them. Few of us know how to build a computer, or write a symphony, but they are nonetheless ours to use and enjoy. Clearly if everyone relied on the strategy of imitating others, the generation of cultural novelty would grind to a halt. This raises the following questions: what is the ideal ratio of creators to imitators, and how creative should the "creative types" be?

## The Model

We investigated this using an agent-based model of cultural evolution referred to as "EVolution of Culture", abbreviated EVOC. To our knowledge, EVOC is the only computational model that enables one to create an artificial world with agents of varying levels of creativity and observe the effect of varying creativity on mean fitness and diversity of ideas in the artificial society. It uses neural network based agents that (1) invent new ideas, (2) imitate actions implemented by neighbors, (3) evaluate ideas, and (4) implement successful ideas as actions. EVOC is an elaboration of Meme and Variations, or MAV (Gabora, 1995), the earliest computer program to model culture as an evolutionary process in its own right, as opposed to modelling the interplay of cultural and biological evolution<sup>1</sup>. The approach was inspired by genetic algorithm (Holland, 1975), or GA. The GA is a search technique that finds solutions to complex problems by generating a population of candidate solutions through processes akin to mutation and recombination, selecting the best, and repeating until a satisfactory solution is found. The goal behind MAV,

<sup>1</sup>The approach can thus be contrasted with computer models of how individual learning affects biological evolution (Best, 1999, 2006; Higgs, 1992; Hinton & Nowlan, 1992; Hutchins & Hazlehurst, 1991).

and also behind EVOC, was to distil the underlying logic of not biological evolution but cultural evolution, *i.e.*, the process by which ideas adapt and build on one another in the minds of interacting individuals. Agents do not evolve in a biological sense—they neither die nor have offspring—but do in a cultural sense, by generating and sharing ideas for actions. In cultural evolution, the generation of novelty takes place through invention instead of through mutation and recombination as in biological evolution, and the differential replication of novelty takes place through imitation, instead of through reproduction with inheritance as in biological evolution. EVOC has been used to address such questions as how does the presence of leaders or barriers to the diffusion of ideas affect cultural evolution.

We now summarize briefly the architecture of EVOC in sufficient detail to explain our results; for further details on the model, we refer the reader to previous publications (Gabora, 1995, 2008a, 2008b; Gabora & Leijnen, 2009; Leijnen & Gabora, 2009; Gabora & Saberi, 2011).

### Agents

Agents consist of (1) a neural network, which encodes ideas for actions and detects trends in what constitutes a fit action, (2) a ‘perceptual system’, which carries out the evaluation and imitation of neighbours’ actions, and (3) a body, consisting of six body parts which implement actions. The neural network is composed of six input nodes and six corresponding output nodes that represent concepts of body parts (LEFT ARM, RIGHT ARM, LEFT LEG, RIGHT LEG, HEAD, and HIPS), and seven hidden nodes that represent more abstract concepts (LEFT, RIGHT, ARM, LEG, SYMMETRY, OPPOSITE, and MOVEMENT). Input nodes and output nodes are connected to hidden nodes of which they are instances (*e.g.*, RIGHT ARM is connected to RIGHT.) Each body part can occupy one of three possible positions: a neutral or default positions, and two other positions, which are referred to as active positions. Activation of any input node activates the MOVEMENT hidden node. Same-direction activation of symmetrical input nodes (*e.g.*, positive activation—which represents upward motion—of both arms) activates the SYMMETRY node. In the experiments reported here the OPPOSITE hidden node was not used.

### Invention

An idea for a new action is a pattern consisting of six elements that dictate the placement of the six body parts. Agents generate new actions by modifying their initial action or an action that has been invented previously or acquired through imitation. During invention, the pattern of activation on the output nodes is fed back to the input nodes, and invention is biased according to the activations of the SYMMETRY and MOVEMENT hidden nodes. (Were this not the case there would be no benefit to using a neural network.) To invent a new idea, for each node of the idea currently represented on the input layer of the neural network, the agent makes a probabilistic decision as to whether the position of that body part

will change, and if it does, the direction of change is stochastically biased according to the learning rate. If the new idea has a higher fitness than the currently implemented idea, the agent learns and implements the action specified by that idea.

### Imitation

The process of finding a neighbour to imitate works through a form of lazy (non-greedy) search. The imitating agent randomly scans its neighbours, and adopts the first action that is fitter than the action it is currently implementing. If it does not find a neighbour that is executing a fitter action than its own current action, it continues to execute the current action.

### Evaluation

Following Holland (1975), we refer to the success of an action in the artificial world as its *fitness*, with the caveat that unlike its usage in biology, here the term is unrelated to number of offspring (or ideas derived from a given idea). Fitness of an action is determined using a predefined equation, Eq. 1, that ascribes a range of fitness values from 0 to 10 to the 729 possible actions. (Six body parts that can be in three possible positions gives a total of 729.) The fitness function used in these experiments rewards activity of all body parts except for the head, and symmetrical limb movement. Total body movement,  $m$ , is calculated by adding the number of active body parts, *i.e.*, body parts not in the neutral position. The fitness  $F$  of an action is calculated as follows:

$$F_{nc} = m + 1.5(s_a + s_l) + 2(1 - m_h) \quad (1)$$

$s_a = 1$  if arms are moving symmetrically; 0 otherwise

$s_l = 1$  if legs are moving symmetrically; 0 otherwise

$m_h = 1$  if head is stationary; 0 otherwise

Note that actions have a cultural version of what in biology is referred to as epistasis, wherein what is optimal with respect to one component depends on what is done with respect to another. Epistasis occurs because what is optimal for the left arm depends on what the right arm is doing, and *vice versa*, and same for the legs.

### Learning

Invention makes use of the ability to detect, learn, and respond adaptively to trends. Since no action acquired through imitation or invention is implemented unless it is fitter than the current action, new actions provide valuable information about what constitutes an effective idea. Knowledge acquired through the evaluation of actions is translated into educated guesses about what constitutes a successful action by updating the learning rate. For example, an agent may learn that more overall movement tends to be either beneficial (as with the fitness function used here) or detrimental, or that symmetrical movement tends to be either beneficial (as with the fitness function used here) or detrimental, and bias the generation of new actions accordingly.

## A Typical Run

Fitness of actions starts out low because agents are initially immobile. They are all implementing the same action, with all body parts in the neutral position; thus action diversity is at a minimum. Soon some agent invents an action that has a higher fitness than immobility, and this action gets imitated, so fitness increases. Fitness increases further as other ideas get invented, assessed, implemented as actions, and spread through imitation. The diversity of actions increases due to the proliferation of new ideas, and then decreases as agents hone in on the fittest actions. In the version of the model used here, fitness values hit a ceiling and converge<sup>2</sup>. Thus, over successive rounds of invention and imitation, the agents' actions improve. EVOC thereby models how "descent with modification" occurs in a purely cultural context.

## Experiments

To carry out our investigation of how varying the level of creativity of individuals affects the fitness of ideas in society as a whole, these experiments used a default artificial world: a toroidal lattice with 1024 nodes, each occupied by a single, stationary agent, and a von Neumann neighborhood structure (agents only interacted with their four adjacent neighbors). Creators and imitators were randomly dispersed.<sup>3</sup> Runs lasted 100 iterations.

In an earlier version of EVOC, in which the ratio of inventing and imitating was always the same for all agents, we found that the society as a whole did best when the ratio of creating to imitating was approximately 2:1 (Gabora, 1995). To incorporate individual differences in degree of creativity, we constructed a version of EVOC that enables us to distinguish two types of agents: *imitators*, that only obtain new actions by imitating neighbors, and *creators*, that obtain new actions by either inventing one or by imitating a neighbor. Imitators never invent at all; they simply copy the creators' successful inventions. Thus all new actions are generated by creators. We also made it possible to vary the probability that creators create versus imitate; each agent can be a pure imitator, a pure creator, or something in between. Whereas any given agent is either a creator or an imitator throughout the entire run, the proportion of creators innovating or imitating in a given iteration fluctuates stochastically. The proportion of creators relative to imitators in the society is referred to as  $C$ . The creativity of the creators – that is, the probability that a creator invents a new action instead of imitating a neighbor – is referred to as  $p$ . If a creator decides to invent on a particular iteration, the probability of changing the position of any body part involved in an action is  $1/6$ .<sup>4</sup>

The society consists of three subgroups:

- $C \times p \times N$  creators attempting to innovate
- $C \times (1 - p) \times N$  creators attempting to imitate
- $(1 - C) \times N$  imitators attempting to imitate

where the number of agents,  $N$  is 1024.

In previous investigations we measured, for different values of  $C$  and  $p$ , the diversity of ideas over the course of a run (Gabora, Leijnen, & vonGhyczy, 2012). We found that the cultural diversity, *i.e.*, the number of different ideas implemented by one or more agent(s), was positively correlated with both the proportion of creators to imitators, and with how creative the creators were. We also obtained suggestive evidence that when creators are relatively uncreative, the mean fitness of ideas increases as a function of the percentage of creators in the society, but when creators are highly creative, the society appears to be better off with fewer creators (Leijnen & Gabora, 2009). However, those simulations were performed with small societies (100 agents), and since action fitness was obtained at only one time slice (after 50 iterations) for all ratios of creators to inventors, these results did not reflect the dynamics of the time series. Given a set of series of accumulating value over time, it is unclear which series is most representative. The series cannot be unambiguously ordered unless for each pair of series one strictly dominates the other, and that is not the case here; the curves representing mean fitness at different values of  $\{C, p\}$  increase monotonically but they often cross and re-cross as time progresses. Thus here we present a more extensive investigation of the relationship between creativity and society as a whole that employs a sophisticated solution to the time series problem.

## Analysis

We used time series discounting which associates a "present value" with any future benefit such that the present value of any given benefit diminishes as a function of elapsed time until the benefit is realized (McDonald & Siegel, 1986). The standard approach in financial settings is exponential discounting. Given a series of benefits  $b_t$ , the Net Present Value (NPV) is defined as:

$$NPV(b) = \sum_{t=1}^N r^{t-1} b_t \quad \text{with} \quad 0 < r \leq 1 \quad (2)$$

The discount rate  $r$  is normally set as  $r = (\frac{100+i}{100})^{-1}$  where  $i$  is the interest rate (in percentage) for the unit period that an investor can obtain from a safe investment.

This basic idea was adapted to analyze the benefit accrued by attaining fit actions for different values of  $C$  and  $p$  in EVOC. The first discounting method used was Time-to-Threshold (TTT) discounting. Since all fitness trajectories were monotonically increasing, those that reached a reasonably high threshold  $\tau$  sooner should be valued higher. We measured how many iterations (time to threshold) it took for fitness to reach  $\tau$ . For these runs,  $\tau = 9$  was used as a measure of optimal fitness to allow for a realistic averaging over time.

<sup>2</sup>This is not the case for another version of the model (Gabora & Saberi, 2011).

<sup>3</sup>In other experiments (Leijnen & Gabora, 2009) we investigated the results of clustering creators.

<sup>4</sup>This gave on average a probability of one change per newly invented action, which previous experiments (Gabora, 1995) showed to be optimal.

Whereas imitators need creators, creators should ignore others if they could do better on their own ( $p = 1$ ). In other words, the fitness prospects of creators working alone can be viewed in a manner analogous to the interest yield of treasury bonds in investment decisions. This logic suggests another kind of modification of the standard discounting method. The second adaptation to the basic notion of discounting we refer to as Present Innovation Value (PIV) discounting. Let  $F_t^{C,p}$  be the mean action fitness at period  $t$  for parameter setting  $\{C, p\}$ . Note that  $F_t^{1,1}$  is the fitness expectation with no interaction amongst agents. We define the PIV for any fitness curve as:

$$PIV(F^{C,p}) = -N + \sum_{t=1}^N \frac{F_t^{C,p}}{F_t^{1,1}} \quad (3)$$

Therefore,  $PIV(F^{1,1}) = 0$ ; creators are indifferent to working alone or in a community with imitation.

## Results

All results are averages across 100 runs. The 3D graph and contour plot for the  $\log_{10}$  TTT discounting analysis of the time series for different  $C, p$  settings are shown in Figures 1 and 2 respectively. Note that by definition a low TTT value corresponds to high mean fitness of actions across the society. The TTT method clearly demonstrates a valley in the adaptive landscape. The line running along the bottom of the valley in Figure 2 indicates, for any given value of  $p$  the optimal value for  $C$ , and *vice versa*. When  $p = 1$  the optimal values of  $C = 0.38$ . When  $C = 1$  the optimal values of  $p$  is 0.19. The global optimum is at approximately  $\{C, p\} = \{0.4, 1.0\}$ .

Figure 1: 3D graph of the  $\log_{10}$  Time-to-Threshold (TTT) landscape of the average mean fitness for different values of  $C$  and  $p$ , with  $\tau = 9$ . The valley in the fitness landscape indicates that the optimal values of  $C$  and  $p$  for the society as a whole are less than their maximum values for most  $C, p$  settings.

Figure 2: Top-view contour plot of the  $\log_{10}$  Time-to-Threshold (TTT) landscape of the average mean fitness for different values of  $C$  and  $p$ , with  $\tau = 9$ . The line, obtained by visually extrapolating over minimum values  $C$  and  $p$ , indicates the set of optima.

The 3D graph and contour plot for the PIV discounting analysis of the time series for different  $C, p$  settings are shown in Figures 3 and 4 respectively. The pattern is very similar to that obtained with the  $\log_{10}$  TTT discounting analysis.

Thus both  $\log_{10}$  TTT and PIV analyses of the time series showed that, although some creativity is essential to get the fitness of cultural novelty increasing over time, more creativity is not necessarily better. For optimal mean fitness of agents actions across the society there is a tradeoff between  $C$ , the proportion of creators in the artificial society, and  $p$ , how creative these creators are.

## Discussion and Future Directions

This investigation yielded results that contradict the widespread assumption that creativity is necessarily desirable. The model is highly idealized, and caution must be taken in extrapolating to human societies. The PIV results assume that creators avoid input from neighbors if doing so would maximize the fitness of their actions. In reality, creative individuals may not behave so rationally. However, the PIV results were corroborated by the TTT results, indicating that the basic pattern does not depend on the assumption of economic rationality.

EVOC agents are too rudimentary to suffer the affective penalties of creativity but the model incorporates another important drawback to creativity mentioned in the introduction: an iteration spent inventing is an iteration not spent imitating. Creative agents, absorbed in their creative process, effectively rupture the fabric of the artificial society; they act as

Figure 3: 3D graph of the Present Innovation Value (PIV) landscape of the average mean fitness for different values of  $C$  and  $p$ . Since the  $x$  axis has been inverted to aid visibility of the adaptive landscape, the valley again indicates that the optimal values of  $C$  and  $p$  for the society as a whole are less than their maximum values for most  $C, p$  settings.

insulators that impede the diffusion of proven solutions. Imitators, in contrast, serve as a cultural memory that ensures the preservation of successful ideas. This suggests that the reason people are not more creative than they are is not just because it is difficult to be creative; there is a cost to society as well.

Our results suggest that families, organizations, or societies may self-organize to achieve levels of both imitation and creativity that are intermediate in order to achieve a balance between continuity and change. The results suggest that imitation is neither just the greatest compliment, nor a form of free-riding, but a valuable social mechanism that serves innovators and imitators alike. Without invention there is nothing to imitate, but invention is considerably more effective in conjunction with imitation.

Limitation of this work include that the fitness function was static throughout a run, and agents had only one action to optimize. In real life, there are many tasks, and a division of labor such that each agent specializes in a few tasks, and imitates other agents to carry out other tasks. Another limitation is that EVOC currently does not allow an agent to imitate only certain features of an idea while retaining features the idea it is currently implementing. Creative change can break up co-adapted partial solutions. Recall that actions have a cultural version of what in biology is referred to as epistasis, wherein what is optimal with respect to one component depends on what is done with respect to another. Once both components have been optimized in a mutually beneficial way (for example, the arms are moving symmetrically), excess creativity can cause co-adapted partial solutions to break down. In future studies we will investigate the effects of using a dynamic

Figure 4: Top-view contour plot of the Present Innovation Value (PIV) landscape of average mean fitness for different values of  $C$  and  $p$ . The line, obtained by visually extrapolating over maximum values  $C$  and  $p$ , indicates the set of optima.

fitness function, and enabling partial imitation. We will also compare our findings to real world data.

If it is the case that social groups can be too creative for their own good, then expensive and widely used programs to enhance creativity through methods such as brainstorming may be counterproductive. The results of these experiments help make sense of findings that creativity is often suppressed in the classroom and in society at large, and that creative individuals often experience discrimination, or worse (Craft, 2005; Cropley & Cropley, 2005; Scott, 1999; Torrance, 1963b, 1963a). (It is well-known that Einstein's dissertation was rejected by the Technische Hochschule in Vienna; he wrote his papers on relativity while working at a patent office.) On the other hand, once the merits of ones' creative efforts become known, this individual's creativity is generally supported or even idolized. In future work we plan to investigate the hypothesis that the social practice of discouraging creativity until the creative individual has proven him- or herself serves as a form of social self-regulation ensuring that creative efforts are not squandered. Specifically, we will use EVOC to test the hypothesis that if individuals who generate creative outputs of low fitness are exposed to social pressures that discourage creativity, and individuals who generate creative outputs of high fitness are encouraged to be creative, the society may self-organize such that it achieves a balance of creative and uncreative individuals (such as the  $C, p$  values indicated by the red line in our experiments).

## Abstract

In referring to a target referent, speakers need to choose a set of properties that jointly distinguish it from its distractors. Current computational models view this as a search process in which the decision to include a property requires checking how many distractors it excludes. Thus, these models predict that identifying descriptions should take longer to produce the larger the distractor set is, independent of how many properties are required to identify a target. Since every property that is selected is checked, they also predict that distinguishing a target should take longer the more properties are required to distinguish it. This paper tests this prediction empirically, contrasting it with two alternative predictions based on models of visual search. Our results provide support for the predictions of computational models, suggesting a crucial difference between the mechanisms underlying reference production and object identification.

**Keywords:** Referring expressions, language production, visual search, computational modeling

## Introduction

When a speaker refers to a target referent in a visual domain, she identifies it for an addressee by using properties which distinguish it from its distractors. For example, in order to identify the object surrounded by a red border in Figure 1, a speaker needs to refer to it using both its colour and its size (*the large blue aeroplane*); leaving out either of these properties would result in an underspecified description.

Most psycholinguistic accounts of reference in such domains assume that the discriminatory value of properties plays an important role, since the objective is to identify an object for the addressee (Olson, 1970). On the other hand, it is also well-established that certain properties are ‘preferred’ in that speakers often include them when they are not required to distinguish the target, thus producing overspecified descriptions (Pechmann, 1989 ; Belke & Meyer, 2002 ; Arts, 2004).

The present paper is concerned with the mechanisms underlying the selection of properties. Specifically, we ask whether this process is best viewed as a *search*, along

Figure 1: An example domain

the lines suggested by current computational models of Referring Expression Generation (REG; see Krahmer & van Deemter, 2012, for a survey). In these models (described more fully in the next section), the decision to include a property in a description requires checking it against the distractor set to determine whether it excludes at least some of them. If speakers do perform such a procedure, then larger domain sizes should result in more effort (and this should be indicated, for example, by increased speech onset times). This is because more objects have to be checked every time a property is considered for inclusion.

This prediction is compatible with a classic finding in the visual search and attention literature, where search time has been shown to increase linearly with domain size (Treisman & Gelade, 1980). However, whereas REG models predict an impact of domain size irrespective of the number of properties required to distinguish a target referent, the task used by Treisman and Gelade only evinces a linear increase with targets distinguished by a *conjunction* of properties (e.g. *blue and large*). When targets are distinguished by a single property, a ‘pop-out’ effect is observed and domain size has no impact.

Yet a third possibility is suggested by more recent visual search models (e.g. Itti & Koch, 2001), which give a more central role to parallel processing. In these models,

an initial, first-pass overview of a visual domain results in the parallel activation of salient features, forming a saliency map. From a production perspective, such models would predict that, irrespective of how many properties are needed for identification, domain size should have no impact on search time because the salient, contrastive features of a referent could be ‘read off’ the saliency map without exhaustive checking against the distractors.

In short, there are at least three alternative models that could account for how a speaker selects properties, each with different predictions concerning the impact on search time of (i) the size of the visual domain in which the referent must be distinguished, (ii) the number of properties that are required to achieve this. In the remainder of this paper we first discuss these models in more detail and then describe an experiment that sought to investigate these relationships. In our experiment, we focus on speech onset time as an indicator of the amount of search effort required to produce a distinguishing description.

### Three alternative models

Computational models of Referring Expression Generation (REG) are core components of systems which automatically generate text or speech from non-linguistic data (Reiter & Dale, 2000). Their aim is to determine the content of a distinguishing description of a referent in a given domain. REG algorithms usually view this process of content selection as a search (cf. Bohnet & Dale, 2005) and this is often modelled as an incremental procedure (e.g. Dale, 1989 ; Dale & Reiter, 1995, as well as several models based on these). The models that this paper is concerned with focus on ‘first-pass’ references, that is, the generation of initial descriptions in domains which are assumed to be mutually known between speaker and hearer.

The input to a REG algorithm is a domain of objects (such as Figure 1), one of which is the target referent. These algorithms iterate through the available properties (for example, the size and colour) of the objects. Each property is considered as a possible candidate for inclusion in the description.<sup>1</sup>

For each property, the algorithm checks whether there is at least one distractor that it excludes. If this is the case, then the property is included in a description and the distractor set is updated. For example, suppose the first property to be considered in Figure 1

is  $\langle \text{COLOUR:blue} \rangle$ . A check of each of the four distractors shows that there are two non-blue objects. Since it has some discriminatory value, this property is added to the description and the distractor set updated to leave only the two remaining distractors. Since, at this stage, the target referent is not yet distinguished (it is not the only blue object, as shown by the presence of the two remaining distractors), the process does not terminate, but considers the next available property,  $\langle \text{SIZE:large} \rangle$ .<sup>2</sup> Upon checking, the algorithm discovers that the two remaining distractors are both excluded by this property. Since, at this stage, there are no remaining distractors, the procedure terminates with a description that contains both size and colour. From the perspective of the present paper, this content selection procedure makes the following important predictions:

1. Search time should increase linearly with the number of distractors, since each candidate property has to be checked against the distractor set to determine its discriminatory value;
2. Since search is incremental and every candidate property is checked, the effect of domain size should be observed irrespective of whether a distinguishing description contains a single property or a conjunction;
3. Independently of (2) above, the more properties are required to distinguish the target referent, the longer the search time should be, because each property represents a cycle in an iterative search procedure.

The first of these predictions is compatible with classic findings in the visual search literature. Treisman et al. (1980) reported a steep linear increase in search time with increasing domain size in tasks in which participants have to determine whether some object is present in a visual domain in response to a question presented beforehand (e.g. *Is there a red vertical?*). Various replications of this effect have shown that reaction time increases by as much as 31ms with every new object (e.g. Spivey, Tyler, Eberhard, & Tanenhaus, 2001). However, the effect only holds when participants search for a target defined by a conjunction of properties. Single property search (e.g. *Is there a vertical?*) evinces a ‘pop-up’ phenomenon, attributed to parallel activation of salient features, which obviates the need for serial search and integration of multiple features. Interestingly, in the case of conjunction search, the linear increase in search time with domain size is altered if participants hear the description of a target *concurrently* with the presentation of a visual scene (Spivey et al., 2001). In this case, the slope is significantly shallower, perhaps because concurrent presentation of description and domain allows listeners to incrementally circumscribe the search domain

<sup>1</sup>An important factor that distinguishes algorithms from each other is how they prioritise properties during search. For example, Dale et al. (1995) propose to prioritise properties based on the preferences evinced by humans in psycholinguistic experiments (e.g. Pechmann, 1989). By contrast, Dale (1989) proposes a model which prioritises properties based on their discriminatory value. Here, we abstract away from these differences, focusing on the basic search mechanisms common to all of them.

<sup>2</sup>We are assuming that the *large* value of the SIZE attribute is determined as part of this procedure, perhaps by an algorithm along the lines described by Deemter (2006).

as each property is processed (cf. Tanenhaus, Spivey-Knowlton, Eberhard, & Sedivy, 1995 ; Sedivy, Tanenhaus, Chambers, & Carlson, 1999, for related observations).

The third model we alluded to in the Introduction makes neither of the predictions of REG models. It is possible that speakers default to a ‘fast and frugal’ heuristic whereby, instead of searching for a distinguishing property or combination thereof, they rely on a first-pass overview of the coarse visual features of the domain to select all the properties that seem to have some contrastive value. Such a procedure would be compatible with more recent models of visual search and attention, where salient contrasts are activated through an initial, parallel process that results in a saliency map (Itti & Koch, 2001). Under this model, we would expect the number of properties required to distinguish a referent to have no impact on search time. We would also not expect the function modeling the impact of domain size on search time to increase linearly.

As the foregoing discussion suggests, REG models view the mechanism underlying reference production as fundamentally similar to that of object identification, namely, as a search process. However, there is a crucial difference which accounts for the different predictions made by the two classes of models.

In reference production, search is *object-driven*. A speaker knows which target is intended. Her task, as it is modelled in REG, is to identify a set of properties which are individually discriminatory (each contributes to the overall goal of identification) and jointly distinguishing. Thus, even determining whether a single property is discriminatory requires a check against the distractor set. By contrast, in the standard identification task, search is *property-driven*: a description of the object serves as an instruction to pick out a particular entity. If the description contains only a single feature, a pop-out search is sufficient, for the listener need not verify that the feature in question has discriminatory value – that assumption should follow from the fact that the speaker is being co-operative and is not including redundant information. Indeed, recent work has suggested that the inclusion of properties with no discriminatory value – a strong tendency among speakers, as we discussed above – results in increased processing effort for listeners, suggesting that they do in fact make this assumption (Engelhardt, Baris Demiral, & Ferreira, 2011).

## Experiment

In the experiment, participants were shown visual domains of the kind displayed in Figure 1 and asked to produce a distinguishing description of the target referent. We measured the time it took participants to initiate a description, as a function of the size of the domain and the number of properties (one or two) required to

distinguish the target.

## Participants

The experiment was conducted at the Tilburg center for Cognition and Communication. Forty native speakers of Dutch participated in return for course credit.

## Materials and design

The experimental stimuli consisted of 64 items selected from a version of the Snodgrass and Vanderwart set of line drawings with colour and texture (Rossion & Pourtois, 2004). The items were selected on the basis of a pretest in which seven native speakers of Dutch were asked to name greyscale versions of the pictures. For the items, we selected only those pictures for which at least 5 out of the 7 speakers agreed on the name of the object. These were subsequently manipulated to create versions in different sizes and colours. For each item, 8 versions of a visual domain were constructed, each consisting of a target referent indicated by a red border, and a number of distractors. The 8 versions represented combinations of the following two factors:

- *Properties* (2 levels): Either size only (s) or both colour and size (CS) were required to distinguish the target. Figure 1 is an example of the CS condition.
- *Distractors* (4 levels): There were 2, 4, 8 or 16 distractors in addition to the target, representing increasing domain size.

In each domain, all objects (target and distractors) were of the same type (e.g. all were aeroplanes). In s trials, distractors were identical to the target except for size. Distractors were also identical to each other (e.g. the target was a small blue aeroplane and all distractors were large blue aeroplanes). In the CS trials, half the distractors were identical to the target except for their size and the other half were identical to the target except for their colour (e.g. the target was a large blue aeroplane, half the distractors were small green aeroplanes and the other half were large blue aeroplanes).

In addition to the experimental items there were 108 fillers. In 64 of these, the target could be distinguished using size only or both size and colour, as in the trials. However, there was variation in the types of distractors (not all distractors were of the same type as the target). In the remaining 64 fillers, the target could be distinguished by using its type only. There were equal numbers of fillers containing 2, 4, 8 or 16 distractors.

In each trial, objects were presented in a sparse grid. For each item, the position of the target was fixed in advance and was the same in all conditions. The position of the distractors was also fixed in the 2-, 4-, 8- and 16-distractor conditions. Both items and participants were randomly divided into 8 groups. Each participant saw exactly 8 items in each condition; item and participant groups were rotated through a latin square so that each

item was seen in a condition by an equal number of participants.

## Procedure

Participants did the experiment individually in a sound-proof booth, wearing a headset through which their descriptions were recorded. The experiment was run using the DMDX package for stimulus presentation (Forster & Forster, 2003). They were asked to imagine that they were describing objects for a listener who could see the exact same objects but did not know which one was the target referent. In order to avoid the use of descriptions containing locative expressions, participants were also told that their putative listener would see the objects in different positions (none of the participants used locatives).

A trial was initiated with a warning bell and a fixation cross appearing for 500ms in the middle of the screen. Subsequently, the visual domain appeared. After they had described the target, participants pressed the Enter key on their keyboard to move to the next trial.

Trials were presented in two blocks to allow participants to take a break. Speech onset time was measured using the DMDX voice trigger from the point when the visual domain was presented to the point when a participant began to speak.

## Data pre-processing

Descriptions were transcribed and annotated for whether they contained size, colour or both. Descriptions in the S condition which contained both size and colour were classified as overspecified. Descriptions in the S condition which contained only colour, or those in the CS condition which contained only one of the two properties, were classified as underspecified. All other descriptions were classified as well-specified. Data from two participants was excluded because they produced utterances which compromised the calculation of speech onset time (for example, starting all of their descriptions with *I see a...*). The remaining 38 participants produced well-specified descriptions 71% of the time, with 27% overspecified descriptions and 2% underspecifications. The relative frequency of over- compared to underspecifications is to be expected, given previous work (see the Introduction).

Speech onset times were manually tuned using Check-Vocal (Protopapas, 2007), a program for the detection and correction of voice key mistriggers (due to lip smacks, coughs, background noise etc) in DMDX result files. For each sound file, we ensured that the speech onset time was taken at the precise point where the participant's description began. In case the description included a determiner, this meant the onset of the determiner. In case a description began with a hesitation (e.g. *uhhhh het kleine rode bed*), the onset time was still the onset of the description, that is, following the initial hesitation.

Following tuning, an onset time was defined as an outlier if it exceeded the mean  $\pm 2SD$  in its condition. 106 data points (4.4%) were considered outliers by this criterion and were treated as missing.

Figure 2: Mean onset times by number of distractors.

## Results

In what follows, we report results based on descriptions which were well-specified, excluding over- and underspecified cases.<sup>3</sup> This is because in the case of underspecified descriptions, participants presumably did not check against the distractor set to see whether a selected property combination was distinguishing; where participants overspecified, the inclusion of a redundant property may not have involved such a check because it was extra information.

Table 1 displays mean speech onset times in each Distractor condition for different levels of Property as well as overall, while Figure 2 displays the relationship between onset times and Distractors. The means show an increase in speech onset time in the CS compared to the S condition. As the Figure shows, the relationship between speech onset time and domain size appears linear.

We report a linear mixed effects analysis with Properties and Distractors as fixed effects, and random intercepts for participants and items.<sup>4</sup> The Properties factor was scaled and centred; Distractors was treated as a continuous variable, since our aim is to model the change in

<sup>3</sup>The statistical tests reported here were also conducted on the full dataset; the general trends are identical to the ones reported here.

<sup>4</sup>A comparison of the model we report here to one with a random intercept and slope for each participant showed that the latter did not provide a better fit to the data (model  $\chi^2 = 8.05, p > .5$ ); neither did adding a random intercept and slope for each item ( $\chi^2 = 3.34, p > .9$ ).

	2	4	8	16	overall

S	1872.30 (458)	1990.95 (566)	1921.73 (209)	2046.73 (473)	1955 (506)
overall	1972.35 (486)	2011.97 (527)	2046.45 (527)	2111.16 (572)	—

Table 1: Mean speech onset times and standard deviations in each condition

speech onset times as a function of continuous increases in domain size.

There were strong main effects of both Properties ( $t = -3.40, p < .001$ ) and Distractors ( $t = 3.72, p < .001$ ), but no interaction ( $t = .22, p > .8$ ). Thus, both the increase in speech onset time with two properties compared to one, and the increase with domain size are reliable.<sup>5</sup> To further investigate the nature of the effect of Distractors, we carried out planned comparisons by re-running a linear mixed effects analysis with Distractors as the only fixed effect and random intercepts for participants and items. For this model, Distractors was recoded as a factor using forward difference coding to perform contrasts between adjacent levels. None of these contrasts proved significant, although the difference between domains with 8 and 16 distractors approached significance ( $p = .06$ ). Post-hoc pairwise comparisons using t-tests with Bonferroni adjustment showed a significant difference between domains with 2 distractors and those with 8 ( $p = .03$ ) and those with 16 ( $p = .004$ ) distractors, but no other differences. This suggests that the primary contrast is between relatively small domains and those with many more objects in the visual display.

## Discussion

Our experimental results show that the time speakers take to produce references is influenced both by the number of distractors from which they have to distinguish the referent and by the number of properties that they need to include in their description in order for it to be identifying.

The effect of domain size was very strong and crucially did not interact with the number of properties required to distinguish the target referent. This is compatible with the predictions of computational REG models, in which every property needs to be checked against the distractor set in order to determine whether or not it contributes to the goal of identifying a target referent. By contrast, the literature on visual search and object identification only reports robust effects of domain size with conjunctions. In our initial discussion, we suggested that this is in part due to the difference between the task of reference production and that of object identification or online reference resolution. A speaker needs to ensure that every selected property contributes to the

overall referential goal.<sup>6</sup> By contrast, there is no need to check contrastive value in a task involving search and identification for an object based on an instruction (e.g. Treisman & Gelade, 1980) or a definite description (as in the reference resolution experiments of Tanenhaus et al., 1995). Here, reliance on pop-up search is a good strategy for targets identified by a single feature (Treisman & Gelade, 1980) whereas, when a description is presented concurrently with a visual domain, each property in a description can be used to circumscribe the set of relevant objects (Tanenhaus et al., 1995 ; Spivey et al., 2001). Thus, the search mechanisms of speakers and listeners are qualitatively different.

A second prediction in relation to domain size was that its effect on speech onset time would be linear. Figure 2 does suggest a linear effect, although the increase becomes less steep as domain size grows larger. We also do not find differences between adjacent levels of the Distractors factor, with post-hoc analyses showing that the primary differences are between the smallest and the largest domains. Further research is required to confirm these findings. Nevertheless, the main effect, which was obtained by modelling Distractors as a continuous variable, does support the predictions of REG algorithms. It also runs counter to the predictions of models of visual search based on parallel activation of salient, contrastive properties (the third class of models discussed at the beginning of this paper), which would predict no main effect.

Finally, the finding that speakers take longer to initiate descriptions containing two properties, compared to only one, also supports the incremental search procedure in REG models, where each candidate property is checked against the distractor set. Although our experimental design does not allow us to determine whether the effect of properties is linear or not, REG models do make an interesting prediction in this regard.

Consider the effect of an incremental procedure of the

<sup>5</sup>The p-values for the LME models were estimated using Baayen's (2008) `pvals.fnc` function, included in the `languageR` package.

<sup>6</sup>The fact that speakers overspecify (that is, add properties that do not contribute to identification) may be due to the incremental nature of reference production, whereby speakers include properties one by one, starting from properties (such as colour) which are highly 'preferred' (Pechmann, 1989). Such properties may have discriminatory value individually, but may turn out to be redundant once the description has been fully formulated. Note, however, that even under this account – which is essentially the account incorporated by the incremental REG models we reviewed above (Dale & Reiter, 1995) – speakers would still check a property for its individual contrastive value.

sort we have described (Dale, 1989 ; Dale & Reiter, 1995) when it selects two or more properties. Since discriminatory value is a prerequisite for selection, every property that is selected results in a decrease in the size of the distractor set, an effect akin to the incremental domain circumscription that Spivey et al. (2001) suggest as an interpretation of their results. Thus every property that is selected leaves fewer objects against which to check the next candidate property, predicting that the effect of properties should be non-linear. This is a possibility that we intend to explore in future work, by including conditions where more than two properties are required to identify the referent.

## Conclusions and future work

This paper focused on the predictions of computational models of reference production, comparing them to some well-known findings in the visual search and attention literature. We reported an experiment that showed that speakers take longer to refer to an object the more properties they require to distinguish it, and the more objects there are in the domain. Our findings lend some support to current computational models, and also highlight some important differences between the search mechanisms involved in reference production and those involved in object identification or reference resolution.

We have identified a number of avenues for future work. In the medium term, we plan to investigate the effect of domain size further in order to determine more precisely the nature of the relationship between domain size and search time. We also plan to investigate the nature of the effect of properties on search time, testing the predictions made by incremental computational models on the effect of adding properties to a description.

## Abstract

How do people make inferences from complex patterns of evidence across diverse situations? What does a computational model need in order to capture the abstract knowledge people use for everyday reasoning? In this paper, we explore a novel modeling framework based on the probabilistic language of thought (PLOT) hypothesis, which conceptualizes thinking in terms of probabilistic inference over compositionally structured representations. The core assumptions of the PLOT hypothesis are realized in the probabilistic programming language Church (Goodman, Mansinghka, Roy, Bonawitz, & Tenenbaum, 2008). Using “ping pong tournaments” as a case study, we show how a single Church program concisely represents the concepts required to specify inferences from diverse patterns of evidence. In two experiments, we demonstrate a very close fit between our model’s predictions and participants’ judgments. Our model accurately predicts how people reason with confounded and indirect evidence and how different sources of information are integrated.

**Keywords:** inference; reasoning; causality; language of thought; probabilistic programming

## Introduction

People often make surprisingly accurate inferences about a person’s latent traits from very sparse evidence. If the second author (NG) loses to the first author (TG) in a ping pong match and afterwards wins against two other lab members, we are fairly confident that TG is a strong player despite only having observed him winning a single game. However, if we consequently find out that NG felt a bit lazy in his match against TG and did not try as hard as he normally does, our belief about TG’s strength might change. This reasoning is not limited to a particular set of potential players, it can be generalized to related situations (such as team matches), and it supports inferences from complex combinations of evidence (e.g. learning that NG was lazy whenever he played a match against a team that included TG) – human reasoning is remarkably *productive*.

How can we best model the flexible inferences people draw from diverse patterns of evidence such as the outcomes of matches in a ping pong tournament? What assumptions about the cognitive system do we need to make to be able to explain the productivity and gradedness of inference? What is the minimum level of abstraction that mental representations need to exhibit in order to support the inferential flexibility that our cognitive machinery displays?

There are two traditional, but fundamentally different ways of modeling higher-level cognition, each with its own strengths and drawbacks: Statistical approaches (e.g. Rumelhart & McClelland, 1988) support graded probabilistic inference based on uncertain evidence but lack some of the representational powers of more richly structured symbolic approaches. Symbolic approaches (e.g. Newell, Shaw, & Simon, 1958), on the other hand, are confined to operating

in the realm of certainty and are ill-suited to modeling people’s inferences in a fundamentally uncertain world. More recently, researchers have started to break the dichotomy between statistical and symbolic models (Anderson, 1996) and have shown that much of cognition can be understood as probabilistic inference over richly structured representations (Tenenbaum, Kemp, Griffiths, & Goodman, 2011).

For instance, causal Bayesian networks (CBN; Pearl, 2000) have been proposed as a modeling framework that combines the strengths of both statistical and symbolic approaches. Given a particular representation of a task that the cognitive system faces, a CBN supports inferences about the probability of competing hypotheses for many different patterns of evidence. However, a CBN is limited to the specific situation it was designed to model, allowing inferences from different observations of existing variables, but not from fundamentally different combinations of objects or events. While some attempts have been made to model more abstract knowledge by constructing CBNs with richer, hierarchical structures (Kemp & Tenenbaum, 2009) or by combining CBNs with propositional logic (Goodman, Ullman, & Tenenbaum, 2011; Griffiths, 2005), CBNs have only coarse-grained compositionality insufficient to support productive extensions over different objects and situations.

Human thought, in contrast, is characterized by an enormous flexibility and productivity (Fodor, 1975). We can flexibly combine existing concepts to form new concepts and we can make use of these concepts to reason productively about an infinity of situations. The *probabilistic language of thought* (PLOT) hypothesis (Goodman & Tenenbaum, in prep) posits that mental representations have a language-like compositionality, and that the meaning of these representations is probabilistic, allowing them to be used for thinking and learning by probabilistic inference. This view of the representation of concepts provides a deeper marriage of the statistical and symbolic view. Because they are probabilistic, they support graded reasoning under uncertainty. Because they are language-like, they may be flexibly recombined to productively describe new situations. For instance, we have a set of concepts, such as “strength” and “game”, in the ping pong domain that we may compose together and apply to symbols such as TG. These combinations then describe distributions on possible world states, which we may reason about via the rules of probability. The PLOT hypothesis has been realized in existing computational systems, including the probabilistic programming language Church (Goodman et al., 2008). Church has several features that enable it to model productive inference from a small set of concepts – in particular, it allows reasoning about placeholder symbols and the forming of complex evidence by composing the concepts.

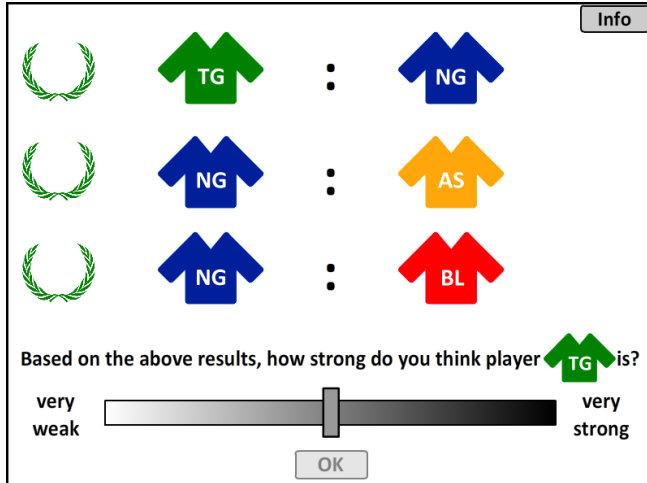

Figure 1: Screenshot of a single player tournament. The winner of each match is indicated by a laurel wreath.

In this paper, we use Church (Goodman et al., 2008), as an instantiation of the PLoT, to explain aspects of people’s flexible concept use, and use the ping pong scenario as a simple case study to illustrate our key points while admitting quantitative empirical evaluation. In two separate experiments, we test the predictions of our modeling approach by examining people’s inferences based on complex patterns of causal evidence. We conclude by pointing out areas of research that are likely to benefit from this modeling framework.

## Modeling probabilistic inferences in Church

Figure 1 shows an example of the inference task that participants faced in the experiments which we will describe below. What representation would be needed to (a) be sensitive to the statistical nature of the evidence and (b) capture the abstract, symbolic structure that remains invariant between this particular situation and other similar situations that could involve different players and different outcomes? Figure 2 shows the Church code that we used to model people’s inferences about a player’s strength based on the results of ping pong tournaments. We chose the ping pong environment because it can be summarized by a relatively simple but rich set of concepts that support productive inferences from a variety of evidence in a variety of situations. We will first introduce the Church language and then explain how this representation captures our intuitive concepts of ping pong.

Church is based on the  $\lambda$ -calculus, with a syntax inherited from the LISP family of languages (McCarthy, 1960). Thus operators precede their arguments, and are written inside grouping parentheses: `(+ 1 2)`. We use `define` to assign values to symbols in our program and `lambda` for creating functions. We could, for example, create a function `double` that takes one number as an input and returns its double. The code would look like this: `(define double (lambda (x) (+ x x)))`. What differentiates Church from an ordinary programming language is the inclusion of random primitives. For example, the function `(flip 0.5)` can be interpreted as a simple coin flip with a weight outputting either

```
(mh-query 1000 100 ;Monte Carlo Inference
;CONCEPTS
(define personstrength (mem (lambda (person) (gaussian 10 3))))
(define lazy (mem (lambda (person game) (flip 0.1))))
(define (teamstrength team game)
  (sum (map (lambda (person)
    (if (lazy person game)
      (/ (personstrength person) 2)
      (personstrength person)))
    team)))
(define (winner team1 team2 game)
  (if (< (teamstrength team1 game)
    (teamstrength team2 game))
    'team2 'team1))
;QUERY
(personstrength 'A)
;EVIDENCE
(and
 (= 'team1 (winner '(TG) '(NG) 1))
 (= 'team1 (winner '(NG) '(AS) 2))
 (= 'team1 (winner '(NG) '(BL) 3))
 (lazy '(NG) 1) ;additional evidence, used in Experiment 2
)
```

Figure 2: Church model of the ping pong scenario.

true or false. Every time the function is called, the coin is flipped afresh. A Church program specifies not a single computation, but a distribution over computations, or sampling process. This *sampling semantics* (see Goodman et al., 2008, for more details) means that composition of probabilities is achieved by ordinary composition of functions, and it means that we may specify probabilistic models using all the tools of representational abstraction in a modern programming language.

We now turn to describing the concepts (see `CONCEPTS` in Figure 2) that are required to represent the ping pong domain (Figure 1). This simple sports domain is built around people, teams and games. In Church, we can use symbols as placeholders for unspecified individuals of these types. This means that we do not need to define in advance how many people participate, what the size of the teams will be, or how many games a tournament will have. We define an individual player’s strength, `personstrength`, via a function that draws from a Gaussian distribution with  $M = 10$  and  $SD = 3$ . The memoization operator `mem` ensures that the strength value assigned to a person is persistent and does not change between games. We next make the assumption that players are sometimes `lazy`. The chance of a person being lazy in a particular game is 10%, specified by using the function `flip` with a weight of 0.1. As mentioned above, we also want to allow for the possibility that individual players form teams – we thus need the overall strength of a team,

Table 1: Modeling assumptions.

concept	description	assumption
<code>personstrength</code>	strength of a player	normally distributed, persistent property
<code>lazy</code>	chance that a player is lazy	$p(\text{lazy}) = 10\%$ , not persistent
<code>teamstrength</code>	strength of a team	individual strengths combine additively
<code>winner</code>	winner of a match	team with greater strength wins

Table 2: Patterns of observation for the single player tournaments. *Note:* An additional set of 4 patterns was included for which the outcomes of the games were reversed. The bottom row shows the omniscient commentator’s information in Experiment 2.

confounded evidence (1,2)	strong indirect evidence (3,4)	weak indirect evidence (5,6)	diverse evidence (7,8)
A > B	A > B	A > B	A > B
A > B	B > C	B < C	A > C
A > B	B > D	B < D	A > D
lazy,game: B,2	B,1	B,1	C,2

*Note:* A > B means that A won against B.

**teamstrength.** Here, we define the team’s strength as the sum of the strength of each person in the team. If a person in the team is lazy, however, he only plays with half of his actual strength. The way in which we can define new concepts (e.g. **teamstrength**) based on previously defined concepts (**personstrength** and **lazy**) illustrates the compositionality of Church. Finally, we specify how the **winner** of a game is determined. We simply say the the team wins who has the greater overall strength. This set of function definitions specifies a simple lexicon of concepts for reasoning about the ping pong domain. The functions are built up compositionally, and may be further composed for specific situations (see below). What’s more, the set of concept definitions refers to people (teams, etc.) without having to declare a set of possible people in advance: instead we apply generic functions to placeholder symbols that will stand for these people. Table 1 concisely summarizes our modeling assumptions.

Now we have a lexicon of concepts (**CONCEPTS**) that we may use to model people’s inferences about a player’s strength (**QUERY**) not only in the situation depicted in Figure 1 but in a multitude of possible situations with varying teams composed of several people, playing against each other with all thinkable combinations of game results in different tournament formats (**EVIDENCE**). This productive extension over different possible situations including different persons, different teams and different winners of each game, renders the Church implementation a powerful model for human reasoning.

A program in Church can be seen as a formal description of the process that generates observed or hypothesized evidence. The **mh-query** operator specifies a conditional inference. Both the evidence provided and the question we are asking are composed out of the concepts that specify the domain. Church completely separates the actual process of inference from the underlying representations and the inferences they license. This allows the modeler to focus on defining the conceptual representation of the domain of interest without having to worry about the exact details of how inference is carried out; it also provides a framework for psychological investigation of representations and the inferences that may be drawn, without committing to *how* these inferences are made – a well-formed level of analysis between Marr’s computational and algorithmic levels (Marr, 1982).

Table 3: Patterns of observation for the two-player tournaments. *Note:* An additional set of 6 patterns was included in which the outcomes of the games were reversed.

confounded with partner (9,10)			confounded with opponent (11,12)			strong indirect evidence (13,14)		
AB	>	CD	AB	>	EF	AB	>	EF
AB	>	EF	AC	>	EG	BC	<	EF
AB	>	GH	AD	>	EH	BD	<	EF
weak indirect evidence (15,16)			diverse evidence (17,18)			round robin (19,20)		
AB	>	EF	AB	>	EF	AB	>	CD
BC	>	EF	AC	>	GH	AC	>	BD
BD	>	EF	AD	>	IJ	AD	>	BC

Hence, in contrast to other frameworks for building psychological models of cognition, such as ACT-R (Anderson, 1996), Church does not incorporate any assumptions about how exactly the cognitive system carries out its computations but merely postulates that inference accords with the rules of probability.

## Experiment 1: Bayesian Ping Pong

In Experiment 1, we wanted to explore how well our simple Church model predicts the inferences people make, based on complex patterns of evidence in different situations. Participants’ task was to estimate an individual player’s strength based on the outcomes of different games in a ping pong tournament. Participants were told that they will make judgments after having seen single player and two-player tournaments. The different players in a tournament could be identified by the color of their jersey as well as their initials. In each tournament, there was a new set of players. Participants were given some basic information about the strength of the players which described some of the modeling assumptions we made (cf. Table 1). That is, participants were told that individual players have a fixed strength which does not vary between games and that all of the players have a 10% chance of not playing as strongly as they can in each game. This means that even if a player is strong, he can sometimes lose against a weaker player.

**Participants** 30 (22 female) recruited through Amazon Mechanical Turk participated in the experiment. The mean age was 31.3 (*SD* = 10.8).

**Materials and Procedure** The experiment was programmed in Adobe Flash CS5.<sup>1</sup> Participants viewed 20 tournaments in total. First, one block of 8 single player tournaments and then another block of 12 two-player tournaments. The order of the tournaments within each block was randomized. Participants could remind themselves about the most important aspects of the experiment by moving the mouse over the Info field on the top right of the screen (see Figure 1). Based on the results of

<sup>1</sup>Demos of both Experiments can be accessed here: [http://www.ucl.ac.uk/lagnado-lab/experiments/demos/BPP\\_demos.html](http://www.ucl.ac.uk/lagnado-lab/experiments/demos/BPP_demos.html)

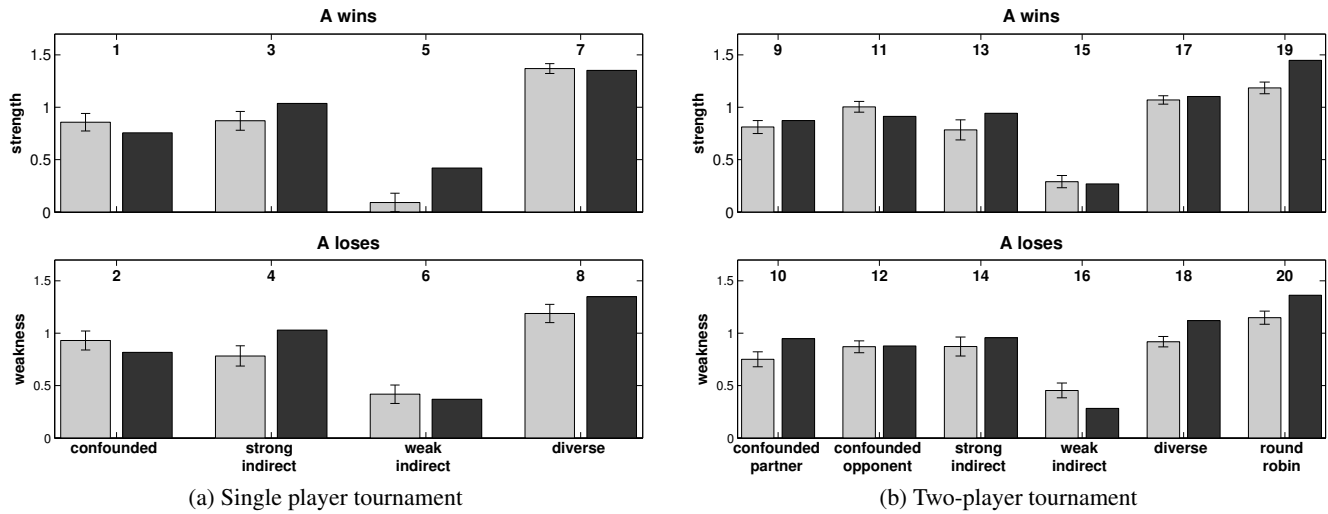

Figure 3: Mean strength estimates (grey bars) and model predictions (black bars) for the single player (left) and two-player tournaments (right). Numbers above the bars correspond to the patterns described in Tables 2 and 3. Error bars are  $\pm 1$  SEM.

the three matches in the tournament, participants estimated the strength of the indicated player on a slider that ranged from -50 to 50. The endpoints were labelled “very weak” and “very strong”. It took participants 7.4 ( $SD = 3.3$ ) minutes to complete the experiment.

**Design** Table 2 shows the patterns of evidence that were used for the single player tournaments. Table 3 shows the patterns for the two-player tournaments. In all tournaments, participants were asked to judge the strength of player A.

For the single player tournaments, we used four different patterns of evidence: *confounded evidence* in which A wins repeatedly against B, *strong* and *weak indirect evidence* where A only wins one match herself but B either continues to win or lose two games against other players and *diverse evidence* in which A wins against three different players. For each of those patterns, we also included a pattern in which the outcomes of the games were exactly reversed.

For the two player tournaments, we used six different patterns of evidence: In some situations A was always in the same team as B (*confounded with partner*) while in other situations A repeatedly played against the same player E (*confounded with opponent*). As in the single player tournaments, we also had patterns with mostly indirect evidence about the strength of A by having his partner in the first game, B, either win or lose against the same opponents with different teammates (*weak/strong indirect evidence*). Finally, we had one pattern of *diverse evidence* in which A wins with different teammates against a new set of opponents in each game and one *round robin* tournament in which A wins all his games in all possible combinations of a 4-player tournament.

## Results and Discussion

In order to directly compare the model predictions with participants’ judgments we z-scored the model predictions and each individual participant’s judgments. Furthermore, we reverse coded participants’ judgments and the model predic-

tions for the situations in which the outcomes of the games were reversed so that both strength and “weakness” judgments go in the same direction.

Figure 3 shows the mean strength estimates (gray bars) together with the model predictions (black bars) for the single and two-player tournaments. The top panels display the situations in which A won his game(s). The bottom panels show the situations in which A lost. Our model predicts participants’ judgments in the single and two-player tournaments very well with  $r = .98$  and  $RMSE = .19$ . A very high median correlation with individual participants’ judgments of  $r = .92$  shows that the close fit is not merely due to an aggregation effect.

In describing the data qualitatively, we will focus on the strength judgments in the top panels (strength and weakness judgments were highly correlated,  $r = .96$ ). In the single player tournaments, A is judged equally strong when he repeatedly wins against the same player (situation 1) or when strong indirect evidence was provided (3). A is judged weakest when only weak indirect evidence is provided (5). A is judged to be strongest when she won against three different players (7). In the two-player tournaments, A is judged equally strong when the evidence is confounded with the partner or opponent and when strong indirect evidence is provided (9, 11 and 13). A is judged to be relatively weak when only weak indirect evidence is provided (15). A is judged to be strong for the situations in which participant’s received diverse evidence about A’s strength (17) and even stronger for the round robin tournament (19).

There appears to be only one prediction that the model makes which is not supported by the data. In the single player tournaments, the model predicts that participants should be slightly more confident about the strength of A when provided with strong indirect evidence (situations 3, 4) compared to when confounded evidence is given (situations 1, 2). However, there is no significant difference between participants’

judgments for strong indirect evidence ( $M = 26.2$ ,  $SD = 15.4$ ) compared to confounded evidence ( $M = 27.8$ ,  $SD = 13.8$ ),  $t(29) = 0.44$ ,  $p > .05$ .

The results of Experiment 1 show that our model predicts participants' inferences very accurately. We have demonstrated that a single and concise representation of the task is sufficient to predict people's inferences for a great diversity of patterns of evidence.

The close fit between our model and participants' inference also shows that our modeling assumptions (e.g. that the team's strength is a linear combination of the individual team members' strengths) generally matched participants' implicit assumptions (cf. Table 1). However, the fact that the model's prediction of a difference between strength judgments based on strong indirect evidence versus confounded evidence was not supported by the data, suggests that participants might have differed in the extent to which they took the chance of laziness into consideration. In fact, only 16 out of 30 participants showed the pattern in the predicted direction. If we increase the probability of a person being lazy in a particular game in the model, it matches participants' average judgments for these situations. Intuitively, if the chances of a person having been lazy in a particular game are increased, there is a higher chance that player A won his game against player B in situation 3 because B was lazy in this round. However, when A wins repeatedly against B, there is hardly any effect of changing the probability of laziness. For example, it is very unlikely when A won three times against B, that B (and not A) was lazy three times in a row.

## Experiment 2: Omniscient Commentator

In Experiment 1 we have shown that our model accurately predicts participants' inferences for a great variety of patterns of evidence from different combinations of teams and outcomes. A still greater variety of evidence is available by composing the basic concepts together in different ways: there is no reason for evidence not to directly refer to a player's strength, laziness, etc. While in Experiment 1, the match results were the only source of information participants could use as a basis for their strength judgments, Experiment 2 introduced an omniscient commentator who gave direct information about specific players. After participants saw a tournament's match results, an omniscient commentator, who always told the truth, revealed that one player was lazy in a particular game. We were interested in how participants updated their beliefs about the strength of player A given this additional piece of evidence. Importantly, we do not need to change anything in the Church code to derive predictions for these situations since all the necessary concepts are already defined.

**Participants** 20 (11 female) recruited through Amazon Mechanical Turk participated in the experiment. The mean age was 34 ( $SD = 9.8$ ).

**Materials, Procedure and Design** Participants viewed 10 single player tournaments which comprised the 8 situations

Figure 4: Mean strength estimates and model predictions. Dark grey bars = estimates after tournament information only, light grey bars = estimates after omniscient commentator info, black bars = model predictions. Error bars are  $\pm 1$  SEM.

used in Experiment 1 plus two additional patterns (IR 1, 2). Participants first judged player A's strength based merely on the match results in the tournament. Afterwards, participants received information from the omniscient commentator about one player who was lazy in a particular match. Participants then rated A's strength for a second time, whereby the slider was initialized at the first judgment's position. It took participants 9.4 ( $SD = 4$ ) minutes to complete the experiment.

The bottom row of Table 2 shows what information the omniscient commentator revealed in each situation. For example, in situation 3 in which participants first saw strong indirect evidence, the commentator then said: "In game 1, Player B was lazy." In the additional pattern (IR 2), A wins against B, B wins against C and D wins against E. The commentator then reveals that E was lazy in game 3. For the patterns in which A lost his game, the results of each match as shown in Table 2 were reversed and the corresponding losing player was indicated as having been lazy. For example, in situation 2, A lost all three games against B and the commentator revealed that A was lazy in game 2.

## Results and Discussion

Figure 4 shows the mean strength judgments (gray bars) together with the model predictions (black bars). The dark gray bars indicate participants' first judgments based on the tournament information only. The light gray bars indicate participant's second judgments after they received the commentator's information. The model predicts participants' ratings very accurately again with  $r = .97$  and  $RMSE = 0.29$ . The model's median correlation with individual participants' judgments is  $r = .86$ . Again, strength and weakness judgments for the corresponding patterns were highly correlated,  $r = .98$ .

Generally, participants lowered their estimate of A's strength (top panel) and weakness (bottom panel) after having received the commentator's information. The fact that

participants do not lower their estimates of A's strength for the two cases in which they received *irrelevant evidence* by the commentator about a player's laziness who was in no relationship with A (IR 1, 2), shows that participants did not just have a tendency to regress towards the mean of the scale in their second judgments.

As predicted by the model, the degree to which participants lowered their strength estimates as a result of the laziness information differed between situations. While participants only marginally lowered their estimates for the *confounded evidence* patterns, estimates went down considerably for the *strong indirect evidence* patterns. As mentioned in the discussion of Experiment 1, finding out in the *strong indirect evidence* situation that A's win against B might have only been due to the fact that B was lazy in this match undermines the relevance of the additional evidence about B's performance in match 2 and 3 for A's strength.

The results of Experiment 2 show that participants, as well as our model, have no difficulty in integrating different sources of evidence to form an overall judgment of a player's likely underlying strength. The model predicts participants' judgments very accurately by being sensitive to the degree to which the initial strength estimate should be updated in the light of new evidence provided by the commentator.

## General Discussion

In this paper, we have demonstrated a novel modeling framework that conceptualizes people's reasoning as probabilistic inference over compositionally structured representations. With a handful of concepts that can combine compositionally and support productive extensions over novel situations and objects, we predict participants' judgments in two experiments with thirty different patterns of evidence in total.

The fact that people can reason flexibly based on different patterns and sources of evidence illustrates the importance of modeling our representational capacities on a sufficiently abstract level. People's use of concepts are not tied to particular situations but extend productively over different contexts. The concept of a *winner*, for example, applies to a whole range of possible games or even to domains outside of games entirely such as winning an election. We have provided a concrete working-example of how such a representation could look like, using the probabilistic programming language Church (Goodman et al., 2008). The fact that our model's predictions corresponded very closely to people's judgments can be taken as evidence that the assumptions we had to make when writing the program, generally matched the intuitive assumptions that people brought to the task. A Church program makes the modeling assumptions explicit and thus allows them to be scrutinized. Furthermore, particular modeling assumptions can also be treated as parameters in the model. For example, as outlined above, different participants seemed to have given unequal weight to the probability that a player might be lazy in a game. Without changing the general structure of our representation, we could account

for these individual differences by allowing for flexibility in our modeling assumptions through, for example, treating the chance of laziness as a free parameter.

In our experiments, we have focused on a single query and only used a small number of the possible patterns of evidence. However, our representation supports many more combinations of queries and evidence. For example, we could ask about the probability that a particular player was lazy in a certain game. Or we could ask which of two teams is likely to win given that we have observed the players perform in some previous games or based on some direct information about their strength. Furthermore, it would require only minimal additions to the concept lexicon to handle evidence such as, "all players in the red jerseys were lazy" or "at least one of the players in the green jerseys is very strong."

To conclude, we have provided only a small glimpse into what we see as a broad research program that investigates people's flexible use of everyday concepts using the tools of probabilistic programming – the probabilistic language of thought hypothesis. We are convinced that this research program has the potential to greatly benefit our understanding of how higher-level capacities of human cognition (such as concept learning, naive physics, and theory of mind) are possible.

## Acknowledgments

We thank Andreas Stuhlmüller for insightful comments and for helping with the Church implementation. This work was supported by a doctoral grant from the AXA research fund (TG), a John S. McDonnell Foundation Scholar Award and ONR grant N00014-09-1-0124 (NG).

## Abstract

Recognizing the speech acts in our interlocutors' utterances is a crucial prerequisite for conversation. However, it is not a trivial task given that the form and content of utterances is frequently underspecified for this level of meaning. In the present study we investigate participants' competence in categorizing speech acts in such action-underspecific sentences and explore the time-course of speech act inferencing using a self-paced reading paradigm. The results demonstrate that participants are able to categorize the speech acts with very high accuracy, based on limited context and without any prosodic information. Furthermore, the results show that the exact same sentence is processed differently depending on the speech act it performs, with reading times starting to differ already at the first word. These results indicate that participants are very good at "getting" the speech acts, opening up a new arena for experimental research on action recognition in conversation.

**Keywords:** Action; Speech acts; Implicature; Pre-Offers; Conversation Analysis; Self-paced reading.

## Introduction

Knowing a language doesn't just require syntax or semantics, but the ability to extract speech acts from our interlocutors' utterances. This is crucial in conversation, since all actions – be they non-verbal or verbal – have implications for how we should respond (Schegloff, 2007): A greeting calls for another greeting, an offer is followed by an acceptance or declination. Scholars in Conversation Analysis were the first to reveal the systematicity of courses of action in turn-taking (e.g. Sacks, Schegloff, & Jefferson, 1974; Schegloff, 2007), moving away from the single act as the fundamental unit of analysis – the perspective of Speech Act theory (Austin, 1976; Searle, 1969) – to the role of sequential context. One of the main observations from this literature is that turns tend to come in pairs of actions and in such *adjacency pairs* the first (pair) part sets up powerful constraints on what type of action can follow (Schegloff, 2007). Moreover, not all actions have equal status. Reflecting an orientation towards *preference structure*, dispreferred actions, such as rejections to invitations, tend to

be delivered with inter-turn gaps, turn-initial delay, hedges or other discourse markers (*uhm*, well) (Schegloff, 2007), while preferred actions (e.g. acceptances) do not. This suggests that conversationalists not only monitor speech for actions but also orient to sequential constraints.

Given that action is the *sine qua non* of conversation, how do we map speech acts onto our interlocutors' utterances, bridging the gap between sentence meaning and action? In some cases this is a simple matter. In the utterance *Please close the door*, for instance, the imperative mood and the adverb *please* function as "special markers" or "illocutionary force indicating devices" (Levinson, 1983; Clark, 1979; Schegloff, 2007) that clearly indicate this is a request. In most utterances, however, the absence of such dedicated vocabulary leaves the propositional content underspecified for the speech act level of meaning. As an example, an assertion like *I have a credit card* can deliver different speech acts, depending on context. When responding to a question from our interlocutor (e.g. *How are you going to pay for the ticket?*), *I have a credit card* functions as an information-giving answer. If it follows an offer of payment (e.g. *I can lend you money for the ticket*), it is used to indirectly decline it. In this case it could be characterized as an indirect speech act, in which "one illocutionary act is performed indirectly by way of performing another" (Searle, 1975). In yet another interchange, if our interlocutor has expressed the need or desire for some means of payment (e.g. *I don't have any money to pay for the ticket*), the same statement of ownership can function as a prelude to an offer, called a Pre-Offer in Conversation Analysis (Schegloff, 1988; Schegloff, 2007). In all three cases, the form and semantic content is underspecified for the action such that the full import of the utterance *I have a credit card* can only be ascertained relative to the context, in this case the prior speech act in the conversation.

There is some psychological evidence that people do extract speech act information online. Using a recognition probe task and lexical decision task, Holtgraves (2008a) addressed whether the comprehension of a sentence like

*Don't forget to go to your dentist* (an “implicit speech act”) entails automatic activation of the speech act performed (reminding). He found that the recognition of such speech acts is automatic, both in written and spoken utterances. A further study (Holtgraves, 2008b) suggests that people recognize and retain in long-term memory the actions that people perform with their utterances. In line with Speech Act Theory and Conversation Analysis, Holtgraves (2008a) argues that “in conversation there is an action dimension, a dimension that does not exist for isolated sentences or texts. Speakers are usually constructing utterances with the intention to perform certain actions, and with the intention of having the recipient recognize those actions” (p. 640).

Clearly, action recognition crosscuts research on topics such as communicative intention and implicature in Pragmatics (Grice, 1975; Levinson, 1983; Sperber & Wilson, 2004), the study of indirect speech acts (e.g. Gibbs, 1979; Clark, 1979; Clark, 1996; Coulson & Lovett, 2010) and discourse processing (e.g. Graesser, Singer, & Trabasso, 1994) in Psycholinguistics, as well as a more general discussion of action and theory of mind in the cognitive sciences. There is limited experimental research, however, on speech act recognition in spoken dialogue. The experimental approach used in Holtgraves (2008a, 2008b) involves artificial tasks (lexical decision and recognition probe) and does not unravel the time-course of action recognition. The puzzle remains: how is it that we can extract speech acts from utterances so efficiently, as evidenced by extraordinarily fast turn transitions (Sacks et al., 1974; Stivers et al., 2009; Levinson, in press)? To address this we are currently planning an Event-Related Potential (ERP) study on action recognition in auditorily presented dialogues to track the time course of action comprehension in real time. The experiment presented in this paper was designed to assess the feasibility of such a study.

## The Experiment

The aim of the present experiment was to investigate participants' competence in identifying speech acts in action-underspecific sentences and explore the time-course of speech act inferencing. To do this we presented target sentences using the self-paced reading paradigm and asked participants to categorize the speech acts and rate how sure they were in the categorization. In the domain of Pragmatics, self-paced reading has been used to investigate the processing of phenomena such as scalar implicatures (Breheny, Katsos, & Williams, 2006), with longer reading times (in comparison to a control) interpreted as indicating the generation of an inference. The self-paced reading paradigm allows us to obtain information on the word-by-word processing of action-underspecific utterances, thereby exploring the time-course of speech act inferencing.

The stimuli in our study consist of a context sentence which is presented auditorily, followed by a target sentence designed to be interpreted as an Answer, Pre-Offer or Declination depending on the context (see Table 1). These

actions are commonly found in conversation and their form and function has been described in the conversation analytic literature.

Table 1: Examples of stimuli in Dutch and translations.

Condition	Context	Target Sentence
Answer	Hoe ga je voor het ticket betalen? <i>How are you going to pay for the ticket?</i>	Ik heb een creditcard. <i>I have a credit card.</i>
Declination	Ik kan je wat geld lenen voor het ticket. <i>I can lend you money for the ticket.</i>	Ik heb een creditcard. <i>I have a credit card.</i>
Pre-Offer	Ik heb geen geld om het ticket te betalen. <i>I don't have any money to pay for the ticket.</i>	Ik heb een creditcard. <i>I have a credit card.</i>

The Answers in our study complete an adjacency pair by responding to a *wh*-question in the first turn. This condition serves as a benchmark for inferencing in the reading time analysis since the gap between literal (sentence) meaning and the action intended is the smallest. Moreover, since the other actions in the study can superficially be viewed as Answers, because they respond to the prior turn, this condition provides a check on whether participants go beyond a simple characterization of the sentences and identify the correct speech act.

The Declinations satisfy an adjacency pair by responding to a proposal (an offer or invitation) in the first turn, but require a somewhat complex inference to infer the action. Conversation analysts have noted that, at least in English, such indirect responses “need not be polite, nor unclear or obfuscatory. For certain activities, in specific sequential locations, responding indirectly may be the most efficient form of communication,” (Walker, Drew, & Local, 2011, p. 17).

The third action is the Pre-Offer, which is a type of pre-sequence. Pre-sequences are preliminary to, or project, the main course of action - in this case an offer (Schegloff, 2007; Schegloff, 1988), demonstrated in the following example:

Bookstore, 2.1: 107 (modified from Schegloff, 2007, p. 35)

- 1 A: I'm gonna buy a thermometer though because I  
2 B: but  
3 A: think she's got a temperature.  
4 C: *Pre-Offer* we have a thermometer.  
5 A: *Go-ahead* yih do?  
6 C: *Offer* wanta use it?  
7 A: *Acceptance* yeah.

Only if the response to the Pre-Offer is positive (line 5) is the offer put forward (line 6). This strategy allows conversationalists to check whether an offer would be welcome or not, preventing them from embarrassment that would arise if an offer were to be rejected.

Crucially, the Pre-Offers differ from the Answers and Declinations in that they do not complete an adjacency pair but rather open up or project a continuation of the sequence (with the response and possibly a subsequent offer). By including Pre-Offers in our study we can not only investigate the impact of sequential context on processing, but also explore whether the distinction between projection (Pre-Offers) and a backward directed inference (Declinations) is borne out in reading times.

Given that the same utterance can be used as an Answer, Declination or Pre-offer depending on the sequential context, in this study we investigate: 1) Can participants reliably categorize action-underspecific speech acts? 2) Does the time-course of speech act inferring differ for these actions as reflected in self-paced reading times? Due to the exploratory nature of the study and lack of research in this area – in particular on Pre-Offers – we do not make specific predictions regarding reading times. However, we speculate that the reading time pattern of Pre-Offers and Declinations may differ relative to Answers, based on the structural properties described above.

## Methods

**Participants** 39 native speakers of Dutch were recruited from the student population in Nijmegen, The Netherlands. Participants were paid 8 euros for participating.

**Materials and Design** The stimulus materials were 126 target sentences, presented visually one word at a time (self-paced reading), which were preceded by 378 auditory context-setting utterances that biased the interpretation of the target as an Answer, Pre-offer or Declination. To maintain a balance of variety and control in the stimulus materials, half of the target sentences started with the pronoun “I” (Dutch *ik*) and the verb “have” (*heb*), e.g. “I have a credit card”. The other half was more varied (including simple utterances like “I am going to the market” and “My brother is a mechanic”). We varied word-length to make the stimuli as natural as possible, but constructed the target sentences such that the final word is critical for understanding the propositional content of the utterance (irrespective of speech act level meaning). In line with reported characteristics of indirect replies (Walker et al., 2011), the target sentences do not involve ellipsis or pronominalization.

To maintain consistency in the way the Declinations and Pre-offers are connected to their contexts, we ensured that there is at least one clear *implicated premise* and an *implicated conclusion* for each sentence-pair: when presented with an utterance that is indirect, the hearer needs to access an implicated premise and combine it with the

proposition expressed to derive the implicated conclusion (Blakemore, 1992).<sup>1</sup>

In order to get a measure of the semantic relatedness between context and target sentence in each condition, Latent Semantic Analysis (LSA) values (Landauer, Foltz, & Laham, 1998) were computed for the English translation of each sentence pair using document-to-document mode with “General reading up to 1st year of college” as the semantic space. The average LSA values for each condition were: Answers 0.13, Declinations 0.32, and Pre-Offers 0.42 (the higher the value, the more semantic similarity).

The stimuli were translated from English into Dutch and checked by two native speakers of Dutch. The sentences were recorded by four native speakers. The recordings of the target sentences were not used in this experiment, since they are presented visually in self-paced reading.

The stimuli were pseudo-randomized and balanced across three lists, such that participants saw each target sentence only once, in one context. After each trial (sentence pair), participants were given a comprehension and rating task. They were first asked to indicate what the second speaker was doing with his response and were given the options of Answering, Offering and Declining (D. *antwoorden, aanbieden, weigeren*). Since Pre-Offer is not a colloquial term, the broader term of offering was chosen. Participants were then asked to rate how sure they were in their categorization decision on a rating scale from 1 (very uncertain) to 7 (very certain). The purpose of the rating task was to assess the feasibility of using the items in future studies.

**Procedure** Participants were given instructions that included one example of each action. They were instructed to imagine that they were listening to a conversation between friends or colleagues, and to read the sentences as quickly as possible, but not too quickly as they would have to “judge the underlying meaning” of the sentences. They were then seated in a chair in front of a monitor in a soundproof experimental booth. On each trial the context sentence was played while a small picture of a loudspeaker was presented at the middle of the screen. 500 msec after the end of the spoken sentence participants were presented with the target sentence in a moving window self-paced reading format (Just, Carpenter, & Woolley, 1982). A series of lines appeared on the screen representing each word in the target sentence. When participants clicked on the mouse the first word appeared and upon subsequent button presses a new word was shown, while the previous word was again replaced by a line. When participants clicked the mouse after the last word had been shown, they were presented with the action categorization question, immediately followed by the certainty rating. There were 126 experimental trials, preceded by a brief practice session.

<sup>1</sup> In the dialogue (A): *I can lend you money for the ticket.* – (B): *I have a credit card*, the implicated premise is that a credit card can pay for things, including tickets. The implicated conclusion is that speaker B does not need A’s help with paying for the ticket.

## Results

**Accuracy** Overall accuracy (number of correct responses in the action categorization question divided by the total number of responses) was very high, 95.8 percent. Accuracy percentages (summarized in Table 2) were very similar across conditions. A repeated measures ANOVA revealed that accuracy was not affected by action [ $F(2, 76) = .07, p = .93$ ].

Table 2: Accuracy and mean certainty ratings.

	Accuracy	Certainty Ratings	
		Mean	SD
Answer	96.0%	6.60	0.36
Declination	96.0%	6.50	0.39
Pre-Offer	95.6%	6.35	0.51

**Ratings** Participants rated how certain they were in answering the action categorization question on a scale from 1 (very uncertain) to 7 (very certain). The overall mean certainty rating was 6.48. Mean certainty ratings for each condition are summarized in Table 2. We conducted a repeated-measures ANOVA on the mean ratings and found an effect of action [ $F(1.42, 53.99) = 11.20, p < .01$  (Greenhouse-Geisser)]. Pairwise comparisons using Sidak adjustment for multiple comparisons revealed that Pre-Offers ( $M=6.35, SD=.51$ ) had lower ratings than Answers ( $M=6.60, SD=.36$ ), [ $p < .01$ ], and Pre-Offers were also rated lower than Declinations ( $M=6.50, SD=.39$ ), [ $p < .01$ ]. The comparison between Answers and Declinations was not significant, [ $p = .15$ ].

**Reading Times** The time between button presses was recorded as the reading time for each word. Extreme values below 100 msec were excluded, as well as values above 1200 msec for non-final words and above 7000 msec for final words (in total 12 outliers). Since online speech comprehension and the subsequent off-line categorization task tap different types of information, error trials were not excluded from the reading time analysis.

Mean reading times for the first word, the verb and the final word of the target sentences were used for the analysis, in addition to the mean reading time of the entire sentence and mean reading time per word (sentence reading time divided by number of words). A repeated-measures ANOVA was carried out to examine the effect of action (Answer, Pre-Offer, Declination) on reading times and post-hoc comparisons were performed using the Sidak adjustment. The conditions started to differ already at the first word, with mean reading time being affected by the action manipulation [ $F(1.69, 64.26) = 5.24, p = .01$  (Greenhouse-Geisser)]. Post-hoc comparisons revealed that first word reading times in Pre-Offers ( $M=259, SD=65$ ) were longer than in Answers ( $M=251, SD=56$ ), [ $p = .03$ ], and Pre-Offers tended to be longer than Declinations ( $M=252, SD=57$ ), [ $p = .06$ ]. The comparison between Answers and Declinations was not significant [ $p = .98$ ].

Table 3: Mean reading times in msec.

		Answer	Declination	Pre-Offer
First Word	Mean	251	252	259
	RT			
Verb	Mean	260	267	265
	RT			
Final Word	Mean	564	622	593
	RT			
Word <sup>2</sup>	Mean	339	354	352
	RT			
Entire Sentence	Mean	1459	1528	1501
	RT			
	SD	584	652	603

At the verb, there was also an effect of action on mean reading time [ $F(2, 76) = 3.41, p = .04$ ]. Pairwise comparisons revealed that verb RTs in Declinations ( $M=267, SD=69$ ) were longer than in Answers ( $M=260, SD=60$ ), [ $p = .048$ ]. The comparison between Pre-Offers and Answers [ $p = .25$ ] was not significant, nor between Pre-Offers and Declinations [ $p = .80$ ].

At the final word, mean reading times also differed between actions, [ $F(1.63, 61.83) = 4.28, p = .03$  (Greenhouse-Geisser)]. Pairwise comparisons on the final RTs revealed that Declinations ( $M=622, SD=447$ ) were marginally significantly longer than Answers ( $M=564, SD=384$ ) [ $p = .052$ ], while there were no differences between Answers and Pre-Offers [ $p = .17$ ], nor Pre-Offers and Declinations [ $p = .41$ ].

An ANOVA on mean RTs per word revealed an effect of action [ $F(2, 76) = 5.73, p = .01$ ]. Declinations ( $M=354, SD=146$ ) took longer than Answers ( $M=339, SD=135$ ) [ $p = .02$ ], and Pre-Offers ( $M=352, SD=147$ ) took longer than Answers ( $M=339, SD=135$ ), [ $p = .04$ ]. There was no difference between Pre-Offers and Declinations [ $p = .95$ ].

Finally, although the RTs for the entire sentence differed descriptively, these differences were not reliable [ $F(2, 76) = 2.73, p = .09$ ].

## Discussion

The present experiment demonstrates that participants categorize the speech acts of sentences whose form and semantic content is underspecified for action with very high accuracy (95.8%). They are able to do so based on limited context (the prior speech act) and without any prosodic information in the target sentence. Importantly, the accuracy was the same for all three actions (Answer, Declination, Pre-Offer). If participants had processed the target sentences superficially, ignoring the speech act content, they could have categorized Declinations and Pre-Offers as Answers.

<sup>2</sup> RT of the entire sentence divided by number of words.

This is the case since the Dutch term for answering (*antwoorden*) also means *to respond* and all three speech acts can superficially be seen as responses. This should have resulted in lower accuracy for Pre-Offers and Declinations vis-à-vis Answers. The high accuracy rate across actions shows that participants go beyond a simple characterization of the target sentences as responses and “get” the correct action. Participants were also very confident in categorizing all actions and rated the certainty of their categorizations on average 6.48 (out of 7). These results provide further support that participants orient to the action content of sentences.<sup>3</sup>

The reading time results demonstrate that the exact same sentence is processed differently depending on the speech act it performs. In all conditions the reading time increased throughout the sentence, but Declinations and Pre-Offers had different trajectories relative to Answers, which had shortest RTs on all measures. Reading times differed already at the first word, with first word RTs in Pre-Offers being longer than in both Answers and Declinations. It should be pointed out that descriptively the difference between the means is small and standard deviation large. Event-related brain potentials might be a more sensitive measure to reveal processing differences at early positions in the sentence. At the verb and the final word however, RTs were longest in the Declination condition.

What could explain the different reading times across conditions? One possible source of difference is the *amount* of inferencing required. In text processing, reading times are predicted to be the longest for words in the text that generate “many online inferences” (Graesser, Swamer, & Baggett, 1996). The fact that Declinations have the longest RTs at the final word may be because *more* inferences (e.g. Gricean implicatures) are needed to relate the sentence to the prior context.

Another source for differences may be the *kind* of inferencing required. Given the exploratory nature of this study we did not make predictions regarding reading time results. However, based on differences in sequence organization, we speculated that Declinations and Pre-Offers would exhibit different reading time patterns relative to Answers. While recognizing the speech act in a Declination requires computation of how the utterance can be understood as the second pair part to the prior proposal, identifying a Pre-Offer involves knowing that an offer will follow in the sequence. Because Declinations close an adjacency pair, they do not heavily constrain the relevant next action. Pre-Offers, on the other hand, call for either go-

ahead (e.g. *you do?*) and a subsequent offer, or a blocking response (*that’s ok*). Pre-Offers, therefore, invite stronger predictive inferences about the next speech act. The distinction between an inference based on a backward bridge to the prior turn in an adjacency pair and an inference based on forward projection of a sequence is akin to the difference between causal antecedent and causal consequence inferences in text processing (e.g. Magliano, Baggett, Johnson, & Graesser, 1993). The reading time differences between Pre-Offers and Declinations provide some indication that the distinction between forward projection and a backward directed inference plays a role in the online processing of speech acts. Why the projective nature of Pre-Offers would call for more processing at the first word, however, is less clear. More research is needed to investigate whether this finding holds for spoken language processing as well.

Considering that action comprehension is crucial for everyday conversation, it seems likely that people can predict upcoming speech acts, making the fast transitions between turns (Sacks et al., 1974; Stivers et al., 2009; Levinson, in press) possible. Neuroimaging studies suggest that people use their knowledge of the wider discourse context to predict specific upcoming words and that prediction is not the result of relatively low-level, word-based priming mechanisms, “but involves a more sophisticated message-level mechanism that can take into account the actual nuances of the preceding discourse,” (Otten & Van Berkum, 2008). Whether and how sequential context and the implicit knowledge of the organization of actions guides the interpretation of utterances is a topic for further investigation. We will explore this in future research using event-related brain potentials.

An alternative explanation for the reading time results is that the experimental manipulation does not address speech act recognition per se, but some other confounding variable such as semantic priming from the context. Latent Semantic Analysis can be used to determine semantic relatedness of two texts and LSA similarity relations have been found to correspond well with the pattern of results in priming studies (Landauer et al., 1998). If semantic priming from the context is the main factor governing the reading times one would expect the condition with the lowest LSA values (least amount of priming) to have the longest mean reading times. The opposite is true: Answers had the lowest average LSA value but the shortest reading times on all measures. This suggests that the differences in reading times across conditions in our study were not due to lexico-semantic relationships between the content words of the context and the target sentences.

## Conclusion

In this study on speech act comprehension we investigated the processing of sentences that perform different speech acts depending on prior context. In each case an assertion is used as a vehicle for some other action, and it is “part of competent membership in the society/culture and being a

<sup>3</sup> Note that the certainty ratings were lower for Pre-offers (6.35) than Answers (6.60) and Declinations (6.50). Since “pre-offer” is not a colloquial term, participants were instructed to categorize Pre-offers as “offering”. The ratings may reflect participants’ awareness that the speech acts they were instructed to label as “offering” are preparatory to, or project, offers and in most cases do not constitute offers in themselves. However, for the purpose of this study it was sufficient that participants could identify speech acts as belonging to one of the defined categories.

competent interactant to analyze assertions of this sort for what (else) they may be doing at this moment, at this juncture of the interaction, in this specific sequential context” (Schegloff, 2007, p. 35). Our study tapped into this competence by addressing two primary questions: how reliably participants can categorize action-underspecific speech acts, and whether the time-course of speech act inferencing differs for the actions as reflected in self-paced reading times.

Participants in our study categorized the speech acts of action-underspecified utterances with very high accuracy, based on limited context and without any prosodic information. Furthermore, the exact same sentence was processed differently depending on the speech act it performed, with reading times starting to differ already at the first word. These findings open up a new arena for experimental research on speech act recognition in conversation.

As a crucial component of social behavior, communication involves actions. Being a competent member of society must require a cognitive architecture that is oriented to speech acts. However, given that the form and content of utterances is frequently underspecified for this level of meaning, assigning speech acts to our interlocutors is not a trivial matter. Having demonstrated that participants orient to the action content of sentences and can categorize speech acts with high accuracy, the next experimental step is to shed light on this ability in spoken dialogues – the foundation of doing things with words.

## Towards historical cognitive science: the case of Ancient Greece

V.V. Glebkin ([gleb1514@gmail.com](mailto:gleb1514@gmail.com))  
Gymnasium 1514, 12 Krupskoi Street  
Moscow, 119311 Russia

### Abstract

This study rests on the two basic ideas: that there has been a visible development of cognitive skills from the Antiquity to nowadays, and that the text analysis is the only way to bring it out. The author addresses the three eminent works: Euclid's *Elements* and the historical treatises by Herodotus and Thucydides to reveal the notable peculiarities of the Ancient Greeks' cognitive style in comparison with the current cognitive models.

### Introduction

Cognitive scientists traditionally look at language as a cognitive system. However, it is not the only acceptable view on language within the scope of cognitive science. The distinguished German historian Reinhart Koselleck emphasized «a methodologically irresolvable dilemma: that every history, while in process and as occurrence, is something other than what its linguistic articulation can establish; but that this "other" in turn can only be made visible through the medium of language» (Koselleck 2004, 223; cf. Pocock 2009, 106–119). Admittedly, this position may just as well be applied to cognition: the way people think is different from verbal representation, but we cannot comprehend how the people of the 19<sup>th</sup> century and earlier used to think and perceive the world without a scrupulous analysis of the texts they created. Although such a view on text as a medium for revealing cognitive models is not widespread amongst cognitive scientists, there are a number of branches within cognitive science that have emerged recently (cognitive stylistics, cognitive poetics etc.), in which scholars apply a cognitive analysis to particular texts, mostly fiction (Attardo 2002; Culpeper 2002; Semino 2002; Tsur 2002; Emmott et al. 2007; Semino 2007). However, we can hardly encounter any works that provide us with a precise analysis of different types of texts, created in the same historical epoch in order to explicate general for these texts cognitive models. To develop an elaborate methodology for such analysis is not a matter of cognitive stylistics or cognitive poetics; it is merely a matter of a special branch of cognitive science which can be called historical cognitive science.

This paper focuses on two case studies, but its bottom line is to provide some conceptual pillars for investigations in this field, in other words, to discover some correlations between the narrative models of the text construction and the cognitive models used by its author. The concept of *cognitive style* will be the main methodological tool for that. This concept is widely applied in different types of researches (Rubin 1970; Berzonsky & Ondrako 1974; Witkin et al. 1977; Logan 1983; Roberge & Flexer 1983; Fuchs 1991; McIntyre & Meloche 1995; Judice 1997; Riding &

Rayner 1998; Riding & Rayner 2000; Tomes 2004; cf. concept of *mind style* in Semino 2002; Semino 2007); although it cannot be called fairly clear-cut (see some criticism in Tomes 2004, 47–48), its gist is quite transparent: a) *cognitive styles* characterize the form rather than the content of cognitive activity; b) they are pervasive dimensions which cut across the disciplinary boundaries; c) they are stable over time; d) they are bipolar, that is, they can be sorted out into opposite pairs (field-dependency – independency; holist – serialist thinking; adaptors – innovators etc.) (Witkin et al. 1977, 15–16; Riding & Rayner 1998, p. 20). The two peculiarities of my applying this term here should be featured as follows: firstly, in this context I mean a cognitive style of a particular culture, but not a particular person; in other words, I address the mode of thinking common to a notable number of culture bearers, involved in different types of intellectual activity; secondly, I seek for some criteria to compare these modes and establish the foundations for cultural-historical typology of cognitive styles.

The only parameter we will focus on is *field-dependency – independency*. Following H. Witkin, the field-independent cognitive style characterizes the tendency to differentiate objects from their surroundings whereas the field-dependent one stresses the strict connection between surroundings and objects. It concerns the subjects themselves as well; people of the field-dependent style are more likely to follow external instructions while field-independent style people prefer to rest on the internal basis for their actions (Witkin et al. 1977, 2–14).

The *field-dependency – independency* opposition, with some necessary corrections, seems to be a fruitful pathway to fit the process of cognitive evolution in phylogenesis. Furthermore, it correlates quite well with some classical researches in this field. I mean the investigations of Vygotsky's school of cultural-historical psychology or, more precisely, the distinction between complex and conceptual thinking (Vygotsky 1986(1934), 96–145) and the idea of field binding (Samukhin et al. 1934; Vygotsky 1984 (1933/34)). Briefly, the essence of this approach can be formulated as follows: unlike concepts which are characterized by a rigid structure and a set of objective features, complexes have flexible and contextually dependent frames. In the case of complex thinking, subjects' cognitive decisions are influenced by their unique experience, and they cannot be described by any general abstract model such as Aristotelian logic. Vygotsky created this model mainly to explain pre-school and primary school child cognitive development, and only outlined its application to phylogenesis. However, his followers applied this approach to different types of cultures and got the im-

portant results. Thus, Alexander Luria (1976), researching cognitive scenarios basic for Central Asia dekchans, pointed out that those scenarios were triggered by psychological fields of their everyday activity. Particularly, the subjects could not see the abstract principles used to classify a given set of objects and failed to identify the odd one out; they found all the objects useful for everyday life. As well, they could not solve syllogisms, conceiving their elements as independent propositions. Furthermore, their answers were based on their everyday experience, and they insisted that they could speak only about the things they had seen before. Further investigations (e.g., Mikheev 1985; Tulviste 1991) confirmed that complex thinking and rigid links with the psychological field of everyday experience can be called the bottom line of the traditional cultures' cognitive style.

At first sight our mind operates in a radically different way. Nevertheless, the investigations of R. Frumkina and her colleagues (Frumkina & Mirkin 1986, Frumkina et al. 1991, Frumkina & Mikheev 1996, Frumkina 2007) found out that complex thinking characterizes cognitive decisions of educated persons in modern culture in a great number of everyday situations. The only difference from the traditional culture is that they can explain their decisions and accommodate them to the experimenter's requests. As a generalization of these results, we can suppose that our cognitive structure has several levels, where complex thinking occupies the lowest, strongly field-dependent level, while different types of theoretical thinking are on the upper ones. In a concrete situation, we, guided by circumstances, resort to the relevant «floor» of our cognitive construction.

Given these standpoints as the background for the further discussion, we have a reason to ask in which cultures these floors emerge. It might seem that they emerge alongside the emergence of a written language and complex forms of social-economic activity in such large-scale civilizations as Ancient Babylon or Ancient Egypt. However, this point is the subject of serious objections. For instance, in Glebkin 2011 I address the Code of Hammurabi, i.e. the Babylonian law code, dated back to around the 18<sup>th</sup> century B.C., and argue that, in dissonance with our expectations, the code structure and its layout are accounted for by a complex thinking model. Consequently, the point that the theoretical mode of thinking is a feature of the Ancient Babylon culture cannot be taken for granted and needs convincing evidence based on a scrupulous analysis of concrete texts.

What cannot be cast in doubt is the fact that theoretical thinking is an important element of the Ancient Greek culture. However, it is the beginning but not the end of the investigation. The question is whether the cognitive style dominant in this culture is similar to the modern one, or it has some notable peculiarities. And, if the latter hypothesis is correct, can we track the trajectory of cognitive evolution within the theoretical mode of thinking? In order to answer this question, I would like to consider the three eminent works: Euclid's *Elements* and the historical treatises by Herodotus and Thucydides.

## The cognitive style of Euclid's *Elements*

It is not a novel insight that modern mathematics (at least, mathematics at school) rests on Euclid's *Elements*. If so, we might expect to see in this work the familiar to us conceptual ideas and basic attitudes. According to common sense, mathematics is not grounded on any socio-cultural environment. Nevertheless, there are persuasive arguments for the opposite view. Thus, the eminent German historian and philosopher Oswald Spengler in his book *The Decline of the West (Der Untergang des Abendlandes)* claimed that every culture has its own mathematics, and the difference between the Ancient Greek mathematical style and that of Modernity is crucial (Spengler 1991 (1918), 41-69). So, let us have a more precise look at the text of the *Elements*.

We start up with the definitions of the first book. Here we encounter some surprises. For example, the definition of a triangle goes like this: *Of trilateral figures, an equilateral triangle is that which has its three sides equal, an isosceles triangle that which has two of its sides alone equal, and a scalene triangle that which has its three sides unequal* (Heath 1956, 1, 2). In modern understanding an equilateral triangle is a particular case of a triangle, and it sounds strange to mark out a scalene triangle as a special type of triangles. However, for the Ancient Greeks the more perfect cannot be a particular case of the less perfect, and it is an equilateral triangle which is a triangle par excellence. The next illustration of this principle is the difference between the concepts of number and magnitude. The definitions related to magnitude are placed in the fifth book of the *Elements*, whereas those related to number are located in the seventh one (Heath 1956, 2, 113-114, 277-278). Some of them are identical, and we can render number as a particular case of magnitude. However, for the Ancient Greeks it is not the case. Number is more perfect than magnitude; unlike the latter, the former has its own visual image, its own εἶδος. The idea of the perfect form, based on a visual perception, is extremely important for the Ancient Greek philosophy and culture. The more perfect the entity is the more perfect form it has. Thus, Parmenides' Being (τὸ ὄν) and Plato's Universe (κόσμος) have the most perfect form, that is the form of a sphere (Parmen. Fr. 7; Pl. Tym. 33b-34a).

The visual ground for cognition can be also illustrated by the "geometric algebra" of the second book. Here, elementary algebraic formulas, such as  $(a+b)^2 = a^2 + 2ab + b^2$ , are proved by employing the language of geometry (see fig. 1). This proof looks rather cumbersome (it occupies two pages, whereas an algebraic proof fits into one line), but here we encounter the fundamental limitations of the Ancient Greek mathematics. Such a "geometrization" of mathematics, its dependence on the visual field determined its frontiers<sup>1</sup>; solution of some third and forth equations was

<sup>1</sup> The "visual vector" of the Ancient Greek mathematics can also be revealed in terminology. Thus, according to Liddell-Scott's Greek-English Lexicon the basic meaning of

the maximum to reach in that scope. The only way to take a further step in this field was to develop the abstract notation system of algebra which meant breaking the links between numbers and their visual ground. Such breaking demanded radical cultural transformations provided by medieval culture.

**Fig. 1. A geometrical proof of the formula**  
 $(a+b)^2 = a^2 + 2ab + b^2$

It may therefore be interesting to sketch the bottom line of this process. From the Ancient Greek perspective, both the Universe and particular natural things were self-sufficient entities, and such self-sufficiency was perceived as perfection (see, e.g., Arist. Phys II 192 b8-30). It means that they contained within themselves a principle of their motion and transformation. In the medieval Christian culture, however, such a principle turns out to be situated outside the Universe. The Universe and particular things become there signs of the transcendental reality, the means to understand the scheme of God. The functional paradigm stands for the eidetic one. What it means for mathematics can be clearly seen if we compare views on number by Plotinus, whose “Enneads” is considered to be the outcome of the Ancient Greek philosophical attitudes, and Augustine, the key person of the early medieval philosophy. For Plotinus numbers are placed between *ἓν* (the One) and *νοῦς* (the Divine Mind), having the higher rank than the other *εἰδωτά* (ideas) (Enn. 6, 6, 8-14), whereas for Augustine numbers are transformed into tools in God’s hands, loosing in this their unique forms. Thus, he introduces numbers, perceived by sense (*numeri sensibilis*), numbers, moving over time (*temporales numeri*) etc. (Epistola III, 2; De musica, VI, 57). The diversity of types and forms of number entails the release from visual-field-dependence, which in turn

gives new opportunities for mathematics, particularly, for the theory of functions.

So, summing up this part of the paper, I would like to highlight the visual-field-dependence as the important feature of the mathematics cognitive style. Now, we move on to the Ancient Greek historical treatises.

## The cognitive style of Herodotus and Thucydides

Let me start with the *History* by Herodotus. This historian is called the “Father of History” because his treatise is the first example of the elaborate systematic analysis of a huge amount of historical data. To some extent his status in science is similar to Euclid’s one. Here, we focus on the first book of the *History* and start up with the methodology. In order to give a more precise analysis of the narrative structure of this book, I first marked out three levels of narration: *external* (the basic level where people are considered social role-holders and their behavior is influenced by their surroundings), *internal* (the level corresponding to feelings, thoughts and decisions of humans as free will persons), *transcendent* (the level characterizing gods’ actions, fate, predestination and other factors which are believed transcendent to the human world). Then I divided the text into some structural elements, namely: *events*; *causal remarks*, situated both within an event and between the events (they explain why the event develops or the subsequent events are connected in this particular way), *expositions*, introducing unknown for the readers, but important for the further narration information about the venue of an event, people engaged in it, etc.; *philosophical, existential et al. reflections and explanations*. The events in turn were sorted out into three groups: “time markers”, i.e. some bare mentions to fill the time gap (e.g., “Not long after the overthrow of the tyrants by the Lacedaemonians, the battle of Marathon was fought between the Athenians and the Persians” (Thuc. Hist., 1, 18; tr. by B. Jowett)) (E0); the single events described briefly (E1); the events described in detail (E2) (although it was not the absolute criterion, the detailed description commonly had more than 2000 characters). Additionally, I recorded whether the event is single or iterative.

Since a comprehensive analysis of all the aspects of the narrative structure would doubtlessly lead to another long article I will restrict myself to the analysis of the 1<sup>st</sup> chapter, just focusing on some observations that should be definitely included in such a debate.

Firstly, 19% of the 1<sup>st</sup> chapter is taken by the events described in detail (E2)<sup>2</sup>. Given that 21% of the chapter is devoted to ethnographic descriptions within expositions, we can stress a slow speed of narration; the historian’s view here is a sensitive to details view of a spectator, but not a bird’s-eye view of a long-term researcher.

qewrśw is “to look at, view, behold”, e.g., “to view the public games”; qewr...a basically means “sending the state-ambassadors to the oracles or games or being a spectator at the theatre or games”, qeərhma – “sight, spectacle, object of contemplation”. Thanks to Aristotle these concepts were shifted from the material world to the ideal one to characterize the process, product and object of intellectual contemplation.

<sup>2</sup> I counted the figure of characters in the Greek text.

The additional evidence for such visual-field-dependence is provided by the fact that 67% (55 from 82) of the events, described briefly (E1), turn out to be spectacular descriptions resting on a visual perception, or, put another way, a kind of performance the audience visualize at the theatre. Let me illustrate it with an episode of the tyrannus Pisistratus returning to Athens: “*Presently his enemies who together had driven him out began to feud once more. Then Megacles, harassed by factional strife, sent a message to Pisistratus offering him his daughter to marry and the sovereign power besides. When this offer was accepted by Pisistratus, who agreed on these terms with Megacles, they devised a plan to bring Pisistratus back which, to my mind, was so exceptionally foolish that it is strange (since from old times the Hellenic stock has always been distinguished from foreign by its greater cleverness and its freedom from silly foolishness) that these men should devise such a plan to deceive Athenians, said to be the subtlest of the Greeks. There was in the Paeanian deme a woman called Phya, three fingers short of six feet, four inches in height, and otherwise, too, well-formed. This woman they equipped in full armor and put in a chariot, giving her all the paraphernalia to make the most impressive spectacle, and so drove into the city; heralds ran before them, and when they came into town proclaimed as they were instructed: “Athenians, give a hearty welcome to Pisistratus, whom Athena herself honors above all men and is bringing back to her own acropolis.” So the heralds went about proclaiming this; and immediately the report spread in the demes that Athena was bringing Pisistratus back, and the townsfolk, believing that the woman was the goddess herself, worshipped this human creature and welcomed Pisistratus*” (Her. Hist., 1, 60; tr. by A. Godley). We can see that the pivot component of this episode is the visual image of Phya-Athena, and its structure in general addresses us to Aristophanes’ or Menander’s comedy.

Secondly, the philosophical reflections are expressed here not through the author’s words, but for the most part by the extended remarks of the characters in the dialogues. For instance, the idea of happiness, extremely important for Herodotus and the Ancient Greek culture in general, is put into the mouth of the eminent Athenian legislator Solon in his talk with Croesus, king of Lydia (Her. Hist., 1, 30-33). The behavior of the characters and the context of the talk are fairly close to Homer’s epos or the ancient tragedy, where the spectator is expected to watch it.

Thirdly, in order to reveal the reasons for historical events, Herodotus refers to both, transcendent powers (fate, gods’ envy) and human intentions dependent on their character, social rank, view on the situation, etc. Most frequently his interpretation is guided by the cumulative principle, in other words, he gives a number of versions without reconciling them. Importantly, however, transcendent factors proved to be involved in human life as initial reference points, and from the matter of fact human quick-wittedness or stupidity appear the main reason for the historical development. A good illustration for

that is Herodotus’ view on oracles and signs. Given the truth of the oracles as a point beyond doubt, he points at the capacity to render oracles and signs as a deciding factor to the successful action and puts the reason for human failures in people themselves rather than in fate or destiny (Hist. 1, 65; 1, 67-68; 1, 71; 1, 91 etc.).

So, in sum, we can conclude, that for Herodotus the cloth of history is woven by particular people who implement their intentions and projects and take into account various circumstances, from weather to oracles and signs, to do their best in that.

Let us look now at the Thucydides’ treatise. At first sight, his narrative manner has nothing in common with the Herodotus’ one. The notable part of events in the 1<sup>st</sup> chapter of his *History* is described with time markers, and the descriptions, resting on a visual perception, occupy just 13% (8 from 62) of the briefly described events. However, in comparison with Herodotus, the events described in detail occupy here much more space (41.5%). Part of them (12.3%) look quite “cinematic” stories (e.g., sea battle between Corinth and Kerkyra (1, 48-53), or constructing the walls around Athens (1, 89-93)), but the key place here (29.2%) is occupied by talks and dialogues, invented by Thucydides. In these dialogues the characters state their views on the situation trying to convince the audience to follow their suggestions. Taking into account their length and position within the text, we can call them the core elements of Thucydides’ treatise. The analysis of these talks leads us to the two main conclusions. Firstly, their composition resembles Euripides’ tragedies. Similar to Herodotus, these talks address a listener, but not a reader. Secondly, even much more intensively than Herodotus, Thucydides insists that human intentions and reasons are the main factor of the historical development. Transcendent level happens to be omitted in his text.

The situation changes radically if we resort to the medieval historiography. Let me illustrate these transformations with *The History of the Franks* by Gregory of Tours. Indeed, we can find here a number of descriptions resting on a visual perception. However, all of them appear signs of transcendent reality, the testimony of its presence in the material world. Here is the illustration: “*At that time Quirinus, bishop of the church of Sissek, endured glorious martyrdom in Christ's name. The cruel pagans cast him into a river with a millstone tied to his neck, and when he had fallen into the waters he was long supported on the surface by a divine miracle, and the waters did not suck him down since the weight of crime did not press upon him. And a multitude of people standing around wondered at the thing, and despising the rage of the heathen they hastened to free the bishop. He saw this and did not permit himself to be deprived of martyrdom, and raising his eyes to heaven he said: "Jesus lord, who sittest in glory at the right hand of the Father, suffer me not to be taken from this course, but receive my soul and deign to unite me with thy martyrs in eternal peace."* With these words he gave up

*the ghost, and his body was taken up by the Christians and reverently buried*" (1, 35; tr. by E. Brehaut).

Another important feature of this text is the lack of direct causal links between events. Similar to Augustine's numbers historical events turn out for Gregory of Tours the tools in God's hands, which leads us to breaking of the visual-field-dependence and gives new opportunities for historiography.

### Conclusion

Now, it is time to return to the general issue raised in the introduction. It is not in doubt that the Ancient Greek culture is theoretical, where we can find most cognitive operations that we perform. However, we can also encounter some special features like visual grounding of cognitive operations. All in all, the question is whether it is correct to speak here about the cognitive development from antiquity to nowadays, or to compare different cognitive styles for the sake of revealing cognitive evolution means to put the shoe on the wrong foot. There is some evidence to support the former hypothesis. Thus, M. de Vega (2008) argues for the existence of two levels of embodiment: a first-order embodiment is "strongly grounded on current perception and action", whereas a second-order embodiment "is much more detached from current perception and action" (ibid., 300). Similarly, we can single out at least two levels of embodiment for mathematics: the one for Euclid's geometry and the other for, say, a functional analysis. So, the general point is that, following the more complex challenges of modern life, the cognitive structure of modern people has got more "floors", and their cognitive styles have much more variations than they used to have in Ancient Greece. The opposition "field-dependency – independency" seems quite productive to describe this development.

## Abstract

Category-based reasoning is central to mature cognition; yet, the developmental course of this fundamental ability remains unclear. We designed a longitudinal study to investigate the development of category-based reasoning. We also took an individual differences approach to identify possible cognitive factors that may facilitate category-based reasoning. In this paper we report preliminary results of our longitudinal investigation into the development of category-based reasoning.

**Keywords:** Induction. Reasoning. Categories. Cognitive Development

## Introduction

A great deal of prior research has investigated the development of category-based reasoning. This work suggests that the fundamental ability to make inferences on the basis of category labels (i.e., category-based reasoning) is early developing (Gelman & Coley, 1990; Gelman & Markman, 1986; Jaswal, 2004; Jaswal & Markman, 2007; Welder & Graham, 2001). In a simple test of this skill, Jaswal and Markman (2007, Experiment 1) presented 24-month-old children with pairs of familiar animals (e.g., *dog* and *cat*). The children watched as the animals engaged in specific activities (e.g., the cat drinks milk and the dog chews on a bone). A third hybrid-animal was then presented (e.g., a cross between a cat and dog) and children were asked to use the props to demonstrate which action the hybrid animal would make (e.g., drink milk or chew on a bone). Importantly, the hybrid animal was designed to look more similar to one of the targets (e.g., The hybrid animal was designed to look more similar to the cat). In the no-label condition the hybrid was referred to generically (e.g., the experimenter labeled the cat-like animal as “*this one*”). In the label condition the hybrid animal was labeled counter-intuitively (e.g., the experimenter labeled the cat-like animal a “*dog*”). In the no-label condition Jaswal and Markman found that 24-month-olds generalized based on perceptual similarity 69% of the time. However, in the label condition, when perceptual similarity was pitted against category information, perceptually-based generalizations

dropped to 37%. These results suggest children as young as 24-months of age can utilize labels to infer category membership.

In a seminal study, Gelman and Markman (1986) examined children’s ability to make inductive inferences using category information that was conveyed by synonymous labels. In this experiment, preschool-aged children were presented with triads of objects and provided with respective labels. The children were told that two of the objects possessed particular properties, and the children were asked to infer which property the third object possessed. For example, children were presented with a bunny and a squirrel and told that the bunny eats grass, and the squirrel eats bugs. Subsequently, the children were asked to determine whether the rabbit ate grass like the bunny or bugs like the squirrel. Gelman and Markman found that children made category-based inductions 63% of the time, which is slightly above chance, and posited that preschool children are sensitive to the cues synonymous labels provide about category membership.

Despite these intriguing findings, there is mounting evidence demonstrating that the course of category-based reasoning follows a more protracted developmental course (Fisher, 2010; Fisher, Matlen, & Godwin, 2011). For example, Fisher et al. (2011) found that children’s ability to make inductive inferences using synonyms is limited to a small set of semantically-similar words that co-occur in child-directed speech according to the CHILDES database (MacWhinney, 2000). In particular, Fisher et al. found that most 4-year-old children were able to perform category-based inferences with synonyms that are likely to co-occur in child-directed speech (e.g., *bunny-rabbit*, *puppy-dog*); however, they were unlikely to make category-based inferences with non co-occurring synonyms (e.g., *alligator-crocodile*, *rock-stone*). This pattern of results was found with both natural kinds and artifacts. Additionally, children’s reliance on category information was found to improve gradually with age. Although 5-year-olds evidenced improvement in their reliance on category information compared to 4-year-olds, the majority of children did not reliably utilize category information

conveyed by non-co-occurring semantically-similar labels until six years of age.

If category-based reasoning has a protracted developmental course, an important question to be addressed is identifying what actually develops that enables children to utilize labels as windows into categories and reliably use this information in the course of induction.

One possibility is that advances in category-based reasoning are facilitated by changes in how children organize knowledge. There is evidence that children begin to organize concepts into networks by 21 months (Arias-Trejo & Plunkett, 2009). There is also evidence that conceptual organization changes over the course of development, with associative networks emerging prior to semantic networks (McCauley, Weil, & Sperber, 1976; Plaut & Booth, 2000). It is also possible that development of executive functioning may facilitate category-based reasoning by allowing children to disengage their attention from – often misleading or irrelevant – surface similarities and consider deeper relational similarities (Sloutsky & Fisher, 2005; Sloutsky, 2010).

The goal of the present research is to examine possible cognitive factors contributing to the development of category-based reasoning. Towards this goal we designed a longitudinal investigation taking an individual differences approach. Specifically, we collected measures of children’s category-based reasoning at Time 1, verbal working memory, IQ, and semantic knowledge organization. Collection of additional measurements (i.e., inhibitory control, non-verbal working memory, semantic priming, and category-based reasoning at Time 2) is currently in progress. In what follows we report the preliminary results of this study.

## Method

### Participants

Participants were 43 four-year-old children from a local preschool (*Age*=4.32 years, *SD*=0.28 years, 20 females, 23 males).

### Materials & Procedure

Children were tested individually in a quiet room adjacent to their classroom by a trained research assistant. The tasks were administered across 6 sessions over the course of approximately 2 weeks. A detailed description of each task is provided below.

#### Category-Based Reasoning Task

The category-based reasoning task consisted of a triad induction task. Visual Stimuli were sets of three identical doors which were presented on a computer; see Figure 1. Verbal stimuli included 9 label triads: 3 triads referring to animate natural kinds, 3 triads referring to inanimate natural kinds, and 3 triads referring to artifacts (see Table 1). The properties participants were asked to generalize consisted of two-syllable blank predicates. Each trial was comprised of a target item, a category-choice, and an unrelated lure (e.g., *rock-stone-grass*). The children were told that the objects

were hiding behind doors. This design was employed to encourage children’s reliance on category information conveyed via labels. This procedure has been successfully used in prior research (Fisher et al., 2011). On every trial children were told what was hiding behind each door.

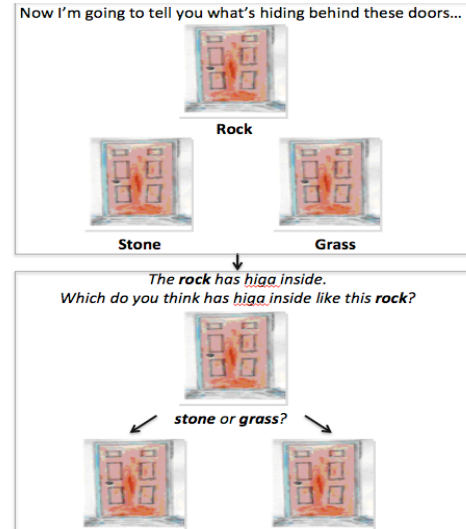

Figure 1: Schematic depiction of the category-based reasoning task. All instructions were given verbally by the experimenter.

Then, children were told that the target had a novel-property and they were asked to generalize the property to one of the test items (the category-choice or lure).

Table 1: Linguistic Stimuli for the Category-Based Reasoning Task

Target	Category Choice	Lure	Property
Rock	Stone	Grass	Higa
Alligator	Crocodile	Butterfly	Omat
Rug	Carpet	Window	Koski
Rat	Mouse	Fish	Lignin
Hill	Mountain	Flower	Erwin
Sea	Ocean	Apple	Manchin
Sofa	Couch	Cup	Creighan
Shoe	Boot	Car	Troxel
Lamb	Sheep	Frog	Matlen

The trials were presented in one of two orders: all trials were randomized for order 1, and for order 2 the presentation was reversed. Presentation order was counterbalanced across participants. The reasoning task was administered during session 2 and again in session 4 to assess stability in children’s generalization performance.

#### Picture Identification Task

The picture identification task served to assess children’s familiarity with the labels used in the reasoning task. Verbal

stimuli included 27 labels (the target, category-choice, and lure from the reasoning task). Visual stimuli consisted of a set of 108 pictures presented on a computer. All instructions and labels were given by hypothesis-blind experimenters. The picture identification task is similar to the Peabody Picture Vocabulary Test (Dunn & Dunn, 1997). On each trial children were asked to point to the object labeled by the experimenter from 4 pictorial response options (the target and 3 lures). The trials were presented in one of two orders. Presentation order was counterbalanced across participants.

#### Intelligence Test

IQ materials consisted of a commercially purchased intelligence test, the *Wechsler Preschool and Primary Scale of Intelligence* (WPPSI). The IQ test was administered in order to assess if children's reasoning performance was related to their general intelligence and/or a particular intelligence component. Eight of the WPPSI subscales were administered over 3 testing sessions in order to obtain an index of children's Verbal IQ, Performance IQ, Processing Speed Quotient, and Full Scale IQ. The WPPSI was administered by the first author of this paper and two trained research assistants.

#### Verbal Working Memory Tasks

Children's verbal working memory capacity was assessed using a simple and complex word-span task. Verbal stimuli entailed 60 words that were arranged into 6 sets. Set length ranged in size from a list length of 2 words to 6 words. Each set was comprised of 3 lists of the same length.

In the simple word-span task, children listened to the experimenter read a series of familiar count nouns, as judged by the MacArthur Communicative Development Inventory (Dale & Fenson, 1996). Then, children were asked to recite the words in the same order in which they were presented. The number of words in each set increased monotonically after children correctly completed two out of three trials within a given set size. For example, if children correctly completed 2 trials with set size 2, they then moved on to set size 3 (for a minimum of 2 trials or a maximum of 3 trials), and then set size 4 (for a minimum of 2 trials or a maximum of 3 trials), and so on until children made two errors within a set at which point testing stopped. The child's score is the longest list length he or she recited successfully. The complex word-span task was identical to the simple word-span task, except that children were asked to repeat items in the reverse order in which they were presented (e.g., If children were given the string, "*duck, house, chair*", the correct response would be "*chair, house, duck*"). The word lists were presented in one of two orders. Presentation orders were counterbalanced across participants.

The simple word-span task was included in the assessment battery in order to assess if children's performance on the category-based reasoning task was related to their general working memory capacity. The complex word-span task was included as it was

hypothesized that the complex word-span task more closely resembled the demands of the reasoning task itself (e.g., both the category-based reasoning task and the complex word-span task contain a memory component as well as a transformation/processing component).

#### Semantic Space Task

Visual stimuli included a game board consisting of a 9x9 grid. Two 1" wooden cubes served as the game pieces. Verbal stimuli consisted of 24 animal pairs. The list of linguistic stimuli is provided in Table 2. In the semantic space task, children are asked to help *Zibbo the Zookeeper* organize his zoo. Children are told that Zibbo wants to put animals of the same kind close together. Children are presented with 24 animal pairs (i.e., a target animal and a test item). Of the 24 animal pairs, 6 dyads were semantically-similar (e.g., *lamb-sheep*), 6 dyads shared a common habitat or setting (e.g., *lamb-horse*), 6 dyads were physically similar – according to size and/or color (e.g., *lamb-swan*), and 6 dyads served as filler trials. Note that the target animal was paired with 3 different animals throughout the game - the category-choice, a physically-similar item, and the habitat match. On each trial, the experimenter shows the child where Zibbo put the target animal (e.g., the experimenter places the game piece on a designated space on the board and tells the child, "*The zookeeper put the crocodile here*"). Then, the experimenter hands the child the second game piece and asks the child where the test item should go (e.g., "*Where do you think the grasshopper should go?*"). The board is then cleared and the experimenter presents the next dyad. The child's response on each trial is recorded so the distance between the target animal and test item can be calculated.

Placement of the 18 critical trials (i.e., semantically-similar dyads, physically similar dyads, or similar habitat dyads) was pseudo randomized to eight potential squares; see Figure 2. Each square was utilized at least twice and no more than three times. The 6 filler trials were randomly assigned to one of the remaining 24 squares in order to encourage participants to use the entire game board. Trials were presented in one of two orders and presentation orders were counterbalanced across participants.

Table 2: List of Stimuli for the Semantic Space Task

Critical Trials			
Target	Category - Choice	Physical Similarity	Habitat
Crocodile	Alligator	Grasshopper	Fish
Chick	Hen	Goldfish	Goat
Lamb	Sheep	Swan	Horse
Whale	Dolphin	Elephant	Octopus
Monkey	Gorilla	Chipmunk	Parrot
Mouse	Rat	Hippo	Pig
Filler Pairs			
1. Zebra/Turkey; 2. Bear/Snake; 3. Panther/ Turtle; 4. Tiger/Butterfly; 5. Frog/Lion; 6. Giraffe/Seal			

Figure 2: Depiction of the game board for the semantic space task. Red squares indicate the location of the critical trials and the yellow squares mark the location of the filler trials.

The semantic space task was included in the assessment battery to assess whether the organization of children's semantic space was related to their performance on the category-based reasoning task. Specifically, we were interested in identifying how children weight different dimensions (e.g., semantic-similarity, physical similarity, and habitat) and whether the distribution of weights to various dimensions enhances or hinders children's ability to successfully make category-based inductions.

## Results

### Picture Identification

The results of the picture identification task suggest that children possessed the prerequisite knowledge to perform category-based induction as children were highly familiar with the labels used in the reasoning task ( $M=0.92$ ,  $SD=0.14$ ). Additionally, the correlation between children's performance on the picture identification task and children's average reasoning score was only marginally significant ( $r=.28$ ,  $p=0.07$ ).

### Category-Based Reasoning Task

As stated previously, performance on the category-based reasoning task was measured twice over the course of 1 week in order to examine the stability of this measure. Mean category-based reasoning at Time 1a and 1b were very similar ( $M=0.62$ ,  $SD=0.22$ ;  $M=0.63$ ,  $SD=0.26$  respectively) and these measures were significantly correlated ( $r=.483$ ,  $p=0.001$ ). Proportions of category-based responses were compared to chance level (0.5) using single-sample t-tests. All mean scores (scores at Time 1a & 1b and average reasoning score) were significantly above chance; all  $t$ 's  $> 3.30$ , all  $p$ 's  $< 0.0022$ .

To investigate individual patterns of responses, participants were classified as either category-based or non-category-based responders. A category-based responder was defined as a participant who gave a category-based response on at least 7 out of 9 (78%) trials (binomial probability = 0.09). At Time 1a and 1b only a small percentage of children were classified as category-based responders (33% and 37% respectively).

To further investigate stability in children's category-based reasoning performance we also examined whether children's classification remained stable across Time 1a and 1b. We found that 67% (29 out of 43) of children were categorized as stable across Time 1a and 1b. Of these children only 19% (8 out of 43) were classified as consistently category-based responders, 49% (21 out of 43) were consistently non category-based, and 33% (14 out of 43) were considered unstable responders; See Figure 3. For the purposes of the remaining analyses the average reasoning score was utilized ( $M=0.63$ ,  $SD=0.21$ ).

Figure 3: Proportion of children classified as consistently category-based, consistently non-category-based, or unstable responders.

### Intelligence Test

Children's mean composite IQ scores and their Full Scale IQ were in the average range ( $MVIQ=107.36$ ,  $SD=24.30$ ;  $MPIQ=107.26$ ,  $SD=14.78$ ;  $MPSQ=92.78$ ,  $SD=23.56$ ;  $MFSIQ=107.05$ ,  $SD=15.79$ ). Children's Verbal IQ and Performance IQ composite scores were significantly correlated with their average performance on the category-based reasoning task ( $r=.33$ ,  $p=0.03$ ;  $r=.31$ ,  $p=0.05$  respectively). However, Processing Quotient was not significantly correlated with children's average reasoning score ( $r=.15$ ,  $p=0.35$ ). Children's Full Scale IQ was also significantly correlated with their average reasoning score ( $r=.50$ ,  $p=0.001$ ).

### Verbal Working Memory Tasks

Children's performance on the simple word-span task was better than their performance on the complex word-span task ( $M=3.07$ ,  $SD=1.32$ ;  $M=1.28$ ,  $SD=1.14$  respectively). A

mean score of 3.07 on the simple word-span task indicates that on average children were able to successfully recall a list length of 3 words. Children's score on the simple word-span task was found to be correlated with their average performance on the category-based reasoning task ( $r=.35$ ,  $p=0.02$ ). A mean score of 1.28 on the complex word-span task suggests that many children obtained a score of 0 on the task as the smallest list length was 2 words. Performance on the complex word-span task was not significantly correlated with children's average induction performance ( $r=.08$ ,  $p=0.60$ ), possibly due to floor effects on the complex word-span task.

### Semantic Space Task

Children's semantic space score was calculated in the following way: First, for each child an average score for each category was calculated (i.e., an average score for semantically-similar dyads, an average score for similar habitat dyads, and an average score for physically similar dyads). Children's scores for similar habitat dyads and physically similar dyads were averaged together to create an average score for non-semantically-similar dyads. This score was subtracted from the average score for semantically-similar dyads to obtain a difference score. Larger difference scores indicate that children placed semantically-similar dyads closer together and non-semantically-similar dyads farther apart. Smaller difference scores indicate that children did not reliably discriminate between semantically-similar dyads and non-semantically-similar dyads.

Table 3: Correlation Matrix

(Note: CB Reasoning = Category-based reasoning, Pic ID = picture identification, SWS = simple word-span, CWS = complex word-span, SS = semantic space, VIQ = verbal IQ, PIQ = performance IQ, PSQ = processing speed, FSIQ = full scale IQ)

	1	2	3	4	5	6	7	8	9
1. CB Reasoning	-	.283	.345*	.082	.460**	.332*	.305*	.149	.496**
2. Pic ID	-	-	.706**	.275	.228	.723**	.100	-.157	.584**
3. SWS	-	-	-	.415**	.313*	.671**	.182	-.038	.578**
4. CWS	-	-	-	-	.126	.170	.188	.009	.202
5. SS	-	-	-	-	-	.384*	.432**	.145	.526**
6. VIQ	-	-	-	-	-	-	.049	-.314*	.800**
7. PIQ	-	-	-	-	-	-	-	.598**	.540**
8. PSQ	-	-	-	-	-	-	-	-	.123
9. FSIQ	-	-	-	-	-	-	-	-	-

Note. \*. Correlation is significant at the 0.05 level. \*\*. Correlation is significant at the 0.01 level

Children's mean score for semantically-similar dyads was 4.37 ( $SD=1.35$ ). Children's score for physically similar dyads and similar habitats was 5.64 ( $SD=1.76$ ) and 5.83 ( $SD=1.60$ ) respectively. Children's mean score for non semantically-similar dyads was 5.74 ( $SD=1.51$ ). Difference scores ranged from -2.58 to 5.67 suggesting considerable variability in children's performance on this task. The average difference score was 1.37 ( $SD=1.88$ ). Children's performance on the semantic space task was found to be significantly correlated with their average performance on the category-based reasoning task ( $r=.46$ ;  $p=0.002$ ).

### Predicting Category-Based Reasoning Performance

There were a total of 8 possible predictors of children's reasoning performance. As can be seen in Table 3, several of the predictors were significantly correlated with each other. Concerns regarding collinearity are allayed as tolerance values for predictors entered into the regression model were within the acceptable range. Children's scores on the simple word-span task, semantic space task, and FSIQ were entered into the model as predictors. Children's average score on the category-based reasoning task was the dependent variable.

The regression model significantly predicted children's average reasoning score,  $F(3, 38)=5.47$ ,  $p=0.003$ . The  $R$  squared value indicates that 30% of the variance in children's performance on the category-based reasoning task was explained by the model. Simple word-span was not found to be a significant predictor ( $\beta=0.08$ ,  $p=0.62$ ); however, semantic space ( $\beta=0.26$ ,  $p=0.11$ ) and FSIQ ( $\beta=0.31$ ,  $p=0.10$ ) were marginally significant predictors of children's reasoning performance.

## Discussion

Overall, the results from this study, although preliminary, point to several findings. First, the analysis of individual patterns of response on the reasoning task replicate previous work (Fisher et al., 2011; Godwin, Matlen, & Fisher, 2011). Specifically, we found that when young children are presented with non-co-occurring semantically-similar labels only a small percentage of children spontaneously engage in category-based reasoning.

Second, the present findings suggest that several factors are related to children's induction performance. We found that children's Full Scale IQ, Verbal IQ, Performance IQ, simple working memory, and semantic space performance were all significantly correlated with children's average reasoning score. Additionally, children's Full scale IQ and performance on the semantic space task were identified as unique predictors of children's performance on the category-based reasoning task according to the regression model. The correlation between semantic organization and category-based reasoning is also consistent with related research on the development of analogical reasoning, which has suggested that children's shift from focusing primarily on perceptual similarity to relational similarity is mediated by increases in domain knowledge (Rattermann & Gentner,

1998). On-going research will examine whether other cognitive factors (e.g., inhibitory control, non-verbal working memory, etc.) are also related to the development of category-based reasoning.

Third, the present study provides novel information on the stability in children's induction performance. This study is the first to our knowledge to look at the stability in children's performance on a conceptual development measure. The findings from this study suggest that children's category-based reasoning performance between Time 1a and 1b is correlated; however, there is still a great deal of variability in children's performance as indicated by the small percentage of children who were classified as consistently category-based across the two time points. Additionally, the longitudinal component of this study will enrich our understanding of the stability in children's inductive reasoning. Once data collection is complete, we will be able to examine whether the percentage of children who are classified as consistently category-based increases with age.

In conclusion, the present study contributes to our understanding of children's emerging ability to engage in category-based reasoning. The contributions of this work include identifying potential factors that may be predictive of children's induction performance as well as the opportunity to investigate the stability of children's category-based reasoning. Future research is needed to extend these findings and disentangle the different hypotheses put forth to explain this fundamental aspect of conceptual development.

### Acknowledgements

We thank Malika Sinha, Laura Pacilio, Alyssa Montanaro, Anna Loiterstein, Like Li, and Kayoung Joung for their help collecting data. We also thank the children, parents, and teachers who made this project possible. This work was supported in part by a Graduate Training Grant awarded to Carnegie Mellon University by the Department of Education (R305B090023 and R305B040063).

## Abstract

Preschoolers often switch a response on repeated questioning, even though no new evidence has been provided (Krahenbuhl, Blades, & Eiser, 2009). Though apparently irrational, this behavior may be understood as children making an inductive inference based on their beliefs about whether initial responses were correct and the knowledgeability of the questioner. We present a probabilistic model of how the questioners' knowledge and biases to be positive should affect inferences. The model generates the qualitative prediction that an ideal learner should switch responses more often following a "neutral query" from a knowledgeable questioner than following queries from an ignorant questioner. We test predictions of the model in an experiment. The results show that four-year-old children are sensitive to questioners' knowledge when responding to a neutral query, demonstrating more switching behavior when the query is provided by a knowledgeable questioner. We conclude by discussing the practical and theoretical implications for cognitive development.

When should a learner abandon their current hypothesis in favor of a new one? It is becoming clear that even preschool-aged children rationally update beliefs and generate new explanations following informative evidence (Gopnik, Glymour, Sobel, Schulz, & Danks, 2004; Schulz, Bonawitz, & Griffiths, 2007; Denison, Bonawitz, Gopnik, & Griffiths, 2010; Bonawitz, Schijndel, Friel, & Schulz, 2012; Bonawitz, Fisher, & Schulz, in press). These tasks often involve assessing children's starting belief state, either presenting the child with new evidence or allowing the child to generate their own evidence, and then eliciting an explanation or judgment. What constitutes "evidence" in these tasks is fairly intuitive; for example, children may be presented with a storybook containing information about two variables that tend to co-occur (Schulz et al., 2007) or they may observe a toy that reacts when certain objects are placed on top of it (Bonawitz, Denison, Gopnik, & Griffiths, 2011).

In addition to revising beliefs following correlational evidence and interventions, children also learn from others. Interestingly, even preschool-aged children do not do so indiscriminately; they use information about informants' knowledge and intent to guide who they trust. For example, children do not trust informants who label familiar objects incorrectly (Koenig & Harris, 2005), who dissent from groups (Corriveau, Fusaro, & Harris, 2009), and even with familiar informants, children update social inferences (Corriveau & Harris, 2009). Similarly, recent research suggests that children use information about informants' intent to guide inferences (Mascaro & Sperber, 2009; Shafto, Eaves, Navarro, & Perfors, in press). Other research has suggested that even four-year-old children make different causal inferences depending on the social context when evidence is presented: direct instruction by a knowledgeable and helpful informant

provides strong constraints on likely hypotheses as compared to accidental information by a not-knowledgeable informant. Even when contrasted with intentional (but not instructional) actions and interrupted demonstrations, preschoolers make stronger inferences about causal structure from direct instruction by leveraging the informant's knowledge and intent (Bonawitz, Shafto, et al., 2011; Buchsbaum, Gopnik, Griffiths, & Shafto, 2011; Butler & Markman, 2010). These pedagogical assumptions have been captured by probabilistic models (e.g. Shafto & Goodman, 2008; Bonawitz, Shafto, et al., 2011), which suggest a rational account of how learners update their beliefs following evidence generated in the context of teaching.

These literatures suggest that preschool children are sophisticated and powerful social learners; they revise their beliefs when evidence is sufficient and use social or instructional contexts to help interpret the strength of the evidence. However, other research suggests that children may abandon hypotheses too capriciously. For example, the effects of repeated questioning on eyewitness testimony in young children have been studied extensively in the context of the judicial system, and work done by Poole and White (1991) found that, in contrast to adults, four-year-olds were more likely to change their responses to repeated yes or no questions. More recently Krahenbuhl et al. (2009) found that children as young as four changed over a quarter of their responses to repeated questions, resulting in a decline in accuracy. In Howie, Sheehan, Mojarrad, and Wrzesinska (2004) four-year-old children were more likely than older children to change responses toward an incorrect answer on repeated questioning. That is, although no additional evidence was provided, by simply asking children the same question a second time, children were very likely to switch their predictions. How might we reconcile these findings with those suggesting that children should only rationally update beliefs following informative evidence?

One explanation for this apparently irrational switching behavior is that seemingly neutral questions such as "Is that your final answer?" may provide strong information in certain social contexts. If preschoolers are sensitive to the potential communicative intent behind such queries, the question itself may be a source of evidence about whether an initial guess was correct. Consider a game in which a sticker is hidden under one of two cups. Suppose an informant asks the child which cup they believe the sticker is under and after the child's initial guess, the teacher asks, "Is that your final answer? Would you like to change your guess?" In which contexts does such a question provide information about the true location of the sticker? Intuitively, it seems obvious that if the

questioner does not know the actual location of the sticker, then the repetition of the question provides little additional evidence; however, a *knowledgeable* questioner might have a good reason for giving the learner with a second chance at answering the question. In these cases, this apparently neutral query is not neutral at all; it is a strong cue to the learner that they should change their answer.

In what follows we will explore the idea that even a “neutral” query carries information about the state of the world when a questioner is knowledgeable. We present a probabilistic model that demonstrates how an ideal learner might evaluate such “neutral” queries in scenarios in which the questioner is knowledgeable and scenarios in which she is ignorant. With the model, we evaluate the conditions under which switching guesses is the rational choice for the learner. We then test the basic prediction with preschoolers in an experiment in which the informant’s knowledge or ignorance is made explicit. We suggest that repeated questioning does indeed lead a learner to switch responses and that even preschoolers are sensitive to the knowledge state of others when making such inferences.

### Modeling learners’ responses to neutral queries

Here we consider a model of “neutral queries”. Bayesian inference provides a natural framework in which to consider how an ideal learner should update her beliefs following this kind of information. In Bayesian inference, the learner’s goal is to update their beliefs about hypotheses,  $h$ , given data,  $d$ , where the degree of belief in a hypothesis given data is denoted  $P(h|d)$ . These updated posterior beliefs are determined by two factors: the learner’s prior beliefs in hypotheses,  $P(h)$ , and the probability of sampling the observed data, assuming the hypothesis is true,  $P(d|h)$ . Specifically, the updated posterior belief in a particular hypothesis is proportional to the product of the prior belief in that hypothesis and the probability of sampling the data given that hypothesis,  $P(h|d) \propto P(d|h)P(h)$ .

Because we are considering only two hypotheses, we can use Bayes Odds to simplify the problem:

$$\frac{P(h_1|d)}{P(h_2|d)} = \frac{P(d|h_1)P(h_1)}{P(d|h_2)P(h_2)}, \quad (1)$$

where  $P(h_1|d)$  is the probability that the sticker is in the first location, given the statement from the informant (“correct”, “incorrect”, “is that your final answer”) and  $P(h_2|d)$  is the probability that the sticker is in the second location given the statement. It is reasonable to assume that the learner has no a priori assumptions about either location, which allows us to cancel out the prior beliefs (i.e.  $P(h_1) = P(h_2)$ ), thus  $\frac{P(h_1)}{P(h_2)} = 1$ .

The main issue is the probability of the statement given the location of the sticker,  $P(d|h)$ . We can model this likelihood with a simple causal graphical model (see Figure 1). Causal graphical models consist of a structure indicating the causal relationships among a set of variables, where nodes are

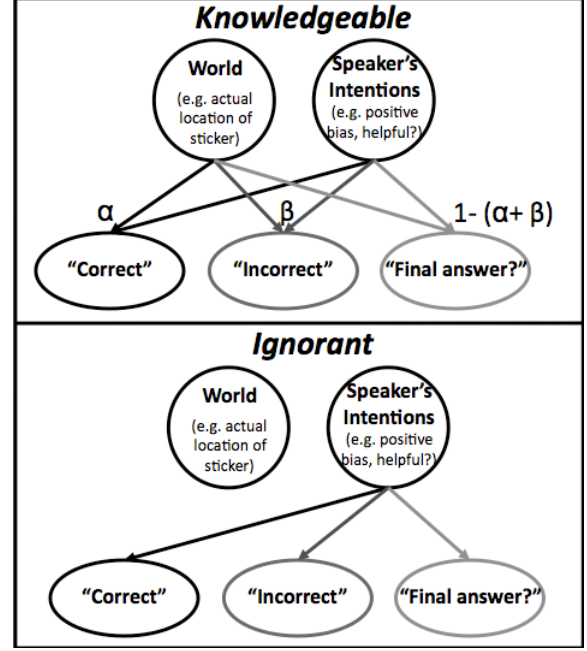

Figure 1: Graphical model depicting dependencies in cases when the informant is *knowledgeable* and *ignorant*.

variables and dependence relationships are indicated by arrows from causes to effects. To complete a graphical model, conditional probability distributions give the probability that each variable takes on a particular value given the value of its causes (Pearl, 2000; Spirtes, Glymour, & Schienens, 1993, see Table 1).

In our model of the problem, the variables include the actual state of the world (“World”, i.e. location of the sticker), the intention of the speaker (to provide helpful feedback, to avoid negative feedback, etc.), and the possible statements the informant can make (“Correct”, “Incorrect”, “Is that your final answer?”). In the first model (*Knowledgeable*) the informant is aware of the actual state of the world. As a result, both the true location of the sticker and the intention of the speaker influence the statement given to the learner. In the second model (*Ignorant*), the informant is not aware of the actual state of the world. As a result, the true state of the world does not influence the statement given to the learner. That is, the state of the world and the information provided are causally independent of each other.

The dependence assumptions captured by the graphical model generate predictions about the behavior of learners. In the case of a knowledgeable informant, given information about the actual state of the world and the informant’s statement, a learner can infer something about the informant’s goals (e.g. to provide positive or negative feedback). Given information about the state of the world and the informant’s goals, a learner could also predict (with some probability) the likelihood that the informant would produce different statements. In our problem, given the informant’s goals and the statement provided, the learner can make an inference about

Table 1: Conditional probability table for knowledgeable graphical model.

Guess	“Correct”	“Incorrect”	“Final answer?”
Correct	$\alpha_c$	$\beta_c \approx 0$	$1 - (\alpha_c + \beta_c) \approx 1 - \alpha_c$
Incorrect	$\alpha_i \approx 0$	$\beta_i$	$1 - (\alpha_i + \beta_i) \approx 1 - \beta_i$

the state of the world. A learner could also make more abstract inferences: given information about the goals of the informant, the statement provided, and the actual location of the sticker, a learner could infer which model (*Knowledgeable* vs *Ignorant*) best captures the knowledge state of the informant.

The specification of the conditional probability distribution provides additional qualitative predictions. In the *knowledgeable* graphical model, we might reasonably argue that if the child chooses the correct location initially, the speaker is very unlikely to say “incorrect”; in this case  $P(\text{“incorrect”}|\text{correct choice}) = \beta_c \approx 0$ . Similarly, if the child chooses the incorrect location initially the speaker is very unlikely to say “correct”,  $P(\text{“correct”}|\text{incorrect choice}) = \alpha_i \approx 0$ . Given these intuitive assumptions, we can compare three possible ways biases about the goals of the teacher might play out in the model’s predictions.

The first possibility is that the informant is *unbiased*. Let us consider the case when the informant is knowledgeable. In this case, the *unbiased informant* is just as likely to say “correct” when the initial guess is correct as “incorrect” when the initial guess is incorrect,  $\alpha_c \approx \beta_i$ . If this is the case, then the learner can not infer whether their initial guess is correct or not if they hear the statement “is that your final answer”. This is because  $P(\text{“final answer?”}|\text{correct}) = P(\text{“final answer?”}|\text{incorrect})$ . That is, the statement “is that your final answer” provides no additional information about the location of the sticker (Equation 1 is approximately equal to 1). Now consider the case where the informant is ignorant. In this case, because the informant has no information about the actual state of the world, the true location is conditionally independent of the statements made by the informant, and the learner cannot make any inferences about the state of the world. Thus, assuming unbiased informants, learners should make the same inferences if asked “is that your final answer” in a *knowledgeable* condition as if asked “is that your final answer” in an *ignorant* condition. This model does not predict the degree to which the learners should switch responses, but it does predict no difference between conditions.

A second possibility is that the informant is *positively biased*. In this model, the knowledgeable informant may be inclined to want to say “correct” following correct initial guesses, but would be reluctant to say “incorrect” following an incorrect initial guess,  $\alpha_c > \beta_i$ . If this is the case, then the statement “is that your final answer” provides support for the hypothesis that the learner’s initial guess was incorrect because she is more likely to hear “is that your final answer” given an incorrect guess than “is that your final answer” given a correct guess (Equation 1 > 1). Thus, the *positively biased* model predicts that a learner should show increased switch-

ing in a *Knowledgeable* condition as compared to an *Ignorant* condition (in which the state of the world is still conditionally independent of the statements and thus does not provide additional information).

The third possibility is that the informant is *negatively biased*. In this model, the informant may be inclined to say “incorrect” following an incorrect initial guess, but would be comparatively reluctant to say “correct” following a correct initial guess,  $\alpha_c < \beta_i$ . If this is the case, then the statement “is that your final answer” provides support for the hypothesis that the learner’s initial guess was correct (Equation < 1) and the learner should show a decrease in switching responses in the *knowledgeable* condition as compared to an *Ignorant* condition.

Note that the precise values of  $\alpha$  and  $\beta$  are not important for the predictions of this model, but the relationship between these variables drives the predictive differences. We investigate three implications of this model: first, do we replicate the finding that preschoolers tend to switch responses following what might be considered a “neutral query”; second, do preschoolers take the knowledge state of the informant into account when inferring whether or not to switch hypotheses; third, do preschoolers assume that the informant is neutral, positively, or negatively biased when they provide a query?

## Experiment: Preschoolers’ switching behavior in response to a neutral query

To investigate the predictions of our model we invited preschoolers to participate in a game where the goal was to guess the location of a sticker under one of two cups. After their initial guesses, children were given some feedback and the opportunity to change their guess. After two training trials in which the experimenter told the child that their first guess was either correct or incorrect, children were given three test trials. In the test trials the experimenter asked the child “Is that your final guess?” after children’s initial guesses. Some children participated in a condition in which the experimenter looked under the cups before generating the query and others participated in a condition in which the experimenter did not look before the query. The critical measure is simply on what percentage of trials children switched their prediction to the other cup by condition.

## Method

**Participants** Thirty-two preschoolers (mean age: 58.6 months; range: 48-79 months) were recruited from local preschools and museums for participation.

**Design** Preschoolers were randomly assigned to either the *Knowledgeable* condition or *Ignorant* condition. Four children were dropped and replaced for demonstrating a side bias (see results) in the *Knowledgeable* condition and five children were dropped and replaced for side biases in the *Ignorant* condition. There were no differences in ages between condition,  $t(30) = 0.35, p = ns$ .

**Materials** 5 pairs of colored cups (pink, blue, yellow, green, orange) were used in the conditions. An animal sticker was placed on the inside of one of the cups in each set.

**Procedure** The experimenter began by pulling aside a pair of cups and showing the child that there was a sticker inside one and no sticker inside the other. The experimenter then said, “In this game, it is going to be your job to guess which cup has the sticker inside. For each set of cups I’m going to ask you twice which cup you think has the sticker inside. After you make your first guess I will ask you once more and you can either keep your guess the same or guess the another cup. If your second guess is right then you get a point and for every point you get we will play a game at the end. So remember you want to try and get your second guess right so you can get a point!” The experimenter then proceeded to take a different pair of cups and said, “Let’s take a look at these two cups. One of them has the sticker inside and it’s going to be your job to guess which one. I’m going to look inside so I know which cup has the sticker.” The experimenter then looked inside and then asked the child which cup they believed had the sticker. Regardless of the accuracy of the children’s guess, the experimenter randomly responded either “Yes that’s right!” or “Hmmm that’s not right” and then asked the child again which cup they believed had the sticker inside. Children did not see the contents of the cup immediately after the trials, so they did not receive feedback as to whether their guesses were correct. The second training trial was the same as the first with the exception that the experimenter reversed the response provided after the child’s initial guess.

The experimenter then began the test trials. In the *Knowledgeable* condition the experimenter said, “I’m going to look so I know which cup has the sticker inside” making their knowledge state explicit. She then proceeded to ask the child which cup they believed had the sticker inside; when the child responded, the experimenter provided no explicit feedback as in the training trials, but instead said, “Okay, you said this cup had the sticker inside. Is that your final guess; which cup do you think has the sticker inside?” Children did not see the location of the sticker. In the *Ignorant* condition the experimenter said, “I’m not going to look inside so I don’t know which cup has the sticker either” making their ignorance explicit; the rest of the condition proceeded as with the *Knowledgeable* condition. At the end of the experiment, the experimenter brought back all the pairs of cups and let the children discover which cups contained the stickers.

## Results

**Coding** Children’s responses were video taped and recoded by an assistant blind to condition; seven children were coded live because either no video consent was provided by the parents or because the view of the children’s pointing response was obstructed. For the remaining 25 children, there was 92% agreement; the errors were caused by obvious Left/Right coding errors and were resolved by a third coder.

Figure 2: The percent of total test trials on which preschoolers switched their guesses in the *Knowledgeable* and *Ignorant* conditions following the neutral query.

**Inclusion Criteria** Because the order of “correct” and “incorrect” feedback was randomly assigned and counterbalanced, and because the experimenter could not control which cup the children would initially guess, some children were unintentionally “trained” to believe that the sticker always was located in the cup to one side. We classify two scenarios in which this side-bias occurs as follows: (1) During the first training trial the participant selects side A and is told that he is incorrect so he switches his guess to side B. On the second training trial, the participant chooses side B again and is told he is correct and so he continues to select side B for all subsequent guesses, both before and after the query. (2) During the first training trial the participant selects side A and is told he is correct and stays with side A. On the second training trial, the participant then chooses side B and is told he is incorrect, which leads him to switch his guess to side A and continue to select side A without switching on all subsequent guesses. In these two cases we have (by virtue of our random design) given the participant evidence that the sticker will always be on the same side. As discussed above nine children were dropped and replaced for this reason.

**Test Results.** Children’s performance on the initial feedback trials was nearly perfect, with children appropriately switching responses following the feedback that they were incorrect on training trials and appropriately staying with their response following the feedback that they were correct (94%). Our measure of interest was whether children switched their predictions in the test trials following the neutral query of “Is that your final answer; which cup has the sticker inside?” On aggregate, there were no differences between the three test trials within condition (*knowledgeable* Fisher Exact  $p = 1$ ; *Ignorant* Fisher Exact  $p = 1$ ), so the switching response of each child was scored as a total of switching responses by condition; children were more likely to switch their responses in the *Knowledgeable* condition (58% of the trials) than were

children in the *Ignorant* condition (33% of the trials; Pearson  $\chi^2 = 6.04, p = .01$ , see Figure 2). Children in the *Ignorant* condition were less likely to switch responses than would be predicted by chance (Binomial,  $p = .01$ ). No age effects were observed within or across conditions.<sup>1</sup>

Taken together, these results show that children take the knowledge state of the questioner into account; they are more likely to switch responses when the questioner is knowledgeable than when she is ignorant. These results are consistent with the *positive bias* model, suggesting that in addition to taking the knowledge state of the informant into account, preschoolers also have the assumption that the informant prefers to provide positive (over neutral) feedback following correct guess outcomes and a preference to provide a neutral query (over negative) following incorrect guess outcomes.

## General Discussion

Recent research investigating children's learning of causal relationships and inferences about knowledgability suggests that while children's behavior is captured by rational models, in certain cases children's behavior appears less sensible, almost capricious. We have focused on children's seemingly irrational tendency to switch their responses when subjected to repeated questioning, proposing that this behavior may be the rational consequence of reasoning about the questioner's knowledge.

In our example, we presented a relatively simple model that accounts for switching behavior by considering the relationship between the kinds of responses informants may give and the relationship of those responses to the true state of the world. The main prediction of the model is that children's tendency to switch in response to questioning should depend on the epistemic state of the questioner. We presented a simple experiment which showed that preschool children switch their guesses more in response to neutral queries by a knowledgeable informant than by neutral queries by an ignorant informant.

Given that we told participants that they would be asked to guess twice, one might wonder whether the neutral queries should provide any information. By virtue of our design, we made it clear to children that the experimenter could also provide positive ("that's right") or negative ("that's wrong") feedback to children. Thus, by instead asking "is that your final answer" on test trials, children could reason about the implications of *not* hearing one of the alternatives. By providing neutral feedback when other feedback was available, the experimenter provided implicit information to the learner.

Our results leave open the question of why children should switch their hypotheses at all in the *Ignorant* condition. The switching pattern observed in the *Ignorant* condition suggests that social inferences about informant's intentions are not the

only explanation for children's switching behavior. One possibility is that regardless of the epistemic state of the questioner, the opportunity to re-evaluate an answer leads children who have a degree of uncertainty about their answers to reconsider their response. If guessing the outcome of a coin toss, there is no necessary reason to guess heads repeatedly. Similarly, in the ignorant condition, children's switching behavior may simply reflect their uncertainty about the correct answer. Recent research suggests that questioning may simply present the opportunity to reconsider hypotheses (Abbot & Griffiths, 2011), which can lead to a new response; deciding to stay or switch are both rationally viable (Denison et al., 2010; Bonawitz, Denison, et al., 2011).

The model highlights the kinds of assumptions a learner must bring to the table. Our empirical results suggest that preschool children must (1) take knowledge state of informant into account, and (2) assume a positive bias in informants. A large and growing body of evidence suggests that children keep track of others' knowledge and use it for various reasoning problems (e.g. Corriveau et al., 2009; Corriveau & Harris, 2009; Koenig & Harris, 2005). To our knowledge, the argument that children assume this positive bias in informants is novel and has interesting implications for learning and cognitive development. For instance, one might reasonably ask whether this bias is a product of experience and whether such experiences would affect the interpretation of neutral queries.

Our model makes additional predictions that may be explored in future work. For example, training children that the questioner has negative biases should lead to a decrease in switching responses. Switching behavior should also be dependent on the degree to which the informant has information about the actual location; neutral queries from an informant with partial knowledge may lead children to switch responses less often than an informant with complete knowledge. Another possibility is to explore the model's predictions over time to see how children learn about the intentions and knowledge of the informant over a series of trials. Finally, older children and adults may bring different assumptions about informants, so finding age-dependent changes may help characterize how social-causal inferences change with development.

Our results raise important practical considerations in science and education. Often times researchers, teachers, and parents ask children questions as a means of evaluating what the child believes. These questions are assumed to be inert, providing no additional information to the child, and the responses are treated as windows into the child's thinking. Our results call both of these assumptions into question. Even seemingly neutral queries provide information to children when posed by someone who can reasonably be assumed to be knowledgeable. And, because they are savvy social operators, children may change their minds in response to these neutral queries. In our experiments, we intentionally chose situations in which children would have weak beliefs about the location of the sticker, because previous research has sug-

<sup>1</sup>Comparing the average number of switches per child across young and old (by median split), we find no differences (Knowledgeable:  $t(14) = -.35, p = .73$ ; Ignorant:  $t(14) = 0, p = 1$ , Aggregate:  $t(30) = -.25, p = .80$

gested that children's prior beliefs play an important role in how they interpret ambiguous evidence (Schulz et al., 2007) and how they account for evidence that conflicts with strongly held beliefs (Bonawitz et al., 2012). We do not know the degree to which children's prior beliefs will interact with inferences in these settings; However, regardless of prior beliefs, neutral queries may act as prod for the child to reconsider what she previously believed and thus may not provide a true window into the child's thinking. Thus, children's responses following repeated questioning in research and education settings should be interpreted with caution.

## Conclusions

Children use various assumptions about a teacher's knowledge and intent to guide their reasoning. Our work takes this idea and expands on it, suggesting that questions originally assumed to be inert and provide no feedback may in fact serve as cues for children to draw inferences from. Learning about the world is an immensely daunting task for young minds, yet children are able to learn rapidly and accurately even in light of limited information. In school settings, at home, and even in eyewitness testimony, we employ repeated questioning as a means to assess a child's beliefs. When asked by a knowledgeable informant, such as a teacher, parent, or attorney, these questions may not simply elicit information about what the child believes, but instead may give the child reason to change their beliefs all together.

# Abstract language comprehension is incrementally modulated by non-referential spatial information: evidence from eye-tracking

Ernesto Guerra (ernesto.guerra@uni-bielefeld.de)

## Abstract

Research on situated language processing has examined how visually depicted objects or concrete action events inform the comprehension of concrete sentences. By contrast, much less is known about how *abstract* sentence comprehension interacts with non-linguistic visual information. Moreover, while non-linguistic information can rapidly inform language comprehension when it is related to sentence content through reference or lexical-semantic associations, it is unclear to which extent this is the case when the visual context is ‘non-referential’ (i.e., not related to the sentence through reference or lexical semantic associations). We conducted two eye-tracking reading experiments to address these two open issues. In both experiments, reading times were shorter when sentences about conceptually similar abstract ideas were preceded by objects (words-on-cards in Experiment 1 and blank playing cards in Experiment 2) that were depicted close together (vs. far apart); and when sentences about conceptually dissimilar abstract ideas were preceded by objects that were depicted far apart (vs. close together). This happened rapidly (first-pass reading times) and incrementally (as the sentence unfolded). Thus, (a) comprehension of abstract language can be modulated by non-linguistic visual information (spatial distance between depicted objects) at the sentence level, and (b) online language comprehension can be informed by visual context even in the absence of an overt referential or lexical-semantic link.

**Keywords:** semantic interpretation; spatial information; non-referential visual context; eye tracking.

## Introduction

Studies in the ‘visual world paradigm’ have contributed extensively to our understanding of how non-linguistic visual information affects sentence comprehension (e.g., syntactic disambiguation: Tanenhaus et al., 1995; semantic interpretation: Sedivy et al., 1999). In ‘visual world studies’, listener’s eye movements are tracked during comprehension of a spoken sentence that describes a given visual environment. Findings from such studies have shown that visual presentation of objects or concrete action events can facilitate incremental structural disambiguation (e.g., Tanenhaus et al., 1995; Knoeferle, Crocker, Scheepers, & Pickering, 2005); that language can rapidly guide visual attention to semantically relevant objects as evidenced by anticipatory eye-movements (e.g., Altmann & Kamide 1999; Kamide, Scheepers, & Altmann, 2003; Kamide, Altmann, & Haywood, 2003); and that distractor objects are inspected more often when they are semantically related (vs. unrelated) to a target word (e.g., Huettig & Altmann, 2005,

2011; Huettig & McQueen, 2007). Visual context not only affects spoken language comprehension rapidly, but also sentence comprehension during reading. Evidence from picture-sentence verification has revealed rapid visual context effects for concrete visual stimuli (e.g., red dots) and sentence content (e.g., *The dots are red*, see Clark & Chase, 1972; also Gough, 1965; Knoeferle, Urbach, & Kutas, 2011; Underwood, Jebbet, & Roberts, 2004).

However, most of these studies have concentrated on sentences about concrete objects and events. While evidence suggests that visual context can rapidly and incrementally inform comprehension of concrete spoken and written sentences, it is unclear to which extent non-linguistic visual context information can influence the processing of abstract language rapidly and incrementally. In examining situated language comprehension, most visual world studies have further relied on a *referential* linking hypothesis (e.g., a noun referencing an object or a verb an action). By contrast, it’s unclear whether visually presented information can influence sentence comprehension when there is no overt referential or lexical-semantic link with sentence content.

## Spatial Distance and Semantic Similarity

Conceptual metaphor theory proposes that abstract meaning is grounded in physical experience through metaphorical mapping (Lakoff & Johnson, 1999). Similarity, for instance, would be grounded in the physical experience of spatial distance. Recent behavioral studies have provided first evidence for a link between spatial distance and similarity. In one study, two visually presented abstract words (e.g., *loyalty* and *boredom*) were judged to be more similar when they were presented close together (vs. far apart), but more dissimilar when they were presented far apart (vs. close together, Casasanto, 2008). In another, similarity-judgment task (on whether two squares on a screen had similar colors or not) speeded decision times were shorter when similarly-colored squares were presented close to each other (vs. far apart), and when differently-colored squares were presented far apart (vs. close to each other, Boot & Pecher, 2010). These rating and response time effects support the view that there is a relationship of some sort between spatial information (the distance between two stimuli) and semantic and visual similarity.

## Accounting for situated language comprehension

The nature and time course of spatial distance effects on cognitive, and in particular, language comprehension processes, however, remains unclear. In summary, we have identified several open issues in research on the interaction between non-linguistic visual information and language comprehension, which we conceptualize as two research questions: (1) Can non-linguistic information rapidly and incrementally modulate the semantic interpretation of abstract sentences? (2) Can non-linguistic visual information modulate language comprehension even in the absence of referential or lexical-semantic links?

Addressing these and other questions is important to advance accounts of situated language comprehension (e.g., the Coordinated Interplay Account, CIA, Knoeferle & Crocker, 2006; Knoeferle & Crocker, 2007). The CIA accommodates visual context effects during spoken language comprehension. It consists of three informationally and temporally dependent stages. A first stage accommodates the processes of incremental sentence comprehension that are the focus of traditional sentence processing accounts. A second stage describes utterance-mediated shifts in (visual) attention. ‘Scene integration’, finally, integrates the linguistic and scene input and informs interpretation based on visual representations. The CIA makes no assumptions regarding the modular status of either the linguistic or visual processes involved. Rather, it outlines the interaction of utterance interpretation, (visual) attention and scene information.

The CIA has been derived from eye-tracking findings on the comprehension of concrete sentences in non-linguistic visual contexts. The rapid and incremental time course with which information in visual context interacts with spoken language comprehension appears to generalize to reading when there is a referential link between visual context and sentence meaning (see Knoeferle et al., 2011 for evidence). Knowing whether rapid and incremental visual context effects are also observed when there is no referential link and when sentences are abstract, would be important for extending the account and refining its language-context linking mechanism. Based on the close time locking of visual context effects and language comprehension in the CIA, we would expect to see spatial distance effects emerge time-locked to when information about semantic similarity becomes available in the sentence. The present research addressed the two research questions (1) and (2) in two eye-tracking reading experiments. The studies examined whether, and if so with which time course, spatial distance effects on semantic similarity processing occur during comprehension of abstract sentences.

### Experiment 1

In Experiment 1, participants inspected a visual context that depicted words on cards either close together or far apart (Fig. 1). Then they read a sentence that was either about

similarity or dissimilarity between abstract nouns (Table 1). After reading the sentence and judging its veracity, they saw a picture and verified whether it was the same as the one that they had inspected before the reading task.

If spatial distance between the cards can modulate the interpretation of semantic similarity, we should see this reflected in reading times. To the extent that the existing findings on spatial distance effects (Boot & Pecher, 2010; Casasanto, 2008) generalize to language comprehension we should see faster reading times for similarity-conveying sentences when the preceding words-on-cards are close together (vs. far apart), and for dissimilarity-conveying sentences when the words-on-cards are far apart (vs. close together). Moreover, if effects of spatial distance are incremental, we should see them at the adjective region of the sentence (see Table 1 for examples) since this is when similarity relations are made explicit and could thus be related to spatial distance from the recent visual context. In principle, effects could appear even earlier, namely at the second noun phrase, since semantic similarity could become available as soon as the two abstract nouns are integrated. Finally, to the extent that these effects are immediate, we should observe them in first-pass reading times.

### Method

**Participants** Thirty-two native speakers of German (mean age: 23.6; range 19-33) with normal or corrected-to-normal vision participated in the experiment for a compensation of 6 Euro. None of them had been exposed to a second language before age 6, and all gave informed consent.

**Materials and Design** We created 48 sentences<sup>1</sup>, each of which had two versions. In one version the sentence expressed *similarity* between two abstract nouns, and in the other version it expressed *dissimilarity* between two abstract nouns (see Table 1 for examples). In addition, we created visual contexts using commercial graphics programs. The visual context showed two playing cards each of which presented an abstract word (see Fig. 1). Card depictions did not change between items but the words on the cards did. The words on the cards always appeared as the first and second noun phrase in the sentence. The two visual contexts and the two sentences made up an item.

A 2x2 within-subjects Latin square experimental design was implemented with two factors (spatial distance and semantic similarity), each with two levels (close vs. far, similar vs. different, respectively). Combinations of the two factors and levels resulted in four experimental conditions: cards far apart vs. close together with a similarity-conveying sentence; and cards far apart vs. close together with a dissimilarity-conveying sentence (see Table 1).

We constructed 96 filler sentences. All of them were grammatical and semantically legal German sentences. However, 72 of them described unrealistic situations (e.g.,

---

<sup>1</sup>One item was removed due to an error in the order of presentation of words.

‘a presentation without good rhetoric should be given more often’), and the other 24 described plausible situations (e.g., ‘on the tram, passengers show their ticket to the inspector’). All filler sentences were preceded by cards in different positions on the screen (e.g., in the upper left and lower right corner) and most of them were blank (N=72). Twenty-four filler sentences, however, had cards with words on them. There were in addition 14 practice trials. A list consisted of 144 trials (48 experimental and 96 fillers trials), which were all pseudo-randomized in four lists. Each list contained only one version of every item. There was at least one filler trial in between two items.

Figure 1: Example visual contexts for the sentences in Table 1 (Experiment 1). The cards moved from the center of the screen either far apart (A, C) or close to each other (B, D). After two seconds, cards turned around (as represented by the semi-circular arrow) and presented two abstract words. The words were either semantically dissimilar (e.g., *Frieden* [‘Peace’] and *Krieg* [‘War’], (A) and (B)) or similar (e.g., *Kampf* [‘Battle’] and *Krieg* [‘War’], (C) and (D)).

**Procedure** Upon arrival in the laboratory, participants received information about the study. After that they were calibrated using a 9-point calibration procedure. Then they completed 14 practice trials. After practice, the experiment began. Each trial was presented as a three-step task. First, participants saw a visual context for six seconds, with two playing cards in different positions. For half of the trials in the experiment (i.e., 24 filler and all experimental trials), cards turned around after two seconds, each showing a word for four seconds. For the other half of the trials, cards turned and showed a blank front for 500 ms. After inspecting the visual context participants read a sentence (see Table 1). They were instructed to try to understand the sentence and to judge its veracity (by pressing either a “yes” or a “no” button). For the ensuing picture verification, participants saw a picture of two cards, and verified (by pressing “yes”/“no” buttons) whether they were identical with the two cards they had seen before the sentence.

Table 1: Example of visual contexts, corresponding sentences, and the resulting condition.

Picture	Sentence type	Condition
Fig.1A	(1) <i>Frieden</i> <sub>NP1</sub> und <sub>coord</sub> <i>Krieg</i> <sub>NP2</sub> <i>sind</i> <sub>VP1</sub> <i>bestimmt</i> <sub>ADV</sub> <i>verschieden</i> <sub>ADJ</sub> .	Far-Dissimilar
Fig.1B	<i>das verriet</i> <sub>VP2</sub> <i>der Anthropologe</i> <sub>NP3</sub> .	Close-Dissimilar
Fig.1C	(2) <i>Kampf</i> <sub>NP1</sub> und <sub>coord</sub> <i>Krieg</i> <sub>NP2</sub> <i>sind</i> <sub>VP1</sub> <i>freilich</i> <sub>ADV</sub> <i>entsprechend</i> <sub>ADJ</sub> .	Far-Similar
Fig.1D	<i>das verriet</i> <sub>VP2</sub> <i>der Anthropologe</i> <sub>NP3</sub> .	Close-Similar

Translation: (1) ‘Peace<sub>NP1</sub> and<sub>coord</sub> war<sub>NP2</sub> are<sub>VP1</sub> certainly<sub>ADV</sub> different<sub>ADJ</sub>, suggested<sub>VP2</sub> the anthropologist<sub>NP3</sub>.’ (2) ‘Battle<sub>NP1</sub> and<sub>coord</sub> war<sub>NP2</sub> are<sub>VP1</sub> surely<sub>ADV</sub> similar<sub>ADJ</sub>, suggested<sub>VP2</sub> the anthropologist<sub>NP3</sub>.’

**Data Analysis** Log-transformed reading times were analyzed using a linear mixed effect regression (LMER), including in a single step main and interaction effects of the factors. We implemented full models with random intercepts for participants and items, and fixed effect random slopes and their interactions for both random intercepts. We analyzed the second noun phrase (NP2) and the adjective region (ADJ), where we should see spatial distance effects on semantic interpretation if those occur time-locked to when semantic similarity between the first two noun phrases becomes available during reading (see Table 1). We further analyzed the VP2 and NP3 regions to see if any spatial distance effects also occur at subsequent regions of the sentence. In these regions we examined three eye-tracking reading measures; first-pass reading (the duration of all fixations from first entering an interest area and prior to moving to another interest area), regression path duration (the time from first entering a region until moving past that region to the right; unlike first-pass reading time, this measure includes reading time following regressions out of the region), and total reading times (the duration of all fixations in a given region, see, e.g., Rayner, 1998).

## Results

For the ADJ region, a similarity main effect was observed across all measures; reading times were shorter for sentences expressing similarity compared to those expressing dissimilarity (all  $t$ -values  $> 2$ ). We also observed a reliable interaction between spatial distance and semantic similarity in first-pass times for the ADJ region ( $t$ -value = -2.04, see Fig. 2): first-pass times were shorter when similarity-conveying sentences were preceded by cards-with-words presented close to each other (vs. far apart). By contrast, first-pass times for sentences that expressed dissimilarity were shorter when they were preceded by cards-with-words presented far apart (vs. close to each other). No interaction effects were observed in other measures. Both VP2 and NP3 regions showed reliable

interaction effect in first-pass reading times and NP3 also in total reading times. These interaction effects were similar as for the ADJ region. For the NP2 region, neither main effects nor interaction effects involving the manipulated factors were observed in any gaze measure.

Figure 2: Log-transformed mean first-pass reading time (with error bars plotting the standard error of the mean) for the ADJ region as a function of sentence type and spatial distance between cards-with-words in Experiment 1.

## Discussion

In Experiment 1, we presented participants with a visual context for which the distance between cards-with-words, was manipulated. Cards were either presented close together or far apart, and they were followed by a sentence that either expressed similarity or dissimilarity of abstract nouns. We observed spatial distance effects on reading times as a function of the semantic content of the sentence. These results suggest that non-linguistic information from the visual context (spatial distance) can modulate interpretation of abstract language (semantic similarity) during online sentence comprehension. Crucially, spatial distance effects on semantic interpretation appeared both rapidly (first-pass) and incrementally (at the ADJ region).

Results from Experiment 1, inform our first research question (whether abstract semantic interpretation can be rapidly and incrementally modulated by non-linguistic information). However, since the visual context for critical items was related to the following sentence through words on the cards, it is possible that effects of spatial distance on semantic similarity interpretation were mediated by, or even depended upon, that link. To address this concern and to answer our second research question (can non-linguistic visual information modulate language comprehension even in the absence of referential or lexical-semantic links?), Experiment 2 relies on the same design and presentation but the cards did not show any words and remained blank.

## Experiment 2

Experiment 2 was identical to Experiment 1 but instead of presenting words on cards, the cards that participants saw

before sentence reading were blank. Seeing the noun phrases on the cards in Experiment 1 could permit participants to integrate similarity of the nouns with spatial information even before sentence reading. If so, this could facilitate and speed up any effects of spatial distance during reading. Using blank cards in Experiment 2 permitted us to see to which extent the effects of spatial distance on sentence reading in Experiment 1 depended upon the repetition of sentential noun phrases on the cards.

## Method

**Participants** Thirty-two further native speaker of German with normal or corrected-to-normal vision (mean age: 24.4; range 20-31) participated in the experiment for a compensation of 6 Euro. All gave informed consent.

**Materials, Design, Procedure and Data Analysis** The experimental design, procedure and data analysis were the same as in Experiment 1. The visual context, however, was modified. While participants in Experiment 1 saw cards-with-words for four seconds, participants in Experiment 2 saw blank cards for three seconds. In both experiments, however, visual context presentation duration was the same (six seconds). We delayed card turning by one second in Experiment 2, since participants did not have to read any words.

## Results

At the NP2 region we observed a similarity main effect, such that sentences that expressed similarity had shorter first-pass times, compared to sentences that expressed dissimilarity ( $t$ -values = 2.04). Moreover, analyses of first-pass times confirmed a reliable interaction between spatial distance and semantic similarity ( $t$ -value = -2.07). Figure 3 shows the interaction pattern in Experiment 2.

Figure 3: Log-transformed mean first-pass reading times (with error bars plotting the standard error of the mean) for the NP2 region as a function of sentence type and spatial distance between cards in Experiment 2.

First-pass times for sentences that expressed similarity were shorter when preceded by blank cards close to each

other (vs. far apart), while reading times for sentences that expressed dissimilarity were shorter when preceded by blank cards far apart (vs. close to each other). No other interaction effects were observed in other measures in this region.

Unlike in Experiment 1, a main effect of similarity appeared in regression path duration at the ADJ region, but no interaction effects were observed for that region. For the subsequent VP2 region, a marginal interaction effect emerged ( $t$ -value = -1.84), with a similar pattern to that at the NP2 region in Experiment 2 and the ADJ region in Experiment 1. Main effects of spatial distance and similarity were observed in regression path duration for the NP3 region, but no interaction effect was found.

## Discussion

In Experiment 2, we manipulated the distance between objects that did not have any overt relation to the semantic meaning of the ensuing sentence. The visual context can thus be described as non-referential in its relationship to the sentence. Moreover, spatial distance between cards was irrelevant for performing the comprehension task (sentence veracity judgments). Yet, we still found rapid and incremental interaction effects between spatial distance and the interpretation of semantic similarity, as reflected in reading times. These findings provide strong support for the role of non-referential spatial information in abstract language comprehension.

## General Discussion

In research on situated language processing, abstract language comprehension has received substantially less attention than concrete language. While results from visual world paradigms have shown that non-linguistic information can rapidly and incrementally modulate comprehension of sentences that relate to objects and events (through referential or associative links), it was unclear whether this effect would generalize to abstract sentences.

We assessed this open issue in two eye-tracking-reading experiments. Experiment 1 provided evidence that spatial information (distance between words depicted on cards) can rapidly and incrementally influence semantic interpretation of abstract sentences. First-pass times at the adjective and subsequent regions of sentences such as ‘battle and war are surely similar, suggested the anthropologist’ were shorter when a preceding display showed cards-with-words close together (vs. far apart). Since objects in the visual context were still related to the sentence in Experiment 1 (through words on cards), Experiment 2 examined whether the rapid spatial distance effects from Experiment 1 extend to a situation in which the visual context (playing cards) was entirely unrelated to the sentence. When cards remained blank rather than showing words (Experiment 2), we observed rapid and incremental effects of spatial distance on reading times as a function of the meaning of the sentences. First-pass times at the second noun phrase and at the second verb in sentences such as ‘peace and war are certainly

different, suggested the anthropologist’ were shorter when a preceding display showed cards-with-words far apart (vs. close together).

Overall, thus, non-linguistic information can rapidly and incrementally influence semantic interpretation of abstract language. These results extend existing similarity-judgment and response-times results (Boot & Pecher 2010; Casasanto 2008), and clarify that non-linguistic information (i.e., spatial distance) can modulate language comprehension and not just similarity judgments and ratings. In this regard, our results are compatible with theories of embodied cognition that attribute an important role to perceptual information in language processing (see Lakoff & Johnson 1999). They also extend findings that suggest abstract language can be related to visual context through lexical-semantic associations. Duñabeitia et al. (2009) showed that listeners rapidly inspected objects (e.g., a nose) that were associated with abstract words (e.g., Spanish *olor*, ‘smell’). What the present findings add is the insight that visual context can in turn influence abstract language comprehension, and that its effects are mediated via subtle mappings between the semantic similarity of nouns and object distance.

The present findings also have important implications for processing accounts of situated language (e.g., the CIA, Knoeferle & Crocker, 2006, 2007). Consider how concrete language is related to visual context in the CIA. The emerging interpretation guides (visual) attention to relevant information in visual context or working memory. As people process a sentential verb, they engage in a search for a matching action either in the immediate environment or in their working memory. When they have found a matching action, verb and action are co-indexed and action information can inform sentence interpretation. Comprehenders can further develop expectations about referents based on lexical-semantic associations between the verb and objects in context.

The present findings corroborate and extend the referential and associative linking mechanism of the Coordinated Interplay Account. First, the spatial distance effects occurred not anywhere during reading but they first emerged at sentence regions that contained information about semantic similarity in both experiments. This was as expected based on the CIA’s close time lock between when the utterance identifies relevant visual context information, and when that context information impacts sentence interpretation. What the present results add is the insight that this closely temporally coordinated interplay extends to non-referential visual context effects (Experiment 2) and abstract language comprehension (Experiments 1 and 2). Future research will examine the subtle differences in the time course of spatial-distance effects in Experiment 1 (ADJ, NP2) compared with Experiment 2 (NP2, VP2).

The findings moreover emphasize the necessity of assuming a fine-grained linking of linguistic and visual information during language comprehension. As semantic similarity is computed during comprehension, it is reconciled with representations of spatial distance between

objects that were neither mentioned in the sentence nor relevant for the sentence judgment task. This ties in with other recent results. Kreysa and Knoeferle (2011) observed rapid visual context effects (of a speaker's gaze and head movements) on spoken language comprehension, and this despite the fact that the speaker was never explicitly referenced to and that comprehenders hardly inspected the speaker during comprehension. Clearly, explicit reference is not necessary for incremental visual context effects.

Together the present and other recent findings argue for highly active visual context effects on language comprehension and highlight the need for multiple (referential and non-referential) mechanisms in informing language comprehension through non-linguistic visual information.

### Acknowledgments

This research was funded by the Cognitive Interaction Technology Excellence Cluster (German research foundation, DFG) and by a PhD scholarship awarded to EG by the Ministry of Education, Government of Chile. The authors want to thank Maria Nella Carminati for advice with the analyses, and the members of the Language and Cognition Lab (CITEC, University of Bielefeld) for their valuable comments on the reported research.

# Trading in a multiplayer board game: Towards an analysis of non-cooperative dialogue

Markus Guhe (m.guhe@ed.ac.uk), Alex Lascarides (alex@inf.ed.ac.uk)

School of Informatics, Informatics Forum, 10 Crichton St, Edinburgh EH1 2HX, Scotland

## Abstract

We collected and analysed a small dialogue corpus of people playing *The Settlers of Catan*. Dialogues are trading negotiations where Gricean maxims of cooperativity often break down as players adopt conflicting intentions in their attempt to win the game. This has consequences for what information players are sharing and for the sincerity of their contributions.

In this paper, we motivate and describe a two-level scheme for analysing non-cooperative dialogues, where both levels are interdependent. Each dialogue move is a move in the game (e.g., an offer to trade), and a coherent contribution to the dialogue so far, connected to a prior segment with a coherence relation, such as indirect answerhood or rejection. Parsing and generating coherence relations is computationally feasible (e.g., Baldridge & Lascarides, 2005), and here we'll argue that their semantics help to identify the game move, even when it is implicated rather than linguistically explicit.

**Keywords:** non-cooperative dialogue; dialogue move; negotiation; *The Settlers of Catan*; JSettlers; multiplayer game.

## Non-cooperative dialogue

Standard accounts of dialogue usually assume that the agents cooperate with one another on at least two levels (Grice, 1975): they coordinate the conventions that govern linguistic meaning (basic cooperativity); and they share attitudes towards what is said, including shared intentions (content cooperativity). Tutoring is a widely investigated example where content cooperativity is a reasonable assumption.

But there are many dialogue scenarios where conflicting preferences compel agents to perform dialogue moves that aren't content cooperative. Such situations range from differences in preferences with relatively low stakes (e.g., whether to go to a French or an Italian restaurant) to very high, life changing, stakes (e.g., a cross examination of a defendant by a prosecutor in court). Lying in court has potential high rewards (if the lie is not uncovered) as well as high penalties (if it is). But telling the truth or lying are just the two extremes in a spectrum of non-cooperative behaviour. To illustrate this, consider the following cross-examination of a defendant by a prosecutor (from Solan & Tiersma, 2005):

- (a) Prosecutor: Do you have any bank accounts in Swiss banks, Mr. Bronston?
- (b) Bronston: No, sir.
- (c) Prosecutor: Have you ever?
- (d) Bronston: The company had an account there for about six months, in Zurich.

The locutionary content of both (b) and (d) are true, but Bronston succeeds in *deflecting* the prosecutor's enquiry with a misleading implicature with (d): (d) implicates that Bronston never had any Swiss bank account, and this is false.

In this paper, we describe dialogue moves in non-cooperative situations, drawing on data from a dialogue cor-

pus of people playing *The Settlers of Catan*. In the corpus, each dialogue move is aligned with a machine readable version of the game state. We present a scheme of the types of dialogue moves that occur in our corpus. Our eventual goal is to build a dialogue system that plays *The Settlers of Catan*, engaging in non-cooperative dialogues like humans do. For such a system, the agent playing the game will use the dialogue moves from that scheme to interact with the other players so as to forward its chosen game moves. This will require us to parse and generate the semantic content of these dialogue moves; we will exploit coherence relations from SDRT for this purpose (Asher & Lascarides, 2003).

## The Settlers of Catan

*The Settlers of Catan* is a multiplayer board game set on the fictional island *Catan*. *Catan* is represented by a map consisting of hexes (see Fig. 1; see [catan.com](http://catan.com) for the full set of rules). Two to four players settle on the island by building settlements and cities connected by roads. It is a zero-sum game: the first player to win 10 victory points wins and all others lose. One obtains victory points by, for example, building a settlement (1 point) or a city (2 points). To build, one needs resources: clay, wood, rock, ore and sheep.

Players take turns and attempt to obtain resources and to build. A turn starts with the roll of dice. Each player potentially obtains or loses resources through dice rolls. This depends on a combination of: the number rolled, the location of game pieces on the board, and the resources currently held. (So, future game states are non-deterministic, necessitating players to calculate the risks of moves). The player whose turn it is can trade resources with the bank or other players and can use resources to build roads, settlements or cities.

Dialogues where the players trade resources surface during game play as the players try to exchange resources with one another. Their decisions about what resources they want and what they are prepared to give up are influenced by what they need to build, e.g. a road requires 1 clay and 1 wood. A player can only build on a location if it touches one of his already existing pieces (road, settlement or city); all settlements and cities must be separated by at least 2 roads (of any player). Thus, players' decisions about trades are not only determined by the decisions about what they want to build and where they want to build it, but also by their estimates of what will most advance, or undermine, the building strategies of the other players (see Thomas, 2003). Players can agree any trade; they can even lie or bluff, as found in classic conceptions of bargaining games (Osborne & Rubinstein, 1990).

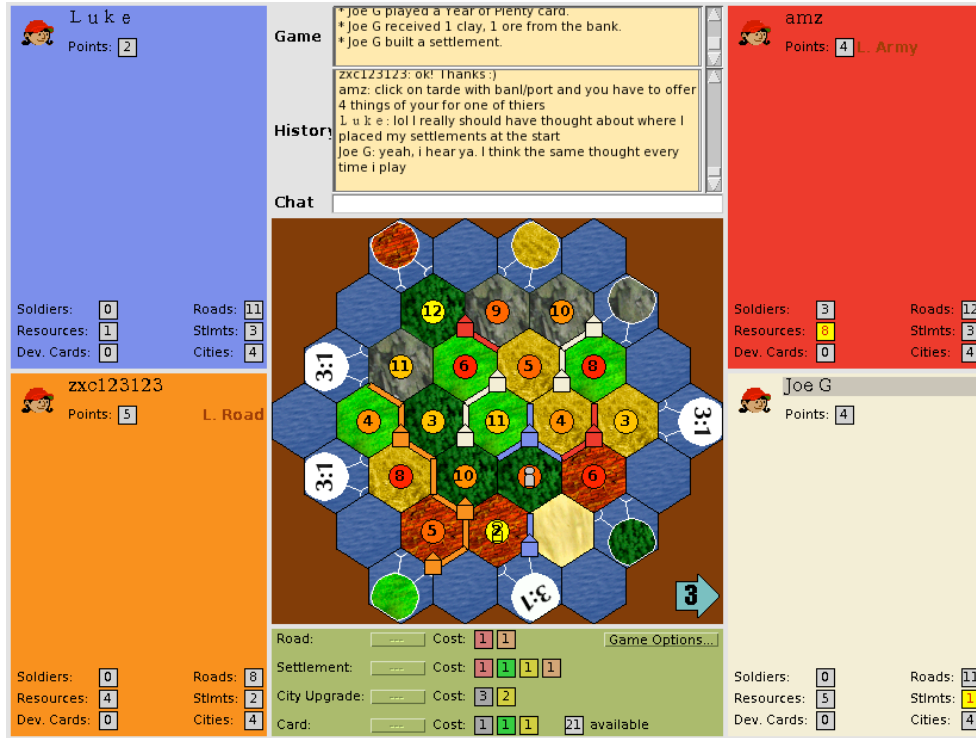

Figure 1: A game of *The Settlers of Catan* in the JSettlers interface.

## Modifying JSettlers for Corpus Collection

To analyse trading dialogues and to perform inferences about an agent's underlying game strategy, one needs a corpus where each utterance is aligned with a machine readable version of its synchronous game state. To this end, we adapted an existing open source implementation of Settlers, cf. Fig. 1 (JSettlers2, version 1.1.12). JSettlers mimics the physical version of the game in that each player can see the whole board but only his own hand (in a colour-coded panel). In JSettlers, trades are done graphically via the interface, see Fig. 2a. The player whose turn it is has two panels containing 'I Give', 'I Get' and colour coded buttons for the other players – he can offer a trade by adding appropriate values for these three items. This prompts the players in question, who can then accept or reject the trade through button clicking.

We adapted this interface to enforce trades to be negotiated linguistically prior to an actual exchange of resources. Specifically, the buttons required to exchange resources are hidden by a 'Register a Trade' button (Fig. 2b), and only one other player can be selected via the colour coded buttons. Players were instructed to first agree a trade via the chat interface and only then 'register' the trade. Clicking 'Register a Trade' revealed the trading interface (Fig. 2a), and enacting the trade is achieved in the same way as the original version of JSettlers.

## Negotiation dialogues

In contrast to other task-oriented dialogues, e.g., the map task (Anderson et al., 1991; Guhe & Bard, 2008), *The Settlers*

Figure 2: (a) A player's hand panel in JSettlers. (b) The modified hand panel during normal game play. Trade is agreed via the chat interface prior to using the panel to register the trade.

of *Catan* is not a cooperative game but a zero sum game: only one player can win, all others lose. Even so, it is sometimes necessary for players to form alliances to block another player from winning, e.g., *don't give tomm wheat, he can win the game if he gets wheat* (from dialogue 1). Because of this, players avoid dialogue moves that might undermine their trustworthiness; they like to *appear* to be cooperative even if they aren't actually cooperating at the content level (i.e., adopting a shared intention), e.g., they may reject a trade even when they are able to perform it by saying *no sorry* (when asked *can I buy wood for 1 ore?* and the player having wood; from dialogue 2). Joint action takes place on multiple levels

simultaneously (Clark, 1996), and we find cooperativity on many levels in our corpus, e.g. all players share a common language, they follow the rules of the game, and they do actually trade with each other.

To analyse trade interactions, it is not necessary to treat the dialogue exchanges within a single game as a single dialogue. Instead, they appear as chunks, especially since the game state changes between trades (thanks to dice rolls, for instance), leading the players to adopt different preferences about what resources they need at the start of a new *dialogue game*, as compared to their preferences at the end of the last one. In addition, the game is too complex for players to reason about the complete game tree anyway; so, they structure their game space, aiming to achieve shorter term goals by using heuristics about how to advance their goal of winning (Thomas, 2003). Because of this structuring of the game space, it is natural to analyse the dialogues in discrete chunks, each addressing a short term goal, e.g. to obtain wood. We adopted this subdivision into dialogue games from the analysis of map task dialogues (Kowtko, Isard, & Doherty, 1993).

We collected an exploratory pilot corpus of 21 games, each containing multiple dialogue games, which we will make available publicly in due course. All participants were native speakers of English and naive to the purpose of the study. Most were students at the University of Edinburgh.

The corpus is not currently annotated because the purpose of collecting it was to obtain a sufficient sample so as to inform decisions about an annotation scheme for the corpus collection proper, which we are engaged in at the moment. For this reason, we have not analysed this pilot corpus in quantitative detail; e.g. with respect to differences between individual players, linguistic features, strategies, or level of cooperativity in the dialogue moves. Instead, we report here on the range of moves that surfaced in this corpus. There are several types of dialogue games (sub-dialogues), e.g., clarifying the rules of the game, discussions of the game state, small-talk, and, most importantly, trade negotiation dialogue games, which also are the most frequent in the corpus. Each trade negotiation constitutes a dialogue game.

We analyse dialogues on two levels, a game-strategic level and a dialogue level. Put differently, we distinguish the level of *what* game move is being made and *how* that move is realised through lexical and compositional semantics plus an assumption that the contribution is coherent in context. This distinction is particularly useful for building an agent that will play *The Settlers of Catan* and be able to communicate with other players using natural language. For building this agent, the game-strategic computations should be separate from the computations needed for understanding and generating dialogue moves for achieving those game strategies.

Please be aware of the potential confusion between the terms *dialogue move* (or: *move in a dialogue game*), which we adopt from the map task, and *game move*. The latter refers to a move in the game *The Settlers of Catan*, e.g., building a road, or trading 1 ore for 3 wheat, while the former refers to

a move in the dialogue or equivalently a type of speech act; this might be a *property* of the utterance (e.g., to question) or a *relation* (e.g., to give an indirect answer), where the successful performance of the speech act depends on the content of both the current utterance and a prior segment of the dialogue. In trading dialogues, game moves (such as to get 1 ore for 3 wheat) are achieved by performing dialogue moves (e.g., by *accepting* a prior offer through uttering *It's a deal*). In trading dialogues, game moves are performed by performing a dialogue move: so accepting a trade may be performed by performing the speech act *Accept*. If not further specified, we are talking of dialogue games and dialogue moves.

## Dialogue Games

### Dialogue moves in the map task

We will take the twelve types of dialogue moves from the map task (Kowtko et al., 1993) as our starting point. Six dialogue moves initiate a new game: **Instruct**: Give an instruction to the fellow player of what to do. **Check**: Request confirmation of whether a previous utterance has been understood correctly. **Query-YN, Query-W**: A yes/no or wh-question about some aspect of the task, except clarification of an instruction (which is a Check move). **Explain**: Provide new information about the goal of the task with respect to the current state.

Then, there are six further moves: **Clarify**: Clarify or repeat a prior utterance or known information. **Reply-Y, Reply-N**: Elicited response to Query-YN, Check or Align. **Reply-W**: Elicited response to Query-W or Check. **Acknowledge**: Acknowledge understanding (can close a dialogue game.) **Ready**: Indicate intention to start a new game.

Not all dialogue moves can be uniquely assigned to just one of these classes; some fulfil multiple functions.

Dialogue games can contain sub-games, creating a nested structure. Again, we follow Kowtko et al. (1993): 'Nesting is considered to occur when a sub-game is initiated whose purpose can clearly be seen as contributing to the goal of the current game ... A break, such as the announcement of a misunderstanding, puts the status of the current game in doubt; the game might continue if the misunderstanding is cleared up, or it might be abandoned.' (p. 3)

We also follow Kowtko et al. in defining dialogue moves as 'an utterance, a partial utterance or a group of utterances, which convey the same specific intent.' (p. 3) In other words, a dialogue move can consist of one constituent or several, and if it is several constituents they may likewise be individual constituents in a further game, thereby creating a hierarchical structure of moves. Dialogue moves are thus defined by their function rather than linguistic form. We provide the analysis of this more detailed level, i.e. how utterances are related, in terms of SDRT (Asher & Lascarides, 2003) below.

### Dialogue moves in *The Settlers of Catan*

The dialogues in our corpus bear many similarities with map task dialogues, but there are also significant differences.

The fundamental structure of a trade negotiation consists

of one player making an offer and another player accepting or rejecting it. Thus, we replace the map task's Instruct move with the Offer and Counteroffer moves, and the moves Acknowledge and Ready are supplemented by Accept, Reject and Retract.<sup>1</sup> The full scheme, including the dialogue moves retained from the map task scheme, is given in Fig. 3.

---

#### Moves initiating a dialogue game

- Check
- Query-YN, Query-W
- Explain
- Align
- Offer
  - Make Complete Offer
  - Make Incomplete Offer
    - Give Specified
    - Get Specified
  - Undo Trade
- Counteroffer
  - Cannot Accept Proposal
  - Could Accept Proposal
- Game-Strategic Comment

#### Other moves

- Clarify
  - Reply-Y, Reply-N
  - Reply-W
  - Acknowledge
  - Ready
  - Accept
  - Complete Offer
  - Reject
    - Cannot Trade
    - Won't Trade
  - Retract
  - Null-move
- 

Figure 3: Dialogue moves in *The Settlers of Catan*.

The Offer, Counteroffer and Reject moves have subtypes. For **Offers**, apart from the rare **Undo Trade** move, where a player requests to reverse a trade, the main distinction is whether an offer is complete. With **Make Complete Offer** a player specifies precisely both what he is prepared to give and what he wants in return, and from whom. In **Make Incomplete Offer** a player only specifies some values of the trade (e.g., the resource she wants, but not how much, nor from whom, nor for what). **Give Specified** dialogue moves only specify what the player wants to trade (*Does anybody want clay?*) **Get Specified** (*I need clay.*) is similar.

As we are investigating the non-cooperative aspect of dialogue, we subdivide **Reject** moves into those where the player **Cannot Trade** because he lacks the required resources, and **Won't Trade**, where he could make the trade but chooses not to. Because we record the game states, we can distinguish Cannot Trade from Won't Trade by looking at the resources of the speaker. Analogously, **Counteroffers** can be made be-

---

<sup>1</sup>*Instruct* is a very map task specific dialogue move – in the map task one person instructs another person to draw a route on a map. While in *The Settlers of Catan* a player may give an instruction to another player, no player is obliged to follow it. Particularly in trade negotiations, no player can instruct another player to do something, which is why we are dropping it here.

cause the player **Cannot Accept the Proposal** or **Could Accept the Proposal** but does not want to do so.

As in the map task scheme, dialogue moves aren't mutually exclusive, e.g., a Counteroffer (of either type) can also be a Make Incomplete Offer (from dialogue 19): *Hardie: i'll trade 2 wheat for 1 wood – Gytis: I need clay or ore*. Taken by itself, Gytis's dialogue move is simply a Make Incomplete Offer, but in this context, it is also a Counteroffer (he wants clay or ore instead of wheat). Note that the Counteroffer is drawn from both what Gytis says and what Hardie says, and to infer this particular Counteroffer one needs to draw on the analysis at the second (the discourse) level, see the next section. It is through recognising the coherence relation between Gytis's contribution and Hardie's, and reasoning about that relation's *semantics* that one infers that Gytis has implicated acceptance of a part of Hardie's offer, i.e. give Hardie 1 wood.

We add some more dialogue moves to this scheme. Players can start a new sub-game by making **Game-Strategic Comments** in the context of trade dialogues, e.g. *don't give tomm wheat, he can win the game if he gets wheat* (dialogue 1).

A **Complete Offer** move completes the trade offer of a Make Incomplete Offer move by specifying the missing information: i.e., it differs from Counteroffer in that no part of the original offer is rejected. Further, as long as a trade has not been concluded, a player who has offered a trade may **Retract** the offer. Finally, because *The Settlers of Catan* is a multiplayer game, a player can decide to stay silent and not to respond to a trade offer. This is a **Null-move**.

Because dialogues are entirely unrestricted, trade dialogue games can be interrupted by other types of dialogue games, e.g. a dialogue game on how to use the hand panel, cf. Fig. 2. We do not consider these cases here.

## Sincerity and Informativeness

Players can be non-cooperative in at least two ways. First, a player  $P_2$ 's response to  $P_1$ 's prior move may reject the goal that underlies  $P_1$ 's prior utterance, even though he was in a position to fulfil that goal: a Won't Trade move, e.g.,  $P_1$  asks for wheat and  $P_2$  responds *no, sorry* despite having wheat. Second, a speaker's utterance may semantically entail and/or implicate content they know to be false. While a player can in principle perform an insincere dialogue move other than Reject, e.g. Offer, in practice such moves are rare (they have little foreseeable benefit but foreseeable penalties should the lie be exposed). So insincere moves tend to be rejections; indeed, they tend to be Won't Trade (and not Can't Trade) rejections.

Our corpus exhibits the whole range from sincere statements to outright lies. We mainly distinguish sincere rejections from deflections and lies. In the following examples from our corpus, we specify the resources a player has when making an utterance by using the abbreviations c (clay), o (ore), s (sheep), wh (wheat) and wo (wood).

**Sincere rejection.** Sincere rejections of both subtypes are possible. A move is sincere only if declarations of the player's

resources are truthful. For example, amz's utterance below is a sincere Can't Trade move; Joe's and Luke's utterances are sincere Won't Trade moves (all taken from dialogue 8):

amz[c=0|o=0|s=1|wh=1|wo=1] i dont have any clay  
 Luke[c=1|o=0|s=0|wh=1|wo=0] I have one clay but I want it  
 for myself?  
 Joe G[c=1|o=0|s=1|wh=0|wo=0] sorry, i'm holding on to  
 mine

**Deflection.** Deflections are misleading implicatures as described earlier; the following extract from dialogue 2 yields a misleading scalar implicature (since Tomm has wheat):

Cat[c=0|o=2|s=0|wh=2|wo=1] anyone for ore or wheat?  
 Thomas[c=2|o=2|s=0|wh=2|wo=3] i have ore

**Lie.** Lies are moves where a player declares false information, e.g., this Reject from dialogue 7:

Lorelei1292[c=0|o=1|s=3|wh=9|wo=1] can anyone give me  
 some clay for some wheat?  
 AM123[c=2|o=0|s=0|wh=2|wo=1] sorry have none of that!

Even assuming AM123 misunderstood the direction of the trade offer, the only available antecedents for resolving the anaphoric expression *none of that* are *wheat* and *clay*; thus, AM123's utterance declares content she knows to be false.

**Null-move.** Trade offers can also be rejected by not answering at all (from dialogue 11):

Britt[c=1|o=1|s=5|wh=0|wo=0] anyone in need of sheep?  
 Simon[c=0|o=0|s=2|wh=4|wo=0] no thanks  
 David A[c=0|o=1|s=1|wh=2|wo=0] ⟨null⟩  
 Din[clay=0|ore=1|s=1|wh=1|wo=1] ⟨null⟩

**Limited informativeness.** It is strategically important to decide how much information about one's own hand a player is willing to reveal. Deflections are a prime example for this.

**Volunteering information.** In contrast to the limited cooperativity exhibited in, for instance, Null Moves, there are also many instances of players behaving much more cooperatively than strictly speaking they need to in order to advance the domain-level game. For instance (from dialogue 3):

Euan[c=0|o=0|s=2|wh=2|wo=1] Anyone got any ore?  
 Cardlinger[c=0|o=1|s=0|wh=7|wo=3] only the 1  
 Joel[c=0|o=0|s=2|wh=2|wo=1] havent had it in awhile

One possible explanation for why players might choose to provide more specific content than simply a direct answer to the question is that by doing so they are more likely to be perceived as cooperative and providing positive face to their interlocutors (Brown & Levinson, 1978), which may be useful later in the game.

## The Dialogue Level: SDRT

The previous section detailed dialogue moves on the agent level. Now we describe how those moves interact with con-

tent at the dialogue level. This link between dialogue moves on the one hand and coherence relations and semantics on the other, is needed for identifying which dialogue moves (or communicative intentions) an agent has revealed during language interpretation, and it is needed for deciding which utterances (or dialogue moves) to make during language production.

Consider the utterance *I need clay*. Without any context, this is a Make Incomplete Offer move. But in the exchange *A: I want wood. B: I need clay*, the same utterance has to be understood in relation to the content of the previous utterance. Reasoning about its coherent use in context leads one to infer that it is a Complete Offer dialogue move.

We are using the framework of *Segmented Discourse Representation Theory* (SDRT, Asher & Lascarides, 2003; Lascarides & Asher, 2009) for specifying such coherence relations. In SDRT's model of dialogue, each dialogue agent *publicly commits* to coherence relations between his own utterance and prior ones, even if they were said by another agent. Shared public commitments then reveal agreed content; inconsistent public commitments reveal disputes. For instance, above, *B* commits to the coherence relation *Plan-Elab(a,b)* (where *a* is *A*'s utterance and *b* is *B*'s). This means that *b* provides information that elaborates a plan for achieving the communicative intention underlying *a*. *Plan-Elab* is a veridical relation: a public commitment to *Plan-Elab(a,b)* entails a commitment to the contents of *a* and *b*. Thus *B* is committed to *a*: he implicates endorsement of it by the illocutionary effects of the speech act *Plan-Elab* that he performed.

Such moves reveal commitments to preferences as well; in our domain, these preferences are (partial) information about offers that an agent would prefer to perform. Cadilhac, Asher, Benamara, and Lascarides (2011) describe a detailed algorithm for computing such preferences from the dialogue's content. It exploits the recursion over the discourse structure that is engendered by coherence relations to build a partial description of each player's preferences, as it evolves through the dialogue exchange, e.g.:

A: I am prepared to give you rock for wood.  
 B: I need clay.

The relation between these utterances is a *Plan-correction*, because *B* corrects *A*'s offer. The Cadilhac algorithm for constructing *B*'s declared preference in context yields that the implied trade is clay for wood. Thus, it computes *which part* of the prior trade was rejected (i.e., getting rock) and captures implicatures about what is accepted; here, the implicature that *B* accepts giving wood. While the *Plan-correction* relation is between whole utterances, the bits that are accepted and rejected are computed on the basis of the semantics of the relation and the semantics (and information structure) of the arguments (Lascarides & Asher, 2009). In contrast, in

A: [I want wood.]<sub>a1</sub> [What do you want?]<sub>a2</sub>  
 B: [I need clay.]<sub>b</sub>

two discourse relations are at work *Q-Elab(a1,a2)* and *IQAP(a2,b)*. *Q-Elab(a1,a2)* means that *a2* is a question

whose possible answers all elaborate a plan for achieving the underlying communicative intention of  $a_1$ . *IQAP* (Indirect Question Answer Pair) relates a question ( $a_2$ ) to a segment ( $b$ ) whose content, together with shared knowledge, defeasibly implies a direct answer to the question.

Default principles for identifying the scope of implicit endorsements and denials from Lascarides and Asher (2009) also mean that B accepts  $Q\text{-Elab}(a_1, a_2)$ . In other words, by committing to the question (via the veridical *IQAP*), B implicates a commitment also to the question's *illocutionary effects*, here  $Q\text{-Elab}(a_1, a_2)$ . This relation, not the content of  $a_2$  itself, yields an interpretation of the question equivalent to *What do you want in exchange for wood?* Thus B's trade offer  $b$  is a combination of A's and B's contributions.

A typical case from our pilot corpus (dialogue 19) demonstrates that such interactions can be even more complex:

Hardie: [anyone got ore?] $_{a_1}$  [1-1 for either clay or wheat?] $_{a_2}$   
Gytis: [I could give 1 ore for 2 clay] $_b$

Gytis's utterance is related in multiple ways to Hardie's  $Plan\text{-Elab}(a_1, a_2)$ . First, through  $b$ , Gytis commits to a *Plan-correction* on Hardie's  $Plan\text{-Elab}(a_1, a_2)$ : he chooses clay over wheat and wants 2 ore instead of 1. Second, he commits to  $IQAP(a_1, b)$ : he indirectly answers he has ore. Finally, he commits to  $Plan\text{-Elab}(a_1, b)$ :  $a_1$  reveals Hardie's incomplete offer for getting ore, which Gytis's response completes.

Thus, without a principled account of discourse relations like SDRT and an algorithm like the one by Cadilhac et al. (2011) for extracting declared preferences from dialogue content, it will be far from straightforward to map actual dialogue into a representation of the underlying trade, or generate dialogues that express one's intended trade.

## Conclusion

We have collected a pilot corpus of trading dialogues within the zero-sum game *The Settlers of Catan*. These dialogues reveal non-cooperative dialogue to be a nuanced affair: while Gricean maxims of cooperativity break down, basic cooperativity is adhered to and speakers often share intentions.

We argued for two interleaved levels of analysis: a game level on which dialogue moves are particular types of game moves; and a dialogue level where the agents' public commitments to coherent interpretations of their contributions are recorded. Both levels are needed for a computationally feasible mapping between utterances and the agents' preferences during language interpretation and production. Thus, for an agent playing *The Settlers of Catan*, dialogue moves are one type of game move the agent can make and must extract from other players' utterances. The semantic representation that is computed by means of coherence relations is the interface to the linguistic subsystems.

Due to the non-cooperativeness of such dialogues, the dialogue moves that players make vary in their sincerity and informativeness. We highlighted moves from our corpus that demonstrate the spectrum, ranging from fully sincere moves through deflections to lies.

In the STAC project (*STRAtegic Conversation*, see acknowledgments), we are currently in the process of collecting the corpus proper, which our research partners in Toulouse will fully annotate with SDRT relations. An implementation of the Cadilhac algorithm will make it possible to extract preferences from discourse structure to semi-automatically annotate the corpus with the agents' preferences (expressed as offers). The relations among preferences, plus the game state (in particular, a player's resources) then serve to determine the game moves. This will be a rich resource for building a dialogue agent that plays *The Settlers of Catan*, empirically grounding the agent's decisions to match what people do.

## Abstract

Finding information by successively following hyperlinks on web pages is a typical task performed on the web. A number of web users search for specific information and several studies have concluded that following the "information scent" is the fundamental process involved in the behavior. The aim of this study was to investigate the relationship between the strength of the "information scent" and user behavior by applying a usability inspection method developed for web usability studies. Three typical usability problems of navigation, (a) a page with a weak scent correct link problem, (b) a page with an unfamiliar correct link problem, and (c) a page with a competing links nested under competing headings problem, were compared with a problem-free page. In this study, we applied the Cognitive Walkthrough for the Web method to simulate a website, and analyze user behavior along with usability problems. Participants were asked to find an article on a simulated encyclopedia website. The success rate, total clicks, total time, fixation count and gaze time were analyzed. The results showed that the critical issues caused by usability problems appear on the target-link page. The results of this study confirm the effect of "information scent" and provide a scientific insight into web navigation.

**Keywords:** information scent; LSA: latent semantic analysis; hierarchical information structure; web usability; eye tracking

## Introduction

Over the last decade, eye-tracking studies have provided detailed insights into the way users interact with websites. In earlier usability studies in web navigation, the level of difficulty of a task for a user was measured by finding the number of clicks required or the time taken to complete the task, where a high difficulty level pointed to usability problems in the web page. Eye-tracking methods have made it possible to analyze user behavior in detail.

Several eye-tracking studies have provided an overall understanding of the behavior of website users based on their eye movements. Nielsen (2006) demonstrated that the eye-movement patterns of website visitors are F-shaped by aggregating a large amount of eye-movement data from web pages. Cutrell & Guan (2007) and Guan & Cutrell (2007) presented a series of detailed studies examining the relationship between the fixation duration, and the ranking and presentation of search results i.e. whether the search results were accompanied by short, medium, or long descriptions. They discovered that providing more

information next to the search results significantly improved performance in information tasks, but degraded performance in navigation tasks, where the performance was assessed in terms of selecting the correct search result and the time taken to complete the task. They argued that the difference in performance was because when users were given longer descriptions, they paid more attention to the description and less to the URL of the search result, which would be of help in assessing the usefulness of the search result. These eye-tracking studies have provided a broad understanding of the behavior of web users.

Habuchi, Kitajima, & Takeuchi (2008) focused on users' cognitive activities, especially their goals and knowledge when searching for information on the web. They explored the relationship between usability problems and web users' eye-movements by independently assessing usability problems using Cognitive Walkthrough for the Web (CWW)<sup>1</sup> (Blackmon, Polson, Kitajima, & Lewis, 2002; Blackmon, Kitajima, & Polson, 2003, 2005; Blackmon, Mandalia, Polson, & Kitajima, 2007). They considered three typical usability problems: the weak scent correct links nested under competing headings problem, the unfamiliar correct link problem, and the competing links nested under competing headings problem. They found that if a webpage had any usability problems, user performance deteriorated noticeably in terms of the total number of fixations in the subsequent link selection stage. The performance was worst on pages with a weak scent problem or an unfamiliarity problem, which resulted in longer fixation durations because users examined the link carefully before selecting it. However, no difference in performance was observed in the initial heading selection stage between pages with usability problems and those without. The study showed that it is

---

<sup>1</sup> Cognitive Walkthrough for the Web (CWW) is a web usability inspection method that can detect several usability problems that a website visitor may encounter while navigating through the website in search of specific information by successively selecting hyperlinks on intermediate navigation pages. It uses a Latent Semantic Analysis (LSA) semantic space (Landauer & Dumais, 1997) to measure the "information scent" i.e. local proximal cues. Web users use the "information scent" to make navigation choices while navigating the web by following hyperlinks (Pirolli & Card, 1999; Blackmon et al., 2002, 2003, 2005; Chi & Suppattanasiri, 2003; Pirolli, 2005).

possible to distinguish between such pages based on the task completion time and total number of fixations. Furthermore, it showed that users' gaze patterns varied depending on the whether the problem was in the link itself, or elsewhere. However, the test material they used consisted of just two samples for each usability problem. To verify their results and draw a general conclusion, results obtained using a larger number of samples must be examined.

The aim of this study is to investigate the relationship between usability problems and information search behavior by applying the CWW method to handle various types of usability problems. In this study, we conducted more experiments and controlled other factors such as familiarity of the desired information. We built a controlled website to study the relationship between usability problems and user behavior.

## Experiment

The task used in this study is an information search task performed within a hierarchically organized information structure. The task difficulty depends primarily on the strength of information scent on each navigation page for a given search target. The three types of usability problems compared are, (1) weak scent correct link problem, (2) unfamiliar correct link problem, and (3) competing links nested under competing headings problem; where problem-free items existed. These usability problems can be detected through CWW.

## Method

**Materials** The Japanese LSA semantic space is necessary for finding usability problems in CWW. It was constructed using corpora from the Japanese language Wikipedia abstract containing 116,038 words and 129,937 contexts. The semantic space of the Japanese LSA consists of 116,038 words and 300 dimensions. Please refer to Takeuchi, & Habuchi (2008) for details.

A simulated encyclopedia website was constructed for this study. It has the same link structure as the Microsoft Encarta website. The menu was two levels deep, with 9 top-level links (called headings) and 93 second level links (called links). Each entry word and its description from the Wikipedia abstract were categorized into one of the 93 links. Usability problems were identified by applying CWW on these articles (Takeuchi, & Habuchi, 2008).

We selected 97 candidate articles, such that each article either had no usability problems, or had one of the following problems: weak scent correct link problem; unfamiliar correct link problem; and competing links nested under competing headings problem (three competing links). The predicted link-click count in this experiment was 2.29 for no usability problems, 3.81 for weak scent, 4.05 for unfamiliar links, and 4.26 for competing links nested under competing headings, according to the CWW model (Blackmon et al. 2007).

The entry words from the selected articles varied in their degree of familiarity for users. As it is desirable for each

entry word from the candidate material to have the same level of familiarity, we conducted the word concept familiarity rating task for the 97 entry words with 48 additional subjects (aged between 20 and 33 years with a mean age of 24.3 years). The familiarity rating scale was from 1 (least familiar) to 5 (most familiar). Finally, we selected 20 articles such that each problem type had 5 articles from which unfamiliar entry words would be chosen (see Table 1). These articles were used as the search targets in the experiment.

**Participants** Thirty-five university students participated in this study. Nine of the participants were excluded: six due to not having sufficient eye-tracking data and three others who reported after the experiment that they misunderstood the task. Twenty-six university students (11 males and 15 females; aged between 18 and 24 years with a mean age of 20.6 years) participated in the experiment. All participants were native Japanese speakers and received compensation for their participation. They had normal or corrected to normal vision. They were all regular users of the internet and were used to browsing with Internet Explorer. They were ignorant of the hypothesis being investigated in the study.

**Apparatus and Procedure** The eye-tracking equipment used was a Tobii X60 eye-tracker with Tobii studio 1.24 software. The minimum fixation duration was set to 40 ms and the fixation radius to 20 pixels. Eye movements were recorded at a sampling rate of 60Hz. The experimental website was opened in Internet Explorer 6 under Windows XP. URL visibility events, mouse movement, and click events were recorded.

The task was to find the relevant article within 130 seconds. The search topic, along with a short description was provided to the participants. The expectation was that participants would build a mental representation of the item, which they would use to evaluate the "information scent" of the navigation pages in the website.

Participants were tested individually. They were first seated in front of a screen-mounted eye-tracking system. Next, they were required to search for the desired information on the simulated encyclopedia website. In each test, the participant was given a target word. On clicking, the target word was replaced on the screen by the heading page containing a description of the search target and 9 headings. Participants made their choice by clicking on one of the sections. If a participant reached the target-link, the target page was shown, and then the next trial began when the participant clicked the "next" button (see Figures 1 and 2). To eliminate order effects, the 20 items were allocated among four blocks and the order of the blocks was counterbalanced. Each participant was given four blocks of five trials each. There was a short break of a few minutes between each block. Participants were tested each session lasted approximately 25 minutes.

The dependent variables were the success rate, time taken to complete the task, total number of clicks, total fixation count and gaze time.

Table 1: Properties of experimental materials.

Property	No. of items	Concept familiarity <sup>1</sup>	Target and Target-link Cosine value	Target-link Vector length
Problem-free	5	1.14 (.41)	.52 (.31)	.16 (.30)
Weak Scent	5	1.20 (.48)	.09 (.00)	.22 (.22)
Unfamiliar	5	1.12 (.42)	.58 (.23)	.08 (.13)
Competing links (3)	5	1.18 (.47)	.45 (.27)	.42 (.00)

<sup>1</sup> Concept familiarity was rated on scale from 1 (least familiar) to 5 (most familiar).

Figure 1: Sequence of events

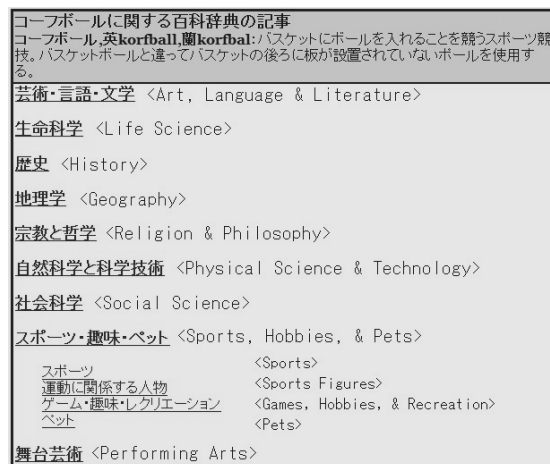

Figure 2: Menu on the target-link page. The top part of the screen shows the target description and the area under it shows the menu. The links that appear under each heading became visible on clicking on the appropriate heading, and the links were only shown for one heading at a time.

## Results

We analyzed the data from when a heading page was opened to when the target link was clicked. An analysis of variance (ANOVA) and several comparisons were performed separately for the success rate, total click count, and the task completion time. These results are shown in Tables 2 and 3, grouped by usability problem type. An ANOVA and several comparisons were also performed

separately for the success rate, total clicks, and total time. The significance level for ANOVA results was  $p < .05$ . A summary of the success rate, total clicks, and total time results for the experiment is presented in Table 2.

**Success rate** Before an angular transformation was performed, the success rate data were skewed: Problem-free = -2.56, Weak scent problem -1.19, Unfamiliarity problem -.53, Competing links problem 1.36. Post-transformation, the skewness was reduced to -2.56, -1.11, -.03, and 1.36, respectively. An analysis of the variance indicated a significant difference between the angular-transformed success rates [ $F(3, 75)=30.20$   $p < .001$ ]. Post hoc testing indicated that the transformed success rate for the “problem-free” case were significantly higher than for cases with a usability problem.

**Click count** Prior to the log transformation, the total clicks data were skewed: Problem-free 1.03, Weak scent problem 0.97, Unfamiliarity problem 0.24, Competing links problems 0.45. Post-transformation, the skewness was reduced to 0.50, 0.36, -0.31, and -0.38, respectively. An analysis of the variance indicated a significant difference among the log-transformed total clicks for usability problems [ $F(3, 75)=51.20$ ,  $p < .001$ ]. Post hoc testing indicated that the transformed click count for the “problem-free” case were significantly less than for cases with a usability problem.

**Solution time** Prior to the log transformation, the solution time data were skewed: Problem-free 1.18, Weak scent problem 0.25, Unfamiliarity problem 0.12, Competing links problems 0.18. Post-transformation, the skewness was reduced to 0.51, -0.07, -0.64, and -0.38, respectively. An analysis of the variance indicated a significant difference in the log-transformed success time for usability problems [ $F(2.58, 64.38)=59.63$ ,  $p < .001$ ]. Post hoc testing indicated that transformed solution times for the “problem-free” case were significantly less than for cases with a usability problem.

## Eye tracking analysis

We conducted eye-tracking analysis for two regions of the web page, the target description area, and the navigation area during each target selection stage. Tables 4 and 5 show the results of the eye tracking analysis.

**Fixation counts** Before analysis, all data were logarithmically transformed.

Table 2: Success rate, total click count, and solution time.

	Success rate	Total Clicks	Solution time
Problem-free	97.7%	3.92 (1.7)	17.1 ( 9.7)
Weak Scent correct link	72.3%	9.45 (2.6)	53.0 ( 9.7)
Unfamiliar correct link	87.7%	6.93 (2.2)	36.6 (15.8)
Competing link nested under the competing heading (3)	84.6%	7.15 (1.6)	35.4 ( 7.2)

Note: Time measurements in seconds. Number shown in parentheses is SD.

**Target-heading selection stage** A two-way analysis of variance was conducted for the fixation counts until the initial heading was clicked. An information area main effect was not obtained [ $F(1, 25) = 2.23$ , n.s.]. Also, the usability problem main effect was significant [ $F(2.77, 69.34) = 25.02$ ,  $p < .001$ ], confirming that the Weak scent problem link pages had significantly more fixations than other pages. Finally, the information area and usability problems interaction was significant [ $F(2.57, 64.35) = 20.19$ ,  $p < .001$ ]. A Bonferroni post hoc analysis of this interaction revealed that the Weak scent and Unfamiliar link pages had more fixations than that the other two cases, regardless of page area. In addition, although the Competing links problem pages had fewer fixations in the goal description area, they had more fixations in the navigation area.

**Transit-link stage** Not all participants saw the extra transit-link page; analysis reduced the participant number from 26 to 19. A two-way analysis of variance was conducted for the total fixation count in the transit-link selection page. An information area main effect [ $F(1, 18) = 111.64$ ,  $p < .001$ ] was significant, confirming that the navigation area was responsible for far more fixations than the target description area. The usability problem main effect was significant [ $F(2.48, 44.63) = 13.02$ ,  $p < .001$ ], which confirmed that the Weak scent or Competing problem link pages had significantly more fixations than the Problem-free pages. The interaction of information area and usability problems was significant [ $F(2.65, 47.67) = 4.81$ ,  $p < .01$ ]. A Bonferroni post hoc analysis was performed and it showed that in total, the Weak scent, and Competing links problem pages had more fixations than the Problem-free pages.

**Target-link selection stage** A two-way analysis of variance was conducted for the fixation counts in the target-link selection page. An information area main effect [ $F(1, 25) = 156.28$ ,  $p < .001$ ] was significant, confirming that the navigation area was subject to significantly more fixations than the goal description area. The usability problem main effect was significant [ $F(2.98, 74.57) = 15.87$ ,  $p < .001$ ], confirming that the Weak scent and Unfamiliarity problem link pages had significantly more fixations than the Problem-free pages. However, Competing links problem pages had fewer fixations than Problem-free pages. The interaction of information area and usability problems was also significant [ $F(3, 75) = 5.16$ ,  $p < .01$ ]. A Bonferroni post hoc analysis confirmed the difference in fixation distribution. Weak scent link problem pages in total had more fixations than Problem-free pages. In the target-description area,

Unfamiliar link pages had more fixations than Problem-free pages. However, Weak scent link pages gathered more fixations in the navigation area.

**Gaze time** Before analysis, all data were logarithmically transformed.

**Target heading selection stage** A two-way analysis of variance was conducted for the gaze time until the target-link was clicked. An information area main effect was obtained [ $F(1, 25) = 4.83$ ,  $p < .05$ ], confirming that the target-description area had significantly longer gaze time than the navigation area. The usability problem main effect was significant [ $F(2.94, 73.59) = 24.18$ ,  $p < .001$ ], confirming that the Weak scent problem link pages had significantly longer gaze time than the other cases. The information area and usability problems interaction was significant [ $F(2.55, 63.72) = 18.05$ ,  $p < .001$ ]. A Bonferroni post hoc analysis of this interaction revealed that the gaze time at the target-description area for Weak scent correct link problem items was longer than that in other cases. However, in the navigation area, Weak scent, and Unfamiliar link problem pages had longer gaze time than the Problem-free pages.

**Transit-link stage** We summed up surveyed areas individually and divided total gaze time by total pages opened. As a result, the number of participants was reduced from 26 to 19. A two-way analysis of variance was conducted for the gaze time for transit-link pages. An information area main effect was obtained [ $F(1, 18) = 83.12$ ,  $p < .001$ ]. The usability problem main effect was significant [ $F(1.62, 29.24) = 10.96$ ,  $p < .001$ ], confirming that Weak scent and Competing links problem pages had significantly longer gaze time than the Problem-free pages. The information area and usability problems interaction was obtained [ $F(1.44, 25.94) = 7.86$ ,  $p < .01$ ]. A Bonferroni post hoc analysis of this interaction revealed that in the target-description area, all usability problem pages had a longer gaze time than Problem-free pages. However, in the navigation area, Weak scent, and Competing links problem pages had longer gaze times than the Problem-free case.

**Target-link selection stage** A two-way analysis of variance was conducted for the gaze time of the target-link selection page. An information area main effect [ $F(1, 25) = 7.55$ ,  $p < .001$ ] was significant, confirming that the navigation area was subject to significantly longer gaze time than the target description area. The usability problem main effect was significant [ $F(2.1, 52.53) = 7.55$ ,  $p < .001$ ], confirming that Competing links problem pages had a lower gaze time than other cases. Unfamiliar link problem pages had a longer

gaze time than the Problem-free case. The interaction between the information area and usability problems was not significant [ $F(1.6, 39.88)=2.32$ , n.s.].

## Discussion

The results indicated clear differences between problem-free and usability problem pages, in the success rate, total clicks and total time. The eye-tracking data showed that users' eye movements for selecting a target link varied depending on the nature of the usability problem. Two main conclusions can be drawn from this study. The first is that usability problems occur from the first heading selection stage in the navigation area. Pages with a weak scent problem had more issues than other pages. Web pages with the latter problems forced users to examine links and the target description more times than for problem-free pages.

The other point was certain characteristics of usability problems were clear at the target-link selection stage. In pages with a weak scent problem or an unfamiliarity problem, it took users longer to select a link. This is presumably because participants had to discern the meaning of the correct link by carefully reading the link label. A possible explanation for this phenomenon is that for the weak scent correct link problem, participants looked at the navigation area several times. In contrast, for the unfamiliar correct link problem, participants remained at one link page for longer. These situations differed from cases of competing links nested under competing headings, where users could immediately select a link because it was a good match for the target and less effort was needed to understand the meaning of the link. We can also say users' eye movement before clicking a link at the target-link selection stage varied according to the usability problem of the targeted link.

Table 3: Mean percentage of shortest path achievement.

Processing Stage	From the start until Target-heading	From Target-heading until Target-link	From the start until Target-link
Problem-free	83.8% (13.9)	72.3% (18.8)	63.8% (16.0)
Weak Scent correct link	54.6% (18.4)	34.6% (16.5)	23.8% (15.0)
Unfamiliar correct link	55.4% (19.8)	51.5% (24.1)	23.8% (15.0)
Competing links nested under the competing heading (3)	53.8% (17.7)	57.7% (16.3)	36.2% (18.8)

Note: Number shown in parentheses is SD.

Table 4: Mean Fixation counts.

Processing Stage	Target-Heading selection stage (n=26)		Transit Link page (n=19)		Target-Link selection stage (n=26)	
Area of web page	Target description	Navigation	Target description	Navigation	Target description	Navigation
Problem-free	15.2 (8.1)	18.9 (12.2)	7.6 (10.7)	53.5 (30.0)	8.1 (6.9)	31.6 (15.8)
Weak Scent correct link	31.7 (14.3)	26.8 (14.5)	23.3 (17.7)	100.5 (48.7)	11.1 (7.3)	55.4 (24.0)
Unfamiliar correct link	16.0 (8.8)	21.6 (10.6)	11.4 (10.7)	65.5 (37.0)	15.9 (13.1)	42.6 (25.2)
Competing links nested under competing heading (3)	12.2 (7.6)	23.2 (12.8)	16.0 (12.9)	73.9 (50.2)	5.4 (5.5)	25.7 (13.4)

Note: Number shown in parentheses is SD.

Table 5: Mean gaze time.

Processing Stage	Target-Heading selection stage (n=26)		Transit Link page (n=19)		Target-Link selection stage (n=26)	
Area of web page	Target description	Navigation	Target description	Navigation	Target description	Navigation
Problem-free	2612 (1650)	3433 (1667)	1306 (1828)	10196 (7101)	1422 (1203)	6112 (2673)
Weak Scent correct link	5556 (2823)	4738 (2205)	4306 (3613)	16806 (9807)	1853 (1269)	9346 (3307)
Unfamiliar correct link	2956 (1606)	4089 (1798)	1830 (1882)	11953 (5767)	2604 (2153)	8731 (3754)
Competing links nested under competing heading (3)	2173 (1446)	3960 (1741)	2668 (2458)	12057 (6333)	1017 (1178)	4521 (1878)

Note: All measurements are on the millisecond time scale. Number shown in parentheses is SD.

## Conclusion

This study aimed to investigate how website visitors search for desired information in web pages with usability problems. Three types of usability problems, the weak scent correct link problem, the unfamiliar correct link problem, and the competing links nested under competing headings problem, were compared against problem-free pages. The results showed that participants' behavior when faced with usability problems was distinguishable from behavior on problem-free pages in terms of the success rate, total number of clicks and total time taken. In addition, it was possible to distinguish the usability problem facing the user from the fixation counts and gaze times at the target-link selection stage.

The eye-tracking analysis expanded on the information gained in previous studies. This study showed that users' eye movement before clicking a link in the target heading and target-link selection stages varies depending on the usability problem. Pages with competing links nested under competing headings have users spending less time before selecting the correct link, but they involve more clicks due to confusion from incorrect links. Pages with a weak scent problem or an unfamiliarity problem have users taking more time to select the correct link.

This study has attempted to explain the relationship between "information scent" and user behavior. In future work, we aim to extract the discriminative behavior when two or more problems exist simultaneously.

## Acknowledgments

This study was conducted while the first author was in the National Institute of Advanced Industrial Science and Technology (AIST). We are grateful to Muneo Kitajima, Professor, Nagaoka University of Technology, for his support and guidance.

## Abstract

One of the largest remaining unsolved mysteries in cognitive science is how the rapid input of spoken language is mapped onto phonological and lexical representations over time. Attempts at psychologically-tractable computational models of spoken word recognition tend either to ignore time or to transform the temporal input into a spatial representation. This is the approach taken in TRACE (McClelland & Elman, 1986), the model of spoken word recognition that has the broadest and deepest coverage of phenomena in speech perception, spoken word recognition, and lexical parsing of multi-word sequences. TRACE reduplicates featural, phonemic, and lexical inputs at every time step in a potentially very large memory trace, and has rich interconnections (excitatory forward and backward connections between levels and inhibitory links within levels). This leads to a rather extreme proliferation of units and connections that grows dramatically as the lexicon or the memory trace grows. Our starting point is the observation that models of visual object recognition – including visual word recognition – have long grappled with the fundamental problem of how to model spatial invariance in human object recognition. We introduce a model that combines one aspect of TRACE – time-specific phoneme representations – and higher-level representations that have been used in visual word recognition – spatially- (here, temporally-) independent diphone and lexical units. This reduces the number of units and connections required by several orders of magnitude relative to TRACE. In this first report, we demonstrate that the model (dubbed TISK, for Time-Invariant String Kernel) achieves reasonable accuracy for the basic TRACE lexicon and successfully models the time course of phonological activation and competition. We close with a discussion of phenomena that the model does not yet successfully simulate (and why), and with novel predictions that follow from this architecture.

**Keywords:** Keywords: Spoken Word Recognition; Time invariance ; Computational models; TRACE.

## Background

Could it be that despite very salient differences, the auditory and visual systems actually rely on the same mechanisms in order to recognize words? One signal has a temporal dimension and is carried by transient sound waves, the other is spatially extended and travels at the speed of light. One signal travels sequentially (over time) through the

cochlear nerve, the other in parallel through the optic nerve. In their own dedicated primary cortical regions, however, both arrive at spatial representations – tonotopic for the auditory system, retinotopic for the visual system. What happens next, according to computational models of visual and spoken word recognition, further hints at some possible unification.

## Modeling spoken and visual word recognition: TRACE and IA

From a psycholinguistic point of view, two early models of word recognition based on the same computational framework have been enormously successful. In the visual domain, the Interactive Activation (IA) model and its extensions (McClelland & Rumelhart, 1981; Grainger & Jacobs, 1996) can account for a large number of robust and sometimes counterintuitive behavioral findings, in a simple and elegant hierarchical structure where units at any level compete to represent the stimulus, and engage in "lobbying" up and down in the hierarchy. In the auditory domain, TRACE (an extension of the IA framework for speech; McClelland & Elman, 1986) continues to produce new insights into human behavior, including close fits to fine-grained estimates of the time course of spoken word recognition from the visual world paradigm (Allopenna et al., 1998; Dahan, Magnuson, Tanenhaus, & Hogan, 2001; Dahan, Magnuson, & Tanenhaus, 2001).<sup>1</sup>

One probably superficial difference between the two models is that between-level connections in IA models of reading typically include both inhibitory and excitatory connections, whereas between-level connections in TRACE

---

<sup>1</sup> It is important to note that current, psychologically tractable models of spoken word recognition do not take real speech as their input. While Grossberg & Myers (2000) have modeled aspects of speech and word processing using real speech inputs, these efforts have not yet yielded a model that can handle speech input and a broad range of phenomena in spoken word recognition. In order to be able to address complex issues in word recognition without first solving all fundamental problems in speech perception, TRACE's inputs (for example) are "pseudo-spectral" acoustic-phonetic features that ramp on and off over time, with temporal overlap between adjacent phonemes providing a coarse analog of coarticulation.

are only excitatory. The evidence that this is superficial comes from demonstrations in visual letter identification that performance is at least as good without inhibitory connections between levels (Rey et al., 2009). A much more serious difference, however, is that the IA model can only recognize words at one location on the retina, whereas TRACE has to recognize words at any point in time.

But this impressive ability of TRACE is only achieved at the price of duplicating each unit for as many time slices as needed in the simulation. That is, the processing units in TRACE form a large memory, with units aligned with time 'slices'. Essentially, there is a copy of every feature, phoneme, and word unit at every time slice (the complete details are more complex – for example, words are only duplicated every 3 time slices; see McClelland & Elman, 1986, for details). When input begins, the first instant of the input aligns with and activates units in the first time slice in memory. As the input continues, it activates nodes aligned with specific time slices. Those units can become and remain active for a considerable time after the input has continued on. Conceptually, this is like marks on a page left by a seismograph – the memory banks contain a trace of the input that has come along. But these are not passive traces, since unit activations flux as a function of excitatory and inhibitory input from other units, and a decay parameter.

Having reduplicated units allows TRACE to solve the temporal alignment problem by brute force; given the input /dad/, it can tell that the phoneme /d/ should be activated twice and how far apart in time the two occurrences are – because the two instances of /d/ are encoded by completely independent /d/ detectors aligned with different points in time. The same applies at the word level; TRACE can tell that /dag/ (the TRACE representation of DOG) occurs twice in /dagtsdag/ (DOG EATS DOG) because the two instances are encoded by independent /dag/ detectors aligned with different points in time.

But this comes at a cost. Consider the number of units per slice: 63 x 3 features, 14 phonemes, and, in the basic TRACE lexicon, 212 words, for 415 units. If we ballpark the number of connections by assuming an average of 8 featural connections per phoneme, and 3 phonemes per word, and allowing for connections between units at adjacent time slices, we would have approximately 47,000 connections per time slice with a 200-word lexicon. If we make the trace approximately 2 seconds long (the duration of echoic memory), we need approximately 83 thousand units and 9.4 million connections. If we increase the lexicon to a more realistic size of 20,000 words and the phoneme inventory to 40, these figures reach approximately 4 million units and 80 billion connections.

One might argue that this may not be an unreasonable scale, given the number of neurons and connections in the brain. However, principles of parsimony (might there be a simpler solution?) and evolutionary pressures to minimize energy consumption would be reasonable motivations to seek a less costly solution to time-invariance. Exploring such an alternative is the purpose of this paper, and we

report first results on a model that achieves decent performance using many fewer nodes and connections than TRACE. With a 2 second layer of time-invariant input nodes and TRACE's 14 phonemes and 212 words, TISK requires 9.7 thousand units and 62 thousand connections. This represents a 9-fold improvement over TRACE for units, and 2 orders of magnitude for connections. Critically, the orders of magnitude in improvement turn out to be proportional to lexicon size: with 20,000 words and 40 phonemes, TISK would require 48 thousand units (TRACE requires 84 times more) and 3.3 million connections (TRACE requires 24 *thousand* times more).

## String kernels

In the machine learning literature, one computational technique that has been very successful at representing sequences of symbols independently of their position goes under the name of *string kernels* (Hofmann et al., 2007). Symbols can be amino-acids, nucleotides, or letters in a webpage: in every case the gist of string kernels is to represent strings (such as "TIME") as points in a high-dimensional space of symbol combinations (for instance as a vector where each component stands for a combination of two symbols, and only the components for "TI", "TM", "TE", "IM", "IE", "ME" would be non-zero). It is known that this space is propitious to linear pattern separations and yet can also capture the (domain-dependent) similarities between them. Although it has been argued in the visual modality that string kernels can account for masked priming effects and are thus likely involved in the early stages of processing, there has been very little investigation of String kernels in the auditory domain (Gales, 2009, being a yet unpublished exception).

Given the demonstrated versatility of the technique, there is every reason to suspect that string kernels could also work in spoken word recognition, where symbols would then be discrete and time-specific phonemes, which would be turned into vectors in the space of time-invariant phoneme combinations. This would entail that the same type of representations are in fact at work in spoken and visual word recognition. However, while one can find some appeal in this unification (this would for instance pave the way to establishing connections between sublexical orthography and sublexical phonology), there remains the nagging problem of how to turn sequences of time-specific phonemes into time-invariant phoneme combinations – that is, how to compute the string kernel for spoken words. Thinking in the unified framework of string kernels suggests that similar problems across modalities can receive similar solutions, and we now introduce our time-invariant alternative to the TRACE model, which handles the transition between time-specific and time-invariant units in much the same way as location-specific and location-invariant units are activated in the visual modality, through the use of symmetry networks (Shawe-Taylor, 1989).

## Model

### Architecture and dynamics

The model is illustrated in Figure 1. It uses the same lexicon and basic activation dynamics as the TRACE model, but a radically different architecture. It is comprised of four levels: inputs, phonemes, nphones (currently, nphones are single phones or diphones) and words. Inputs consist of a bank of time-specific feature units as in TRACE, through which a wave of transient activation pattern travels. However, this input layer is deliberately very simplified compared to its TRACE analog, given that at any time there is always at most one input unit active – inputs do not overlap in time, and do not code for phonetic similarity (that is, the /d/ unit is equally similar to /a/ and /t/, as each unit can either be on or off; we will address phonetic grain in future work). This input level sends activation forward to the phoneme level. The time-specific phoneme level consists of 10 banks of 14 phonemes that serve as input to the network (the limitation to 10 is completely arbitrary, but sufficient for single-word recognition; there are only 14 phonemes because we are using the 14 phonemes implemented in TRACE). Input phonemes are introduced one at a time and activate the time-invariant nphone level via feedforward connections. Phoneme-to-nphone connection weights are set according to a gradient weighting scheme that we will shortly describe. The nphone level consists of  $196 + 14$  units, one for each phoneme and for each of the 142 possible diphones that can be composed with the set of phonemes. Units at this level compete with one another via lateral inhibition, and send activation forward to the time invariant word level through excitatory connections, whose weights were normalized by the number of nphones of the destination word. The word level consists of 212 units, one for each of the original words in the TRACE lexicon, with lateral inhibition between words, and feedback excitatory connections from words to nphones.

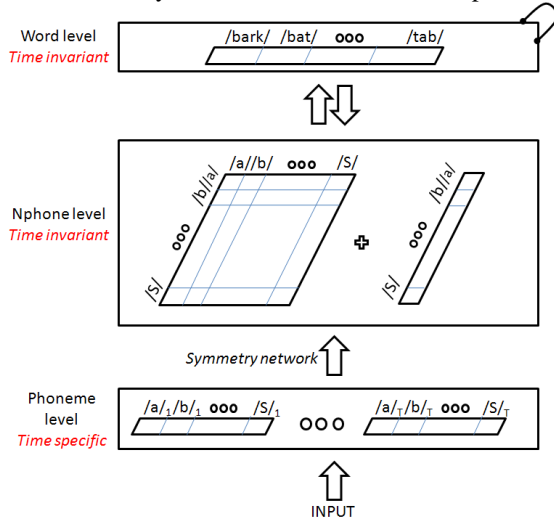

Figure 1: The TISK model - a time-invariant architecture for spoken word recognition.

Note that feedback serves several functions, as does lexical-phonemic feedback in TRACE: it provides a basis for lexical effects on phoneme decisions; it makes the model more efficient and robust against noise (Magnuson et al., 2005); and it provides an implicit sensitivity to phonotactics – the more often a phoneme or nphone occurs in lexical items, the more feedback it potentially receives. Feedback in models of spoken word recognition is a controversial topic (see McClelland et al., 2006; McQueen et al., 2006; Mirman et al., 2006), which we do not address here; our aim is to see whether a model with a radically simpler computational architecture compared to TRACE can (begin to) account for a similar range of phenomena in spoken word recognition.

Units in the model are leaky integrators: at each cycle, all units are activated according to the net input they receive and to their previous activation, minus a decay term, as described in equation 1:

$$A_i(t) = \begin{cases} A_i(t-1) * (1 - Decay) + Net_i(t) * (1 - A_i(t-1)), & \text{if } Net_i > 0 \\ A_i(t-1) * (1 - Decay) + Net_i(t) * A_i(t-1), & \text{if } Net_i < 0 \end{cases}$$

and where the net input of unit  $i$  at time  $t$  is given by:

$$Net_i(t) = \sum_{j=1}^k w_{ij} a_j(t)$$

The python code for the model as well as the list of parameters are available upon request to the first author. We now describe how the connections between phonemes and nphones are set in the model.

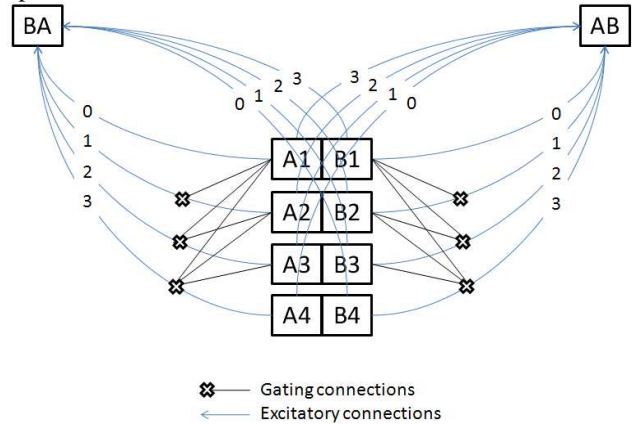

Figure 2: A symmetry network for time-invariant nphone recognition that can distinguish between anaphones.

### A symmetry network for phonological string kernels

The problem we are confronting here is to achieve time-invariant recognition while still distinguishing between transposed phoneme combinations. Since we must recognize a succession of phonemes like  $[/a_t, /b_{t+1}]$  whatever time “ $t$ ” is, we need to be able to recognize each phoneme /a/ and /b/ at any “ $t$ ”. But since each unit must activate at any time, how then can we activate unit /ab/ rather than /ba/ at the nphone level?

This issue of selectivity (here, between “anaphones”: words with the same phonemes in different order) versus invariance (here, to position-in-time) has long been identified in the fields of visual recognition and computer vision, and has recently received attention in a series of articles investigating invariant visual word recognition (Dandurand, Grainger, & Dufau, 2010; Dandurand, Hannagan, & Grainger, 2010; Hannagan, Dandurand & Grainger, 2011). The solution adopted in the present model is illustrated in Figure 2, and was inspired by what has been learned through this recent work on the way various backpropagation networks deal with the selectivity versus invariance dilemma (to our knowledge this solution has not yet been proposed in spoken word recognition models). Briefly stated, this consists of correlating phoneme-to-nphone connection strengths with phoneme position-in-time, as illustrated in Figure 2 (blue excitatory connections). If the weights from phoneme units  $/a_1/$ ,  $/a_2/$ , ...,  $/a_T/$  to diphone unit  $/ab/$  decrease linearly from  $T-1$  to zero, and if on the contrary the weights from phoneme units  $/b_1/$ ,  $/b_2/$ , ...,  $/b_T/$  to diphone unit  $/ab/$  increase at the same pace from zero to  $T-1$ , then presenting the input sequence  $[/a_t/ \ /b_{t+1}]$  will always result in a constant net input for  $/ab/$  whatever the time “ $t$ ” is, and it will result in a smaller constant net input to  $/ba/$ . By setting the weights from these phoneme units to the transposed diphone  $/ba/$  in exactly the opposite pattern, and by setting once and for all a common activation threshold for every diphone unit anywhere between these two net inputs, one can ensure that the network can always neatly distinguish between  $/ab/$  and  $/ba/$ . To prevent sequences with repeated phonemes like  $[/b_1/ \ /a_2/ \ /b_3/]$  from activating large sets of unwanted nphones like  $/bi/$ ,  $/b^{\wedge}/$ , it is however necessary to introduce gating connections (black connections in Figure 2), whereby for instance  $/b_1/$  disables the connection between all future  $/b_{t>1}/$  and diphones  $/*b/$  (where “ $*$ ” stands for any phoneme but  $b$ ).

Other architectures exist that can operate the transition between time-specific phonemes and time-invariant nphones, but the symmetry network we introduce within this model builds on a solution found by the backpropagation algorithm, and has thus arguably a headstart in learnability. It also seems to provide a faithful implementation of the “string kernel” code recently described by Hannagan & Grainger (2011).

## Results

### Recognition rate

We presented the model with every word in its 212-word lexicon. A word was counted as correctly recognized if it had been the most active lexical unit for ten cycles in a row before the deadline, which was set to 100 cycles. Recognition performance was similar across different operational measures of recognition. With these settings, the model correctly recognizes 98% of the 216 words. We consider this satisfactory for a first test of a new computational approach, although the TRACE model

reaches 100% recognition. A consideration of the few unrecognized words, like  $/triti/$  and  $/st^{\wedge}di/$ , is instructive in that they were often confused with their cohort candidates (e.g.  $/trit/$  and  $/st^{\wedge}di/$ ), which activate exactly the same nphones but one (resp.  $/ti/$  and  $/id/$ ). This confusion can only happen in the current model when two phonemes are closely repeated at the end of a relatively long word, since the importance of any one nphone for recognition of a word is currently inversely proportional to how many nphones it activates. We note that a model whose nphone-to-word weights would be set following other criteria (for instance, the conditional probability of the word given the nphone) would give more importance to diagnostic nphones and reach perfect accuracy.

### Competitor effects: Cohort, rhyme and embedding

Figure 3 shows the average cohort and rhyme effects in the model (left panel) and in TRACE (right panel). The curves were calculated by averaging across trials the activation levels of all targets (“target” curve in black), of all words that started with the same phonemes as the target (“Cohorts” curve in red), of all words that ended with the same phonemes as the target (“Rhymes” curve in blue), of all words contained in the target (“Embeddings” curve in purple) and of all other words (“Mean of all words” curve in grey).

Figure 3: Average activations in the lexicon, when partitioned for each trial as Target, Cohort words, Rhyming words, embedded words and All words.

Left panel: TISK model.

Right panel: TRACE model.

Apart from superficial differences in zero-valued versus negative resting levels, Figure 3 shows that the agreement between models is good on competitor effects. Indeed the magnitude and ordering of the Cohorts, Rhymes and Embeddings effects is similar in the two models, relative to the baseline Mean of all words.

The behavior exhibited by both models also mirrors the cohort and rhyme effects that have been reported in humans performing for instance the so-called “visual world” task. In a nutshell, overall candidate words that begin like the target are more active early on during processing while those that

end like the target are more active later one during processing, without ever rising to the activation level of the target, or going below the activation level of unrelated words.

## Discussion

The previous results tentatively suggest that a time-specific model of spoken word recognition like TRACE could in principle be replaced by a time-invariant alternative (TISK). This raises the questions of whether there is indeed any kind of evidence for time-invariant phonological representations in the brain, above and beyond considerations of parsimony, and whether one could find predictions that would allow us to uniquely distinguish between the time-invariant and time-specific candidate models. We now address these two questions.

### Neural evidence for time invariant spoken word recognition?

Researchers interested in the neural representations for visual words are blessed with the Visual Word Form Area, a well-defined region in the brain that sits at the top of what is still known as the ventral visual stream, and is demonstratively the locus of our ability to read words (Gaillard et al., 2006), but critically not to hear them. Until recently, the common wisdom was that by the mere virtue of its situation in the brain – if not by its purported hierarchical architecture with increasingly large receptive fields – the VWFA was bound to achieve complete location invariance for word stimuli. However recent fMRI studies show that, and computational modeling explains why, a significant degree of sensitivity to location is present in the VWFA Rauschecker et al. (2011). A trained, functional model of location invariance for visual words explains why this can be so: in this model the conflicting requirements for location invariant and selectivity conspire with limited resources, and force the model to develop in a symmetry network with broken location symmetry on its weights. This in turn produces “semi-location invariant” distributed activity patterns, which are more sensitive to location for more confusable words (Hannagan, Dandurand & Grainger, 2011). Thus brain studies have already been highly informative and have helped constrain our thinking on how the brain recognizes visual words.

But attempts to proceed in the same way for the auditory modality quickly run into at least two brick walls. The first is that there is no clear homologue of the VWFA for spoken words. This might be because the speech signal varies in more dimensions than the visual signal corresponding to a visual object; a VWFA homologue for speech might need to provide invariance not just in temporal alignment, but also across variation in rate, speaker characteristics, etc. While there have been reports of hints of such invariance and/or multidimensional sensitivity in the superior (Salvata et al., in press) and medial (Chandrasekaran et al., 2011) temporal

gyri, a VWFA homologue for speech has not yet been detected.

The second is that paradigms for testing time-invariance are less easily designed than those which test location-invariance in the visual case. Varying on Rauschecker et al. (2011) however, we can propose a task that tests for the presence of time-specific word representations, in which subjects would be presented with a sequence of meaningless sounds where one spoken word would be embedded. By manipulating the position of this word in the sequence, one could then test whether a “blind” classifier could be trained on the evoked fMRI activation patterns to discriminate which activation patterns correspond to which positions-in-time. A clear demonstration that a classifier is unable to “blindly” map phonological patterns to position-in-time would be good evidence for the model we have introduced. In the alternative scenario, a successful blind classifier would be a smoking gun for this model. Following on our work in the visual modality, we would then need to consider a revised version with limited and shared units that could possibly achieve semi-time invariant representations.

### Specific predictions

A specific prediction of this model concerns the treatment of repeated phonemes in a word. As we have seen, the TRACE model deals with both cases by assigning activation to different time-specific units, whereas the model we have introduced must activate for instance the same “na” unit in “banana” at two different times. Finding evidence against this central feature would plainly falsify the model. However it is still unclear at this point how this would really manifest in the model (for instance would words with repeated diphones such as “banana” get more activation from the diphone level than in the TRACE model?). In fact one critical test for the current model will reside in its ability to handle such inputs in a way that is consistent with humans. If the expected differences with TRACE are indeed obtained, experimental evidence could then be gathered with the “visual word paradigm” by presenting targets and distractors with or without repeated diphones. Similarly, one would expect the same phenomena to be within reach of empirical investigations for repeated words in a sentence.

## Conclusions

We have presented a computational model of spoken word recognition (TISK) that achieves a close-to-perfect word recognition rate (98%), while also exhibiting the ability to account for basic aspects of phonological competition – the time course of cohort and rhyme effects. This time-invariant alternative uses vastly (orders of magnitude) less computational resources than its time-specific counterpart, TRACE, the economy in number of units being inversely proportional to the number of time steps allowed as input and (in TRACE) memory at all levels or (in our model) at the phoneme level. A notable property of the model is that the computational mechanisms involved – string kernels and symmetry networks – are exactly the same as have been

proposed in the visual word recognition literature, paving the way to a possible unified account of word recognition across modalities. Finally we have pointed to where we think specific predictions of the model should arise, and we have put forward a new task that makes the model more easily falsifiable.

## Abstract

Despite its frequent use, much is unknown about how the n-back task is performed and how it relates to working memory. We conducted a detailed analysis of the accuracy and reaction time data from a 4-back version of the task and compared the results with previous results from an adaptive training version of the task. The experiment was also designed to test the novel predictions of a computational model of n-back performance. The assessment results were largely consistent with both the training data and the model predictions.

**Keywords:** working memory; executive functioning; n-back; working memory training; computational model.

## N-back and Cognition

The n-back task is used both to measure (Owen et al., 2005) and improve (Jaeggi et al., 2008) working memory (WM). It is considered a memory updating task, and updating is thought to be a core component of working memory (Miyake et al., 2000). However, the task is not consistently or strongly correlated with performance on complex working memory span tasks, such as operation span or reading span (Kane et al., 2007). Furthermore, despite transfer to measures of fluid intelligence, n-back training has not been found to transfer to other measures of WM (Jaeggi et al., 2008; Li et al., 2008).

To better understand n-back performance and its relation to WM, the present study provides a detailed analysis of 4-back data. This study builds on a previous analysis of an n-back training task (Harbison, Atkins, & Dougherty 2011) by testing if the results from an adaptive, training version of the n-back task are replicated in a non-adaptive, assessment version of the task. The present study also tests new predictions made by the computational model of n-back performance based on that training data (Harbison et al., 2011).

## The N-back Task

In the n-back task participants are presented with a sequence of stimuli (e.g., letters). As each stimulus is presented, participants are asked to compare the current stimulus with the stimulus that occurred  $n$  items prior in the sequence. For example, in the 4-back version of the task, participants

might be presented with the letter sequence “H-G-S-M-L-T-...”. If the next letter in the sequence is “S” then participants should respond “target” as the current letter matches the letter occurring four letters prior. If the next letter is anything else, then the correct response is “non-target”. Not all non-matching letters are the same in terms of difficulty. Lures, stimuli that match an item near to but not at the target location, are more difficult than fillers (stimuli that are neither lures nor targets). Participants are less accurate and take longer to respond to lures relative to fillers (Gray, Chabris, & Braver, 2003; Harbison et al., 2011; Kane et al., 2007; McCabe & Hartmen, 2008; Oberauer, 2005). From the example, the letters “H”, “G”, “M”, and “L” are lures. They match the 6<sup>th</sup>, 5<sup>th</sup>, 3<sup>rd</sup>, and 2<sup>nd</sup> letter back, respectively, but not the 4<sup>th</sup> letter back. Letters such as “F”, “P”, and “R” are fillers.

In the training version of the n-back task the level of  $n$  varies as a function of participant performance. The  $n$  level is increased when participants perform well and decreased when participants perform poorly at their current  $n$  level. In contrast, assessment versions of the task are non-adaptive; participants are given a set number of trials at predetermined levels of  $n$ .

## Previous Results

Performance on the n-back task is not often the focus of the experiments in which the task is used. Instead, the n-back task is either used to measure or to improve WM. Therefore, despite its frequent use, there remains a lack of detailed data on n-back task performance (for exceptions see Gray et al., 2003; Kane et al., 2007; McCabe & Hartmen, 2008; Oberauer, 2005).

Previously, we (Harbison et al., 2011) identified four results that characterize n-back training task performance. First, accuracy for target trials varies as a function of serial position. Figure 1a shows the results for sequences of 4-back from the training data; participants demonstrated primacy for target trials whereas this effect was weak to non-existent for lure and filler trials. Here the lures were one position away from the target, so they matched either the 3<sup>rd</sup> or 5<sup>th</sup> back stimuli. Second, in the reaction time (RT) data, we found that participants were faster making correct than

incorrect responses on lure and filler trials. This was not found for target trials. Figure 2a shows the mean RT data from 4-back sequences of the training data. Third, correct responses to targets and lures were made at approximately the same rate. Fourth, and perhaps least surprising, we found that participants made correct responses more quickly to filler stimuli than to either targets or lures. While only the results from 4-back are shown, the results are generally consistent across n levels of 3- to 7-back in the training data, with minor discrepancies at 1-, 2-, and 8-back.

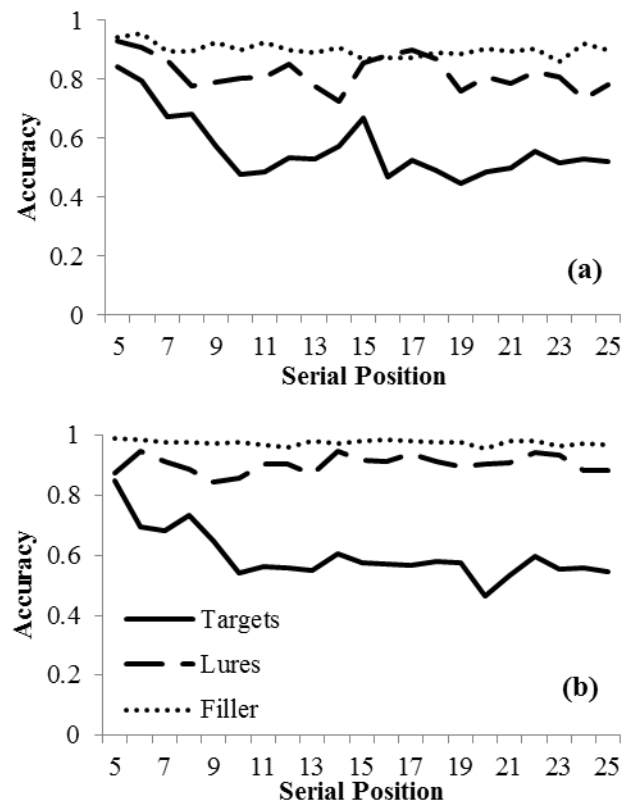

Figure 1. Participant (a) and Model (b) accuracy across serial position from the 4-back performance in a training experiment (Harbison et al., 2011).

We developed a two-process model of recognition to account for these accuracy and RT results (Harbison et al., 2011). The model assumes that when each stimulus in a sequence is presented, participants first generate an estimate of familiarity. If the stimulus is not familiar, the response is “non-target”. If the stimulus is familiar, then an attempt is made to determine if it does indeed match the stimulus occurring n items back through the process of recollection. If the recollected item matches the current stimulus, then a “target” response is made. If the recollected item does not match, then the “non-target” response is made. Finally, if recollection fails, the model guesses. RT predictions are based on the number of processes necessary to respond (familiarity = 1, familiarity and recollection = 2, familiarity, recollection, and guessing = 3). The model’s performance

on the 4-back training stimuli is shown in Figures 1b and 2b. The model captures the main qualitative patterns observed in the participant data. For example, according to the model the observed primacy for targets is due to the interference of previous items in the sequence on the maintenance of subsequent items (i.e., proactive interference). While both targets and lures are reliant on the same processes, familiarity and recollection, primacy is predicted more for targets as participants are expected to be much more likely to guess “non-target” than “target” when recollection fails as targets are much less frequent (only 20% of the stimuli are targets) Therefore, guesses are most likely to lead to correct responses for lure trials and incorrect responses for target trials.

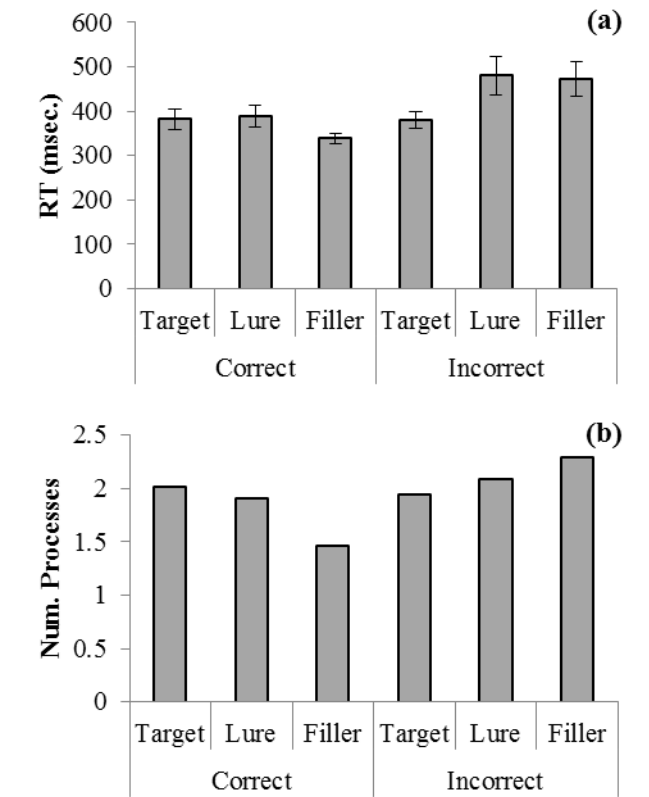

Figure 2. Participant (a) and Model (b) reaction time data from 4-back performance in a training experiment (Harbison et al., 2011).

### N-back Model Details

The n-back model is implemented within the HyGene framework (Thomas et al., 2008) and consists of three components: a representation of the current stimulus, the active subset in memory, and semantic memory. Stimuli are represented by a concatenation of an item vector and the current context vector. The elements in both the item and context vectors can take on the value of 1, -1, or 0. Here 0 represents lack of information about a feature, 1 indicates a feature’s presence and -1 its absence. Each item’s representation and the initial context vector are generated

randomly. However, the current context changes with each new stimulus. Specifically, when a new stimulus is presented each element of the current context has some probability of randomly changing to a new value. This probability is a parameter in the model (pDrift).

**Familiarity** The first step in processing a new stimulus is judging its familiarity to items in the active subset by

$$S_i = \frac{\sum_{j=1}^M P_j T_{ij}}{N_i}, \quad \text{Eq. 1}$$

where  $S_i$  is the similarity of the probe (P) and the  $i$ -th trace in memory ( $T_i$ ).  $j$  is the index of the element in the item representation for both the probe and the trace.  $N_i$  is the number of elements that are non-zero in the trace, the probe, or both.  $M$  is the number of traces in the active subset. The similarity is cubed to calculate the activation ( $A_i$ ) of each trace. Finally, the activations of all the traces in the active subset are summed to get the echo intensity for the probe. If the echo intensity is less than or equal to 0, then the item is unfamiliar and the “non-target” response is made. Otherwise, the model moves to the recollection process.

**Recollection** The model attempts to recollect the stimulus that occurred in the  $n$ -th back location when the current stimulus is familiar. This is performed by first trying to reinstate the  $n$ -th back context. Each element in the current context is changed to the  $n$ -th back context with some probability, pReinstate. This is the second parameter in the model.

Next, the (partially) reinstated context is used to probe the active subset. Equation 1 is again used but now the context portion of the representation serves as the probe instead of the item portion. Also, instead of summing the activations to get the echo intensity, the activations are used to create an echo content, a noisy representation of the item that occurred with the  $n$ -th back position by

$$C = \sum_{i=1}^M A_i T_{ij}. \quad \text{Eq. 2}$$

To identify the item from the noisy representation, the model uses the item representation from the echo content as the probe for activating the item representations stored in semantic memory. Again the results of equation 1 are used to generate the similarity and the activation, but this time semantic memory is probed and instead of using the activations to generate echo intensity or echo content, the activations are used to determine the probability of sampling and recovery from semantic memory. Specifically, the probability of sampling an item in semantic memory is calculated by

$$p(\text{Sample}_i) = \frac{A_i}{\sum_{j=1}^W A_j}, \quad \text{Eq. 3}$$

where  $W$  is the number of items in semantic memory. Therefore, the probability of sampling an item in semantic memory is equal to its relative activation. After sampling an item, an attempt is made to recover that item. Recovery is successful if the activation of the sampled item is greater than the threshold tRetrieval, the third parameter in the model. If the recovered item matches the current stimulus, then the response is “target”. If it does not match, the response is “non-target”. If retrieval fails then the model guesses.

**Guessing** The probability of guessing target is equal to the base rate probability of targets in the sequence. This probability was .2 in both the training study and in the present experiment.

**Encoding** After a response is made the current stimulus is encoded by the model. The representation of the item and the current context are stored in the active subset of memory. Each item in the active subset competes with every other item. Specifically, each feature in an item’s representation can only be non-zero for one item in the active subset. This assumption is based on the process of overwriting (Oberauer & Lewandowsky, 2008). To reduce competition, the model attempts to remove irrelevant items. In the case of 4-back, any item that occurred more than 4 items prior, from the active subset is irrelevant. Each time a new stimulus is encoded an attempt is made to remove all the irrelevant items currently in the active subset of memory. The probability of removing irrelevant items is the final parameter of the model, pRemove.

## Limitations of Previous Results

The results from the previous training study provided a starting point but there are a number of reasons why a replication and extension is needed. The present study is motivated by a desire to get cleaner data than is acquired from training studies. In training versions of the  $n$ -back task, the level of  $n$  fluctuates as a function of participant performance. Therefore, the amount of data that each participant provides for each level of  $n$  can vary substantially. For example, in the previous training study some participants never reached 4-back (i.e., were never successful enough at 2- and 3-back to reach 4-back). Some participants quickly advanced past 4-back to get to higher levels of  $n$ . Finally, some participants were stuck at 4-back for a while, as their accuracy was not high enough for  $n$  to increase or low enough for  $n$  to decrease. More generally, at lower levels of  $n$ , the majority of data is from participants that have the most difficulty performing the task. At higher levels of  $n$ , there is only data from participants that either excelled at the task from the beginning or participants that improved and are near the end of their training.

Another limitation of the reported training data was that it was drawn from a larger WM training study in which participants performed a number of different WM and WM-related training tasks and assessments. Extensive practice on

these tasks might have changed how they approached the n-back task.

In addition, the n-back model makes a number of predictions that are not tested by the previous data. First, it predicts gradual improvement in accuracy as lures move further from the target position. Lures one away from the target position (3- and 5-back when n is 4) should be more difficult than lures two positions away (2- and 6-back). Furthermore, lures the same distance from the target position are predicted to have the same approximate difficulty ( $n+2$  lures =  $n-2$  lures,  $n+1$  lures =  $n-1$  lures). The predictions are shown in Figure 3b. These predictions, like all other predictions presented, are made using the same parameter values as used in Harbison et al. (2011) for matching the training data ( $p\text{Drift} = .33$ ,  $p\text{Remove} = .15$ ,  $p\text{Reinstate} = .75$ ,  $t\text{Retrieval} = .10$ )

Second, unlike accuracy predictions, RT predictions are not symmetric around the target position. RTs for lures closer to the current stimulus should take longer to respond to correctly than lures further away from the current stimulus. That is, lures that match the 2-back position should take longer to reject than lures in the 6-back position. In contrast, the time it takes to make incorrect responses to 2-back and 6-back lures should not differ. These predictions are shown in Figure 5b.

We conducted a new experiment in which all participants had extensive experience at a moderately high level of n, 4-back. 4-back was chosen because in the training study most participants were able to reach that level, 4-back allowed lures two positions away that were not the immediately prior stimulus (2-back), and because the previous 4-back data showed the same reaction time profile as was shown at higher levels of n. This pattern was not as consistent at lower levels of n, specifically 1- and 2-back.

## Experiment

One hundred and forty-seven participants were randomly assigned into one of two counterbalanced conditions which determined if the participants performed sequences with lures first or second. Seventy-four participants were in the lure-first condition, seventy-three lure-second. Both conditions performed 16 sequences with lures and 16 sequences without lures. Each sequence was 25 letters long and contained five targets and either eight or zero lures. When the lures were present, there were two of each type in the sequence (2-, 3-, 5-, and 6-back lures). After completing the 4-back task, participants performed the block span and letter-number sequencing (LNS) tasks as measures of WM (Atkins et al., 2009).

## Results

Note that all differences reported have a p value of .05 or less. Also, unless otherwise noted, within-participant analyses were used. As such, the figures showing results averaging over participants can be misleading. Finally, there were no significant differences due to condition assignment

(lures first or lures second). Therefore, order is ignored in the reported analyses.

**Accuracy** The mean accuracy data by trial type is shown in Figure 3a. With or without lures, participants were most accurate with filler items and least accurate with target items. Performance on lures two away from the target (2- and 6-back) was worse than filler and better than performance on lures one away (3- and 5-back) from the target position. There was not a significant difference between lures the same distance away from the target. Comparing performance on sequences with lures against sequences without lures, there was not a significant difference in target performance, but participants were significantly better on filler items when there were lures.

Figure 3. Participant (a) and Model (b) mean accuracy by trial type.

**Serial Accuracy** As shown in Figure 4a, participants showed primacy for target trials. Also, performance on lures two away from the target position were consistently better than performance on lures one away from the target position. Note that while target accuracy dropped below 50% in middle and later serial positions, this is not really chance performance, as participants would be expected to respond “target” only 20% of the time if they guessed “target” with the same probability as targets in the sequence.

**Reaction Times** As in the training data, participants were significantly faster to respond correctly to lure and filler items than they were to respond incorrectly, as shown in Figure 5a. In contrast, target RT was not significantly different for correct and incorrect responses. Also as in the training data, participants were quickest to respond to filler items correctly.

There was not a significant difference between 6-back and 2-back lures for incorrect responses, but there was for correct responses. This pattern of results was predicted by the model. However, there were also some inconsistencies with the previous data. Inconsistent with both the training data and the model's predictions, the present experiment found incorrect filler responses were faster, not slower, than the incorrect responses to lures, on average. Also, participants were quicker to respond to target items than predicted by the model. Both correct and incorrect target responses were significantly faster than the average lure responses.

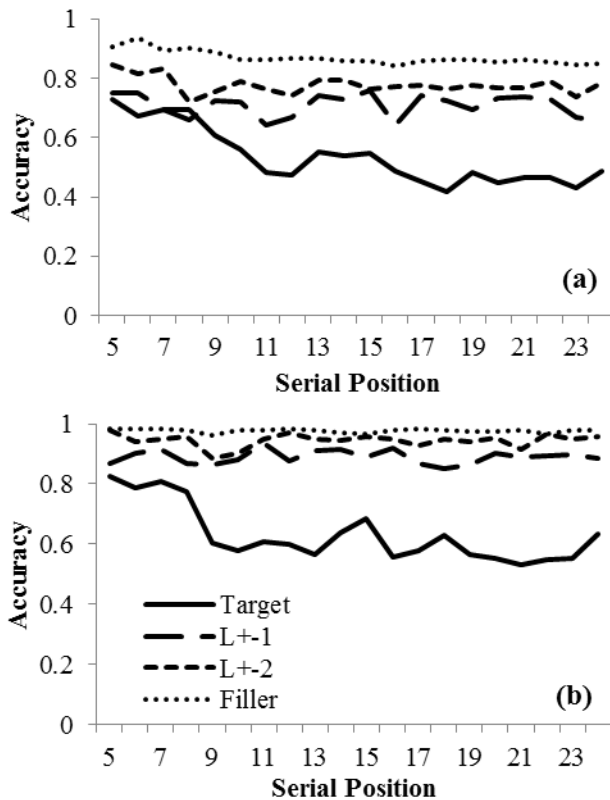

Figure 4. Participant (a) and Model (b) serial accuracy results by trial type.

**Working Memory** There was a weak but significant correlation of both LNS and block span with target performance ( $r$ 's from 0.188 to 0.283). Lure and filler accuracy were not correlated with these WM measures ( $r$ 's < 0.135). This result is consistent with previous assessment versions of the n-back Oberauer (2005) but not previous

training data (Harbison et al., 2011) which found the relationship with lure but not target performance.

Figure 5. Participant (a) and Model (b) reaction time results by trial type and accuracy.

## Discussion

The results from the 4-back task are largely consistent with the results of the adaptive, training version of the n-back task where difficulty is adjusted based on participant performance. In the present experiment three of the four results were replicated: target accuracy showed primacy, incorrect responses took longer than correct responses for lure and filler stimuli, and correct responses to filler items were faster than responses to any other trial type. In these ways the results are consistent with both the training data and the n-back model that was based on the training data.

In addition, the new data supported two novel predictions made by the n-back model. First, lure accuracy fit the predicted pattern, with lures one away from target position being more difficult than lures two away from the target position, while lures the same distance away were performed with approximately the same accuracy. Second, reaction times were predicted by the model to be longer for correct responses to 2-back than 6-back lures despite equivalent accuracy and equivalent RT for incorrect responses. It should be noted that the model was constructed using training results with lures only in positions one away from the target position, and yet was able to accurately

predict performance on lures two away from the target position both in terms of accuracy and reaction time.

The results were not without discrepancies. Participants in the present experiment were faster at responding both correctly and incorrectly to targets than either found in the training data or predicted by the model. Also, incorrect filler responses were not the slowest overall responses in the present data. Instead, incorrect lure responses were the slowest. Both of these results, plus the fact that participants showed a different RT profile in the training version of the n-back task at n levels of 1 and 2 from the general trend found at n levels 3 and above indicate the model is at best incomplete. One natural extension of the model which could account for at least some of these results is to include the area of direct access in addition to the activated subset of long-term memory currently implemented (Cowan, 1988). Items in the area of direct access would be able to forgo the recollection process, as they would be immediately available.

The present study provides additional support for the account of n-back performance as driven by recognition processes. Both target (Oberauer, 2005; the present study) and lure (Harbison et al, 2011) performance have been found to correlate with other WM assessments. Both of these trial types rely on recollection according to the present model. In contrast, filler trial performance can be accounted for by familiarity alone and has not been found to be related to other measures of WM. This could account for the inconsistent and/or weak relationship between overall n-back performance and other measures of WM as a large portion, often more than half, of the stimuli in a given n-back sequence are filler trials.

The purpose of this study is to improve the understanding of the cognitive mechanisms behind performance on the n-back task. As with other working memory tasks which correlate with many higher level cognitive processes, it is important to determine what is being measured by the n-back assessment and what might be improved by training versions of this task (Shipstead, Redick, & Engle, 2012). The results suggest that the relationship between n-back performance and other measures of working memory are dependent on a specific process, recollection, or the ability to comply with the demands of the task and inhibit responses based on familiarity alone in order to use recollection as the basis for response.

## Abstract

The present study investigates how a conversational agent can facilitate explanation activity. An experiment was conducted where pairs of participants, who were enrolled in a psychology course, engaged in a task of explaining to their partners the meanings of concepts of technical terms taught in the course. During the task, they interacted with a conversational agent, which was programmed to provide back-channel feedbacks and metacognitive suggestions to encourage and facilitate conversational interaction between the participants. Results of an experiment suggested that affective positive feedbacks from conversational agent facilitate explanation and learning performance. It is discussed that a conversational agent can play a role for pedagogical tutoring and triggers a deeper understanding of a concept during an explanation.

**Keywords:** pedagogical agents; explanation activities; affective learning.

## Introduction

The ever-evolving information and communication technology has made it possible to support human cognition by using systems which aids human interaction. Many researchers in computer science are tackling on the theme of developing embodied conversational agents to support education. Recent studies on cognitive science and learning science show that collaborative learning facilitates understanding or acquisition of new concepts depends greatly on how explanations are provided. In this study a collaborative activity of making explanation is experimentally investigated by using a conversational agent that serves as a teaching assistant. The goal of the experiment is to find out what kind of feedback from the agents is most conducive to successful learning performance.

## Related work

### Explanations during collaborative activities

Number of studies on collaborative problem solving in cognitive science revealed how concepts are understood or learned. Researchers have shown that asking reflective questions for clarification to conversational partners is an effective interactional strategy to gain a deeper understanding of a problem or a concept (e.g. Chi, Bassok, Lewis, Reimann, & Glaser, 1989; Miyake, 1986; Salomon,

2001; Okada & Simon, 1997). It has also been demonstrated that the use of strategic utterances such as asking for explanation or providing suggestions can stimulate reflective thinking and meta cognition involved in understanding a concept. Playing different roles during explanation is also said to help problem solvers reconstruct external representation and concepts (Shirouzu, Miyake, & Masukawa; 2002).

Studies that are discussed above suggest that how well one can explain is the key to understanding and learning of a concept. However, explanation becomes successful if people have difficulties in retrieving and associating relevant knowledge required for explanation activity. Researches on collaborative learning have reported that these difficulties rise among novice problem solvers (Coleman, 1998; King, 1994). Also, it may not help learn a concept if people cannot communicate with each other as in when, for example, they use technical terms or phrases unknown to others (Hayashi & Miwa, 2009).

It is assumed that one of the ways to help collaborative problem solvers is to introduce a third-person or a mentor who can facilitate the task by using prompts such as suggestions and back-channels. However, it is often difficult for one teacher to monitor several groups of collaborators and to supervise their interaction during explanation in actual pedagogical situations. Recently there are studies which demonstrate that the use of conversational agents that act as educational companions or tutors can facilitate learning process (Holmes, 2007; Baylor & Kim, 2005). Unfortunately, it has not been fully understood if and what kinds of support by such agents would be more helpful for collaborative learners. In this paper, the author will further investigate this question through the use affective expressions.

### Pedagogical conversational agents as learning advisers

Researchers in the field of human computer interaction have conducted a number of experimental studies which involve the use of pedagogical agents (e.g. Kim, Baylor & Shen, 2007; Reeves & Nass, 1996; Graesser & McNamara, 2010). One point to be taken into consideration in studies of human performance is the affective factor. This factor influences people's performance in either negative or positive ways and

several studies reported that such factors are especially important in learning activities (Baylor & Kim, 2005). For example, Bower & Forgas (2001) revealed that positive moods can increase memory performance. Mayer & Turner (2002) also demonstrated that positive state of mind can improve text comprehension.

Moods may affect the performance of human activities both verbally and non-verbally. In a study by Kim, Baylor, & Shen (2007), which examined how positive and negative comments from conversational agents affect learning performance, a pictorial image of an agent was programmed to project a textual message to the participant; in the positive condition, a visual avatar produced a short comment like "this task looks fun", while in the negative condition, it produced a short comment like "I don't feel like doing this, but we have to do it anyway". The results showed that the conversational agents that provided the participants with comments in a positive mood furnished them with a higher motivation of learning.

The studies discussed above suggest that the performance of explanation would also be enhanced if suggestions are given in positive mood either verbally or through visual feedbacks.

## Research Goal

This study investigates how conversational agents can facilitate understanding and learning of concepts. This paper will focus on an agent which has a role that assists paired participants to explain concepts to their partners during the collaborative peer-explanation activity. A natural language processing agent monitored the interaction between the participants and provided prompts to them which were generated by pre-defined rules. The research goal of this study is to understand if the use of positive expressions provided by a conversational agent facilitates collaborative learners' understanding of concepts.

## Method

### Experimental task and procedure

The experiment was conducted in a room where the computers were all connected by a local area network. Participants were given four technical terms presented on the screen. They were: 'schema', 'short-term / long-term memory', 'figure-ground reversal', and 'principle of linguistic relativity', which had been introduced in a psychology class. Along with the keyterms, a brief explanation of the concept was described by a few sentences. They were asked to describe the concepts of these words. After this pre-test, they logged in the computer and used the program installed in a USB flash drive (see the next section for detail). The pairs of participants were communicated through the chat program and one of the paired participants was instructed to explain to their partner the meanings of the words presented on their computer screen one by one. When two of the four concepts were explained to their partner, they switched the roles and the other partner explained the

rest of the two words to his/her partner. This was repeated but the words they explained the second time were different from those in the first time. All participants received the same prompts of suggestions from the agent on how explanations should be given and how questions should be asked about the concepts. After this pre-test, they took the same test in the post-test. The descriptions of the concepts they provided in the post-test were compared with those of the pre-test to analyze if the participants gained a deeper understanding of the concepts after the collaborative activity. The whole process of the experiment took approximately 80 minutes (see Figure 1).

Figure 1: Experiment flow.

## Experimental system

In the experiments, a computer-mediated chat system was set up through computer terminals connected via a local network and the interactions of the participants during the activity were monitored. The system used in the experiments was programmed in Java (see Figure2).

Figure 2: Experimental Setting.

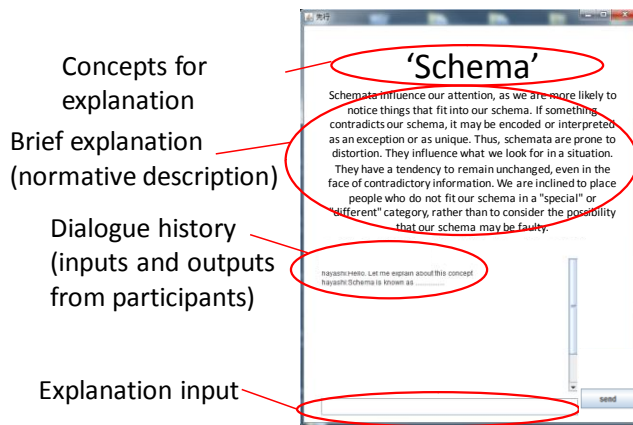

Figure 3: Screenshot of the chat system.

The system consists of three program modules of Server, Chat Clients, and Agent, all of which are simultaneously activated. Multi-threads are used so that the server program can send all messages to the clients' chat system and the agent simultaneously.

The pedagogical agent used in this study is a simple rule-based production system typical of artificial intelligence. It is capable of meaningfully responding to input sentences from users and consists of three main modules: Semantic Analyzer, Generator, and Motion Handler (see Figure 4).

Figure 4: Architecture of message production.

Textual input of all conversational exchanges produced by paired participants is sent to the semantic analyzer of the conversation agent. The semantic analyzer then scans the text and detects keywords relevant to the concepts if they

are being used in the explanation task (e.g. "I think that a *schema* is some kind of *knowledge* that is used based on one's own *experience*." (detected key words are shown in bold italic). Next, the extracted keywords are sent to the working memory in the generator and processed by the rule base, where various types of rule-based statements such as 'if X then Y' are stored to generate prompt messages (if there are several candidates of matching statements for the input keywords, a simple conflict-resolution strategy is utilized). When the matching process is completed, prompt messages are selected and sent back to the working memory in the generator. The messages generated by the rule base are also sent to the motion handler module to activate an embodied conversation agent, a computer-generated virtual character which can produce human-like behaviors such as blinking and head-shaking. Each output message is textually presented in a text filed on the computer display (See next sections for details).

Several types of output messages are presented by the agent depending on the content of input text from the participants (see Table 1 below for examples). Only short back-channels are sent when there are several related key words in a text (Type 1 output); Messages of encouragement are given when the agent detects some keywords related to the target concept (Type 2 output, Type 3 output, Type 4 output).

Table 1: Types of output messages from the agent.

Type of messages	Examples
<u>Input messages</u> (Detected key words are in Bold)	"I think that a <b>schema</b> is some kind of <b>knowledge</b> that is used based on one's own <b>experience</b> ."
<u>Output: type 0</u> Back-channels	"That's the way", "Keep going!", "Um-hum"
<u>Output: type 1</u> Positive Suggestion (Used in Positive condition)	"Wow! You used a few very good keywords. That's great! It is better if you explain it from a different perspective!"
<u>Output: type 2</u> Negative Suggestion(Used in Negative condition)	"Well, you used few keywords. That is not enough. It is not satisfactory unless you explain it from a different perspective."
<u>Output: type 3</u> Normal Suggestion (Used in Neutral condition)	"You used few important keywords. Try to explain from a different perspective."

## Participants and conditions

In this study, 90 participants participated in the experiment. The participants were all undergraduate students who were taking a psychology course and participated in them as part of the course work. They were randomly assigned to three conditions, which varied with respect to how prompts of

suggestions were presented and how conversational agents were used (see the sections below for details).

To find out how affective factors influence the task of explanation, three types of avatars were created: one is the positive agent with friendly facial expression which was used for the "positive condition", and the negative agent with unfriendly facial expression which was used for the "negative condition", and finally the neutral agent with no facial expression which was used for "neutral condition". In the positive condition ( $n = 31$ ), the participants were given positive suggestions, which were synchronized with the facial expressions of the positive agent. In the negative condition ( $n = 28$ ), the participants were given negative suggestions, which were synchronized with the facial expressions of the negative agent. In the neutral condition ( $n = 31$ ), the participants were given suggestions without emotional expressions.

The messages were given through chat dialogue and the virtual character moved its head gestures while the participants chat on the computer (For examples of suggestion for the conversational agent see Table 1). Since there was odd number of participants in positive and neutral condition, one group was composed by three.

### Dependant variables

To evaluate the outcome of (1) quality of the performance of learning, and (2) interaction process, two types of measures were used.

First, for the learning performance, the results of the pre- and post- tests were compared to find out how the explanation task with different conditions facilitated their understanding or learning of the concepts. For the comparison, their descriptions were scored in the following way: 1 point for a wrong description or no description, 2 points for a nearly-correct description, 3 points for a fairly-correct description, 4 points for an excellent description, and 5 points for an excellent description with concrete examples. It was judged that the greater the difference in scores between the two tests the higher the degree of the effect of explanation.

Second, for the analysis of explanation process, all the dialogs during the task were analyzed. The main focus of the analysis was to investigate what kind of explanations were used during their interaction. Each dialog sentences that included explanations were coded by the following two categories: (1) explanations that were made by using terms and phrases presented by the system (see Figure 3 for an example of the description), and (2) explanations that were generated based on subjective inference. The former is called "normative explanations". On the other hand, the utterance in the latter is called "subjective explanations".

## Results

### Quality of performance

The results showed that the participants' understanding of the concepts improved after the explanation task in all

conditions (see Figure 5). The vertical axis in Figure 5 represents the average scores of the tests for the three groups at the times of pre- and post- tests. A statistical analysis was performed using a 2 x 3 mix factor ANOVA with the two evaluation period (the pre-test vs. the post-test) and the three conditions with different feedback (Positive vs. Negative vs. Neutral) as independent factors.

Figure 5: Results of the quality of the performance of learning.

There was significant interaction between the two factors ( $F(2, 87) = 3.388, p < .05$ ). First, an analysis of the simple main effect was done on each level of the feedback factor. In the Positive, Negative, and Neutral condition, the average scores in post-test was higher than pre-test respectively ( $F(1,87) = 254.397, p < .01$ ;  $F(1,87) = 172.796, p < .01$ ;  $F(1,87) = 155.812, p < .01$ ). Next, an analysis of the simple main effect was done on each level of the period factor. In the pre-test, there was no differences between conditions ( $F(2,174) = 0.202, p = .82$ ). Although in the post-test there were differences between conditions ( $F(2,174) = 9.094, p < .01$ ). Further analysis on the post-test was conducted using the Ryan's method. Results indicate that the average score of Positive condition was higher than Negative condition and the average score of Positive condition was higher than Neutral condition respectively ( $p < .01$ ;  $p < .01$ ). There were no differences between Negative condition and Neutral condition ( $p = .51$ ).

The overall result suggests that the collaborative activities facilitated the participants' understanding or learning of the concepts more when the positive suggestions were presented to the participants.

### Interaction process

Figure 6 indicates the relationships between the usage of normative explanations and subjective explanations. The vertical axis represents the average ratio of each participant's explanation type. The horizontal axis shows each of the three conditions.

The analysis of ANOVA with the factor of explanation type (normative explanations vs. subjective explanations)

was conducted on each condition. The results show that participants in the Neutral condition and Negative conditions used more subjective explanations than normative explanations, respectively ( $F(1, 27) = 7.326, p < .05$ ;  $F(1, 30) = 25.116, p < .01$ ). On the other hand, there were no statistical differences between the two conditions in the Positive condition ( $F(1, 30) = 0.46, p = .50$ ). These results indicate that participants in the Negative and Neutral conditions made explanations mostly based on subjective explanations.

Figure 6: Results of the type of explanation activities.

## Discussion

### Affective expressions of the conversational agent

The results of the experiment suggested that the greater the positive affective expressions from the conversational agent the more it can facilitate explanation activities which leads to a deeper understanding of concepts (i.e., Positive condition > Negative condition, Positive condition > Neutral condition). The results of the dialogue analysis somewhat support these result. That is, participants in the Negative and Neutral condition used more subjective inferences and interpretations about the key concept instead of using normative phrases, which might led to construction of misunderstandings on the concepts. On the other hand, participants in the Positive condition used normative expressions that were on track. It is assumed that the affective expressions generated by the agents facilitated the participants' motivation to keep their attention to the computer system which provided important information.

These results provide more reliable findings than those compared with experiments conducted by the authors' previous work (Hayashi, 2012). In those experiments, the influences of affective feedbacks were examined during collaborative activities. Unfortunately, there was no neutral condition and dialogue analyses were not further conducted. The present study makes it clear that positive emotions expressed by a pedagogical agent facilitated explanation activities at the interaction level. This suggests that the participants might have paid more attention during the interaction process and worked harder when they received positive comments than they received neutral and negative

comments. One of the interesting finding is that, the learning performance of the participants in the Negative condition and Neutral condition were the same in this experiment. It is assumed that negative affective feedbacks were not able to trigger such motivation and enhance performance as much as the Positive condition. This may be affected by the lack of attention to the agent. This point will be further investigated elsewhere.

### Awareness towards the conversational agent

Studies in social psychology have suggested that work efficiency is improved when a person is being watched by someone, or, that the presence of an audience facilitates the performance of a task. This impact that an audience has on a task-performing participant is called the "audience effect". Another relevant concept on task efficiency, but from a slightly different perspective, is what is called "social facilitation theory". The theory claims that people tend to do better on a task when they are doing it in the presence of other people in a social situation; it implies that person factors can make people more aware of social evaluation. Zajonc (1965), who reviewed social facilitation studies concluded that the presence of others have positive motivational affects.

Holmes (2007) is one of the experimental studies which investigated the effects of a tutoring agent. In this experiment, an agent, which played the role of an assistant, was brought in to help a participant who explained a concept. In the experiment, three different environments were set up for the 'explaining activity'. They were: (1) two participants working with a text-based prompt, (2) two participants working with a visual image of pedagogical agent which produced a text-based prompt (3) one participant working with a visual image of pedagogical agent which produced a text-based prompt (in this setup, participants did not have a human co-learner and directly interacted with the agent). The result showed that the participants in the last two conditions did better than the first where only textual prompts were presented. It also showed that the participants in the second condition did not engage in the explanation activity as much as those in the third. The first finding of Holmes (2007) is that the participants in the last two conditions, who worked with the agent, performed better may be attributed to the fact that their task of explanation was being watched or monitored by the agent. Also, the second finding that the effect of the agent for the participants in a pair was not as high as for those directly interacting with it alone may be because the level of attention of the participants in the second condition was not as great as that in the third condition; it may be that the participants in the second were less conscious of the presence of the monitoring agent than those in the third group.

These results of the present study suggest that participants would do better in the task of explanation if they are more conscious of the presence of the agents or if they are given an explicit direction to pay attention to the agent. The

results of the present experiment provide new evidence that the positive feed backs made by the agents can facilitate such "audience effect".

### Conclusion and future work

The present study investigated the effectiveness of the use of a conversational agent in a collaborative activity, where paired participants explained each other the meaning of technical terms taught in a psychology class for a better understanding. Conversational agents were used to encourage and facilitate the students' interaction through both verbal and visual input. The experimental results suggested that the presence of a conversational agent with positive expressions can trigger a deeper understanding of a concept during an explanation.

Pedagogical agent can play several different roles for collaborative learning activities and several studies have looked into the effectiveness of the use of a pedagogical agent with different roles. For example, Baylor & Kim (2007) investigated the effectiveness of the use of a pedagogical agent which plays the roles of an expert teacher, a motivator, and a mentor (both an expert and motivator). However, not much is known yet about what roles it can play effectively. Another issue to be further investigated is the effect of the personality of the agent upon these roles. These and other related topics need to be further studied in future.

### Acknowledgments

I appreciate all students who participated in this experiment. I also want to thank my student advisee Shin Takii (Ritsumeikan University) and Rina Nakae (Ritsumeikan University), Yuichi Mizuno (Ritsumeikan University) for helping me to conduct the experiment.

# Knowledge and Political Categorization

Evan Heit (eheit@ucmerced.edu)

Stephen P. Nicholson (snicholson@ucmerced.edu)

School of Social Sciences, Humanities and Arts  
University of California, Merced  
Merced CA 95343 USA

## Abstract

A nationally representative sample of US adults completed two political categorization tasks. The first was to identify the political parties for hypothetical candidates with information given about demographics and stands on issues. The second task was to decide whether to vote for each candidate. On the identification task, judgments about whether a person is a Democrat were almost a perfect mirror image of judgments of whether a person is a Republican. In general, respondents were very successful in the identification task; there was a strong correlation with objective probabilities. Likewise, respondents were successful at the voting task, in terms of their own party interests. Success at these two tasks was positively correlated with a measure of political knowledge. The pattern of responses was also influenced by the political party of the respondent; suggesting that feature weights depended on party membership. Implications for models of categorization and reasoning are discussed.

**Keywords:** Categorization; Expertise; Probability Judgment; Political Cognition.

## Introduction

We propose that political parties should be conceived of as categories. Following Rosch & Mervis's (1975) seminal work on categorization, political parties have a horizontal dimension corresponding to typicality structure, e.g., Mitt Romney is a more typical Republican than is Ron Paul. It is then appropriate to ask what is the function of political categories (cf., Anderson, 1991; Billman & Heit, 1988; Markman & Ross, 2003), beyond labeling individuals as party members. One key function is to support voting, which can be seen as a category-based inference, e.g., knowing that Mitt Romney is a typical Republican would lead many people to vote for him in a Presidential election.

In previous research (Heit & Nicholson, 2010) we have collected typicality judgments for a set of real political candidates. College students rated the individuals either on typicality as a Democrat or typicality as a Republican. The relation between the two sets of ratings was strong, negative, and linear, with a remarkable correlation of -0.9957. Essentially, whatever made an individual more typical of one party was seen to make that individual less typical of the other party (cf., Rosch & Mervis, 1975; Verbeemen, Vanoverberghe, Storms, and Ruts, 2001). It was not possible to be typical of both parties, or atypical of both parties. The results contrasted with other opposing

pairs of categories, male versus female jobs and healthy foods versus junk foods. We concluded that for political categories, there is a highly systematic and polarized representation of knowledge.

Although the results were extremely strong, the study itself had limitations. For example, students may not be representative of voters at large. We did not systematically study the effects of demographic variables such as level of political knowledge (which might be low for college students) and party of the respondent. Because the stimuli were simply names of public figures, we could not tell which information about these figures was being used. Also, the dependent variable, typicality, has disadvantages, because it is not objective and it may not map directly onto real political behavior such as voting.

Hence, the present experiments substantially improved upon Heit and Nicholson (2010). Each experiment involved several hundred adults from a nationally representative sample of US adults, with information collected about political knowledge and party membership. The stimuli were descriptions of hypothetical candidates in terms of demographic information (race, gender, number of children) and stands on issues (government spending and abortion). Information about each candidate's political party was omitted from the stimuli; however the objective probability of being a Democrat or Republican based on demographics and stands on issues could be determined from national survey data. In Experiment 1, the task was to identify each candidate's party. In effect, we were examining whether respondents could correctly categorize candidates as Democrats or Republicans when this information is withheld. In Experiment 2, the task was voting; respondents were asked how likely they would be to vote for each candidate. A key measure of interest was whether respondents voted the party line, i.e., Democrats voting for Democrats and Republicans voting for Republicans. In general, we were interested in whether performance on these two tasks depended on political knowledge and party membership of the respondent. We also examined the influence of various cues, to see if different cues were used for the two tasks and by different sub-groups of respondents.

In the cognitive science literature on categorization, perhaps the most closely related work addresses the effects of expertise on biological categorization. For example, Johnson and Mervis (1997) studied categorization of

songbirds, reporting shifts due to expertise. In effect, what was the subordinate level for non-experts became the basic level for experts. Medin and Atran (2004) reviewed an extensive set of studies showing effects of knowledge and group membership on biological categorization, cautioning against conclusions drawn just from Western college students. For example, Medin, Lynch, Coley, and Atran (1997) conducted a study of tree experts including taxonomists, landscapers, and maintenance workers. They reported differences in categorization and reasoning due to the goals of each type of expert. These differences appeared to be mediated by differences in feature weighting for particular areas of expertise. (See Hayes, Heit, & Swendsen, 2010, for a further review of knowledge effects on category-based reasoning.)

With regard to the issue of political knowledge, political science research has generally been pessimistic. Political scientists have emphasized that the US public is largely ignorant of politics (e.g., Delli Carpini & Keeter, 1996). The mass public is reported to have minimal levels of political attention and information as well as incoherent and unstable attitudes (e.g., Converse, 1964). Despite these low levels of information and political understanding, most citizens appear to make do with simple political heuristics such as relying on single cues, e.g., party labels (e.g., Lau & Redlawsk, 2006). Notably, in the present study, we require participants to make judgments from multiple cues, while information about party labels is withheld. Hence, we are addressing whether the pessimistic view from political science is supported.

## Experiment 1

### Method

**Participants.** A total of 598 US adults participated, in September-October 2010, as part of the Cooperative Congressional Election Study (CCES). Only self-identified Democrats or Republicans were included, and because the political knowledge measure referred to party control of

both houses of the state legislature, adults from Nebraska and Washington, DC were excluded.

**Materials.** The key stimuli were the nine hypothetical candidate descriptions; examples are shown in Table 1. Candidates were described in terms of gender, race, number of children, position on government spending, and position on abortion. The objective probability of each person being a Democrat or a Republican was determined with survey data from the 2008 American National Election Study (ANES). Across the nine descriptions, the objective probability ranged from 10% to 91% in increments of about 10%. On the survey itself, respondents were informed that each candidate was either a Democrat or a Republican. Approximately half of the respondents were asked to judge the probability that each was a Democrat; the remainder judged the probability that each was a Republican.

The knowledge measure was based on eight questions. Four questions required the respondent to correctly identify the party controlling the US Senate, the US House of Representatives, and the two legislative chambers in the respondent's home state. Four more questions asked respondents if they recognized the names of public officials (governor, two US senators, and US representative). Based on a rough median split, respondents with seven or eight correct responses were considered high knowledge, and the remainder were considered low knowledge.

**Procedure.** Respondents participated at their own pace, as part of a larger Internet-based survey.

### Results and Discussion

In a conceptual replication of Heit and Nicholson (2010), the relation between these two kinds of judgments was extremely strong, negative, and linear,  $r = -0.9977$ . (See Figure 1.) Consistent with the findings of Tversky and Koehler (1994), the results showed binary complementarity, that is, there was neither evidence for subadditivity or superadditivity, and complementary pairs summed to an average of 99.2%.

Table 1: Sample Stimuli for Experiments 1 and 2.

Description	Obj. Prob. of Democrat
Joanna is a white female with no children who enjoys watching television, exercising, and discussing politics with friends. In a recent political discussion he voiced the opinion that government provides about the right amount of services and that, by law, abortion should never be permitted.	20.9%
Emily is a white female with no children who enjoys watching television, exercising, and discussing politics with friends. In a recent political discussion she voiced the opinion that government should provide many more services and that, by law, abortion should be allowed under some circumstances.	49.5%
George is an African-American male with no children who enjoys watching television, exercising, and discussing politics with friends. In a recent political discussion he voiced the opinion that government provides about the right amount of services and that, by law, a woman should always be able to obtain an abortion.	72.7%

Figure 1. Subjective probability candidate is a Democrat versus subjective probability candidate is a Republican.

Figure 2 shows average subjective probability judgments plotted against objective probabilities. For this composite measure, all judgments were pooled; judgments about whether a candidate was a Republican were subtracted from 100% to put them on the same scale as judgments about whether a candidate was a Democrat. The correlation between subjective and objective probabilities is remarkable,  $r=0.9557$ , indicating that collectively, respondents were able to identify candidates' party affiliation based on very limited information. Most of the data points fall above the main diagonal, indicating that the proportion of Democrats in the stimulus set was somewhat overestimated overall. The subjective probability judgments have a somewhat smaller range than the objective probabilities.

Of course, the remarkable success of respondents at judging party membership in the aggregate need not be reflected at the individual level. Still, individual respondents were successful. The median correlation between objective and subjective probability, at the individual level, was 0.7523, and the mean correlation was 0.6203. The fact that the mean is lower than the median reflects that a small number of respondents did very poorly at this task.

The mean correlations varied as a function of knowledge and partisanship of the respondents. The mean correlations for high knowledge Democrats, low knowledge Democrats, high knowledge Republicans, and low knowledge Republicans were 0.7214, 0.5597, 0.6265, and 0.5575, respectively. A two-way ANOVA revealed a main effect of knowledge, with high knowledge respondents showing higher correlations,  $F(1, 591)=15.32$ ,  $p<.001$ . Neither the effect of party membership or the interaction between knowledge and partisanship reached the level of statistical significance.

We next conducted analyses of the cues used by respondents in each sub-group. The question addressed was what information was used in making these political categorization judgments, and whether use of information varied across groups. Essentially, we conducted four regression analyses, predicting probability judgments based on the cues of gender, race, number of children, position on government spending, and position on abortion for each sub-group. Because each respondent contributed judgments for nine items to the analysis, we used a version of the generalized linear model that accommodates clustered data (as implemented in the generalized estimating equation module in SPSS Version 18). Gender was coded 0 for male and 1 for female; race was coded 0 for white and 1 for African-American; position on government spending was arbitrarily coded as a 1, 2, or 3 with higher values indicating a more favorable position; and position on abortion was arbitrarily coded as a 1, 2, or 3 with higher values indicating a more permissive position.

Figure 2. Objective probability candidate is a Democrat versus subjective probability candidate is a Democrat.

Before describing the findings, it is worth noting that as in the real world, within these stimuli there was multicollinearity among the cues. We had created stimuli with the aim of covering a wide range of probabilities in intervals of 10%, rather than breaking up the usual correlations. In some cases, the demographic and issue variables were strongly correlated with each other. Hence, regression coefficients should be interpreted with caution. With this point made, Figure 3 shows the standardized regression coefficients across the five cues. In general, the regression coefficients are rather similar across sub-groups. Perhaps the most interpretable difference is that stand on abortion, a highly predictive cue, has more weight for high expertise Democrats than for low expertise Democrats, and for high expertise Republicans than for low expertise Republicans. Paying more attention to this cue would lead

to greater success for the high expertise respondents at the identification task. Unexpectedly, the African-American cue shows negative weights. In fact, this cue had a strong positive correlation with identification as a Democrat. For example, in a simple regression for all respondents, predicting judgments from just the African-American cue, the standardized regression coefficient was 23.16. However, stand on abortion was correlated with African-American, and acted as a suppressor variable. In a regression with just these two predictor variables, the standardized regression coefficient for abortion is 30.60 and the coefficient for African-American drops to -13.69. Therefore, we would emphasize the similarity of regression coefficients across sub-groups, and avoid overinterpretation of specific values.

As an interim summary, we note that so far there is evidence for main effects of expertise, with higher knowledge respondents being more successful at the categorization task. There is little evidence for group (party) differences or differences in feature weighting. Overall, respondents' success at using multiple cues to identify party membership suggests a much more optimistic view than the standard view from political science, that people can, at best, make basic judgments if party label information is supplied.

Figure 3. Estimated regression coefficients for low-knowledge and high-knowledge Democrats, and low-knowledge and high-knowledge Republicans.

## Experiment 2

Having shown in Experiment 1 that respondents can successfully identify party membership of hypothetical candidates, in Experiment 2 we investigated voting judgments on these same candidate and compared these responses to identification judgments.

### Method

From the same survey as in Experiment 1, a different set of 573 US adults participated, screened according to the same

criteria. Political knowledge was measured as in Experiment 1.

Again, the key stimuli were the nine candidate descriptions shown in Table 1. However, respondents were asked how likely they would be to vote for each candidate, on a scale from 0% to 100%.

## Results and Discussion

Figures 4 and 5 show the average voting probability judgments across the nine descriptions as a function of objective probability of being a Democrat, for respondents who identified themselves as Democrats and Republicans, respectively. For Democratic respondents, there was a strong, positive relation between a candidate's objective probability of being a Democrat and the average probability of voting to support. The correlation was 0.9000. The figure is suggestive of a threshold function, with the three candidates least likely to be Democrats attracting a low level of votes, and the five candidates most likely to be Democrats attracting a level of votes above 50%. For Republican respondents, there was a negative relation, although not quite as strong as for Democrats,  $r = -0.6606$ . Hence, the results suggest that both Democrats and Republicans tended to vote the party line (Democrats more so), even when explicit party information was not given. It is interesting to compare these correlations to the overall correlation for Experiment 1, in which respondents' probability judgments for party identification had a 0.9557 correlation with objective probability. Clearly, voting judgments are not the same as party identification judgments. Any lack of voting the party line in Experiment 2 is not due to respondents' inability to identify candidates' political parties.

We next examined these correlations at the level of individual respondents. For Democrats, the median correlation was 0.7823, and the mean correlation was 0.5004. For Republicans, the median correlation was -0.4057, and the mean correlation was -0.2971. As in Experiment 1, the median and mean correlations at the individual level are lower than the aggregate correlations, but they still suggest more party-line voting by Democrats. For a finer-grained analysis, we looked at mean correlations as a function of knowledge and partisanship of the respondents, with high or low knowledge operationalized as in Experiment 1. The mean correlations for high knowledge Democrats, low knowledge Democrats, high knowledge Republicans, and low knowledge Republicans were 0.6009, 0.4013, -0.3351, and -0.2396, respectively. For the purpose of an ANOVA examining tendency to vote the party line, correlations for Republican participants were multiplied by -1, for this analysis only. A two-way ANOVA revealed a main effect of knowledge, with high knowledge respondents showing stronger correlations,  $F(1, 569) = 11.09$ ,  $p < .001$ , and a main effect of party membership, with Democrats showing stronger correlations,  $F(1, 569) = 23.24$ ,  $p < .001$ . The interaction between knowledge and partisanship did not reach the level of statistical significance.

Figure 4. Objective probability candidate is a Democrat versus voting probability, for Democrats.

Figure 5. Objective probability candidate is a Democrat versus voting probability, for Republicans.

As in Experiment 1, we next conducted analyses of the cues used by respondents in each sub-group. Because of multicollinearity, the results should be taken as suggestive rather than definitive. Figure 6 shows the standardized regression coefficients across the five cues. Unlike Experiment 1, the regression coefficients varied considerably across sub-groups. It appears that Democrats were more influenced by demographic cues such as gender and number of children than are Republicans, although high knowledge Democrats were less influenced by demographic cues than low knowledge Democrats. It appears that Democrats were more influenced by stand on abortion and Republicans were more influenced by stand on government

spending. Use of these issue cues appears to be greater for high knowledge participants than for low knowledge participants. Again, the African-American cue shows negative weights for Democratic respondents. In fact, Democrats were much more likely to vote for African-Americans than for whites. For example, in a simple regression for all Democrat respondents, predicting judgments from just the African-American cue, the standardized regression coefficient was 15.91. In a simple regression for all Republican respondents, predicting judgments from just the African-American cue, the standardized regression coefficient was -0.86. Hence, Republicans were barely influenced by this demographic cue. Therefore, we would emphasize that cue utilization for voting appeared to differ considerably as a function of partisanship and political knowledge, and indeed the cues for voting are not the same as the cues for party categorization.

Figure 6. Estimated regression coefficients for low-knowledge and high-knowledge Democrats, and low-knowledge and high-knowledge Republicans.

In sum, like Experiment 1, Experiment 2 suggests an optimistic view of US voters, using multiple cues to vote for their party interests, even when party labels are omitted from descriptions. Interestingly, the pattern of responses for voting was different than for identification, so it did not seem that respondents treated the two tasks as the same. In Experiment 2, there were also robust differences in responses due to expertise and party membership.

## General Discussion

The results of the present experiments replicate Heit and Nicholson (2010) in terms of showing a highly polarized electorate. Just as our previous study found an almost perfect negative correlation between typicality in Democrat and typicality in Republican, here in Experiment 1 we found an almost perfect negative correlation between estimated probability that a candidate is a Democrat and estimated

probability that a candidate is a Republican. In Experiment 2, we found that Democrats and Republicans not only showed different patterns of voting for the same candidates, but also used different cues or feature weights. Democrats paid more attention to candidate's personal information and stand on the abortion issue, whereas Republicans focused on government spending. Although we previously concluded that "The opposite of Republican is Democrat," here we found that Democrats and Republicans did not simply disagree with each other, but actually cared about different issues and characteristics of candidates.

The respondents were remarkably successful at the identification and voting tasks. In the aggregate, the correlation between subjective judgments and objective probabilities was nearly .96, and the correlation for the median respondent very respectable, about .75. (We would refer to the "wisdom of crowds" phenomenon documented by Surowiecki, 2004, to explain the stronger performance at the aggregate level.) On the voting task, respondents were able to vote correctly—vote in their own party interests—even when labels were omitted.

In terms of connections to categorization research, we see commonalities with research on expertise in biological categorization (e.g., Medin et al., 1997, Medin & Atran, 2004). Democrats and Republicans can be seen as experts who see the same candidate but have different goals, just as taxonomists, landscapers, and maintenance workers would see the same tree with different goals. These differences are mediated by the level of expertise of each voter, suggesting there are different feature weights for identification and voting tasks, and for Democrats and Republicans. At this point, we can only pose the question of whether these feature weights are optimized for the tasks in the sense of Nosofsky (1986) and Kruschke (1992).

Indeed, what appears on the surface to be a feature weighting effect might have a different underlying explanation. For example, Heit (1998) showed that a Bayesian model of inductive reasoning can explain what appears to be a selective weighting effect in reasoning about either anatomy or behavior of animals (Heit & Rubinstein, 1994) not in terms of selective weighting but in terms of a hypothesis space that reflects feature co-occurrences. This account can be generalized to address a variety of selective effects in both induction and categorization (Kemp, Shafto, & Tenenbaum, 2012).

To conclude, we believe that studies of political cognition provide an interesting opportunity for the development and testing of computational models of categorization and reasoning.

## Abstract

Recent re-analysis of traditional Categorical Perception (CP) effects show that the advantage for between category judgments may be due to asymmetries of within-category judgments (Hanley & Roberson, 2011). This has led to the hypothesis that labels cause CP effects via these asymmetries due to category label uncertainty near the category boundary. In Experiment 1 we demonstrate that these “within-category” asymmetries exist before category training begins. Category learning does increase the within-category asymmetry on a category relevant dimension but equally on an irrelevant dimension. Experiment 2 replicates the asymmetry found in Experiment 1 without training and shows that it does not increase with additional exposure in the absence of category training. We conclude that the within-category asymmetry may be a result of unsupervised learning of stimulus clusters that emphasize extreme instances and that category training increases this caricaturization of stimulus representations.

**Keywords:** Categorical Perception, Category Labels, Perceptual Learning, Category Learning, and Language

## Introduction

**Categorical perception.** Our perceptual systems fail overwhelmingly to be precise replicators of reality in the way a camera or a microphone is, because these systems have not evolved to create a veridical representation of reality. Though constrained by overall neural architecture and the inertia of representations in primary sensory areas (Petrov et al., 2005), our perceptual systems consistently learn to create useful, but potentially distorted, representations of reality (Landy & Goldstone, 2005).

Often, this perceptual learning produces experiences that do not reflect the continuous variation of reality. Instead they warp that variability into discrete groupings such that entities that fall within a group are less discriminable than physically equally spaced entities that fall in different groups, a process known as categorical perception (CP; Harnad, 1987).

While some of the focus in CP research has been on assessing if particular categories are innate through cross-cultural studies (Kay & Reiger, 2003; Roberson & Davidoff, 2000; Sauter et al., 2011), early studies of CP focused on phonemes (Liberman et al., 1957) which show systematically different category boundaries based on an individual’s native language (Logan et al., 1991).

Learned CP has been shown in the visual modality across a variety of dimensions including hue and saturation (Goldstone, 1994), line drawings (Livingston et al., 1998), and morphs between arbitrarily paired faces (Kikutani et al., 2008; 2010).

**Category labels and CP.** An alternative framework suggests that the presence of category labels, and not perceptual changes, are responsible for CP effects (Pisoni & Tash, 1974). In this view the category label can be seen as an additional feature: entities in different categories have different labels thus having an additional feature unique for each category. This causes similarity to decrease and discrimination accuracy to rise. Items in the same category have the same label and thus either their similarity increases or remains constant leading to discrimination accuracy that does not increase.

Hanley and Roberson (2011) point out that the accuracy in assigning category labels is not constant across distance to the category boundary. Items farther away from the boundary are more likely to be categorized correctly than items closer to the category boundary. This viewpoint is consistent with many models of category learning that do not incorporate perceptual learning, including decision boundaries (Ashby & Maddox, 1990) and many exemplar-based (Nosofsky, 1986) models of category learning.

**Within-category discrimination asymmetries.** In perceptual discrimination testing in which a target object (X) must be held in memory and compared to itself and a foil object (A and B, respectively), if A is more likely to be assigned the same category label as X than B, then the probability of selecting A as the answer should increase relative to if A and B are equally likely to be assigned to categories. Therefore, when the target object is farther away from the category boundary than the foil and thus more consistently labeled in the category, accuracy will increase because the target object is more likely to be selected. Similarly, when the foil object is farther away, accuracy will decrease because the foil object will be selected more frequently (compared in both cases to cases in which no labeling asymmetry exists).

Hanley and Roberson (2011; see also Roberson et al., 2007) find this asymmetric within-category advantage for more perceptually extreme targets across a wide array of stimuli for which CP effects have been shown, including color across cultures (Roberson & Davidoff, 2000; Roberson et al., 2000; Roberson et al., 2005), facial emotions (Roberson et al., 2007), morphed celebrity faces and morphed unfamiliar but trained faces (Kikutani et al., 2008; 2010). They failed to find an advantage for more extreme faces among morphed unfamiliar and either untrained (Kikutani et al., 2008) or covertly exposed (Kikutani et al.,

2010) conditions. Recently, Sauter et al. (2011) failed to replicate the within-category asymmetry across cultures for morphed facial emotions despite showing CP effects.

**CP within categories.** Recent evidence has demonstrated (Gureckis & Goldstone, 2008; Hendrickson et al., 2010) that CP effects emerge not only between categories but also within categories. For example, two objects that belong to the same learned category (receiving the same label) may nonetheless have increased discriminability if they belong to different clusters within the category when compared to the case in which they belong to the same cluster. Within-category CP effects occur when the distribution of members of a category is structured into clusters (sub-groups within each category) rather than distributed uniformly (e.g. Goldstone, 1994) or normally (e.g. Ashby & Maddox, 1990).

These within-category CP effects are consistent with models of categorization in which the discriminability of items is not only affected by their category label but also by the learned clustering of items regardless of their labels (Love et al., 2004; McDonnell & Gureckis, 2011). These learning processes account for both within and between category CP effects through representational change: learning new clusters or prototypes that warp the similarity between entities either within or between categories (Goldstone & Hendrickson, 2009).

**Within-cluster discrimination asymmetry.** Interestingly, Gureckis and Goldstone (2008; see also Hendrickson et al., 2010) also found that the magnitude of the CP effects on both the category relevant and the category irrelevant dimensions increased as categorization accuracy improved. Importantly, neither of these CP effects were found before training.

Using this kind of stimuli space, the label ambiguity account of CP hypothesizes that the within-category asymmetry should emerge with the CP effect along the category-relevant dimension and is in fact causing the categorical perception effect. This would be for discriminations perpendicular to the category boundary in a two-dimensional space (see Fig. 1).

What remains unclear is if, within each category, a similar asymmetry should emerge parallel to the category boundary. A strict category label account suggests this should not occur because all stimuli would be equidistant to the category boundary and thus categorized equally accurately. This strict viewpoint would need to postulate a second mechanism to account for within-category CP effects.

Conversely, a category label ambiguity theory of CP that allows each cluster within a category to have a unique label would predict that the asymmetry will occur along the category-irrelevant dimension and that the emergence of the asymmetry will cause the within-category CP effect. The main purpose of this work was to investigate the emergence of within-category asymmetries along both the category relevant and irrelevant dimensions. A pre-post design was used to assess the relative timing during training of the emergence of CP effects and within-category asymmetries.

## Experiment 1

In the first experiment we tested these predictions by measuring perceptual discrimination accuracy along both relevant and irrelevant dimensions before and after category training. The stimuli and category structures were identical to previous studies (Gureckis & Goldstone, 2008; Hendrickson et al., 2010) that showed CP effects both dimensions. The perceptual discrimination task was a two alternative forced choice (2AFC) XAB task similar to those reported by Hanley and Roberson (2011). The within-cluster asymmetry and the standard CP effect were measured along the category relevant and category irrelevant dimensions before and after category training.

## Method

**Participants.** 80 Indiana University undergraduates participated in this experiment for course credit. 1 participant was excluded from analyses for failing to conclude the experiment within the allotted time (60 min).

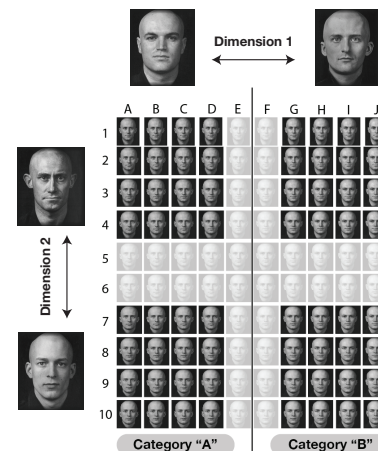

Fig. 1: Stimuli varied along two arbitrary dimensions (1 and 2) forming a 10-by-10 grid of blended faces. The light grey stimuli were not used in discrimination or categorization, introducing a source of within-category structure (two clusters of faces within each category). The vertical line between columns E and F shows an example category boundary used during category learning (the other boundary was a horizontal line between rows 5 and 6).

**Materials.** A 2-dimensional 10 by 10 matrix of bald male faces was created using a standard morphing technique (Steyvers, 1999). Each dimension was created by morphing between two faces selected from Kayser (1997). The two selected faces were roughly equally spaced in the multi-dimensional space based on a pilot similarity judgment task. The 100 stimuli that constitute the full matrix were created by equally morphing between all unique pairs of 10 faces in each of the two dimensions of faces (see Fig. 1).

**Procedure.** The task consisted of a block of 192 discrimination trials (pre-categorization phase), followed by 8 blocks of 16 categorization trials (categorization phase),

and a second block of 192 discrimination trials (post-categorization phase).

Each discrimination trial followed the XAB pattern: a target stimulus (X) was presented for 500 ms in the center of the screen followed by a response screen containing a target and a foil (A and B) stimulus presented horizontally until a response was made. A 500 ms blank screen was presented between the two screens and between trials there was a pause of 1000 ms. Participants were instructed to determine whether A or B was identical to X. The “target” is the option identical to X, and the “foil” is the other choice.

Target and foil face stimuli were selected such that they were identical along one dimension and were separated by 2 face stimuli in the 10 X 10 stimulus space along the other dimension. This spacing was determined by pilot studies to avoid ceiling or floor performance. The two central rows and columns were not used as either targets or foils.

Participants completed 384 discrimination trials broken up into the two blocks). Each block of 192 trials consisted of 12 unique trials in each row (and each column): the first and fourth stimuli in the row were compared four times, the fourth and seventh were compared four times, and the seventh and the tenth stimuli were compared four times (see Fig.1). Within each pair each stimulus was the target twice and with the target occurring equally often on the left and right position. These comparisons were made for 8 rows (excluding the middle two) and 8 columns (or rows), both parallel and perpendicular to the category boundary.

Each categorization trial consisted of a face stimulus appearing in the center of the screen. The two category labels appeared below the stimulus indicating which key (“q” or “p”) should be pressed to indicate that category label. The assignment of labels to keys was randomized on each trial. After participants respond, feedback indicating the correct category label was presented for 1000 ms followed by a pause of 1000 ms between trials. Each non-grey stimulus from Fig. 1 was presented twice in random order during category training.

## Results

**Categorization Performance.** A repeated measures ANOVA with block as a factor revealed a significant effect on categorization accuracy  $F(7,546) = 21.75, p < .0001$ , categorization accuracy improved throughout training.

A linear regression between distance to the center of the category space and categorization accuracy was performed separately for each dimension (category relevant and irrelevant). There was a significant improvement in accuracy for stimuli more distant on the category relevant dimension,  $F(1,236) = 73.7, p < .0001$  but no significant change in categorization accuracy as a function of distance along the irrelevant dimension  $F(1,236) = 1.47, p = .23$ .

**Discrimination Performance.** All discrimination trials were coded in three ways. Half the trials varied along the category relevant dimension (perpendicular to the category boundary) and half along the irrelevant dimension. Discrimination trials

were also coded on the relative extremeness of the target and foil objects: an equal number of trials were coded as “foil more extreme”, “target more extreme” and “equal.” Finally, for traditional CP analyses, the “foil more extreme” and “target more extreme” trials were grouped as Within trials, “equally” extreme trials were coded as Between trials. Between and Within trials could be relative to the category relevant or irrelevant dimension.

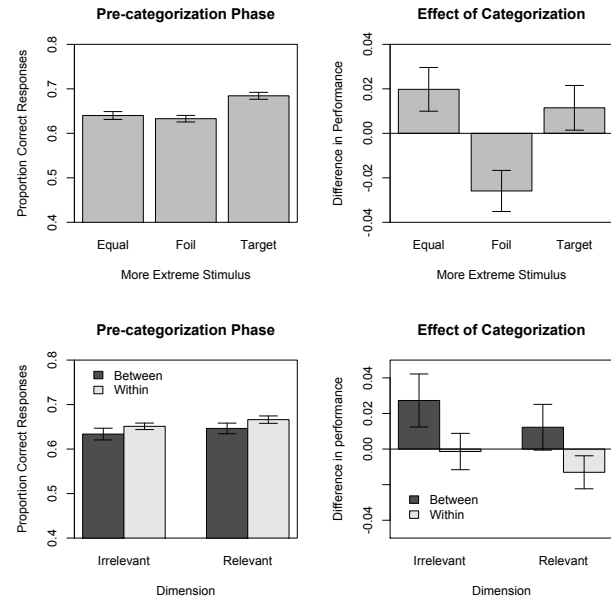

Fig. 2: Experiment 1 Results. Top-left: pre-categorization target-foil extremeness. Top-right: change in target-foil extremeness after categorization. Bottom-left: pre-categorization CP effects, split by dimension. Bottom-right: change in CP effects after categorization, also split. Error bars represent standard errors.

**Pre-categorization phase.** The graph in the top-left panel of Fig. 2 depicts the pre-categorization results, divided by extremeness condition. A 3 x 2 repeated measures ANOVA with relative extremeness (Equal vs. Foil vs. Target) and dimension (Relevant vs. Irrelevant) revealed a main effect of stimulus extremeness,  $F(2,156) = 16.15, p < .0001$ , but no main effect of dimension,  $F(1,78) = 2.06, p = .16$ , or interaction,  $F(2,156) < 1$ . Pairwise comparisons revealed that discrimination accuracy is higher when the target is the more extreme stimulus when compared to when the foil is more extreme,  $p = .0001$ , and when they are equally extreme,  $p = .001$ . The last two types of discrimination trials did not differ,  $p = 1$ . All  $p$  values were adjusted for multiple comparisons using a Bonferroni correction.

The results from the pre-categorization task considering the traditional CP analyses are depicted in the bottom-left panel of Fig. 2. A 2 x 2 repeated measures ANOVA with CP type (Within vs. Between) and dimension (Relevant vs. Irrelevant) as factors revealed a main effect of CP type,  $F(1,78) = 4.34, p = .04$ , with Within more accurate than Between, but no effect of dimension,  $F(1,78) = 1.68, p = .20$ , or interaction between the two variables,  $F(1,78) < 1$ .

**Change in discrimination performance after learning.** The pre-categorization analyses of extremeness and CP type were performed on the change in discrimination performance due to categorization. The change was computed by subtracting the pre-categorization discrimination accuracy from the post-categorization. The top-right panel in Fig. 2 depicts the results for the extremeness effects and the bottom right depicts the same results in terms of CP type.

A 3 x 2 repeated-measures ANOVA with relative extremeness and dimension as factors revealed a main effect of extremeness,  $F(2,156) = 6.89, p = .001$  but no main effect of dimension,  $F(1,78) = 1.33, p = .25$  or interaction,  $F(2,156) < 1$ . Pairwise comparisons revealed that performance changed equally for target more extreme and equally extreme,  $p = 1$ . The change in accuracy for the foil more extreme condition was significantly less than the other types: target more extreme ( $p = .03$ ) and equal ( $p = .005$ ).

To further investigate if accuracy performance improved with categorization, we performed a series of one-sample *t*-tests for each one of the extremeness conditions. The change in accuracy did not significantly differ from 0 for the target more extreme condition,  $t(78) = 1.11, p = .27$  but was significantly lower for foil more extreme,  $t(78) = -2.75, p = .007$ . The change in accuracy of the equal condition was marginally greater than 0,  $t(78) = 1.87, p = .06$ .

A 2 x 2 repeated-measures ANOVA revealed a main effect of CP type,  $F(1,78) = 5.75, p = .02$  but no main effect of dimension,  $F(1,78) = 1.38, p = .24$ , or interaction between the two variables,  $F(1,78) < 0$  (Fig. 2, bottom-right).

## Discussion

The results of Experiment 1 are not consistent with the hypothesis that category label ambiguity causes CP patterns. The pre-categorization phase in Experiment 1 indicates that the asymmetries seen in 2AFC tasks do not depend on the category or verbal codes assigned. More specifically, the results show that discrimination accuracy is higher when the target is more extreme than the foil alternative in the absence of any previous categorization learning. CP patterns were not observed before categorization despite the presence of the within-category asymmetry; in fact the reverse of the CP effect was marginally significant before categorization.

That the asymmetry exists before categorization suggests that it is a result of unsupervised learning processes rather than explicit category labels (Gureckis & Goldstone, 2008; Love et al., 2004). It remains unclear if the unsupervised mechanism is cluster labeling or perceptual change. We revisit this point in the general discussion.

Extremeness along the category relevant dimension predicted categorization accuracy but extremeness along the irrelevant dimension did not. This suggests that the asymmetry along the irrelevant dimension, both before and after categorization training, was not produced by differences in category labeling accuracy.

Categorization training did produce the expected CP effect: Between improved more than Within. This effect was modulated by an asymmetry among the Within trials, the foil

more extreme trials showed decreased performance and the target more extreme showed significantly higher change. This asymmetry is consistent with the category label ambiguity hypothesis and occurred after category training.

The changes in discrimination performance differ between the relevant and irrelevant dimensions. This may have been due to the extensive opportunity for unsupervised learning of cluster structure during pre-categorization discrimination.

## Experiment 2

One hypothesis that must be tested is if the asymmetric change in discrimination performance found after categorization training in Experiment 1 can be accounted for by the increased exposure to the stimuli instead of learning categories. This hypothesis is tested in Experiment 2, which is similar to Experiment 1 in that it consists of two critical blocks of discrimination judgments. However, another block of discrimination trials was substituted for the categorization task. Thus, by comparing performance in the first and last blocks of discrimination trials, which had roughly the same number of exposures to the stimulus as in Experiment 1, we can test the effect of experience with the stimulus space in the absence of categorization experience.

## Method

**Participants.** 76 Indiana University undergraduate students participated in this experiment for course credit. Two participants were excluded from analyses because they did not conclude the experiment in the allotted time (60 min).

**Procedure.** This experiment followed the same general procedure of Experiment 1 except for the exclusion of the categorization phase. Participants completed 3 blocks of discrimination trials. Each block was identical to those in Experiment 1.

## Results

All discrimination trials were coded similar to Experiment 1 but collapsed across dimension because no category boundary was learned. Discrimination trials were coded on the relative extremeness of the target and foil stimuli: an equal number of trials were coded as “foil more extreme”, “target more extreme” and “equal.” Finally, to compare to traditional CP analyses, the “foil more extreme” and “target more extreme” trials were grouped as Within trials, “equally” extreme trials were coded as Between trials.

**1<sup>st</sup> discrimination block.** The accuracy results for the first block of discrimination by extremeness condition are shown in the upper left corner of Fig. 3.

A repeated measures ANOVA revealed a main effect of stimulus extremeness,  $F(2, 146) = 9.03, p < .0001$ . Pairwise comparisons further revealed that trials in which the target was more extreme resulted in better discrimination than trials in which the foil was more extreme,  $p = .006$ , and also trials in which the two stimuli were equally extreme,  $p = .01$ . Finally, there is no difference in accuracy between trials in

which the foil was more extreme and trials in which both stimuli were equally extreme,  $p = 1$  (Fig. 3, top-left panel).

In the traditional CP analysis (despite no category training occurring), discrimination accuracy is higher for Within than Between discrimination trials,  $t(73) = -2.01$ ,  $p = .05$  (see Fig. 3, bottom-left panel).

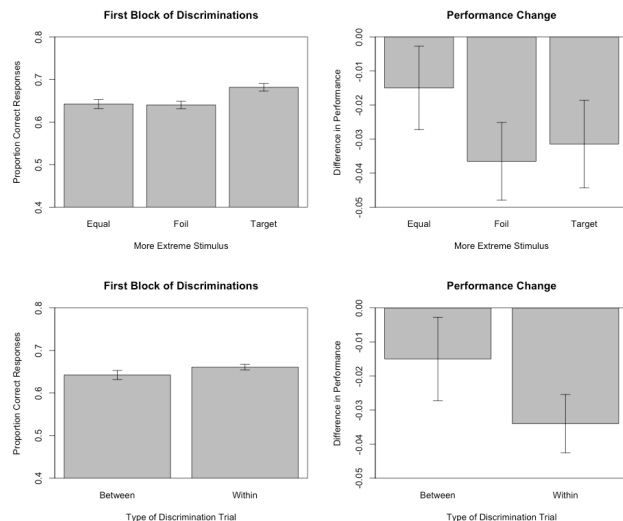

Fig. 3: Experiment 2 results. Top-left: Block 1 target-foil extremeness. Top-right: change in target-foil extremeness after prolonged exposure. Bottom-left: Block 1 CP effects. Bottom-right: change in CP effects after exposure. Error bars represent standard errors.

**Change in discrimination performance.** We computed the difference in accuracy between the last and first blocks to analyze the possible learning effect through successive exposure to discrimination trials. The top-right panel in Fig. 3 depicts the results considering the extremeness analysis while the bottom-right panel shows the results organized in terms of CP analyses.

A within-subjects ANOVA performed on these data revealed no main effect of stimulus extremeness,  $F(2,146) = 1.22$ ,  $p = .30$ . Similarly, when analyzing the change in performance between the last and first blocks of discrimination trials for Within and Between discriminations (see bottom right panel of Fig. 3) there are no significant differences in performance between the two types of discrimination trials,  $t(73) = -1.65$ ,  $p = .1$ .

**Categorization (Exp. 1) vs. Exposure (Exp. 2)** Categorization training ( $M = 0.011$ ) led to significantly higher change in discrimination performance relative to exposure ( $M = -0.031$ ) for target more extreme,  $t(151) = 2.62$ ,  $p = .01$ , as well as for equal trials, (cat.  $M = 0.020$ , exp.  $M = -0.015$ ,  $t(151) = 2.16$ ,  $p = .03$ ). On the contrary, there was not a significant difference between the change in discrimination accuracy for categorization ( $M = -0.026$ ) and exposure ( $M = -0.036$ ) for foil more extreme trials,  $t(151) = 0.72$ ,  $p = .47$ .

## Discussion

The results from the first block of discrimination trials replicate those found in the pre-categorization phase of Experiment 1. The asymmetry between the target and foil more extreme trials existed without category training and when CP patterns were not found.

Without category training, however, comparing the first and last blocks of discrimination in Experiment 2 did not show a change in performance consistent with the CP effect or a change in the difference between equal, target or foil more extreme trials. Performance for all trial types decreased in a consistent way across all trial types. This is likely due to fatigue considering the great number of trials participants complete without any feedback.

Finally, the categorization in Exp. 1 resulted in significantly different performance change for equal and target more extreme trials than what was seen with exposure alone (Exp. 2). However, this was not the case for foil more extreme trials. This suggests that category training improves discrimination for between-category judgments as well as for within-category judgments in which the target is more extreme than the foil.

## General Discussion

The presence of the within-category asymmetry before categorization and for each of the clusters refutes the hypothesis that the asymmetry alone can account for CP patterns or that the asymmetry is a direct result of explicit category labels. Instead these results are consistent with an unsupervised learning mechanism that is sensitive to the distribution of items within categories (Love et al., 2004; McDonnell & Gureckis, 2011) and a decision process for discriminations that distorts extreme exemplars to produce category caricatures in the distribution of items (Goldstone, 1996; Goldstone et al., 2003; Roberson et al., 2007).

The change in discrimination performance after categorization shows an increase in the asymmetry in Experiment 1 but not in Experiment 2. The fact that the asymmetry increases on the category relevant dimension as well as the irrelevant dimension is a challenge to the category label ambiguity hypothesis (Hanley & Roberson, 2011). To account for this behavior, the labeling hypothesis must be expanded to allow individual clusters within categories, learned via unsupervised mechanisms, to be assigned unique labels as in SUSTAIN (Love et al., 2004) or other semi-supervised learning models (McDonnell & Gureckis, 2011).

However, the fact that the effect of extremeness in a 2AFC task is observed before any category learning has taken place points to a biasing effect of extremeness within a stimulus set rather than category learning *per se*. Consequently, the relative change in performance seen after category learning might result from category learning processes that produce warped caricatures by shifting perceptual representations toward the stimulus extremes (Goldstone, 1996; Goldstone et al., 2003). This account is consistent with the relative improvement in between-category (and cluster) judgments as well as target more extreme judgments after categorization

relative to exposure alone for both the relevant and irrelevant dimensions.

We believe the strongest message from this work is the critical importance of measuring the change in perceptual discrimination performance to understand the learning mechanisms that underlie CP. Going forward, we plan to expand this analysis to look at changes in within-category asymmetries under conditions of verbal interference that may impair label usage (Hendrickson et al., 2010; Roberson et al., 2007) and formalize the unsupervised learning predictions in an extension of the SUSTAIN computational modeling framework (Love et al. 2004; Gureckis & Goldstone, 2008).

## Abstract

How do people learn to group and re-group objects into labeled categories? In this paper, we examine mechanisms that guide how people re-represent categories. In two experiments, we examine what is easy and what is hard to relearn as people update their knowledge about labeled groups of objects. In Study 1, we test how people learn and re-learn to group objects that share no perceptual features. Data suggest that people easily learn to re-label objects when the category structure remains the same. In Study 2, we test whether more general types of labeling conventions -- words that do or do not correspond with object similarities -- influence learning and re-learning. Data suggest that people are able to learn either kind of convention and may have trouble switching between them when re-structuring their knowledge. Implications for category learning, second language acquisition and updating representations are discussed.

**Keywords:** categories, labels, learning and transfer, knowledge change

## Introduction

An eighth-grade science student will happily tell you that she has just learned the electrons and nucleus of an atom are very similar to the planets and sun in our solar system. She now has a “multi-body orbiting systems” category with both of these systems as members. This approach is a classic example of transferring knowledge: information she previously learned about the solar system can be applied to the atom. But the story doesn’t end there: a physicist will tell you the truth is that an atom doesn’t really work that way, electrons are quantum wave functions that do not orbit a central point. New information causes the analogy to break down and if the eighth-grader continues to study physics she will learn new categorizations because the solar system belongs with systems explained by Newtonian mechanics while the atom belongs with quantum systems.

The process of relearning categories and reshaping knowledge is important not only for shifting from novice to expert but also for learning new ways to use words. Many languages group objects, relations and events in different ways (e.g., Majid, Boster, & Bowerman, 2008; Malt, Sloman, & Gennari, 2003; Wolff, Jeon, & Yu, 2009) and second language learners must categorize in new ways in order to speak their second language conventionally.

In laboratory category learning tasks, relearning has been studied using highly structured, binary dimensions. Using 3-dimensional binary stimuli, Kruschke (1996) found a clear hierarchy in the speed of relearning. Preserving the same

classification rule but reversing the response options is relearned the fastest, and switching to a new classification rule that involves a previously relevant dimension is more quickly learned than a rule using a previously irrelevant dimension. This pattern of results is consistent with the reversal learning literature (e.g., Kendler & D’Amato, 1954) and successfully modeled with straightforward extensions of many attention-shifting exemplar-based categorization models (e.g., Kruschke, 1996).

The main goal of this work is to examine category re-learning for categories that are not clearly defined by rules. Many categories in the world and in language do not obey a simple rule-based classification scheme, and it is interesting to consider the challenges that learners may face as they structure and re-structure their knowledge about these categories. In this work, we focus on how people learn to group and re-group objects into labeled categories.

Examining how people re-learn to group objects into categories has the potential to reveal insights into three important issues. First, does existing evidence about category learning and re-learning (e.g., with rule-based categories) extend to other kinds of categories? This is important to understand for more general theories of knowledge development. Second, how do people represent labeled groups of objects? What role does a label play in structuring knowledge (e.g., label-as-feature vs. label-as-category-marker, Deng & Sloutsky, 2012; Gelman & Markman, 1986)? This hotly-debated issue may benefit from data about patterns of re-learning because transfer paradigms are a useful way to assess what has been represented, on the logic that people are better able to re-learn structures that closely match what they had originally represented (e.g., Kruschke, 1996). Finally, second language learners are a large part of the world’s population and when people learn a new language they often must learn to categorize objects in different ways. What are the mechanisms that guide this re-representation?

As a first step toward these aims, here we consider a variety of potential changes between initial learning and relearning. In the experiments described below, people first learn a category structure and then are asked to relearn across a variety of potential changes. These changes reflect potential real-world relearning situations and the question becomes: what is easy and what is hard to re-learn as people re-structure their knowledge about labeled groups of objects?

## Study 1: Re-learning with unrelated objects

In Study 1, we examined several learning and re-learning relationships. In all scenarios, participants first learned to label nine objects. These nine objects were grouped into three categories; three labels were paired with three objects. After learning the initial categorization, participants re-learn. We manipulated what information remained constant and what changed between learning phases. Participants faced re-learning scenarios in which either the objects, the labels, the grouping of objects, and/or the mapping between groups and labels changed (see Table 1). Scenarios in which people quickly adapt to new object-label mappings are likely to be scenarios that conserve whatever representations they learned from labeling the original nine objects. Scenarios that people find more difficult likely overlap less with the learned representations. Thus, how easy it is to adapt to new object-label mappings has the potential to reveal some aspects of how people represent labeled objects.

Several patterns of re-learning data would be informative. In particular, the data may distinguish whether learners represent the information in the following ways: (a) Learners associate each distinct object with its appropriate label, or (b) Learners associate objects with labels, and also represent that the three similarly labeled objects are related to each other. That is, despite the fact that objects never appear together participants may learn the object groupings by virtue of sharing a label. Relearning patterns can also disambiguate between the potential interference or benefit of relearning new pairings or groupings of old objects compared to novel objects. We examine these questions in the following experiment.

Figure 1: (a) An initial learning structure with 9 objects randomly assigned to 3 labels (by row). (b) A re-learning structure in the Re-Group & Re-name condition. Old objects grouped in a different way with novel labels.

## Method

**Participants.** 180 Indiana University undergraduates participated for course credit. 38 participants failed to complete the study in the allotted time and were excluded from analyses. Participants were randomly assigned to one of seven conditions ( $n = 19$  to  $23$  for each condition).

**Materials.** Figure 1 shows the objects and labels that one participant might see during (a) learning and (b) re-learning. For object stimuli, 72 unique segments were formed by fitting a spline through 8 randomly perturbed points along a 90-degree arc. Objects were created by combining 4 segments; a unique set of 18 objects was created for each

participant by sampling without replacement from the set of segments and arranging them to form a continuous outline. Labels were novel words from the set of {*beme*, *vade*, *kipe*, *coge*, *zune*, *tyfe*}. Other than the final “e” for all words, no letter was repeated across labels.

**Design.** All participants completed an original learning phase and then a re-learning phase. For each participant, nine of 18 objects and three of six labels were randomly selected for the initial learning phase. The remaining objects and labels were used in re-learning if needed. Conditions were defined by the changes between learning and re-learning (see Table 1).

Table 1: Re-learning Conditions in Study 1

Re-learning Condition	Items		Grouping Structure Conserved		Object-Label Associations Conserved	
	Objects	Labels	Yes	No	Yes	No
Learned	Old	Old	✓		✓	
Re-map	Old	Old	✓			✓
Re-name	Old	New	✓			✓
Re-group	Old	Old		✓		✓
Re-group & Re-name	Old	New		✓		✓
Recycled Name	New	Old		✓		✓
Novel	New	New		✓		✓

In some cases, new mappings between objects and labels were prompted only by substituting either new objects or new labels for the old objects and labels already learned. For example, a participant in the **Recycled name** condition might have used “*beme*” to label three objects during learning and then learned to re-use “*beme*” to label a novel three objects during re-learning. Similarly, a participant in the **Re-name** condition might have first learned that three objects were all called “*beme*” and then re-learned that they are all called “*zune*,” a name that had not been presented before. In these conditions, participants saw one set of objects [or labels] during learning and a different set of objects [or labels] during re-learning.

In other cases, new mappings between objects and labels reorganized the structure of previously learned categories using old objects. For example, consider a participant who first learned that three objects are each called “*beme*,” another three are each called “*zune*,” and a final three are each called “*coge*.” In **Re-map**, they might later re-learn that the first three are now called “*zune*,” the second three “*coge*,” and the third three “*beme*.” The grouping of objects is intact, the mapping between objects and labels is not. In **Re-group**, they might later re-learn that “*beme*” is now used for one object previously called “*beme*,” one object previously called “*coge*,” and one object previously called “*zune*.” This breaks the grouping of objects. In **Re-group & Re-name**, they might later learn to use “*kipe*,” a label not previously presented, to label three objects that had previously been called “*beme*,” “*coge*,” and “*zune*.” This breaks the grouping of objects and uses new labels.

Two other conditions gave participants no conflict with what was learned before – in one they continued with the

same objects, labels, and mapping between them as they had originally learned (**Learned**) and in another they learned about totally new objects and labels (**Novel**).

**Procedure.** On every trial, participants saw one object and three possible labels (Figure 2). The starting position of the cursor was equidistant from all response options and the location of labels was randomly determined on every trial. Participants were asked “Which category does this belong in?” The object and labels remained on the screen until the participant made a response. Afterward, feedback appeared above the object for 1200 ms: “Correct [Incorrect]! This is a \_\_\_\_.” Feedback included the correct label for all responses. There was a 400 ms pause between trials.

Figure 2: A sample trial.

Participants completed the learning phase in blocks of 9 trials. In each block, every object was presented once. Participants continued in this learning phase until they were correct on at least 8 out of 9 trials in a block for 4 consecutive blocks. Thus, everyone learned the original categories to criterion.

Participants then started the re-learning phase, reading these instructions: “You are doing great. In the next section the categories may change.” The re-learning phase consisted of 5 blocks in which all of the 9 stimuli were presented 3 times.

## Results

**Initial Learning.** The minimum number of blocks to reach criterion during the initial learning was 7 and the maximum number was 94. Participants reached criterion with a mean of 34.1 and a median of 31.0 blocks.

**Re-learning.** People’s performance in the relearning phase depended on block and condition. Re-learning data were analyzed using an ANCOVA, with categorization accuracy as the dependent variable, condition (7 levels) as a factor, and block (5 blocks) as a covariate. There were main effects of Condition ( $F(6, 135) = 23.1, p < 0.0001$ ) and Block ( $F(1,561) = 491.5, p < 0.0001$ ), and a significant interaction between Condition and Block ( $F(6,561) = 12.9, p < 0.0001$ ).

In order to interpret the interaction between Condition and Block, the trajectory of accuracy across block for each subject was clustered into groups and the distribution of each category within clusters was compared. The trajectories were clustered with methods to estimate the appropriate number of clusters (Kaufman & Rousseeuw, 1990). This technique identified two clusters, where one cluster was characteristic of three conditions: Learned (all 19 subjects), Re-name (19 of 20), and Re-map (16 of 21). These were conditions in which the original grouping of

Figure 3: Participants’ mean accuracy by condition across re-learning in Study 1. Re-learning was faster than Original Learning. Of the re-learning conditions, Learned, Re-name, and Re-map show higher performance than the others.

objects were conserved from learning to re-learning (i.e., the first three rows of Table 1). The other cluster was characteristic of three conditions: Novel (14 of 19), Recycled Name (14 of 20), and Re-group & Re-name (17 of 23). The Re-group condition was equally split between both clusters (10 of 20 in each).

## Discussion

Performance during relearning depended on whether or not the groupings of objects were maintained from learning to re-learning. The three conditions in the higher accuracy cluster – Learned, Re-map, and Re-name – all conserved the grouping of objects from learning to relearning. The conditions strongly consistent with the lower accuracy cluster – Re-Group & Rename, Recycled Name, and Novel – did not preserve any groupings, either because they consisted of novel objects or because the three objects mapped to one label in relearning had not been mapped to a common label during learning.

The participants in the Re-group condition were equally split between the two clusters. In this condition, the nine objects that people saw during learning and re-learning were the same. Three of these were associated with the same name (one per label) during learning and re-learning, while the remaining six became associated with a different name during relearning (due to re-grouping the objects). The split between clusters suggests participants in this condition may have used different strategies, with some individuals less disrupted by the re-grouping because they were able to use object-label mappings that were identical between learning and re-learning but others learned representations that strongly relied on groupings, which were not conserved.

Study 1 suggests that labels — novel or re-purposed — are relatively easy to re-map to a group of objects. Learning new object groupings or re-groupings is more difficult.

These data suggest that learners may have successfully represented more than object-to-label mappings for each individual object and instead capitalized on structure among objects. We discuss this idea further after considering another interesting case of learning and re-learning.

## Study 2: Re-learning with related objects

The objects in Study 1 could be grouped into categories in only by using the labels because the objects shared no segments. How do people learn and re-learn *related* objects? In what way(s) does similarity among objects influence object grouping and impact re-learning?

To examine these issues, we again used a category learning and re-learning paradigm in Study 2. There are three main differences in Study 2: (a) objects were created such that they had structured similarity because some objects contained the same segments in the same locations; (b) the nature of mapping between objects and labels was manipulated to be consistent or inconsistent with object similarity. The mapping from training could either persist or switch from learning to re-learning; (c) all re-learning scenarios used novel labels and old objects. The non-control conditions in Study 2 all involved breaking the grouping of objects with the goal of understanding how relearning is influenced by the mapping between object similarity and category labels.

## Method

**Participants.** 107 Indiana University undergraduates participated in this study for course credit. 30 participants (evenly distributed across conditions) did not complete the study in the allotted time and were excluded from analyses. Participants were randomly assigned to one of six conditions ( $n = 11$  to 14 per condition).

**Materials.** Objects were created by combining four segments from a set of 72 segments. Nine objects were created for every participant. Instead of randomly selecting unique segments without replacement for each location of every object, some segments repeated across objects.

Specifically, two segments of every object also appeared in exactly two other objects (see columns 2 and 4 of the stimuli dimensions in Table 2). No two objects shared more than one segment and the location of the repeated segments was constrained so that they were not adjacent to each other. The other two locations were unique segments sampled without replacement (columns 1 and 3).

Further, in order to avoid possible preferences for a particular spatial location (e.g., whatever appears in the “top left quadrant” is easier to learn because of looking tendencies), a random number between 1 and 360 was selected for every participant and all objects for that person were rotated that many degrees.

In all conditions, different labels were used during learning and re-learning. For learning, three labels were randomly sampled without replacement from the same set of labels used in Study 1. The remaining three labels were used during re-learning.

Table 2: Stimuli and condition structure in Study 2

Stimuli	Learning		Re-Learning	
	Many	One	Many	One
1 1 1 1	A	A	D	D
2 1 2 2	C	A	E	E
3 1 3 3	B	A	F	F
4 2 4 1	B	B	E	D
5 2 5 2	A	B	F	E
6 2 6 3	C	B	D	F
7 3 7 1	C	C	F	D
8 3 8 2	B	C	E	E
9 3 9 3	A	C	D	F

*Objects:* Four segments per object, columns indicates a location. Within a column, the same number indicates an identical segment. Across columns, numbers are unrelated. *Learning & Relearning:* Letters indicate labels. In “One” columns, a label matches one segment (Learning-One, Segment 2; Relearning-One, Segment 4). In “Many” columns, no single feature matches a label.

Figure 4: Example categories (Study 2). “One”: shared segment in upper right. “Many”: All unique segments.

**Design.** Categories were defined by the nature of segment-to-label mapping. The One category structures had a one-to-one mapping between segments in a location and labels (see Table 2). The Many structures did not have a one-to-one mapping, and never shared a segment within a category.

**Conditions were defined by the type of structures in learning and re-learning.** Learning and re-learning structures were combined so that some participants continued in the same style of mapping (One-One; Many-Many conditions) while others switched (One-Many; Many-One conditions). All participants in these conditions learned new ways to group objects during re-learning regardless of the type of mapping in learning and re-learning, the group of objects that shared the same label changed.

Two additional control conditions did not change the category structure between learning and re-learning though novel labels were introduced. In “Same One” participants started and remained in a “One” structure and in “Same Many” participants stayed in a “Many” structure.

**Procedure.** Learning and re-learning was exactly like Study 1. After re-learning, people did a re-test in which they tried to recall the label that they had *originally* learned for every object. They were instructed “In this final section we will ask you about the first labels you learned. You will not be told if you were correct or not, please do the best you can.” The re-test trials only displayed the original labels and no feedback was provided. People saw each object 8 times.

## Results

**Initial Learning.** People reached criterion in about the same number of blocks during each kind of initial training (One:  $M = 35.2$ , Many:  $M = 41.7$ ,  $t(75) = 1.5$ ,  $p = 0.14$ ).

Figure 5: Participants' mean accuracy in Re-learning (Study 2). The Same conditions are easy, followed by Many-Many, Many-One, and to some extent One-One. One-Many is more difficult, like the Original Learning.

**Relearning.** People's performance in the relearning phase depended on block and condition (Figure 5). Re-learning data were analyzed using an ANCOVA, with accuracy as the dependent variable, Condition (6 levels) as a factor and Block (5 blocks) as a covariate. There were main effects of Condition ( $F(5,71) = 12.7$ ,  $p < 0.0001$ ) and Block ( $F(1,302) = 275.4$ ,  $p < 0.0001$ ), and a significant interaction between Condition and Block ( $F(5, 302) = 9.5$ ,  $p < 0.0001$ ).

Like Study 1, a clustering analysis was performed using the accuracy data across block for every participant and was best fit with 3 clusters. The highest accuracy cluster was most consistent with the two conditions in which object groupings did not change from learning to re-learning: Same Many (10 of 12) and Same One (12 of 14). A second cluster was most consistent with the two conditions that did change groupings but started with the Many mapping: Many-One (7 of 11) and Many-Many (9 of 12). The third cluster was most consistent with the One-Many condition (10 of 13). The One-One condition was equally consistent with the second and third clusters (6 of 13 in each). Thus, switching from a One structure, where a segment and label are paired, to a Many structure, where many segments map to a label, appeared to be particularly challenging.

**Re-test.** After re-learning, people's memory for the originally learned labels did not appear to be strongly influenced by Condition or Block. Memory accuracy was analyzed using an ANCOVA with accuracy in the re-test as the dependent measure, Condition (6 levels) as a factor and Block (4 blocks) as a covariate. A marginal effect of Condition was found ( $F(5,70) = 2.2$ ,  $p = 0.062$ ). No

significant effect of Block was found ( $F(1,222) < 1$ ,  $p = 0.5$ ). There was no significant interaction between Condition and Block ( $F(5, 222) = 1.4$ ,  $p = 0.21$ ).

To better understand the marginal effect of Condition, pair-wise post-hoc tests showed that the accuracy in the Many-Many condition ( $M = 0.73$ ) was significantly lower than Same-Many ( $M = 0.91$ ,  $p = 0.006$ ). All other conditions were not significantly different ( $p > 0.01$ ).

## Discussion

When people learned novel labels for objects, they had the easiest time if the original groupings of objects were preserved. Using new words to talk about old groups was equally easy whether or not the original groupings were mapped to labels based on repeated, shared segments or based on individual items. If the grouping of objects was disrupted, however, people who had originally learned a Many mapping (i.e., item-specific association with labels) re-learned faster than those who had learned a One mapping (i.e., repeated-segment association with labels).

Why is it easier to learn new labels for new groups after having first learned an item-specific labeling convention than after having learned a labeling convention that capitalizes on perceptual similarity? Learning that words are used for similar objects (i.e., One-One and One-Many) may have directed attention to a common, predictive feature for each word. Re-learning to label these objects may be hard when this feature is no longer predictive. But shifting attention to different features might be easier if you have learned that words are used on an object-by-object basis – this is a useful approach during “re-learning” even when the particular mappings change. Thus, generalizations about “labeling conventions” may influence later re-learning.

Interestingly, people may learn labeling conventions that capitalize on perceptual similarity in different ways. In this study, participants in the One-One condition were equally split between the two clusters. The group of people who were clustered with the Many-Many and Many-One conditions may have been able to re-learn easily because they discovered the new shared feature during re-learning. In addition to the original associations between objects and labels, these people may have learned that there *is* a feature that predicts a label. They then successfully transferred this generalization during re-learning. The other group of people in this One-One condition may have learned the original association between a shared feature and its label but not the higher order pattern and could not later shift their attention.

Re-learning is even more challenging if people must overcome not only a learned association between a specific feature and a label, but also the higher-order generalization that there *will be* one feature that predicts each label. This is the situation of learners in the One-Many condition, and indeed, they performed the worst during re-learning.

Is there more than one way to successfully re-learn after having learned a labeling convention that is item-specific? This is an open question. In the Many-Many and Many-One conditions, people initially learned item-specific mappings

between objects and labels. In the re-learning, even though people in the “Many-One” condition could have learned to associate labels with shared features, they also could have learned these associations in an item-specific way. The fact that people in the Many-Many and Many-One conditions showed similar re-learning trajectories suggests that this may have been a common strategy. Thus, it is possible people in all re-learning scenarios were likely to continue using whatever labeling convention they had originally used (either item-specific, or shared feature). It just happens to be that an item-specific strategy leads to success throughout learning and re-learning, while a labeling convention that relies on perceptual similarity (shared features) does not.

## General Discussion

Data from two experiments suggest that people easily learn to re-label objects when the category structure remains the same from original to subsequent learning. Further, people can learn multiple labeling conventions – words do or do not correspond with object similarities – but may have trouble switching between them when restructuring their knowledge. Like advantages for using relevant dimensions when re-learning rule-based categories (Kruschke, 1996), there are advantages to using existing category structures when re-learning arbitrary or similarity-based categories.

The advantage for shared structure, as well as shared labeling conventions, may help to explain some difficulties that adults face when learning a second language. It should be especially hard to learn new labels for objects that are organized differently in the two languages compared to objects that are categorized similarly. Moreover, an intriguing possibility is that once learners have made higher-order generalizations about the kinds of non-linguistic structure that predict labels, they may find it hard to “start from scratch” and build new associations as they construct different similarity spaces. Interesting test cases of this idea would be to see if L2 learners make systematic labeling errors based on L1 structure (and change over the course of L2 learning), and also whether object similarity spaces are predictably different in bilinguals than monolinguals.

Labels may play a critical role in forming categories and shaping representations (e.g., Goldstone, 1994; Goldstone & Hendrickson, 2009) and these representational changes may persist during subsequent use. The re-learning tasks used here raise interesting questions about how labels may wax and wane as drivers of representation and re-representation. We suggest that a focus on *change over time*, together with approaches that test knowledge structures at a single moment will enrich our understanding of these issues.

Learning any particular structure can be a double-edged sword. Subsequently learning a very similar structure may be easy, but it may be much harder to learn very different structures. In the case of language, different labeling conventions may promote relatively richer or shallower encoding of individual object representations. For example, if it is possible to successfully label objects by paying attention to a single shared feature, then using labels to learn

these categories may promote a representation that prioritizes this feature. But, if it is necessary to pay attention to multiple aspects of objects in order to talk about them, then people will (e.g., Slobin, 2003). Thus, the complexity of the mapping between labels and structures might shape subsequent representations via perceptual learning (Goldstone & Hendrickson, 2009). It may be easy to use them in some situations, but harder in others.

In general, transferring knowledge to new situations is easier after deeply encoding the relevant structure and certain kinds of initial exposure promote this kind of encoding (e.g., Day & Goldstone, 2011; Gentner & Markman, 1997). It is an interesting open question to consider what aspects of language learning – what labeling conventions, used at what points of learning about the relevant structures and categories in one’s world – support different trajectories of developing object representations.

# A Matter of Process Accuracy: Observing or Inferring the Criterion of Few or Many Exemplars

Maria P. Henriksson (maria.henriksson@psyk.uu.se)

Department of Psychology, Uppsala University  
SE-751 42, Uppsala, Sweden

## Abstract

Can we tailor fit the training to enhance judgment accuracy by changing to the learning format that invites the most effective cognitive process for the task environment at hand? The results from a study on multiple-cue judgments revealed that observing the cues and the criterion of exemplars simultaneously with no feedback involved in the training, a learning format predicted to invite exemplar memory processes, was the better learning option when there were few unique exemplars in training. Inferring the criteria of different exemplars and receiving outcome feedback during training, a learning format predicted to invite cue-abstraction, was the better learning option when there were many unique exemplars in training. Implications for the notion of an initial “rule bias” suggested by several previous studies are discussed.

**Keywords:** rule-bias; observation; feedback; cue-abstraction; exemplar memory

## Introduction

Virtually all research on multiple-cue judgment has involved the learning format *feedback learning* and multiple-cue learning has often, more or less explicitly, been regarded as an analytic or rule-based process, where outcome feedback is used to adjust cue weights and to test hypotheses about the cue-criterion relations (Klayman, 1988). The *Cue-Abstraction Model* (CAM; e.g. Juslin, Karlsson & Olsson, 2008) is a cognitive model capturing many of these properties of the judgment process, assuming explicit knowledge about cue-weights and a controlled integration of information by an additive rule (see the Method section for more information about this model). If the analytic, abstract knowledge assumed with the CAM accurately reflects (or well approximates) the task environment, the judgments become independent of the concrete exemplars encountered during training. Judgment accuracy for old exemplars experienced in training and new exemplars should thus be similar, with ability to extrapolate the judgments beyond the observed range of training exemplars (DeLosh, Bussemeyer, McDaniel, 1997).

However, feedback learning is not the only learning format. In the related domain of category learning there is a growing interest in investigating the effects of *observation learning* where no feedback is involved and people learn from observing the cues and the criterion (see, e.g., Ashby, Maddox, & Bohil, 2002). There is also some evidence that exemplar memory processes can better describe the performance with observation learning than with the

standard feedback learning format (Estes, 1994). A recent study on multiple-cue judgments revealed evidence that observation learning invites exemplar processes and is able to exploit more complex task environments with resulting superior performance when the cues are multiplicatively related to the criterion in the task environment (Henriksson, Enkvist & Juslin, 2012). This suggests that exemplar processes might be used by observation learners who only have to store the information about exemplars in memory and use the similarity to these stored exemplars when assessing the criterion value of new exemplars in subsequent judgments. In contrast to the predictions for CAM, exemplar processes predicts that judgment accuracy for old exemplars experienced in training is superior to the judgment accuracy for new exemplars, and that judgments cannot extrapolate beyond the training range of exemplars (DeLosh et al., 1997; Medin & Schaffer, 1978; Nosofsky, 1986). See Method section for more information about this model.

In categorization, Rouder and Ratcliff (2004) have found evidence that exemplar processes provides a better account of the data when there are few and distinct exemplars and rule-based processes provides a better account of the data when the exemplars are confusable and not distinct from each other, for example when exemplars are probabilistically assigned to a category. It is conceivable that exemplar processes might be more vulnerable to the number of unique exemplars in the task environment. As the number of different exemplars increases with experience, the memorization might become difficult with interference between exemplars. Thus, the accuracy of exemplar processes might be constrained to task environments where there are a limited number of training exemplars. On the other hand, a cue-abstraction process might require experience of many different exemplars varying on the cue-dimensions for testing and fine-tuning hypotheses about the relative cue-weights and the relationship between cues and the criterion. The prediction for the multiple-cue judgment task is therefore that the better relative fit of EBM (i.e., clearer advantage for EBM over CAM), the better the judgment accuracy when there are few exemplars in training. When there are many training exemplars the prediction is that the better relative fit of CAM the better judgment accuracy.

The recurring “rule bias” (Ashby, Alfonso-Reese & Turken., 1998, p. 467), an initial inclination for analytical processes, is perhaps not surprising considering that the feedback format is often applied in studies on categorization and multiple-cue judgment. It is possible that feedback

learning per se invites relatively more cue-abstraction (CAM) or at least reinforces that kind of process. However, it is reasonable to appreciate that exemplar processes can act as a back-up process whenever rule-based processes fails to exploit the task environment (Juslin et al., 2008; Karlsson, Juslin & Olsson, 2008). It is possible that the previous reported shifts to exemplar processes (Ashby et al., 1998; Erickson & Kruschke, 1998; Kalish, Lewandowsky & Davies, 2005) may in part be mediated by a spontaneous shift to observation learning. For example, if the task is difficult to learn by testing explicit hypotheses against feedback, the participant could start to randomly guess the missing value and wait for the correct outcome feedback to appear. Then, the participant will have the same information as an observation learner who only has to store the information in memory for subsequent use.

In sum, the predictions are that with few exemplars, observation is predicted to produce higher accuracy than feedback by inviting the EBM. With many exemplars, feedback learning is predicted to produce higher judgment accuracy than observation by inviting the CAM (see Figure 1 for the predictions).

Figure 1. Predicted judgment accuracy and invited processes for feedback and observation learners after training with few or many exemplars.

## Method

### Participants

Sixty-four students from Uppsala University volunteered. Seven were excluded since their test performance indicated no learning. Of the remaining 57 participants, 40 were women and 17 men with the average age of 24.86 ( $SD=7.20$ ).

### Materials, Procedure, and Design

A computerized multiple-cue learning task was presented to the participants instructing them to learn the suitability for an unspecified job based on values ranging from 0-10 on four cues describing different applicants. The cues were *independent*, *thoughtful*, *detailed-oriented*, and *practical* and they were stated on the computer screen along with the cue-value describing each individual exemplar.

The criterion  $c$ , the degree of suitability of the exemplar is a linear, additive function of the cues  $C$ , with the most important cue with a relative weight of .4 and the second-most important cue with a relative weight of .3 and so forth

(see Equation 1)<sup>1</sup>. The assignment of the labels of the cues to the relative cue-weights was counterbalanced across the participants.

$$c = 500 + .4 \cdot C_1 + .3 \cdot C_2 + .2 \cdot C_3 + .1 \cdot C_4 \quad (1)$$

Among the  $11^4$  possible exemplars that can be generated, two sets of training exemplars were sampled, each with a criterion ranging from 510 to 590. The 16 training exemplars in the condition *few exemplars* were presented 10 times in a randomized order. In the condition *many exemplars* the 16 exemplars were presented only once along with 144 other exemplars in a randomized order (in total 160 training trials in each condition). At test, the 16 exemplars reoccurred together with 14 new exemplars, all with criterion values ranging from 500 to 600. The 30 test exemplars were presented twice in a randomized order. At test, 12 of the old exemplars experienced in training were matched to 12 new exemplars with the same criterion in order to examine new-old differences.

A 2 x 2 factorial design was used and participants were randomly assigned to one of four experimental conditions. The independent variables were the learning format (observation and feedback) and the numbers of exemplars in training (few or many). All participants were told that they were going to learn the degree of suitability of different presented applicants. Half of the participants were told that they should learn by observing the cues and the criterion of different exemplars, similar to screening lists of previous employees' characteristics and degrees' of suitability (observation learning). The other half was told that they should observe the cues describing each individual exemplar and predict the missing criterion value. After each judgment, outcome feedback about the criterion was provided to the participant (feedback learning). Half of the participants in each learning condition experienced few unique training exemplars and the other half experienced many unique exemplars. After the training phase a test phase followed that was identical for all participants. All participants were informed that no feedback should be received during or after this test phase.

### The Models and Dependent variables

The *Cue-Abstraction Model* (CAM; e.g. Juslin et al., 2008) assumes that the participants abstract cue-weights in training, analogue to linear regression weights. When they later judge the criterion of a probe, they use the knowledge of the cue-weights to integrate the linear additive impact of the cues. For each cue  $C_i$ , the weight  $w_i$  ( $i=1 \dots 4$ ) is used when adjusting the criterion  $\hat{c}$  of a probe  $p$ ,

<sup>1</sup> Two cues were positively related to the criterion and two cues were negatively related to the criterion so as not to make identification of cue-directions trivial (i.e., with high cue-values always predicting high suitability and low cue-values always predicting low suitability).

$$\hat{c}_p = a + \sum_{i=1}^4 \omega_i \cdot C_i \quad (2)$$

where the intercept  $a$  and the weights  $\omega$  are parameters in the model.

The *Exemplar-Based Model* (EBM) refers to a version of the generalized context model (Nosofsky, 1986) that is applicable to multiple-cue learning (e.g., Juslin et al., 2008). As many exemplar-based models assume (e.g., Medin & Schaffer, 1978; Nosofsky, 1986), people store memory traces of concrete exemplars together with the outcome. At the time of judgment, people retrieve similar exemplars from long-term memory. According to the Generalized Context Model (GCM: Nosofsky, 1986), the similarity to stored exemplars depends on the attention to the cue dimensions and the sensitivity for the distance between the exemplars in the psychological space. The distance between the probe  $p$  and an exemplar  $j$  is given by,

$$d_{pj} = h \left[ \sum_{m=1}^4 w_m |x_{pm} - x_{jm}|^r \right]^{1/r} \quad (3)$$

where  $x_{pm}$  and  $x_{jm}$  are values of the probe and the exemplar on cue dimension  $m$  ( $m=1..4$ ),  $w_m$  are attention weights on cue dimension  $m$ , and  $h$  is a parameter that captures the sensitivity for the distance between the exemplars in the psychological space. The sensitivity varies from 0 to  $\infty$ . The attention weights on cues vary between 0 and 1 and are constrained to sum up to 1. Euclidian metric is used and  $r$  is set to 2. The overall similarity between a probe  $p$  and exemplar  $j$  is assumed to be a nonlinear decreasing function of their distance  $d_{pj}$  in the psychological space,

$$S(p, x_j) = e^{-d_{pj}} \quad (4)$$

EBM implies that the criterion  $\hat{c}$  of a probe  $p$  is assessed by,

$$\hat{c}_p = \frac{\sum_{j=1}^4 S_j \cdot c_j}{\sum_{j=1}^4 S_j} \quad (5)$$

where  $S_j$  is the similarity to exemplar  $j$ , and  $c_j$  is the criterion of exemplar  $j$ . The estimated criterion of a probe is the weighted average of the criteria of similar exemplars retrieved from long-term memory, where the similarity is the weight (see Juslin et al., 2008).

This exemplar model and the cue-abstraction model (Juslin et al., 2008) were fitted individually to the responses by each participant in the test phase. A cross-validation procedure was used in the modeling and the model fit is measured by *Root Mean Squared Deviation* (*RMSD*) between the model prediction and the judgment<sup>2</sup>. Judgment accuracy in the test phase is measured by *Root Mean Squared Error* (*RMSE*) between the judgment and the

criterion. Hence, the lower value of *RMSE*, the better judgment accuracy. Deltafit ( $\Delta$ fit), a measure of the relative differences in fit of EBM and CAM was computed by subtracting the *RMSD* for CAM from the *RMSD* for EBM so that negative values corresponds to a relatively better fit for EBM and positive values corresponds to a relatively better fit for CAM. Separate analyses of the correlations between the deltafit and judgment accuracy (*RMSE*) can therefore be calculated in order to explore how useful the two cognitive processes are for achieving accuracy when experiencing few or many training exemplars.

## Results

A split-plot ANOVA revealed only a significant within-effect of *RMSD* for CAM and EBM,  $F(1, 53)=20.82$ ,  $p<.001$ . The model with the average best fit was the CAM ( $RMSD_{CAM}=11.10$ ,  $SD=3.82$  vs.  $RMSD_{EBM}=14.2$ ,  $SD=5.59$ ). The variance explained by the CAM was significantly higher for feedback learners regardless of the number of training exemplars ( $r^2_{CAM}=.73$  and  $.77$ ;  $r^2_{EBM}=.61$  and  $.61$ ). Though CAM was found to be the better fitting model for observation by the *RMSD*, the variance explained by the CAM was not significantly higher than for EBM ( $r^2_{CAM}=.86$  and  $.80$ ;  $r^2_{EBM}=.77$  and  $.71$ ).

In line with the predictions, a split-plot ANOVA with the judgment accuracy of the matched old and new exemplars at test revealed that there was a significant interaction between the learning formats and the matched exemplars,  $F(1,53)=4.76$ ,  $p=.034$ . Observation learners had significantly better accuracy judging the old exemplars that had been experienced in training compared to judging the matched new exemplars. This result suggests that exemplar based processes are used by observation learners. No systematic difference in judgment accuracy between matched old and new exemplars was found for feedback learners, suggesting that cue-abstraction is used by feedback learners (see Figure 2 for illustration of the results).

Figure 2. Judgment accuracy (*RMSE*) for the matched old and new exemplars at test for observation and feedback learners after training with few or many exemplars. Lower value of *RMSE* signifies better judgment accuracy. Vertical bars denote 95% Confidence intervals.

<sup>2</sup> The 2 x 30 judgments of the test exemplars were randomly split into two sets for each participant so that each exemplar occurred once in each set.

In line with the predictions, the deltafit (i.e., the relative fit of the models) had a positive correlation with *RMSE* when there were few training exemplars,  $r_s = .33$ ,  $t(26)=1.78$ ,  $n=28$ ,  $p=.04$  one-sided, a result that suggest that the better fit for EBM, the lower the *RMSE* (thus better judgment accuracy). With many experienced exemplars in training, the deltafit had a negative correlation with *RMSE*,  $r_s = -.34$ ,  $t(27)= -1.88$ ,  $n=29$ ,  $p=.04$  one-sided, a result that suggest that the better fit for CAM, the lower the *RMSE* (thus better judgment accuracy). The two correlation coefficients differed significantly ( $p < .01$ ).

A two-way ANOVA with judgment accuracy (*RMSE*) as dependent variable revealed no main effects of the number of experienced exemplars or learning formats. However, there was a significant interaction effect,  $F(1, 53) = 4.17$ ,  $p = .046$ . In line with the prediction, observation learners had marginally significantly better judgment accuracy than feedback learners after training with few exemplars ( $M = 13.41$  vs.  $15.92$ ,  $SD = 3.69$  vs.  $5.08$ ,  $p = .06$  by planned comparison). On the other hand, feedback learners had marginally significantly better judgment accuracy than observation learners after training with many unique exemplars ( $M = 11.58$  vs.  $13.69$ ,  $SD = 4.76$  vs.  $3.39$ ,  $p = .09$  by planned comparisons). As illustrated in Figure 3, the number of exemplars affects more the overall performance for feedback learners than for observation learners. This is consistent with the claim by Juslin et al. (2008) that whenever a cue-abstraction fails to exploit the task environment, it is better to shift to exemplar memory that can act as a back-up process.

Figure 3. Overall judgment accuracy (*RMSE*) for observation and feedback learners after training with few or many exemplars. Lower value of *RMSE* signifies better judgment accuracy. Vertical bars denote 95% confidence intervals.

## Discussion

This study revealed support for the hypotheses that observation learning is more efficient when few unique exemplars had been experienced, whereas feedback learning is more efficient when many unique exemplars had been experienced in training. The modelfit revealed a dominance

of CAM for both observation and intervention. It is possible that the hypothesized processes invited by the learning formats are more easily detected early in the training as in Henriksson et al. (2012). However, the relative fit of the models and the accuracy of judging old and the matched new exemplars was in line with the predictions and suggested that exemplar memory is invited by observation learning and cue-abstraction is invited by feedback learning. The result is in line with the results reported by Rouder and Ratcliff (2004) suggesting that a rule-based process is better able to exploit a task environment when there are many exemplars and that exemplar memory is better able to exploit a task environment when there are few exemplars.

The results in this paper opens for the possibility that the “rule bias” in many studies on categorization and multiple-cue judgment (e.g., Ashby et al., 1998; Erickson & Kruschke, 1998; Juslin et al., 2008; Kalish et al., 2005) may in part be reinforced by the frequent use of the feedback learning format in experiments. However, with a different learning format such as observation there might have been a “bias for exemplar memory” instead. As Juslin et al. (2008) suggest exemplar processes might act as a back-up process that are used whenever rule-based processes fails.

Ashby et al. (2002) has suggested that observation learning might be a learning format that captures many learning situations for children, as when parents teach their children by pointing to objects or persons in the environment and the child is assumed to learn by observing the characteristics of the object. The results from this experiment are in line with previous research that observation is associated with more exemplar processes (Estes, 1994; Henriksson et al., 2012). There is some evidence that 9 to 11 years olds compared to adults have difficulties using cue-abstraction and instead rely on exemplar processes even when a task environment facilitates cue-abstraction. Not fully matured frontal lobe structures, important for working memory, is one explanation for the observed difficulties in using cue-abstraction among the preteen children (Von Helversen, Mata, & Olsson, 2010). Aging might also affect working memory capacity, and as has been shown in categorization, younger adults and elderly perform at similar levels when learning is based on observation learning. But when learning is based on feedback, younger adults outperform older, suggesting that working memory and set-shifting abilities are important in feedback learning (Schmitt-Eliassen et al., 2007). One successful application of the idea of different learning formats is that observation learning seems to offer patients with Parkinson’s disease a way to learn that circumvents their deficits for rule-based processing in categorization (Shohamy et al., 2004). The result from my study suggest that you also can tailor fit the training with few or many exemplars to enhance judgment accuracy by changing the learning format.

In this study, two generic or archetypical cognitive processes in their pure form have been compared, but it is of course possible that people rely on a mix of processes. It is

possible that the invited processes in different learning formats can in combination with demands from the task environment transform into a hybrid process and in the future it is reasonable to incorporate models such as SUSTAIN (Love, Medin & Gureckis, 2004) or the Varying Abstraction Model (Vanpaemel & Storms, 2008) to name a few. In terms of such mixed or hybrid models, the results reported here can be understood as a change in the relative dominance of the two processes, where observation learning invites relatively more EBM and feedback learning invites relatively more CAM.

# Identifying Kinematic Cues for Action Style Recognition

Shohei Hidaka (shhidaka@jaist.ac.jp)

Japan Advanced Institute of Science and Technology,  
1-1 Asahidai, Nomi, Ishikawa 923-1292, Japan

## Abstract

Recognition of emotional states from other's actions is one of key capability for smooth social interaction. The present study provides a computational-theory-level analysis on which feature may take a crucial role in recognition of emotional attributes in human actions represented as point-light display. Lead by the previous theoretical works and empirical findings, the velocity and acceleration profile was investigated as a major feature of emotional attributes classification. The results showed that emotional attributes in actions as well as action types could be identified by covariance of velocity profiles among multiple body parts. Since, despite different velocity profiles in different actions, these features for emotional attributes were found commonly in multiple different actions, it suggests that the action styles may be mediated by an information channel parallel to action types per se.

**Keywords:** Action style recognition; biological motion; emotion; social cognition.

## Introduction

Our bodily motion is coherent, smooth and effortless. From bodily motion, we perceive other's state such as mood, emotional expression, and intention (Blake & Shiffrar, 2007). Perception of other's state takes a crucial role in social context. Although most of us can easily "read" what others intend to do through their actions, there is a significant gap from the physical motion – a set of trajectories of multiple body parts with a large degree of freedom (Bernstein, 1967). Recognition of motion is vitally important to any animal kinds. Detection of another animal, possibly a pray, a predator, or a conspecific, and the following detailed identification what it is and how it may behave is essential to take an emergent actions to it (Johnson, Bolhuis, & Horn, 1985). Humans are social animals. Not surprisingly, our visual system is highly specialized to recognize others' state. The present study aims to provide a computational-level description on how people recognize emotional status in others' actions.

### Perception of biological motion

How do we recognize implicit patterns in different styles of actions? The past experimental literature has explored capacity of motion perception using point-light displays (Johansson, 1973) in which the point-lights attached in major joints are only visible in the dark background (Figure 1a). Thus the available information is point-wise kinematic motion in multiple body parts. Despite of the limited information, people can recognize identity (Troje, Westhoff, & Lavrov, 2005), gender (Kozlowski & Cutting, 1977; Troje, 2002), emotions (Pollick et al., 2001; Atkinson, 2009; Hobson & Lee, 1999), dynamics such as the weight of a

lifted object (Bingham, 1987) of actions from point-light displays.

Not only demonstrating human capacity, the studies using point-light display have suggested features extracted in action perception. Accumulating empirical studies on action perception have suggested that velocity and its higher order derivatives in a single or multiple body parts as one of major correlates to emotional attributes in actions: duration of action (Pollick et al., 2001), velocity (DeMeijer, 1989), acceleration (force or the second order time derivatives) (Chang & Troje, 2008; 2009) and jerk or the third order time derivatives (Cook, Saygin, Swain, & Blakemore, 2009), pairwise counter-phase oscillation (Chang & Troje, 2008; 2009). In particular, we highlight the contribution of the higher order derivatives of velocity and importance of its covariational structure. Of relevance, Chang & Troje (2009) found that, not one of either but a pair of feed motion was a major cue for discrimination of walking direction.

### Past computational models on action recognition

Consistent to these empirical findings, most of the theoretical approach works on some kind of statistical regularities among motion profiles. According to a recent review (Troje, 2008), perception of biological motion has the multi-level processing on local and global motion properties. The feature processing consists of four layers from early (low-level) to late (high-level) processing: life detection, structure-from-motion, action recognition, and style recognition. The system detect autonomous agent, and construct body structure from its detailed analysis, then is followed by more detailed action analysis.

A couple of computational models are available for structure-from-motion and action recognition (Giese & Poggio, 2003; Lange & Lappe, 2006), and a few for post-action-recognition-level style perception (Troje, 2002; Pollick, Lestou, Ryu, Cho, 2002; Davis & Gao, 2004) in vision science. In the model of structure-from-motion and action recognition, the model identifies body structure and subsequently actions from the pixel-based visualization of point-light displays. In Giese & Poggio (2003), the model was built based on neuro-physiological findings on visual cortex, and was applied to recognition of action types and action direction in normal, masked, or scrambled point-light displays.

While, the post-action-recognition-level models for style perception typically assume the either/both 2D or 3D point-light on the major joints and also which action is to be executed is readily available prior to the recognition of action style (Troje, 2002; Davis & Gao, 2004; Pollick et al., 2001). For example, Troje (2002) have proposed a computational model of gender identification in gait

presented as point-light display. The model was built upon the three stages: First a set of postures is encoded based on Fourier decomposition, the low-dimensional projection of extracted features is obtained by principal component analysis (PCA), and then it is fed to classifier (as a similar model, see also Davis & Gao (2004)).

### Simple, transparent, yet general model

Although the previous theoretical works have offered successful pattern recognizer for biological motion, there are three shortcomings. First, most of the studies have been closed in one special type (or its slight variant) of action which often has a unique constraint such as periodicity (e.g., walking, running; e.g., Troje, 2002). Second, related to the first point, a limited number of body parts specialized for each action tends to be (e.g., arm movement for tennis swing (Pollick et al., 2002) ). Although not all the model is specialized, in turn, such a generalized model typically loses transparency of mechanism as a cost of generality (For example, multi-layer physiologically-plausible model, Giese & Poggio, 2003). One of drawback of complex models (using nonlinear filters or feature decomposition technique such as Fourier decomposition and PCA) is that the estimated parameters do not necessarily offer interpretation on which natural features are informative such as body parts and time course (Pollick & Paterson, 2008). Moreover, such model often outperformed human recognition (Troje, 2002; Davis. & Geo, 2004; Pollick & Paterson, 2008) rather than explaining use of features in human recognition.

### The theoretical assumptions in the model

In the present study, we employed the simplest possible framework – a variant of linear regression – in order to characterize the motion cues in whole body interaction for multiple types of actions and emotional attributes. The model has the three major assumptions as follows. (1) The major joint (point-light) is specified and readily available prior to action and style recognition as well as the previous post-structure-from-motion models. Specifically, the point-light coordinate was directly fed to the model. (2) The velocity profile (and its higher-order derivatives) is supposed a primary source of information for style recognition. (3) The model integrates local (single-joint motion) and global (multi-joint motion) in form of linear combination. This is simply implemented as linear regression in which the best linear combination of them was estimated by optimization of recognition/classification performance.

On the other hand, we *do not* assume that action is specified prior to recognition of action style, instead we rather expect to find generalizable features of action style common in multiple types of actions. Since people can recognize different styles in unconventional actions (Moore, Hobson, & Lee, 1997; Hobson & Lee, 1999), a model for human biological motion is required to be general for multiple actions.

Specifically, in the present study, we analyzed the human bodily actions while the actors were given different emotional contexts (Ma et al., 2006). These actions are

experimentally manipulated which emotional context was intended to be under each action performance. Given such a set of human actions, our first goal is to recover the latent emotional attributes which the actor intended to hold (or so experimentally manipulated) from the physical motions. By doing so, we describe how the emotional attributes are expressed in the different bodily actions. More specifically, we focus on the following questions: Is it possible to find a general features regardless of different types of actions? If so, which types of features take crucial roles?

## Biological motion library

Ma et al. (2006) have created an open-access biological motion library, consisting of data recorded from a motion tracking system (point-light actors: Figure 1a). The dataset contains 30 naïve actors each performing 5 actions (walk, knock, lifting, throw, and combinations of the four actions) in 4 emotional contexts (angry, happy, sad, and neutral) (see Ma et al., 2006 for more detail). Each action was performed after the subject was given a background story manipulating the emotional context how the subject is supposed to perform the action. In the present study, we used a subset of actions mainly using right hand, i.e., knock, lift, and throw. As an example, the joint angle of right arm and its angle velocity while 5 repeating the same actions is drawn in 1b.

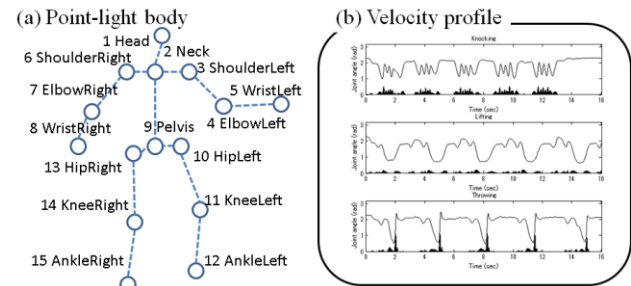

Figure 1: (a) Point-light actor (no link in the model and behavioral test), (b) A temporal profile of right-hand-elbow-shoulder joint angle (solid line) and its velocity profile (black) in 5 repeating knock, lift, and throw actions.

## Model of Emotion Recognition from Actions

We analyzed a subset of the data from biological motion library (Ma et al., 2006). This subset included 15 male and 15 female actors performing 3 different actions (knock, lift, throw) in each of 4 different emotional contexts (neutral, angry, happy, sad). Although the model was trained with actions with neutral emotion as well as actions with emotional attributes, only the three non-neutral emotions were used in the test to facilitate comparison to behavioral data. The additional neutral actions in the training data give the model a chance to learn actions in emotionally neutral context which human subjects have experienced out of laboratory experiment. Each action in each emotional context was repeated 5 times on each of 2 trials, producing 3600 actions in total.

### Features: covariance of velocity, acceleration, and jerk.

In order to implement previous theoretical findings regarding velocity profiles as a cue for biological motion perception, we used the velocity, acceleration, and jerk covariance profiles to identify actions and emotions. Each of these was used to define features for the regression model. Features came in two kinds: local and global. For instance, variance of acceleration is a local motion property (single-point motion) that captures smoothness of motion over an interval. The covariance of acceleration between multiple points is a global motion property that captures the degree of temporal coordination between two body parts. Variance/covariance was evaluated for each action defined by joint-angle of right arm (see also Ma et al., 2006 for details). We used a nested model structure to identify the contribution of each kind of information to action and emotion identification. The simplest model was a velocity-only model that included only the single-point variance and two-point covariances for each joint. This model was subsumed by an acceleration model that also included acceleration variance and covariance, and both were nested in a model that included jerk variance/covariance information. Since, at each moment, velocity and acceleration of 15 body parts were obtained, 15 variances and 105 covariances were obtained for each action. Thus, a total 120, 240, or 360 dimensions across pairwise body parts were used for classification in the Velocity, Acceleration and Jerk models, respectively. Because it produced the most parsimonious fits to behavioral data, the Acceleration model was analyzed most extensively, and is the model discussed if a different model is not mentioned specifically.

### Classification with automatic dimension reduction

These normalized variance and covariance features were used to classify emotions and actions using a multi-class sparse logistic regression model (Yamashita et al., 2008). Model parameters were estimated in a hierarchical Bayesian framework, which penalizes parameters that do not contribute significantly to improving prediction. This is done with a sparsity that reduces the likelihood of the model in proportion to the number of non-zero parameters ( $w$ ) multiplied by a scaling parameter  $\lambda$  (Figure 1c for its graphical model). Specifically, the probability of each action  $i$  belonging to class  $k$   $P(y_{ik})$  follows the multinomial distribution with probability represented as logistic function of linear combination of the given features  $x_{ij}$  for data  $i$  of dimension  $j$  with the weights  $w_{jk}$  as follows.

$$p(y_{ik}) \propto \left( 1 + \exp \left( \sum_j x_{ij} w_{jk} \right) \right)^{-1} \quad (1)$$

The loglikelihood of class of data given by Equation 1 combined with the prior probability on the weights  $w$  is maximized. The sparseness prior is given as follows.

$$p(w_{jk}) \propto \sqrt{\lambda_{jk}} \exp(-2^{-1} \lambda_{jk} w_{jk}^2)$$

$$p(\lambda_{jk}) \propto \lambda_{jk}^{-1}$$

where weights follows the gamma distribution with the hyper parameter  $\lambda_{jk}$  which follows a fixed-parameter gamma distribution (Jeffrey's prior). This prior prefers zero-value

weights, and thus penalize non-zero weights without sufficient information to classification of the given data.

Thus, without any free parameter to adjust, most of weights on non-relevant dimensions were supposed to be excluded from the model on course of optimization.

The each action in the dataset is randomly assigned either training or test samples. The 3300 training samples were used to estimate the parameters in the classification model, and its performance with the 300 test samples was evaluated. The reported results were averaged across 10 randomly generated sets of test/training samples.

Figure 2: The sparse logistic regression linking the velocity features to given emotion/action class.

### Classification performance in the model

The average correct classification of the Acceleration model with velocity and acceleration profile as features was 97.5% for action types and 69.73% for emotion classes at 33% as chance level of both action and emotion classification. The response patterns of the model in emotion classification were shown at the bottom panel in Figure 2. In order to evaluate the model's prediction on the action/emotion classification, we conducted the behavioral study on action/emotion classification. The detail of the model's prediction would be discussed with the behavioral data.

### Behavioral study: action/emotion classification

In order to test the prediction of the proposed model, we run behavioral experiment in which adult participants were asked to classify the type of actions and emotions given human actions presented as a point-light display. A subset data from the biological motion library was used as stimuli.

#### Participants

10 graduate students at Indiana University were recruited.

#### Material

Action-emotion stimuli were sampled from the biological motion library (Ma et al., 2006). Nine pairwise combinations of 3 actions (knock, lift, and throw) and 3 emotions (angry, happy, sad) were sampled from each of 3 selected actors. This yielded 27 video clips in total. The viewing angle was fixed to look down the actor from actors' left side, so that the view capture the both front and side aspects of actions. From this fixed angle, point-lights from different joints rarely overlapped.

#### Procedure

The experimental procedure consisted of two separated phases. In familiarization phase, 9 video clips (3 actions by 3 emotions) which were not used in the following phase were presented on a computer monitor simultaneously. Each was accompanied by a label identifying both the action and emotion in the clip. Participants were told that they would

be asked to categorize similar clips by action and emotion, and that they should watch the clips until they instructed to watch the clips until they were satisfied that they felt they could do so.

A test phase followed immediately after the familiarization phase. Each participant watched a series of 15 second in which a point-light actor performed one of the 3 actions in the style of one of the three emotions. Participants were asked to determine the action and emotion in each video. Presentation of the stimulus on each trial was ended either when the clip ended or when the participant pressed a button to advance to the next trial. The test phase consists of 27 trials, with presentation order randomized by participant. Together, the familiarization and test phases lasted approximately 10 minutes for each participant.

## Results and Discussion

The proposed model provides quantitative prediction on classification of emotional attributes based on statistical structure in velocity profiles. Here we compared classification performance of action and emotion in the human behavior and the models. The correct ratio in action classification was nearly perfect in both human (98.61%) and the Acceleration model (97.5%) to chance level 33%. The correct ratio in emotion recognition was comparably medium level in both human (68.98%) and model (69.73%) to chance level 33%. The result showed the model achieved comparable performance in biological motions in both action and emotion classification.

### Data fitting and comparison of models

Since the action classification was nearly at ceiling, we analyzed the classification error patterns emotional classification in detail (Figure 3). Figure 3 shows the proportion of responses for each type of emotion. In order to analyze which kind of feature human subjects utilized, we compared the three variant of the models with nest-structure feature sets: *Velocity* model with only velocity profile, *Acceleration* model with velocity and acceleration profile, *Jerk* model with velocity, acceleration, and jerk (up to the third order derivative). The goodness-of-fit for each model was evaluated to what extent human responses in the behavioral data followed a multinomial distribution with the average proportion of responses in each model as parameters. Note that, although the feature set in the models were different, none of the three models were optimized for fitting of the behavioral data (thus no free parameter). Instead they were optimized to classify the emotional attributes in actions. The log-likelihood of data for Velocity, Acceleration, Jerk model were -93.931 ( $R^2 = 0.810$ ), 90.051 ( $R^2 = 0.890$ ), and -89.116 ( $R^2 = 0.900$ ), respectively. The likelihood ratio test revealed significant difference in likelihood of Velocity model from the other two models ( $\chi^2(1) > 3.8807$ ,  $p < 0.05$ ), but did not find significant difference between Acceleration and Jerk model ( $\chi^2(1) = 0.7479$ ,  $p = 0.33$ ). This result of model comparison suggested that velocity profile alone was not sufficient to capture behavioral patterns, but velocity and acceleration profile

might be sufficient since the additional jerk profile made little additional contribution for data fitting. Therefore, hereafter we analyzed the Acceleration model as the representative model.

### Action-specificity of emotion attributes

Next, we tested the hypothesis that recognition of emotion attributes is specific to each action types. If so, the model trained to classify emotional attributes for each action (*Action-specific* model) would capture behavioral patterns better than the model trained to classify them for all the three actions together. The log-likelihood of Action-specific acceleration model was -90.6381 ( $R^2 = 0.890$ ) which is slightly worse but not significantly different from that of non-action-specific acceleration model ( $\chi^2(1) = 0.5871$ ,  $p = 0.444$ ). Therefore, the action-specific model did not necessarily offer a better account for human recognition.

### Classification with only average velocity

One of largest qualitative difference between human and model was found in the proportion of response “happy” to angry action: human recognizers confused angry with happy more than with sad, whereas the model recognizers confused it with sad more than happy. According to the post-experimental interview to the participants, many of them reported that they relied on average velocity of actions. Typically angry actions tended to be fast, sad actions were slow in the current stimuli, and happy ones were in the middle of them. This may be a potential reason why for human perceiver angry actions tended to be confused with happy ones rather than with sad ones, and also the model did not included as its features for classification.

Therefore, in order to evaluate the contribution of average velocity, we performed additional analysis. A past study has reported that the average velocity, or duration of from beginning to end of action, (and its correlated factors such as duration) was one of major correlates to subjects’ rating of emotion attribute (Pollick et al., 2001). Indeed, we found the angry actions were fast and sad actions tended to be slow on average in the data used in the present study. The four-way ANOVA on the factor (emotion types, action types, repetition, and trial), revealed the significant main effect of all the factors but trials ( $p < 0.01$ ).

However, the average velocity of the actions alone was not enough for classification of action style. The correct ratio using the average velocity, duration, peak velocity of each action was 35.9% (chance level 25%) which was not comparable to human performance (68.98%). Even after we classify the subset of data separate for each action, the classification performance did not improve significantly (Average of three actions: 36.4, Knock: 34.1, Lift: 38.0%, Throw: 37.1% for the chance level 25%). This result suggested the average velocity of actions alone could not fully explain the action style recognition.

In sum, the current model-based analyses suggested that the covariance profile of acceleration in multiple body parts carried significant amount of information on emotion attributes in actions. Despite of very different velocity profiles in three actions, knock, lift, and throw, the

classification of emotion regardless of the actions was as successful as action-specific classification. This result suggested that, to some extent, emotional attributes in actions were more general rather than specific for each action.

Figure 3: The response patterns for each emotion type in human subjects (upper panel) and the model (bottom panel).

### Distributed cues in emotion recognition

Next, we analyzed the effective feature dimensions for each emotion attribute in the Acceleration model. In the sparse logistic regression, the fewest possible feature dimensions were automatically selected among all the given dimensions. The selected dimensions, variance and covariance of acceleration profiles, were supposed to be a spatiotemporal “template” informative to action/emotion attributes. Thus we analyzed which features are specified for each of emotion attributes. Figure 4 depicted the inter-connection between body parts which were identified as significant features for emotion discrimination (see also criterion of the dimension selection in the model). In each panel of Figure 4, the thin and thick lines indicate covariance of velocity and acceleration for a pair of body parts respectively which is also coded by intensity in the adjacent matrix. The number of effective dimensions for velocity/acceleration and local (variance)/global (covariance) was shown at the bottom right panel.

We found the numbers of effective velocity dimensions (either local or global) were consistent with the average velocity: the largest number of effective dimensions in angry actions which tended to be performed fast, meanwhile the smallest number of them in sad actions which tended to be performed slow. Also the total number of effective dimensions for each action was consistent to the classification performance (Figure 3): the model found fewest effective dimensions for happy actions and had lowest accuracy in identifying them. Overall, we found more global features (pairwise covariance) than the local features (single-point variance). This result suggested that the emotional attributes were distributed rather than specific to a small number of body parts. Since these patterns found in the present model were directly interpreted as those on

body parts or their relationship, they would offer a specifically testable prediction on which body parts may be potentially informative.

Figure 4: The variance/covariance in velocity profile significantly relevant to each emotion attribute mapped on a body scheme. The white and gray cell indicates effective variance/covariance of velocity and acceleration, respectively. No lower triangle cells were presented due to its symmetricity. The bottom right panel showed the number of effective dimensions for each emotion attribute.

### General Discussion

In the present study, we provided a computational model which specifies characteristic kinematic features for recognition of emotional attributes in actions. Following the lead of the past studies, we analyzed the velocity profile with special attention. Classification with covariance of velocity and acceleration profile among multiple joints showed comparable performance as good as human classification. Moreover, by comparing multiple models trained with different feature types, it suggested that (1) velocity alones was not sufficient but combined with acceleration or higher order derivatives might characterize the human emotion recognition, and (2) there may be common emotional attributes invariant to action-specific motion profiles.

#### Action style as parallel process rather than hierarchy

The present analysis showed that, based on covariance of velocity profile across whole body, emotion attributes may be characterized beyond specificity of each action. However, recent review on action recognition offers a contradictory view to the present study: recognition of action style needs action recognition in prior to it. According to a recent review (Troje, 2008), perception of biological motion is multi-level processing on local and global motion properties. The feature processing consists of four layers from early (low-level) to late (high-level) processing: life detection, structure-from-motion, action recognition, and style recognition. Once both agent and action are identified, pattern recognition at a “subordinate” level (Rosch, 1988) helps to retrieve further information about the details (i.e., action style) of both.

In the present study, we propose an alternative view on action style perception: The emotion attributes can be identified with or without pre-specification of action types.

In the present analysis, we found that the model without action-specific features can account for behavioral classification performance as well as that with action-specific features. Therefore, we speculate that action style is “parallel” process rather than hierarchical one to action recognition which may be coded independently from the action types.

### Future works

One of the future directions is to extend the behavioral study so that we can evaluate subjects’ attention to body parts and its time course using an additional measure (e.g., eye movements). The extended behavioral study would allow us to directly test the model’s detailed prediction about which body parts and their relationship may be informative to action/emotion classification (Figure 4).

### Acknowledgments

The author is grateful to Daniel Yurovsky for his discussion on the current manuscript. This study was supported by Artificial Intelligence Research Promotion Foundation and Grant-in-Aid for Scientific Research B No. 23300099.

# The Atoms of Cognition: A Theory of Ground Epistemics

Seng-Beng Ho ([hosengbeng@nus.edu.sg](mailto:hosengbeng@nus.edu.sg))

Temasek Laboratories, National University of Singapore  
5A Engineering Drive 1, #09-02, Singapore 117411

## Abstract

We propose a set of “atomic cognitive operational representations” on which higher level cognitive representations and processes can be built, thus providing fundamental building blocks for cognitive mechanisms necessary for intelligent actions. The fundamental concepts involved are elemental temporal changes of some quantities and in this representational scheme the temporal dimension is explicitly represented to fully characterize the meanings of the concepts involved at the epistemic ground level. This provides full grounding for all subsequent concepts that are built upon them, allowing cognitive systems embodying these concepts to have full and complete understanding and characterization of the concepts involved that it can use for various cognitive ends. This provides a firm theoretical foundation for the study of cognition and intelligence.

**Keywords:** representation; operational representation; spatiotemporal representation; conceptual grounding; fundamental building blocks of cognition; experiential memory

## Introduction

Unlike the physical sciences, “standard” paradigms for scientific investigation of cognitive phenomena still do not exist for the sciences of cognition and intelligence (Arbib, 2002; Gazzaniga, 2008; Russell & Norvig 2010). Chief among the achievements of the physical sciences is the discovery of various fundamental particles and forces that provide the foundation for the understanding of physical reality. These fundamental particles and forces form the necessary and sufficient building blocks upon which the characterization of all other higher level physical phenomena can be constructed.

We show that a set of representations, which we refer to as “atomic cognitive operational representations” or *ACORs*, can perform an equivalent function of providing the fundamental building blocks for building cognition. Like elementary particles and forces, *ACORs* allow ground level semantics to be represented and all higher level semantics and cognitive operations to be based on them. As a dual of physical ontology, the atomic cognitive operational representations provide the *cognitive ontology* for building all cognitive phenomena.

In our theory, a set of correctly formulated ground level “atomic” building blocks of cognition will be necessary for allowing all cognitive processes to be constituted. Furthermore, the same fundamental building blocks apply at all epistemic scales to enable useful knowledge to be derived through cognition for intelligent functioning. Consider the following.

Before the advent of science, we dealt with the world as best we could, at a level of description provided by our natural sensory systems. Take for example the case of a tree as perceived by our human senses. From a distance, a tree can be sensed and conceptualized as consisting of a trunk, some branches and many leaves. However close up, our senses can tell the texture and the detailed shapes of the trunk, the branches and the leaves, and perceive their movements. The detailed perception of these subparts of a tree in turn provides us with the necessary knowledge to be able to use those subparts for various purposes, such as for decoration or other more functional ends. When the wind blows and the leaves on a tree move, the softness of the movement might allow us to “imagine” using the leaves as a broom for the purpose of sweeping, or as a fan to fan oneself; in due course, we might proceed to act on those ideas when the need for them arises. This would be the characterization of the tree at an epistemic ground level at which normal perception operates to provide useful information for a cognitive system to function intelligently.

As science improves our understanding of the natural world, our conceptualization of trees goes beyond just trunk, branches and leaves as they appear to our natural senses. We discovered chlorophyll and the photosynthetic processes, for example. These biological processes involve much smaller entities – various molecules – and attendant complicated interactions that our natural senses cannot detect directly. With this deeper understanding, we reach another epistemic ground level. It is the thesis of this paper that no matter which ground level we are looking at – i.e., whether it be the earlier one reached by our natural senses or the deeper ones reached through scientific means – the same fundamental building blocks of cognition are involved in subserving cognitive mechanisms from which intelligent actions emerge.

With the fundamental building blocks, we put the sciences of cognition and intelligence on a firm theoretical foundation, much as what the theory of fundamental particles and forces has done for the physical sciences.

## The Atomic Operational Representations of Appearance and Existence

The vast canvas of space-time is the arena in which physical and mental processes take place. One fundamentally important concept that any mental process must deal with is appearance and existence (of objects, events and processes). We begin with the formulation of the atomic concept of appearance.

Figure 1a shows a one dimensional space with 5 discrete positions  $x_0 - x_4$ . At time  $t_0$  it contains nothing. At time  $t_1$ , something appears at position  $x_1$ . It could be an elemental bit of substance or a point of light. Now, assuming an intelligent system has perceptual detectors that can sense and signal something appearing at a certain spot at a certain time and has an explicit *experiential memory* that can store its perceptual experiences and lay them out in a spatial extent for simultaneous processing, Figure 1b shows what the explicit experiential memory looks like in the time interval  $t_0$  to  $t_1$ . Figure 1b also shows a spatiotemporal “appear” template that can pick up this change in the physical situation in the one dimensional space. Basically this template encodes the meaning of “appear.” It captures the situation in which in a moment in time just prior to the appearance of something, there was nothing in that point in space and in the next moment something came into existence. In the spatiotemporal template, time is spatialized and the temporal dimension is explicitly represented.

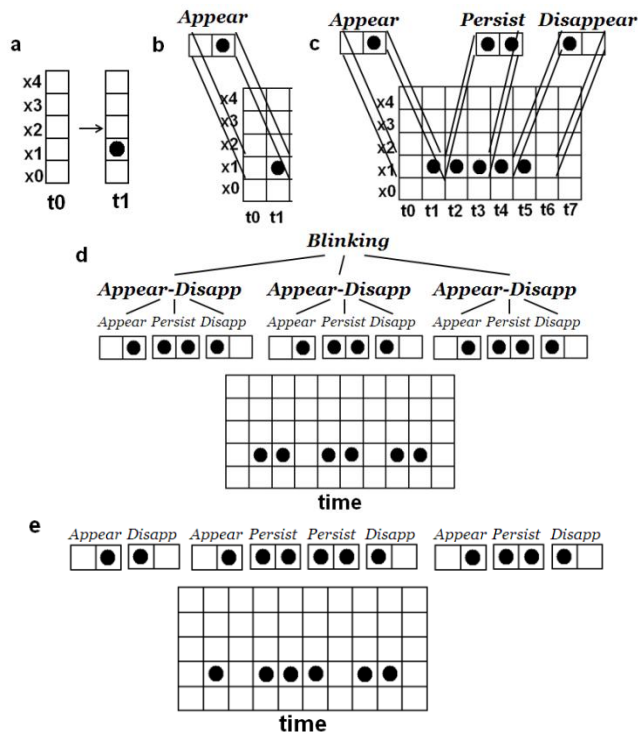

Figure 1: Atomic operational representations for “appearance” and related concepts. a. Appearance of an object at a specific time and location. b. The experiential memory and the “appear” operational representation. c. “Persist” and “disappear” operators. d. Concept of “blinking.” e. Re-composing operators – cognitive manipulatability.

It should be stressed that the elemental “blob” that is picked up and represented in the experiential memory of Figure 1b may or may not correspond exactly to an elemental “blob” in the physical world. It is an “elemental”

bit of occurrence as characterized by the sensory organ of the cognitive system relevant to the cognitive task at hand. Depending on the resolution of the sensory system and the cognitive task involved, the “blob” could correspond to an atom in the physical world, a vehicle or a person, or the recognizable points on a human body or on the leaves of a tree. It could also be something created by other internal mental processes in a “mental space.”

We submit that this spatiotemporal *appear* template captures the full meaning of *appear* at the ground level. For the purpose of identifying an *appear* event, the template is used as follows: it is matched to the spatiotemporal patterns in the experiential memory as shown in Fig 1b. If there is a match, an *appear* event is identified to have taken place.

The *appear* template, other than being useful for the purpose of identifying or recognizing the occurrence of an *appear* event, is also usable in the opposite direction – that of *generating* the action or idea of *appear*. Assuming that an intervening system is available to translate an intelligent system’s intention into physical realization, the intelligent system can act, under the direction of the *appear* template, to move a material substance into a specific point in space and thus making it “appear” at that location, to materialize a bit of substance from nowhere at a specific point in space, or to cause a point of light to appear at a specific point, etc. These are examples of “make-appear” – the *appear* template used in the generation direction. The *appear* template can also be used to generate an “idea” (i.e., a bit of “mental substance” – e.g., the mental analog of a corresponding physical quantity – or something more abstract) at a point in a mental space for the purpose of mental manipulation. An example of a mental space would be the spatiotemporal representational structures that hold the experiential memory for mental manipulation, such as the structure shown in Figure 1c that might be implemented using a computer memory. Generation of ideas in the mental space is also sometimes referred to as “imaging” or “imagining” (Kosslyn 1994). We will refer to this characteristic of these atomic operational representations as “operational bidirectionality” – i.e., they can be used for recognition as well as generation.

We thus term the *appear* spatiotemporal template an “operational representation” as it encodes the meaning of an operational concept – *appear* – directly in terms of the operations that it performs. Such an operational representation is *atomic* in that it captures knowledge at the ground level. An atomic operational representation is *elemental* in that it represents a smallest discrete change in the spatial and temporal dimensions relevant to the cognitive task at hand. A more succinct description of “atomic operational representations” is “atomic operators.”

Figure 1c depicts two other concepts related to *appear* – “persist” and “disappear.” Together with *appear*, they can be used to capture the process of something appearing at a point, persisting (existing) for some time, and then disappearing. Figure 1b and 1c also suggest that these

templates or operators can be picked up from the environment, in the same manner as the “cookie-cutter” approach described by Uhr and Vossler (1981) – i.e., when a subpattern is perceived in the environment, it is simply “cut-out”/“picked-up” and stored as an elemental pattern to be used later to match with further pattern information coming in through the perceptual system to recognize future occurrences of the subpatterns. This is usually known as an unsupervised learning process (Duda, Hart & Stork, 2001; Fukushima, 1988; Malsburg, 1973). Whereas in Uhr and Vossler (1981), the “cookie-cutters” work on static images containing certain spatial patterns, thus they extract sub-features of the *spatial* patterns for the purpose of characterizing these patterns, the corresponding application here would be extracting *spatiotemporal* sub-patterns that serve to characterize activities or changes in the environment, external or internal to the cognitive system.

Figure 1d shows how higher level concepts can be built upon the atomic operators of *appear*, *persist* and *disappear* – if something alternately appears and disappears over time, the concept of “blinking” can be used to encapsulate the process. The higher level concepts are firmly grounded through the atomic operational representations. This process is termed “cognitive hierarchy construction.”

Figure 1e shows how the atomic operators can be recombined into novel sequences that may not have been encountered in the environment earlier in a generation process through the conceptual hierarchy, directed by reasoning and problem solving requirements. This characteristic is referred to as “cognitive manipulability” – i.e., these representations can be directly manipulated in cognitive processes.

Base on the foregoing discussion, the critical characteristics of operational representations in general and atomic operational representations in particular are summarized as follows:

1. *Explicit Temporal Representation* - the temporal dimension is explicitly represented in operational representations – this requires the intelligent system utilizing the representation to have an explicit experiential memory – temporal changes are laid out in a spatial extent for simultaneous processing.
2. *Elemental Representation* – atomic operators are elemental in that they represent the smallest discrete changes in the respective dimensions.
3. *Cognitive Hierarchy Construction* – higher level concepts can be built directly upon the lower level as well as the atomic level operational representations.
4. *Operational Bidirectionality* - operational representations can be used for recognition as well as generation purposes. Recognition and generation can involve things, events and processes in both the physical environment and the mental space.
5. *Unsupervised Extraction* – atomic level as well as higher level operational representations can be extracted from the environment in an unsupervised learning process.

6. *Grounding of Representations* – atomic operational representations are grounded directly in the environment or the mental space, higher level representations are grounded on the atomic representations.

7. *Cognitive Manipulability* – The operational representations, atomic or higher level, can be recomposed and cognitively manipulated in cognitive processes.

The atomic operational representations capture and encode “meaning” in the operations themselves. For example, *appear* is not defined in terms of other atomic or non-atomic concepts but is instead defined directly in the recognition and generation operations that it stipulates.

## Atomic Operational Representations of Movement

Again, using events in a discrete one dimensional space, we illustrate the atomic operational representations associated with movements in Figure 2. In Figure 2a, we show the operational representational characterizations of a point object appearing at a certain location, moving “up” and “down” in the one dimensional space, and then disappearing. There are basically two kinds of spatiotemporal templates associated with atomic movements – “move-up” and “move-down.” Here we also introduce a more specific kind of *appear* template called “strict-appear” – i.e., the appearance of something in a specific location is not caused by things moving into the location. If the earlier, more general *appear* in Figure 1 is used, then at every location where the point object moves into, the *appear*

template will be triggered. Similarly for *disappear* – we introduce a “strict-disappear” template. The “stay” template is similar to the *persist* template in Figure 1. It is interesting to note that the concept of *stationarity* – “stay” – can only be represented adequately if there is an explicit temporal dimension that can capture and encode the meaning of “no change in position in time.” Similarly for the concept of “persist” – “no change in the state of existence” – depicted in Figure 1c.

Figure 2a shows a cognitive hierarchy built upon the atomic operational representations of appearance and movement, reaching a level where the concept of “trajectory” is formed. Other than *trajectory*, concepts such as “jerky trajectory” can emerge from the conceptual hierarchy, as shown in Figure 2b.

Figure 2c shows the concepts of *acceleration* (an “upward” acceleration) and *deceleration* (an “upward” deceleration) captured in their corresponding operational representations. Again, here we can see that the *meanings* of *move-up*, *move-down* or *acceleration* and *deceleration* are captured directly in the corresponding associated operations stipulated by the operational representations.

### Atomic Operational Representations of Scalar and General Parameters

At any given point in physical space, a physical quantity, such as the hardness of some substance or the brightness of a point of light, may change elementally. Similarly, in mental space, the strength of an idea or feeling may also change elementally. These non-spatial scalar parameters are represented in the same manner as the spatial parameters as atomic operational representations as shown in Figure 3a, using the examples of a physical parameter such as “brightness” or a mental parameter such as “pain” that increases and decreases over time.

Atomic movement through space (physical or mental), which involves an elemental change in spatial position, can be considered a special case of a change in something, so does a change in the state of existence in space – i.e., *appear* or *disappear*. Therefore, the most general characterization of all the atomic operators including those that capture non-spatial parameters is that they characterize an elemental change of these parameters, spatial or otherwise, across elemental time. Figure 3b shows a generalized atomic operational representation of parameter change – like a “God particle” of atomic operators – that subsumes all possible atomic operators.

The number and kind of atomic operators that can be found in a particular intelligent organism or system depends on the parameters that are necessary for its survival or intelligent operations. For example, if an organism needs salt for survival and has the necessary sensory apparatus to detect the presence of salt with varying intensities over time, then for the purpose of cognitive processing it would need “saltiness” atomic operators. In conscious perception such as that typically experienced and reported by human beings, the atomic level parameters typically appear as indivisible

cognitive entities endowed with certain “qualia” such as pain, sadness, anxiousness, brightness, darkness, redness, saltiness, sweetness, spatiuousness, etc. These atomic level cognitive parameters as appear to consciousness can vary in their intensities over time but otherwise have no further internal structures scrutinizable by consciousness.

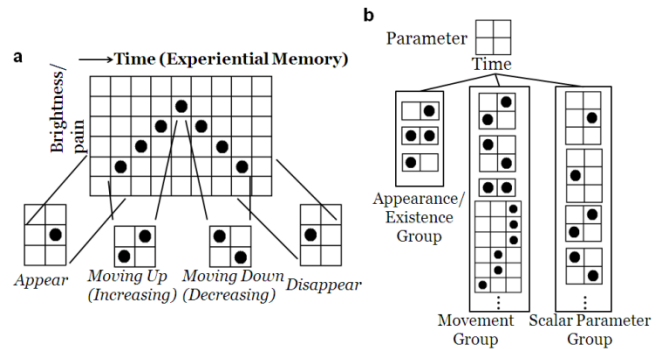

Figure 3: Other operational representations. a. Atomic operational representations of scalar parameters (brightness or pain) increasing and decreasing over time. b. Generalized atomic representation of parameter change.

### Representing and Reasoning about Time

If a cognitive system provides for the explicit representation of time through an experiential memory such as that described above, it can lead to another interesting mental operation, which is the conceptualization of time as a “thing” and the “movement” of it mapped onto spatiotemporal dimensions in the cognitive system’s *mental space-time* that allows the cognitive system to cogitate about time itself. Figure 4 shows the representations and operations involved for this.

In Figure 4 we re-label the horizontal axis as “cognitive time,” to distinguish from the “real” physical time out there in the real world. (All previous labels of “time” in Figures 1 - 3 should rightfully be “cognitive time” as these operational representations are *mental* entities.) Here, time is characterized as a “thing” that can “move.” Normally, we would conceptualize time as something that moves on inexorably with a “constant speed.” In the physical universe, it is hard to ascribe “speed” to time as one needs a time reference to talk about speed, and such “super-time” is non-existent. However, in our mental processes, we can freely cogitate about these possibilities. Firstly, we often imagine real-world events going faster or slowing down. Therefore time can “accelerate” or “decelerate,” and that would be applying the *acceleration* or *deceleration* operators as depicted in Figure 2c in the time representation here. We sometimes wonder if time has a beginning or end, and these would correspond to applying the *appear* and *disappear* operators as shown in Figure 4. If we cogitate whether time can come to a halt, that would correspond to applying the *persist/stay* operator. And in physics the concept of time reversal has been invoked to explain certain physical phenomena and that would correspond to applying

a *move-down* operator as shown in Figure 4. The concept of time travel to the past or future would correspond to a sudden jump or accelerated movement to a different “point” in “time” from the present point. Our reasoning processes with time thus use similar mental processes as we use for space, once time is conceptualized as a “thing” and its “movement” mapped onto spatiotemporal dimensions in our mental space-time.

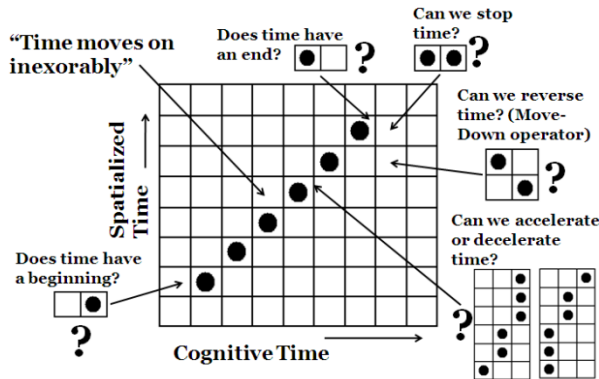

Figure 4: Cogitating about time. Representations capturing the movement, acceleration, deceleration, halting, beginning (appearing), ending (disappearing), and reversal of time for the purpose of cogitation about time.

## Representing Interactions

The interactions between objects can be characterized using operational representations. Figure 5a shows a situation in a one dimensional world in which 2 objects hit each other and are reflected. The concepts of “meet”, “part” and “reflect” can arise in this situation as shown in Figure 5a and be encoded in the form of operational representations. Figure 5b shows the situation with an alternative physics where a moving object penetrates a stationary object and no reflection takes place. The concept of “penetration” can likewise be characterized at the ground level through operational representations.

## Extended Spatial Objects and Higher Dimensional Representations

The object to be represented by an operational representation can also be an extended object consisting of more than one point. Each point on the object can be represented by an atomic operational representation. If all the points on an object move in unison, it is a rigid object (the concept of “rigidity” can be characterized by some higher level operational representations building on top of the atomic operators in the same vein as the *blinking* and *trajectory* concepts shown in Figures 1d and 2a respectively). Otherwise, the object is deformable and the deformations can be characterized by how the points on the object move relative to each other likewise through the use of some higher level characterizations of the deformations built-up from the atomic operators.

Figure 5: Interactions captured in operational representations. a. Two objects reflect off each other. b. Penetration of one object through another one.

An atomic operational representation that represents elemental movements in one of 8 directions in a 2-dimensional (2D), discrete, and Cartesian space would be a cube of 3X3X1 as shown in Figure 6a. If some liquid on a flat surface moves and changes shape more or less in a plane, its complex shape changes can be captured by the 3D (2D space + 1D time) atomic movement operator as shown in Figure 6a. Higher level characterizations of the liquid movement can be built from the 3D atomic operators.

Figure 6: Complex object representations. a. Liquid moving and changing shape in 2D and the associated 3D atomic operator. b. Leaves and 3D micro trajectories of all their elemental movements.

Figure 6b shows a plant’s leaves whose movements can be characterized using the atomic operators that can lead to the intelligent construction of a “broom” or “fan” made from leaves – i.e., having captured and understood a certain soft character of the potential elemental movements of the leaves on the tree, the cognitive system is then able to *imagine* the use of the leaves for the purpose of sweeping dirt or fanning air to cool oneself. For characterizing the leaves, because of 3D movements, a 4D atomic movement operator (3D space + 1D time) is needed. Bare branches will not function correctly as a broom or a fan because their elemental parts lack certain surfaces that can move in a certain “soft” manner. This understanding requires the high resolution ground level characterization of the potential movements of the leaves as captured by the 4D atomic movement operators and higher level characterizations of the movements built on the 4D atomic operators.

The atomic operational representations are the fundamental building blocks of cognition. All events and processes – including the operations of natural phenomena ranging from the micro to the cosmic scales (e.g., from the operations of bacteria to trees, weather, events and processes in the heavens, etc.), operations of human-made machineries (e.g., the operations of the finest mechanical contraptions to the operations of a gargantuan rocket, etc.), and mental operations (e.g., thinking processes in general, abstract mathematical manipulations in the mind, etc.) – are fundamentally cognitively describable based on the atomic operational representations.

## Discussion

It is not a coincidence that the “mental” atomic operational representations described in this paper for the purpose of cognitive processing bear a strong resemblance to the usual “physical” spatiotemporal representations many a scientist and engineer employs to represent physical events and processes for the ease of understanding and manipulating them. This is because there is an intimate link between the physical and the mental world. Spatiotemporal representations are fundamental and lie at the very foundation of the descriptions of all events and processes that can take place in this reality. Cognitive processes are the dual of the physical processes in that they seek to represent the physical processes but they have additional and unique characteristics and operational requirements as described in this paper as they need to manipulate the representations in certain cognitively useful ways.

The grounding of concepts, and hence the learning of the atomic operators, would take place in the early days of a cognitive system’s interaction with the environment (e.g., the infant stage in humans). Future studies of cognitive developmental processes could direct their investigative efforts to uncover whether or how these atomic operators are learned and used.

Our atomic operational representational scheme dictates that the temporal dimension needs to be represented explicitly for the adequate capture of the ground meanings of concepts. Hence, it follows that for a system to qualify as “cognitive,” it must have the capability of representing and manipulating the temporal dimension explicitly. A critical mechanism that subserves explicit temporal representation is the experiential memory (Figure 1b). Neuroanatomically, the experiential memory can be identified with the hippocampus, which is supposedly the neural structure responsible for memory over time – episodic memory (Anderson et al, 2007). In this paper, for the sake of exploring the basic principles we describe the experiential memory as a structure that simply lays out the temporal information in an uncompressed manner. In reality, because of the amount of information in the temporal domain that a cognitive system needs to process, compression in the time dimension is probably necessary. We submit that the hippocampus performs both the experiential memory function as well as the compression function necessary for

its practical functioning. We also submit that for a system to have “cognitive abilities” and be considered a “cognitive system”, it must possess a structure that functions like the hippocampus or the experiential memory that processes and represents temporal information explicitly. This allows it to truly conceptualize and understand events, processes and causality in the world. Even the concept of *stationarity* and *changelessness* can be captured adequately only if there is an explicit temporal representational dimension as discussed above. Hence, artificial or natural neural networks systems that merely reproduce certain input-output mappings of some seemingly “intelligent” processes are “reflexive” and do not qualify to be characterized as “cognitive systems.”

A last and interesting fact to note is that the spatialization of time in operational representations parallels the spatialization of time in relativity which brought us a deeper understanding of the reality in which we inhabit (Lorentz et al, 1923).

## Acknowledgments

I thank Dr. Kenneth Kwok and the anonymous reviewers for their suggested changes to the manuscript.

# Simple heuristic or knowledge-based inference?

## Model comparison of binary choice inference

### Abstract

We investigated the processes of making inference in binary choice tasks. We proposed statistical models for two simple heuristics and two knowledge-based inferences, and compared how well these models could explain the observed patterns of inferences. It was found that the best model for explaining choice patterns varied depending on the inference problem. In particular, results suggested that participants used a simple heuristic when they had difficulty in retrieving clues pertaining to the inference problem. In contrast, when participants could retrieve enough clues pertaining to inference problems, they made inferences based on these clues.

**Keywords:** simple heuristics; knowledge-based inferences; binary choice inferences; model comparison

### Introduction

In the last decade, a highly controversial topic in research on judgment and decision-making has been the *recognition heuristic* (Goldstein & Gigerenzer, 2002). When the recognition heuristic is applied to a binary choice problem, the inference rule is described as follows:

“If one of two objects is recognized and the other is not, then infer that the recognized object has the higher value with respect to the criterion.”  
(Goldstein and Gigerenzer, 2002, p.76)

For example, consider the following question, “Which city has the larger population, Tokyo or Chiba?” In this problem, the recognition heuristic predicts that when a person recognizes Tokyo but not Chiba, the person will infer that Tokyo has the larger population.

Many researchers have discussed the recognition heuristic from theoretical, empirical, and rational perspectives. For example, in the journal *Judgment and Decision Making*, a special issue on the recognition heuristic was published in 2010 and 2011, which included 24 papers in three volumes.

In particular, researchers have been interested in whether the recognition heuristic is actually used in making inferences. Some researchers have claimed that people often make inferences based on the recognition heuristic in binary choice situations, in which people recognize one of the objects in a pair<sup>1</sup> (Goldstein & Gigerenzer, 2002; Pachur, Bröder, & Marewski, 2008; Pachur & Hertwig, 2006; Reimer &

katsikopoulos, 2004; Snook & Cullen, 2006; Volz et al., 2006). In contrast, others have argued that although people make inferences using the recognition heuristic in some R-U pairs, people often make inferences using knowledge pertaining to the inference problem when such knowledge is available (Bröder & Eichler 2006; Hilbig, Pohl, & Bröder, 2009; Glöckner & Bröder, 2011; Newell & Fernandez, 2006; Newell & Shanks, 2004; Oeusoonthornwattana & Shanks, 2010; Oppenheimer, 2003; Pohl, 2006; Richter & Späth, 2006).

The recognition heuristic can be applied only to R-U pairs. Thus, although many studies have accumulated evidence for both the arguments, they have focused on the processing of inference in R-U pairs. Then, how do people make inferences when they recognize both objects of the pair? Previous studies have assumed that in the case of R-R pairs, inferences are made by using knowledge (e.g., Goldstein & Gigerenzer, 2002; Hilbig, 2010). As described above, many studies have suggested that when people have knowledge in addition to mere recognition, inferences are affected by the knowledge. However, specific models of knowledge-based inferences have not been proposed to date.

Furthermore, people may make inferences using a simple heuristic such as the recognition heuristic, even in the case of R-R pairs. For example, Hertwig, Herzog, Schooler, and Reimer (2008) proposed a *fluency heuristic*, which is an inference strategy using the retrieval fluency of objects, and Honda, Abe, Matsuka, and Yamagishi (2011) proposed a *familiarity heuristic*, which is the inference strategy using the familiarity of objects.

The goal of the present study was to examine binary choice inferences in not only R-U pairs, but also in R-R pairs. Brighton and Gigerenzer (2009) argued that when examining the validity of the recognition heuristic, alternative models should be proposed and compared. Accordingly, we approached the above issue by comparing models. In particular, we examined binary choice of population inferences, by comparing the validity of models representing a simple heuristic and knowledge-based inference.

### Models of binary choice inference

For each pair of cities, the two cities can be ordered by their actual populations, and we name them accordingly. For example, if cities X and Y are presented, and the city X has a larger population than city Y, we call city X the “larger city,” and city Y the “smaller city.”

<sup>1</sup> Hereafter, depending on the recognition of objects in a pair, we use following abbreviations: R-U (Recognized-Unrecognized), R-R (Recognized-Recognized), and U-U (Unrecognized-Unrecognized).

## Simple heuristic

We examined inferences in not only R-U pairs, but also in R-R pairs. Simple heuristics that can be applied to both R-U and R-R pairs are appropriate for this purpose. Hence, we used the fluency heuristic and the familiarity heuristic for modeling simple heuristics.

**Fluency heuristic.** This model is based on Hertwig et al. (2008). They have defined the model as follows: If two objects, a and b, are recognized, and one of the two is fluently retrieved, then infer that this object has the higher value with respect to the criterion (p. 1192). Based on this definition, the response pattern in pair  $i$  in the binary choice task is represented by the following variable,  $Flu_i$ :

$$Flu_i = \frac{Flu_{Si} - Flu_{Li}}{Flu_{Li} + Flu_{Si}} \quad (1)$$

where  $Flu_{Li}$  and  $Flu_{Si}$  represent the fluency for the larger and smaller cities in pair  $i$ . The range of this variable is  $-1 < Flu_i < 1$ <sup>2</sup>. Given a pair in which participants were more fluent with the smaller city,  $Flu_i$  took a value less than 0. In contrast, for a pair in which participants were more fluent with the larger city,  $Flu_i$  took a value larger than 0. If participants were equally fluent with the larger and smaller cities,  $Flu_i$  approached 0.

**Familiarity heuristic.** This model is based on Honda et al. (2011). It assumes that when there is a difference in familiarity between two cities, people will infer that the more familiar city has the larger population. Response patterns in pair  $i$  in the binary choice task are assumed to be represented by the following variable,  $Fam_i$ :

$$Fam_i = \frac{Fam_{Li} - Fam_{Si}}{Fam_{Li} + Fam_{Si}} \quad (2)$$

where  $Fam_{Li}$  and  $Fam_{Si}$  represent the familiarity for the larger and smaller cities in pair  $i$ . The range of this variable is  $-1 \leq Fam_i \leq 1$ <sup>3</sup>. Given a pair in which participants were more familiar with the smaller city,  $Fam_i$  took a value less than 0. In contrast, for a pair in which participants were more familiar with the larger city,  $Fam_i$  took a value larger than 0. If participants were equally familiar with the larger and smaller cities,  $Fam_i$  approached 0.

## Models: Knowledge-based inference

Some researchers have pointed out that people use available knowledge in binary choice inferences. Although it might be difficult to clarify the specific processes of knowledge-based inferences, previous findings have been straightforward: When people have knowledge pertaining to population size, that knowledge directly affects the inference processes. For example, when one knows that a city has a professional soccer team, implying a larger population, that city

is more likely to be picked in a binary choice. Contrarily, when one knows that a city is rapidly aging, implying a declining population, it is unlikely to be chosen.

We assumed that people are clued to retrieve information when making inferences about the population of cities, as to whether the cities are large, or small. Based on this assumption, we modeled two knowledge-based inferences, a Z-score model and a Decision by Sampling model.

**Z-score model (ZM).** This model assumes that people have correct knowledge of absolute population sizes of cities, and that the availability of knowledge depends on their familiarity with cities. In each list, we calculated the z-scores for 15 cities (See Table 1). Using the z-scores, the response pattern in pair  $i$  is represented by the following variable,  $ZM_i$ :

$$ZM_i = \frac{Fam_{Li}z_{Li} - Fam_{Si}z_{Si}}{\alpha(z_{\max} - z_{\min})} \quad (3)$$

where  $z_{Li}$  and  $z_{Si}$  denote z-scores for the larger and smaller cities in pair the  $i$ , and  $z_{\max}$  and  $z_{\min}$  denote maximum and minimum z-scores in the list. In this equation,  $\alpha$  is a positive constant determining the range of this variable. The most important feature of  $ZM_i$  is that when people are familiar with a small city (i.e., the city with a negative z-score), that city is unlikely to be chosen. This feature differs from the familiarity heuristic, which assumes that familiarity leads to choice.

**Decision by Sampling (DbS).** As noted above, ZM assumes that people have correct knowledge about population sizes. However, this assumption may be inappropriate. Hilbig, Pohl, and Bröder (2009) suggested that participants have knowledge about the relative ranks of a criterion value within a given set. Thus, we have proposed another model of knowledge-based inference, Decision by Sampling (DbS), which was originally proposed by Stewart, Chater, and Brown (2006).

In this model, the subjective value of an object is determined by relative rank. In the present study, we assumed that knowledge about population sizes is determined by the relative rank in the list. The rank of each city in the list is calculated using following equation:

$$r = \frac{R-1}{14} - 0.5 \quad (4)$$

where  $R$  is the rank of the population in a list in an ascending order (the specific value of  $r$  for each city is shown in Table 1). The value,  $r$ , ranges from -0.5 to 0.5 depending on population size. Using  $r$ , the response pattern in pair  $i$  is represented by following variable,  $DbS_i$ :

$$DbS_i = \frac{fam_{Li}r_{Li} - fam_{Si}r_{Si}}{\beta} \quad (5)$$

where  $r_{Li}$  and  $r_{Si}$  denote  $r$  for the larger and smaller cities in pair  $i$ , respectively. Value  $\beta$  is a positive constant determining the range of this variable. The feature of this variable is analogous to  $ZM_i$ . Thus, when people are familiar with a small city, it is unlikely to be chosen in binary choice inferences.

<sup>2</sup> In the present study, fluency is operationally defined using elapsed time for city recognition. See the Results and Discussion.

<sup>3</sup> We set the minimum values of  $Fam_{Li}$  and  $Fam_{Si}$  with zero. See the Results and Discussion section.

## Experiment

### Method

**Participants.** Japanese undergraduates from Wako University, Keio University, and Toho University ( $n = 79$ ; 26 men and 53 women) participated in this experiment. They were given course credits for participation.

**Tasks and Materials.** We conducted three tasks, a binary choice task of population inference, measurement of familiarity, and a recognition task.

In the binary choice task, participants were presented with two Japanese city names and were asked to choose the city that they thought had the larger population.

In this task, we used Lists A and B (Table 1) that were used in Honda et al. (2011). Honda et al. (2011) suggested that these two lists differ in availability of knowledge pertaining to populations, and participants made inferences using different strategies. Inference patterns for List A could be well explained by the familiarity heuristic. In contrast, patterns of population inference using List B could be well explained by differences in the actual populations, indicating that participants had a good knowledge about the population sizes of cities on List B.

For the recognition test, participants were asked whether they knew the 30 cities that were presented in the binary choice task. For the measurement of familiarity, participants were asked how well they knew the 30 cities presented in the binary choice task.

**Procedure.** The three tasks were individually conducted using a computer, and they were presented in the following order: binary choice task, recognition task, and measurement of familiarity.

In the binary choice task, when participants pressed the key named, “Next,” the focal point “\*” was presented for 2000 ms on a computer screen. Then, two city names were

presented on the scree. Participants responded to the question by pressing one of two keys assigned to make a choice. Participants were instructed to respond as quickly and correctly as possible. Half of the participants first received 105  $\left(\frac{15 \times 14}{2}\right)$  pairs from List A, then 105 pairs from List B.

The other participants were presented the lists in the opposite order. The presentation order of the listed cities was randomized.

In the recognition task, by pressing the key named, “Next,” the focus point “\*” was presented for 2000ms, then a single city name was presented. Participants responded to the question by pressing one of two keys named, “Recognized,” or “Unrecognized.” The time that elapsed between the presentation of city name and the participants’ key-press was recorded. Participants were instructed to respond as quickly and correctly as possible.

For the measurement of familiarity, pressing the key named, “Next,” presented the participants with a city name. They were asked to rate their familiarity with the city using a 100-point scale shown on the screen. The scale ranged between (*not know at all*) on the far left to (*know a lot*) on the far right.

The above three tasks took 45-60 minutes to complete.

## Results and Discussion

In the following analysis, we operationally define familiarity with cities based on participants’ responses during the measurement of the familiarity task. Unrecognized cities were assigned a zero. Retrieval fluency for a city was operationally defined, based on the elapsed time recorded in the recognition task, as in Hertwig et al. (2008). It was assumed that the more quick the recognition response was, the more fluent was a participant’s retrieval of an object.

The constant values,  $\alpha$  and  $\beta$ , were set at 100. The range of  $ZM_i$  and  $DbS_i$  are  $-1 < ZM_i \leq 1$  and  $-0.5 \leq DbS_i \leq 1$ .

Table 2. Correlation coefficients among four models.

	List A			List B		
	$Fam_i$	$ZM_i$	$DbS_i$	$Fam_i$	$ZM_i$	$DbS_i$
$Flu_i$	0.628	0.070	0.059	0.622	0.229	0.384
$Fam_i$	-	-0.113	-0.017	-	0.451	0.597
$ZM_i$	-	-	0.857	-	-	0.826

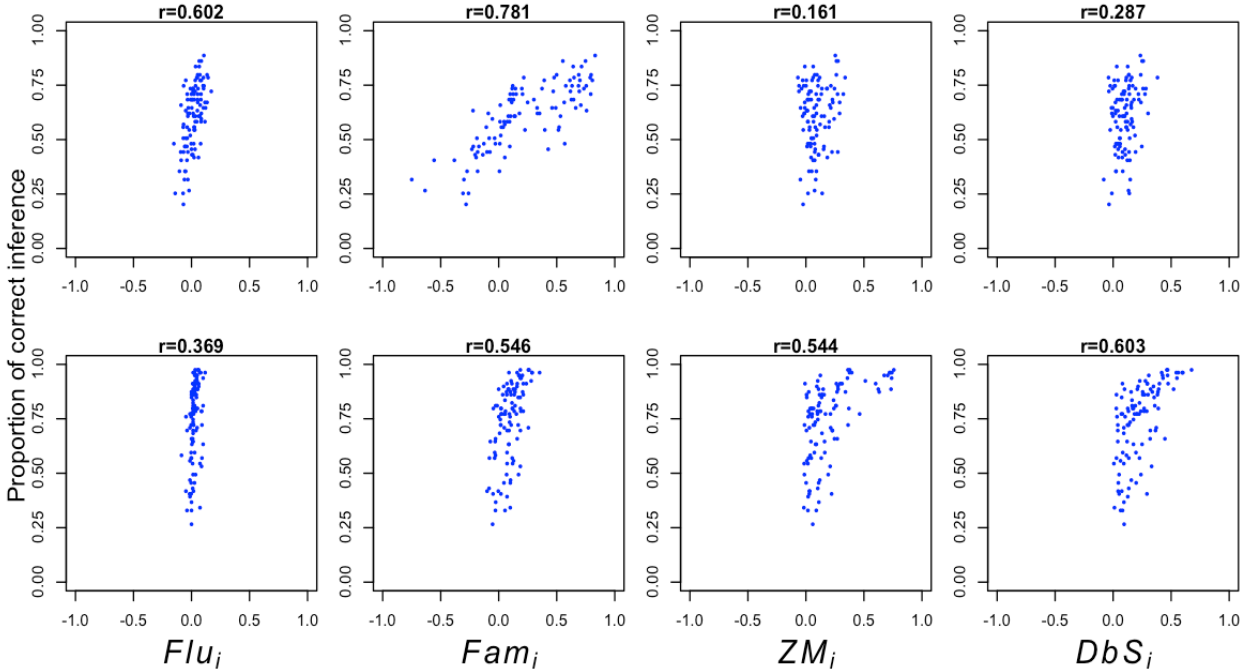

Figure 1. Relationship between choice pattern and variables of the four models. The upper four figures demonstrate results for List A, and the lower for List B.

### Analysis of aggregated data

**Similarity among models.** Although the four models were based on different assumptions about the processes of inference, predictions of binary choice might be analogous. Thus, we analyzed the similarity among the four models.

For 105 pairs on Lists A and B respectively, we calculated  $Flu_i$ ,  $Fam_i$ ,  $ZM_i$ , and  $DbS_i$  using mean familiarity or fluency for each city. Then we analyzed similarities among the four models in terms of correlation.

Table 2 shows the correlation coefficients among the variables. It was found that two heuristic models were analogous to each other. So were two knowledge-based inference models. Similarity between the heuristic and knowledge-based inference models varied depending on the list. With List A, heuristic models did not show a similarity with knowledge-based inferences. However, heuristic models showed a moderate similarity with the knowledge-based inference models in List B.

**Predictions of choice patterns.** Next, we examined the relationship between variables of the four models and choice patterns. For choice patterns, we used proportion of correct choice (i.e., rate of the larger city choice in a pair). For 105

pairs from Lists A and B respectively, we calculated the proportion of correct choice, and then examined correlations between the proportions and  $Flu_i$ ,  $Fam_i$ ,  $ZM_i$ , and  $DbS_i$ .

Figure 1 shows this relationship. As to the results of List A (the upper four figures), the two heuristic models predicted the choice patterns better than the knowledge-based inference models. In particular, a strong relationship between  $Fam_i$  and choice patterns was observed. Hence, these results suggest that the familiarity heuristic explains inference processes in List A.

The results for List B showed a different picture. Of the knowledge-based inference models,  $DbS_i$  showed a stronger relationship with the choice patterns than the others. Although  $Fam_i$  also showed a relationship with choice patterns comparable with  $DbS_i$ ,  $DbS_i$  will be a more appropriate model than the familiarity heuristic to explain choice patterns in List B. List B consists of well-known cities, and therefore, it is quite likely that participants could retrieve many clues pertaining to population size (Honda, et al., 2011). As a result, participants could have knowledge about population size such as relative rank, which is assumed in  $DbS_i$ .

Table 3. Median of correlation coefficients among four models.

	List A			List B		
	$Fam_i$	$ZM_i$	$DbS_i$	$Fam_i$	$ZM_i$	$DbS_i$
$Flu_i$	0.914	-0.027	0.062	0.142	0.071	0.098
$Fam_i$	-	-0.024	0.116	-	0.102	0.132
$ZM_i$	-	-	0.908	-	-	0.823

Table 3. Results of multilevel-logistic regression analysis (log likelihood).

List A			
Fluency	Familiarity	ZM	DbS
-4093	-4022	-4687	-4658
List B			
Fluency	Familiarity	ZM	DbS
-4638	-4498	-4504	-4484

Taken together, it was found that choice patterns were explained by different models depending on which list was used. In List A, heuristic models explained choice patterns better than knowledge-based inference models. In contrast, in List B, where participants were predicted to easily access many clues pertaining to the population size, choice patterns were explained by knowledge-based inference models better than heuristic models.

#### Analysis of individual data<sup>4</sup>

**Similarity among models.** As in the aggregated analysis, we first analyzed the similarity of correlations among the four models. We calculated correlation coefficients for each participant, and examined the distribution of the coefficients.

Table 3 provides medians of correlation coefficients for the six pairs. In List A, results were analogous to those in the aggregated data analysis. However, the observed similarities were much stronger than with the aggregated data analysis. For List B, similarity between two knowledge-based inference models was observed as in the aggregated data analysis. However, similarities were not observed between the fluency heuristic and familiarity heuristic. Moreover, similarity was not observed between the two heuristics and two knowledge-based inferences.

Thus, we found that there was no similarity between the two models at the individual level, even when it was observed with the aggregated data.

**Predictions of choice patterns.** Next, we examined choice patterns using individual data. Specifically, we adopted a model-based approach using a multilevel-logistic regression analysis (Gelman & Hill, 2007). We compared the four models that predicted the choice patterns in terms of model fitting.

The four models, fluency heuristic, familiarity heuristic, ZM, and DbS are represented as follows:

$$\log \frac{P_{CLi}}{1 - P_{CLi}} = aFlu_i + b \quad (6)$$

$$\log \frac{P_{CLi}}{1 - P_{CLi}} = aFam_i + b \quad (7)$$

$$\log \frac{P_{CLi}}{1 - P_{CLi}} = aZM_i + b \quad (8)$$

$$\log \frac{P_{CLi}}{1 - P_{CLi}} = aDbS_i + b \quad (9)$$

where  $P_{CLi}$  denotes the choice rate for the larger city in pair  $i$ . Values  $a$  and  $b$  denote free parameters for weight and intercept, respectively. For Lists A and B, these four models were regressed, based on individual data from 79 participants. Then we assessed the goodness of fit of the models using log-likelihood values. Table 3 shows the result of this analysis. For List A, the familiarity heuristic resulted in the best fit among the four models. For List B, DbS was a better fit than the other models.

Hence, findings based on individual data were analogous to those based on aggregated data. It was found that participants changed their inference strategies, depending on the list. Choice patterns with List A were well explained by the familiarity heuristic, and those with List B were well explained by DbS.

### General Discussion

In the present study, we examined the processes of inference regarding binary choices by model comparisons. We proposed statistical models for simple heuristic and knowledge-based inferences. It was found that the familiarity heuristic well explained the inference patterns for List A, and that DbS well explained those for List B. These findings suggest that people use different strategies depending on the situation.

The most important difference between Lists A and B is how easily people can retrieve clues relevant to population size. Given that List B consisted of well-known cities (Hon-

<sup>4</sup> In the following analyses, we excluded U-U pairs.

da et al., 2011), participants could easily retrieve clues pertaining to population size. For larger cities, participants could retrieve many clues suggesting that the population size would be large. Similarly, participants could retrieve many clues suggesting smaller population sizes for small cities. As a result, inference patterns could be well explained by knowledge-based inference models. Note that DbS explained the inference patterns better than ZM. This finding suggests that participants could have a good sense of population size in relative level. This is consistent with the findings of Hilbig, Pohl, and Bröder (2009).

On the other hand, participants might not have retrieved clues relevant to population size, and then used a simple inference strategy, such as the familiarity heuristic. In other words, a simple heuristic is the likely strategy when people have difficulty in retrieving clues relevant to inferences. This finding is consistent with the framework for understanding heuristics proposed by Shah and Oppenheimer (2008).

## Same- and cross-person compound contributions in dialogue

### Abstract

In natural conversation people sometimes build larger grammatical, semantic and pragmatic units out of multiple turns or installments. The incremental and collaborative character of these ‘compound contributions’ presents challenges for theories of natural language processing. Compounds produced over successive turns by one person have often been analysed in essentially the same way as compounds produced by multiple people. In some recent accounts this putative equivalence has been taken as evidence for the claim that within- and cross-person language processing are fundamentally interchangeable. However, in this paper we present an analysis of compound contributions in a corpus of ordinary dialogues which shows that same- and cross-person compound contributions are constructed in different ways and have different semantic and pragmatic effects on the organisation of dialogue. In particular, we show that they differ in the pragmatic environments in which they occur and that they have different consequences for subsequent turn-taking and interpretation. This asymmetry highlights the need for models of dialogue that account for not just the inherent incrementality of dialogue, but the different status of each contributor towards a turn-in-progress.

**Keywords:** Dialogue; compound contributions.

### Introduction

*Compound contributions (CCs)* – dialogue contributions that continue or complete an earlier contribution, see e.g. (1) – are the paradigm case of coordination in dialogue and constitute a critical test case for theories of *natural* language processing.

- (1) **Daughter:** Oh here dad, a good way to get those corners out  
**Dad:** is to stick yer finger inside.  
**Daughter:** well, that’s one way.  
[from Lerner (1991)]

CCs are of interest to dialogue theorists because they provide evidence about how contributions can cohere with each other at multiple levels – syntactic, semantic and pragmatic (though of course they are not the only way). They also indicate the radical context-dependency of conversational contributions, which can, in general, be highly elliptical without disrupting the flow of the dialogue. CCs are a dramatic illustration of this: speakers must rely on the dynamics of the unfolding context (linguistic and extra-linguistic) in order to guarantee successful processing and production.

Much of the work on CCs has studied cross-person cases, in different disciplines and under a variety of different names, including *collaborative completions* (Clark, 1996; Poesio and Rieser, 2010), *co-constructions* (Sacks, 1992), *joint productions* (Helasvuo, 2004), and *split utterances* (Purver et al., 2006).

Linguistic studies show that grammatical constraints are respected across speaker and hearer (see e.g. Gregoromichelaki et al., 2009). In Finnish (which has rich inflectional morphology), and Japanese (a verb-final language), cross-person CCs within a single clause conform to the strict syntactic constraints of the language, despite the change in speaker (Helasvuo, 2004; Hayashi, 1999).

From a psycholinguistic point of view, the phenomenon of CCs seems compatible with mechanistic approaches as exemplified by the Interactive Alignment model of Pickering and Garrod (2004), which claims that, all things being equal, it should be as easy to complete another’s sentence as one’s own. According to this model, speaker and listener ought to be interchangeable at any point. A similar stance is taken by the grammatical framework of Dynamic Syntax (DS: Cann et al., 2005). In DS, parsing and production are taken to employ the same mechanisms, leading to a prediction that CCs ought to be strikingly natural (Purver et al., 2006).

From an organisational point of view, it has been claimed that turn-taking operates not on individual conversational participants, but on ‘parties’ (Schegloff, 1995). For example, a couple talking to a third person may organise their turns as if they are one ‘party’, rather than two separate individuals. Lerner (1991) speculates, following Sacks (1992), that cross-person compound contributions can clarify the formation of such parties, as they reveal a relationship between syntactic mechanisms and social organisation. He claims that this provides evidence of one way in which syntax can be used to organise participants into “groups”.

Because a sentence is obviously a prototypical instance of that thing which is done by a unit. Normally, some single person. That then permits it – for those who have the wit to do it – to be a way that some non-apparent unit may be demonstrated to exist.

We get, then, a kind of extraordinary tie between syntactic possibilities and phenomena like social organization. That is, an extremely strong way that these kids go about demonstrating that, for one, there is a group here, is their getting together to put this sentence together, collaboratively. (Sacks, 1992, p145)

These different approaches all treat cross-person compound contributions as being in some sense equivalent to turns produced by a single participant, in syntactic, semantic or pragmatic terms. However, there are few studies of same-person CCs, and those that there are (e.g. Goodwin, 1979; Walker, 2004) focus on the subset of *expansions*, which add material to an already potentially complete contribution (2), excluding *completions*, which involve the addition of syntactic material which is required to make the whole compound contribution (syntactically) complete (3).

- (2) **T:** It'll be an E sharp.  
**G:** Which will of course just be played as an F.  
[BNC G3V 262-263]
- (3) **D:** Well I do know last week thet=uh Al was  
 certainly very (pause 0.5s)  
**R:** pissed off [Lerner (1996), p260]

Like cross-person expansions, same-person ones are viewed as a highly productive way of utilising grammatical constraints for interactional purposes. Walker (2004) notes "it would seem that increments can be added to almost any possibly complete turn at talk, placing the practice alongside other generic conversational practices such as self- and other-initiated repair" (p167).

This type of treatment again suggests that there should be no differences to supplying a continuation to a prior turn, regardless of who produced the initial contribution. However, none of these studies have directly compared same- and cross-person CCs. We here present a corpus study to bridge this gap.

## Hypotheses

We examine two basic questions. First, whether the internal construction of CCs i.e., the syntactic and pragmatic ways in which the component parts are tied together, is the same in the same- and cross-person cases. Second, the external organisation of CCs; whether CCs as a whole are integrated into conversational organisation in the same way as as a conventional turn.

Following the existing literature we analyse the internal structure of the CC in terms of; a) the syntactic relationship between the components i.e. whether they are expansions or completions (as described above), b) repair i.e. whether the continuation of the CC is used to perform an edit or amendment on the antecedent and c) separation i.e. how closely together the antecedent

and continuation parts of a CC are normally placed. For the external organisation of CCs we examine the pragmatic organisation of the sequences in which CCs occur. Specifically, the patterns of turn-taking (who will speak next) and ratification (who acknowledges or responds to the CC). We also consider the placement of CCs with respect to backchannels. Backchannels are short acknowledgements like 'aha' or 'mmm', often produced in overlap with a speakers turn, which provide feedback to a speaker but don't typically lead to a change of speaker.

If there is no fundamental syntactic or cognitive difference between same- and cross-person CCs (e.g. Pickering and Garrod, 2004; Cann et al., 2005) then, all things being equal, we would expect that they should have the same distribution of expansions/completions, repairs and antecedent-continuation separations.

**Hypothesis 1** *Same-person and cross-person CCs have the same patterns of internal construction.*

In addition, if a CC functions as a single turn that just happens to have been produced in two (or more) parts (potentially by more than one person), rather than being a distinctive form of contribution, then they should be integrated into the conversation as a whole in the same way as non-compound turns. This would predict that the patterns of backchannels, turn-taking and ratification should, all things being equal, be the same for CC and non-CC turns. Moreover, this external organisation should be the same for both same-person and cross-person CCs. In a typical conversational sequence once a speaker has finished someone else will usually – although not always – speak next. Similarly, people do not normally acknowledge or ratify their own turns.

**Hypothesis 2** *The people who produce a CC should be less likely than other participants to speak next. They should also be less likely than other participants to ratify or acknowledge the CC.*

## Method

To investigate similarities and differences between same- and cross-person CCs, a corpus analysis of CCs in the spoken portion of the British National Corpus (BNC: Burnard, 2000) was carried out. This part of the corpus contains a large number of genuine spoken dialogues across a wide range of people and situations, allowing us to examine the prevalence of CCs in a variety of dialogues not restricted to the task-based dialogues which previous corpus studies tend to have analysed.

## Materials and procedure

For this exercise, the portion of the BNC annotated by Fernández and Ginzburg (2002), chosen to maintain a balance between what the BNC defines as *context-governed* (drawn from a particular domain e.g. business meetings, school classes, radio interviews) and *demographic* (recorded by volunteers during their daily lives)

dialogue, was used. This portion comprises 11,469 *s-units* – roughly equivalent to sentences<sup>1</sup> – taken from 200-turn sections of 53 separate dialogues.

**Annotation scheme** The dialogues were annotated according to the protocol outlined in Purver et al. (2009), and summarised in table 1, below.

Tag	Value	Explanation
end-complete	y/n	For all s-units: does this s-unit end in such a way as to yield a complete proposition or speech act?
continues	s-unit ID	For all s-units: does this s-unit continue the proposition or speech act of a previous s-unit? If so, which?
repairs	number of words	For continuations: does the start of this continuation explicitly repair words from the end of the antecedent? If so, how many?
start-complete	y/n	For continuations: does this continuation start in such a way as to be able to stand alone as a complete proposition or speech act?

Table 1: Annotation tags

## Results

person:	Same-		across-		Cross-	
	all				(all)	
	N	%	N	%	N	%
overlapping	0	0	0	0	18	5
adjacent	840	44	0	0	262	80
sep. by overlap	320	17	0	0	10	3
sep. by backchnl	460	24	456	63	17	5
sep. by 1 s-unit	239	13	229	32	16	5
sep. by 2 s-units	31	2	31	4	4	1
sep. by 3 s-units	5	0	3	0	1	0
sep. by 4 s-units	4	0	4	1	0	0
sep. by 5 s-units	1	0	1	0	0	0
sep. by 6 s-units	2	0	2	0	1	0
Total	1902		726		329	

Table 2: BNC antecedent/continuation separation

As discussed in Howes et al. (2011), the transcription conventions used when compiling the corpus can affect the raw results; in particular, the BNC convention of dividing contributions into “sentence-like units”, and in transcribing overlapping interruptions by interlocutors in linear time order, may result in an over-estimate of the number of same-speaker within-turn CCs. However, even excluding such within-turn and overlapping cases, and looking only at across-turn cases, there are over

<sup>1</sup>*S-units* are defined as “sentence-like divisions of a text”, and *utterances* are defined as “stretches of speech usually preceded and followed by silence or by a change of speaker”. Utterances may consist of many s-units; s-units may not extend across utterance boundaries. While s-units are therefore often equivalent to complete syntactic sentences, or complete functional units such as bare fragments or one-word utterances, they need not be: they may be divided by interrupting or overlapping material from another speaker.

twice as many same-person CCs (726) as cross-person CCs (329) – see table 2.

Many CCs have at least one s-unit intervening between the antecedent and continuation. In same-person cases, once we have excluded the within-turn CCs, this must always be the case; the intervening material is usually a backchannel (63%) or single other s-unit (32%, often e.g. a clarification question), but two intervening s-units are possible (4%) with up to six being seen. In cross-person cases, 88% are adjacent or separated only by overlapping material, but again up to six intervening s-units were seen, with a single s-unit most common.

## Completeness

As can be seen from table 3, the end- and start-completeness figures for same- and cross-person CCs are strikingly similar. The majority of both same- and cross-person continuations (71% to 72%) continue an already complete antecedent, with only 28-29% therefore being *completions*.

person:		Same-				Cross-	
		all	across-			(all)	
		N	%	N	%	N	%
Antecedent	Y	1367	72	513	71	236	72
end-complete	N	535	28	213	29	93	28
Continuation	Y	224	12	99	14	45	14
start-complete	N	1678	88	627	86	284	86
Repair	Y	77	4	34	5	32	10
	N	1825	96	692	95	297	90
Total		1902		726		329	

Table 3: BNC completeness and repair

These figures are even more striking when we consider the placement of arbitrary split points. In the experiment reported in Howes et al. (2011), artificial CCs were created in text chat dialogues, resulting in only 37% of fake CCs having a split point at a point where the antecedent could be considered end-complete (i.e. expansions) with 63% therefore appearing to be continuations.

This can be taken as evidence that participants in dialogue tend to wait for syntactic cues that suggest a possible opportunity for speaker change (referred to by conversation analysts as ‘transition relevance places’) before taking the floor – even where they construct their contribution as a continuation to a prior utterance.

## Repair

Although we are using only limited notion of **repair**, which only takes into account the amount of repetition or reformulation of words from the end of the antecedent at the start of the continuation, we believe that repair, as formulated, can be taken as an index of the difficulty of integrating the continuation to the syntactic material offered in the antecedent. This being the case, then under a model in which speakers and hearers are interchangeable (such as the interactive alignment model) the

proportion of repairs should be the same in same-person CCs as cross-person CCs, as there should be no increased difficulty in integrating one's continuation to another's antecedent as there would be to one's own. There should also not be any effects of where the split point occurs on the prevalence of repair.

However, cross-person continuations are significantly more likely to repair their antecedents than same-person cases (32/329, 10% vs. 34/726, 5%;  $\chi^2_{(1)} = 9.82, p = 0.002$ ), showing that there are differences between distributions of same- and cross-person CCs. In other words, although the distributions regarding completeness were equivalent and supported Hypothesis 1, it isn't this simple, and there appear to be additional constraints associated with continuing another's prior contribution that do not necessarily apply when continuing one's own.

## Backchannels

Similarly, there are different distributions of CCs in which the continuation follows a backchannel between same- and cross-person CCs. Same-person cases are more often produced as a response to a backchannel (63% of across-turn cases follow a backchannel, whilst even discounting adjacent cases only 40% of cross-person CCs do) suggesting that shaping one's next turn as a response to feedback is a common strategy in dialogue. Note also that 13% of all s-units in the corpus sample were backchannels<sup>2</sup> so there are actually a greater proportion of same-person cases following a backchannel than would be expected by chance, suggesting that backchannels may be used as a cue for participants to perform a *continue* grounding act (Traum, 1994).

## CA categories

In terms of specific types of CCs, the most common of the CA categories are Lerner's (1996) hesitation-related *opportunistic* cases, which make up 3-5% of same- and 10% of cross-person CCs, meaning cross-person opportunistic cases are more common than same-person ones (same, across-turn 36/726, 5% vs. other 32/329, 10%;  $\chi^2_{(1)} = 8.53, p = 0.003$ ). Interestingly, the breakdown of cases into those where the antecedent ends with an unfilled versus a filled pause also shows a difference between same- and cross-person cases: an other person is more likely to offer a continuation after an unfilled pause, than after a filled pause (antecedents ending in '*er(m)*' 35 continued by same, 13 by other; ending in '<pause>' 19 continued by same, 19 by other;  $\chi^2_{(1)} = 4.77, p = 0.03$ ). This finding backs up claims by Clark and Fox Tree (2002) that filled pauses can be used to indicate that the current speaker's turn is not yet finished and thus have the effect of holding the floor.

<sup>2</sup>This figure is based on the BNC part of speech tags, and as such may incorrectly include some answers to yes/no questions.

Lerner's compound TCU cases (*instead of*, *said/thought* etc, *if-then* and *when-then*) account for 2-3% of same-person and 1% of cross-person CCs, though note that these could be underestimates, as his non-syntactic cues (e.g. contrast stress and prefaced disagreements) could not be extracted. Rühlemann's (2007) *sentence relative* cases come next with 1-2%.

In contrast, the most common pattern (for same- and cross-person CCs) is the addition of an extending clause, either a conjunction introduced by '*and/but/or/nor*' (36-42%), or other clause types with '*so/whereas/nevertheless/because*', and the (other) category.

## Next speaker

To see if there are any effects on turn-taking or apparent party-membership, the 329 cross-person CCs were further annotated according to who spoke after the continuation and whether the conversation was dyadic or multiparty. Of the 53 dialogues, 34 were dyadic and 19 multiparty (though as observed in Eshghi (2009), many segments of multiparty dialogue are also dyadic in nature, we leave this to one side). This equates to 4919 turns in dyadic dialogues, in which there were 204 cross-person CCs (4.15%) and 2961 turns in multiparty dialogues with 125 cross-person CCs (4.22%). These proportions are not different (204/4919, 4% vs. 125/2961, 4%;  $\chi^2_{(1)} = 0.03, p = 0.87$ ), which is surprising – if cross-person CCs are used to indicate party-membership we might expect a greater proportion in the multiparty dialogues. This could be taken to suggest that parties are not common in these annotated dialogues.

There is no difference in the proportion of occasions in which the participant who contributed the continuation also provides the next contribution, thus holding the floor (50/204, 25% vs. 26/125, 21%;  $\chi^2_{(1)} = 0.600, p = 0.44$ , in line with the figure of 3/15, 20% reported in Szczeppek, 2000a). However, in all dialogues the proportion in which the supplier of the continuation retains the floor is lower than in general. For all annotated s-units in the dialogues there is no change of speaker in 41% of cases, compared to 23% of cases following a cross-person CC (4791/11469, 41% vs. 76/329, 23%;  $\chi^2_{(1)} = 44.424, p < 0.001$ ), suggesting that the continuation is treated as a separate turn and that interlocutors supplying a continuation do not assume they have a right to retain the floor.

## Ratification

Supporting the idea that ratifications ought to be more common in dyadic dialogues, if only appropriate when addressed to the original speaker, cross-person CCs are ratified or rejected by the initial speaker in (marginally) more cases in dyadic than multiparty cases (82/204, 40% vs. 37/125, 30%;  $\chi^2_{(1)} = 3.769, p = 0.052$ ). This does suggest that in dyadic dialogues cross-person CCs are

more often interpreted by the antecedent owner as addressed towards them, potentially as a form of repair which requires acknowledgement or ratification, and not interpreted as simply the mechanistic articulation of predictable material by another.

Cross-person CCs are also more likely to be ratified or rejected in completions than expansions (59/93, 63% vs. 79/236, 34%;  $\chi^2_{(1)} = 24.600, p < 0.001$ ). This is surprising if completions are merely the vocalisation of already predicted material (as in the interactive alignment model, for example), or if they are taken to be explicit acknowledgements (in a grounding model) as they should not then need either explicit evaluation or additional completion by the contributor of the antecedent.

In total, 138/329 (42%) of cross-person CCs are ratified; which is not rare, suggesting that cross-person continuations are often treated as not part of the same single unit as the antecedent. In a grounding model this suggests that these cases are those which are taken to be repairs, or new discourse units though note that we cannot distinguish between these possibilities. However, if they are treated as repairs then they are not treated as within-party repairs analogously to self-repairs, because these should also not require ratification.

## Discussion

Contrary to the predictions of Hypothesis 1, although there are similarities between same- and cross-person CCs, for example in the distributions of expansions versus completions, there are also significant differences. Cross-person continuations are more likely to start with explicit repair/reformulation of the antecedent. This suggests that people use CCs to do different things in the same and cross-person cases. Repairs are interesting in this context because they are not predictable continuations of the preceding contribution and therefore provide a counter-example to the idea that CCs are appropriately analysed as essentially the same turn but with a switch of producers. Perhaps more interestingly, they also suggest the operation of a more strategic process. It is generally observed that people avoid repairing other people's turns (known in Conversation Analysis as the preference for self repair; Schegloff et al., 1977). The observed pattern might be one that we would expect if cross-person CCs, in virtue of being constructed as a continuation of the speakers utterance, provide a device that enables a less exposed or 'face-threatening' form of other repair (as Lerner (1993) hypothesised). This works as a repair strategy to the extent that the completed CC is understood as 'belonging' to the producer of the antecedent of the CC. However, as we go on to discuss, our observations about patterns of turn-taking suggest that this is not straightforwardly the case.

Opportunistic CCs (after a '<pause>' or 'erm') are in general more likely to be cross-person cases; however

there are again pragmatic constraints – cross-person CCs are more likely where the antecedent ends in an unfilled rather than a filled pause. This suggests participants are aware of turn-taking or sequential expectations, and that speaker and hearer roles carry different responsibilities.

There also seem to be different places when same- and cross-person continuations are offered; the majority of cross-person continuations are adjacent to their antecedents, whilst even considering within-turn cases this is not so for same-person continuations. Same-person continuations are far more likely to follow a backchannel or single other s-unit than cross-person cases, suggesting that it may be the feedback from one's interlocutor(s) that leads to producing something syntactically tied to one's own prior contribution.

Contrary to Hypothesis 2, ratifications are offered following a cross-person CC; something which should be rare if the speaker of the antecedent were treating the continuation as if they themselves had just finished their turn. The assumption that cross-person CCs operate as a single turn that just happens to have been produced by more than one interlocutor, is perhaps an artefact of syntactic analyses that idealise away from the key organisational features of conversation. The evidence from CCs suggests that they might be better characterised as separate contributions that build parasitically on prior contributions, meaning that syntax is not an organising structure in the production of dialogue, but a resource that can be flexibly exploited by participants.

That ratifications were also more likely to be offered following a completion rather than an expansion, suggests that completions can also not be taken to be solely grounding devices, but must also be being treated by the antecedent owner as at least potentially repairing the incomplete antecedent (in which case an acknowledgement is appropriate).

This means that although one can unproblematically finish or continue another's utterance, this does not give it the same status as if they had completed or continued it themselves and has consequences for how we model CCs in particular and dialogue in general. There are several ways in which this might be approached. Either continuations by another are generally treated as repairs (and not exclusively as particularly strong forms of acknowledgement) or they are not taken to be acknowledgements at all. Given that continuations tend to be offered when common ground is presumed to be shared it could be the case that it is the presumption of shared common ground which requires acknowledging, or rejecting. Alternatively, it might be the fact that the incoming participant is aligning themselves with the initial speaker that requires acknowledgement, and not the content itself.

From a dialogue modelling perspective, we would want to be able to tell when a human agent's contribution con-

tinues some prior contribution – either their own or the system’s – in order to correctly analyse the semantics of the discourse, which is non-trivial given that antecedents do not have to be (and often are not) incomplete, or adjacent to the continuation.

The system should also be able to produce naturalistic continuations, and respond appropriately (e.g. by acknowledging a continuation from the user) including in terms of turn-taking. One example is the use of expansions – the system need not compute a complete sentence, but could use previously parsed input as a starting point. As dialogue models are very often in highly constrained contexts in which the system seeks information from the user, appropriate strategies involving CCs could be using incomplete antecedents to invite a user completion (for example, the travel agent system might ask “You want to go to...?”) and appendor questions (“...by bus?”) – see Hough (2011), for a preliminary outline of such a system.

# Language acquisition in Down Syndrome from embodied perspective: How body constrains language acquisition?

P. Hristova (phristova@cogs.nbu.bg), H. Toushek (chrissidt@yahoo.com), G. Petkov (gpetkov@cogs.nbu.bg)

Department of Cognitive Science and Psychology, New Bulgarian University, 21 Montevideo Street  
Sofia 1618, Bulgaria

## Abstract

Parents of children with Down syndrome (DS) were asked to fill a questionnaire about how much their children understand and how well they use words. It was found that word acquisition is affected not only by word frequency, but also by whether a word is related to eventual misbalance of the body. The results are in favor of the hypothesis that the constraints of the human body may cause systematic variations of language acquisition as long as keeping the body balance is a typically difficult motor task for DS children. Additionally, we also found an asymmetry of the acquisition of the verbs and the nouns, depending on their frequency and relatedness to eventual misbalance of the body.

## Introduction

Usually learning of a native language takes several years. During their first years of life children learn thousands of linguistic symbols and constructions used by people around them. How does this extensive learning happen? Glenberg, A.M., Havas, D., Becker, R., & Rinck, M. (2005) conclusively argue backed up with the Searl's Chinese room and the Harnad's symbolic marry-go-around argument, that language must be grounded outside the linguistic system. Language gets meaning from what is already meaningful for children, i.e. perceptions, actions and emotions. Many cognitive psychologists, however, would agree that the initial states of language acquisition are grounded in perception and action, since at least, the first symbols can be considered as gaining meaning from these modalities. The problem mainly concerns the mature language processing where the role of bodily states for language use is still debatable (Glenberg et al, 2005). Recently, however, a study on body-specificity hypothesis has shown that right-handers activate the left-premotor cortex during lexical decision on manual-action verbs, while left-handers activate the right premotor cortex (Willems, Hagoort, Casasanto, 2010). Hence, it seems reasonable to assume that different bodies lead to different representation of environmental categories and therefore, to predict that body differences are connected to specific differences in language usage.

The goal of this study is to provide preliminary evidence that specific body constraints correspond to specific patterns of language acquisition. The possibility that the human mind and body were evolutionary shaped by language in a way that allows language production and comprehension is largely recognized nowadays (for a review, Pinker, S., 2000), but the opposite direction is still fairly underestimated. In other words, there has been no attempt, at least to our knowledge, to investigate systematic variations in *language acquisition* due to particular body constraints.

We start from the consistent evidence for specific difficulties in the Down Syndrome population (Lauteslager, 2004; Winders, 1997) for problems with maintaining balance and posture (i.e., insufficient stability, lack of trunk rotation and delayed reaction speed) that according to Lauteslager (2004) leads to a peculiar compensatory symmetrical manner of moving, mainly characterized by lack of variability. Every move that threatens the balance seems to be problematic for children with Down Syndrome (DS). Thus almost every stage of the typical motor development is a hardship for a DS child, who usually is able to maintain head control, sitting, standing, climbing, walking, jumping etc. considerably late in his/her development. But importantly, the way DS child acquires the motor skills important for independent locomotion is different from the typically development trajectory and is characterized by preference toward symmetrical movements with a lot of external support. The main reason considered to be responsible for the specific motor development of DS children is the low muscle tone (i.e. hypotonia) that affects individuals from this population in different degree but is present from birth and persist throughout life.

To summarize, the low muscle tone constraints motor development of DS children, causing problems with maintaining balance and posture, which in turn leads to development of specific symmetrical movements, movements with a lot of external support and static motor behaviour (Lauteslager, 2004). Thus we hypothesize that word for actions and objects that threaten body posture and balance will be represented differently from DS population compared to normally developing one.

Unfortunately, it is difficult to predict how these specific body constraints would change language acquisition. It is possible that children with DS will acquire the meaning of words that are problematic for their motor planing and behaviour much later than other words which do not tread body posture and balance. In other words, because it is difficult for them to walk, run, climb, swing etc. they will avoid such behaviors and the respective situations that require these actions. If this hypothetical scenario really takes place, then the direct sequence should be a substantial underrepresentation of such nouns and verbs that in some respect threaten their balance and body posture.

But we may expect just the opposite result as well, namely that children with DS will know better the words, associated with maintenance of posture and balance than the other words. If children with DS are raised in a stimulating environment, which encouraged them to walk, to bring the ball, to jump, to ride etc. they will finally master these actions. Moreover, during this process of pure motor

development child's attention necessarily should be focused on the accomplishment of movements that are difficult for them. Hence everything that happens at this moment of keen attention can be potentially encoded better, including the labels for the body movement, hopefully provided from people around them. Since, it was reported that they have substantial deficits in sustained attention (i.e. attention toward a given stimulus that allow its efficient processing) (Brown, Johnson, Paterson, Rick Gilmore, Longhi and Karmiloff-Smith, 2003), the attention toward a difficult action seems to provide a prolonged period of focused attention that may facilitate encoding at least of the label of the action and the associated with this action objects.

To sum up, we expect a substantial difference in both understanding and production of words, associated with body posture and balance in DS children. At this point, we don't have any strong theoretical reasons to narrow down our expectations. But, since we plan to study understanding and production of word in home-raised children with DS (i.e. hopefully, these children were stimulated to interact actively with the surrounding physical and social environment) we assume that the mere association of a given word with posture and balance maintaining will facilitate its knowledge.

### **Language acquisition in children with Down Syndrome**

Overall, children with DS acquire language at slower rates than typically developing children on the same chronological age. They produce shorter sentences and tend to omit function words (i.e., articles, prepositions, pronouns, etc.) (Chapman, 1995). Language comprehension in DS is usually superior to language production, but still significantly behind their level of cognitive development (Miller, 1992), mental age (Vicari, Caselli, Gagliardi, Tonucci, & Volterra, 2002) or vocabulary size (Singer et al, as cited in Tomasello, 2006). Overall the linguistic abilities of children with DS are surprisingly behind the ones expected on the bases of their cognitive abilities.

But actually the picture is much more complicated. A few studies point to the possibility that language acquisition in DS has its own profile, which turned to be different from the one of typically developing children. When asked to repeat words and sentences children with DS omit a significantly higher number of articles, verbs, and prepositions than typically developing children and children with specific language impairment, matched on mental age (Caselli, Trasciani, & Vicari, 2008). The authors explain these differences with the specific repetition task administered to children that certainly relies on different cognitive abilities, including verbal short-term memory, executive control etc., that are usually reported to be poorer in DS than in mental age-matched children with typical development. However, general cognitive impairments can hardly explain why exactly verbs, articles and prepositions are preferentially omitted by children with DS rather than nouns and modifiers.

On other hand, another line of research points to the fact that verb acquisition poses specific difficulties to DS children, since verb understanding strongly relies on syntactic development (Tomasello, 2006), which is reported to be dramatically delayed in this specific population (Fowler, 1990 as cited in Tomasello, M, 2006). Naigles, Fowler, & Helm (1995) point out that verbs incorporate both semantic and syntactic knowledge and thus mastering of verb meaning should depend on both of these components: "specific lexical and syntactic information concerning each individual verb must be accrued in order to establish stable verb representations".

Overall, based on the Caselli et al (2008) and Naigles et al. (1995) findings we may expect that children with DS will underrepresent verbs compared with nouns. With respect to our hypothesis, also seems much easier to imagine how verbs are learned through out specific actions than nouns, for example. Hence, the expected effect of embodiment on language acquisition, if any, should be predominantly expected in the domain of verb learning.

Then, our question is what will happen with word learning in general and verb learning in particular, if some actions are more difficult for an individual than others.

### **Investigation**

We asked parents of children with Down syndrome and parents of typically developing children, matched on age (control group) to judge on a 7-point scale how well their children understand and how well they use the respective words. We designed a list of 172 Bulgarian words, controlled for objective frequency, length, type (noun or verb), and balanced with respect to embodiment, i.e. the degree of association between a given word and maintenance of body posture and balance (see section Stimuli below).

Whereas, expectedly, the results for the control group reached a ceiling effect for all words, the data of DS group seems to follow an interesting trend.

### **Method**

#### **Design**

The design of the study was 2(diagnoses of trisomy 21: yes/not) x 2(objective frequency: high/low) x 2(length of the word: long/short) x 2 (type of the word: noun or verb) x 2(embodiment: high/low) factorial design. The dependent measures were the ratings, given from the parents of the children, to the understanding and to the production of the respective words.

An additional independent factor – concreteness/abstractness was measured for control considerations (see the next section - Stimuli).

#### **Stimuli**

We achieved the objective frequency of 355 Bulgarian words from a corpus of 70 stories, included in the training

program for public kindergartens in Bulgaria. The length of the words varied uniformly between 3 and 11 letters.

On the next step, we asked two native speakers to judge each of the word on a 7-point scale according to the instruction: “Please, rate on a 7-point scale how much each of the following concepts or actions disturbs body posture or balance”. For example, both experts gave high ratings to verbs like rush toward, jump, and scramble. Both experts gave high ratings to nouns like fight, stroke, and ball. On the other pole, low ratings were given for verbs like rill, mistake, love; and nouns like sky, gold, sign... The highest disagreements between the expert’s ratings were 3 (on a 7-point scale).

Finally, we chose 172 words from the whole list (100 verbs and 72 nouns) and formed 86 pairs of words with polar ratings according to their embodiment (relatedness to dis-balance of the body) and fixed objective frequency and length. More precisely, we ensured that for each verb (respectively noun) with a specific length, frequency, and low embodiment, there is another verb (respectively noun) in the list with same length and frequency but with high embodiment. The length of the words was distributed among 3 and 11 letters with a dominance of 4-8 letter words.

If the value of the words according to frequency and embodiment dimension are discretized onto “high frequent”, “low frequent”, and, respectively “high embodied” and “low embodied”, the overall distribution of the stimuli would be the one shown in Table 1.

Table 1. Distribution of the stimuli – verbs on the top panel; nouns on the bottom panel.

<i>VERBS</i>		frequency		
		low	high	total
embodiment	low	31	16	47
	high	35	18	53
	total	66	34	100
<i>NOUNS</i>		frequency		
		low	high	total
embodiment	low	21	19	40
	high	17	15	32
	total	38	34	72

For an additional control, we asked 14 adults (10 women and 4 men) on mean age of 22.5, to rate the words according to their concreteness/abstractness. This was an additional ad-hock variable, used to control for: First, whether our measurement of embodiment wasn’t actually a measurement of concreteness. Second, whether concreteness is the better predictor of understanding and usage of words then the other factors. Thus, for each of the 172 words we had also an average rating of its concreteness/abstractness on a 7-point scale (1- very concrete...7- very abstract).

## Procedure and participants

Eight parents of children with DS (seven mothers and one father) were asked to evaluate each of the words according to two criteria:

First, how much they think that their child understand the respective word.

Second, how appropriate their children use the respective word.

The ratings were given on a 7-point scale. The order of the words was random for every participant. The parents worked at home. At the beginning of the questionnaire, they should fill the age of the child as well as additional health problems, if any. All parents were duly confident that the data are confidential and will be used for statistical purposes only.

The same procedure was used for a control group of the parents of ten children without DS.

The age the children with DS were between 4 years and 4 years and 7 months. Half of the children (4) were girls and the other half (4) – boys. Two of the children had corrected to normal vision, 2 had heart problems (one of them was diagnosed also with West Syndrome). All children with DS were with full trisomy 21and not mosaic. All parents of DS children in our study were recruited from Bulgarian Down Syndrome Association and were with university education.

The group of the typically developing children was matched in age and sex to the DS children in our study. None of them did not have heart or vision problems. All parents again were with university degree of education.

## Results

First of all, we received a clear ceiling effect for the children from the control group. The mean rating for understanding was 6.662, st. dev. 0.623 for all words; the mean rating for usage was 0.659, st. dev. 0.708.

The respective mean ratings for the DS children, however, were:

For understanding: mean rating 3.887, st. dev. 1.883; for usage: mean rating 1.772, st. dev. 1.002

The rest of analyses were on the results from the DS children only and reflect the pattern of language understanding and production observed and reported from their parents. The data for all DS children were averaged by item (172 independent words) and we analyzed the impact of embodiment, frequency, length and type of the words two dependent variables – mean rating of understanding and mean rating of production.

For control (see below, at the end of the section Results), we aggregated the data by subject as well and repeated the analyses assuming within-subject design (each subject was an independent case).

**Results for understanding, depending on objective frequency, length of the words, type of the words**

(verbs/nouns) and embodiment (how much each concept or action disturbs body posture or balance)

The Univariate ANOVA analysis on *understanding* detected main effect of the frequency ( $F(1, 164) = 12.031, p = 0.001$ ) and of the embodiment ( $F(1, 164) = 8.730, p = 0.004$ ). There was not significant main effect of the type of the word (verb or noun): ( $F(1, 164) = 1.465, p = 0.228$ ). In other words, parents in our sample estimated words with high objective frequency as the words that their children understand better than the words with lower objective frequency. Interestingly, words with high embodiment were also rated as significantly more knowable for children with DS than words, associated with less posture disturbances and balance difficulties.

There were not significant interactions among pairs of the variables but it was a significant triple interaction among frequency, embodiment, and type of the word ( $F(1, 164) = 4.708, p = 0.031$ ). Figure 1 illustrates this interaction:

Figure1: The influence of the frequency and embodiment on the understanding of the words by the children with Down syndrome was different for the verbs (upper panel) and nouns (bottom panel)

Thus, the pattern of understanding of the words was found to be completely different. Whereas both high frequency and high embodiment support understanding (not much surprisingly), it happen that embodiment doesn't support understanding of low frequently nouns.

The length of the words influenced understanding of the verbs ( $F(1, 98) = 9.246, p = 0.003$ , obtained by a linear regression analysis): according to parents of DS children their children understand shorter verbs better than longer ones. However, the length doesn't influence significantly understanding of the nouns: ( $F(1, 70) = 0.125, p = 0.725$ ). One may argue that this is due to the fact that children learn first the nouns, thus the influence of the length became slower. However, we didn't found a significant difference between the overall level of understanding of the verbs and the nouns. It should be mentioned, however, that it was a significant correlation between length and frequency ( $r = -0.279, p < 0.001$ ).

The final control measurement – concreteness/abstractness of the words, correlated with embodiment ( $r = -0.244, p = 0.001$ ) and didn't correlated with the other independent variables.

Whereas it was a main effect of abstractness on understanding ( $F(1, 164) = 6.739, p = 0.010$ ), there were no any interactions (neither paired, neither triple) with the other factors (i.e., embodiment, frequency, length and type of the word). Thus, our interpretation is that embodiment is different measurement from concreteness and that the interesting interaction on Figure 1 is due to the relatedness of the words to a possible disturbance on the balance of the body, instead of concreteness/abstractness.

**Results for production, depending on objective frequency, length of the words, type of the words (verbs/nouns) and embodiment (how much each concept or action disturbs body posture or balance)**

Although the ratings for the other dependent measure – correct usage of the words – were much lower, the results followed similar pattern according to all analyses:

It was main effect of the frequency ( $F(1, 164) = 11.885, p = 0.001$ ) and of the embodiment ( $F(1, 164) = 4.582, p = 0.034$ ). In contrast with the results for the understanding, it was a significant main effect of type of the word too: ( $F(1, 164) = 11.216, p = 0.001$ ). The nouns received higher ratings.

There were not any pair interactions. The triple interaction between frequency, type of word, and embodiment was with a marginal significance only: ( $F(1, 164) = 3.046, p = 0.0083$ ).

Length of the word influenced usage of the verbs ( $F(1, 98) = 14.126, p = 0.000$ ) and doesn't influence the usage of the nouns ( $F(1, 70) = 0.055, p = 0.815$ ).

It was main effect of abstractness ( $F(1, 164) = 4.137, p = 0.044$ ) without any paired or triple interactions. For comparison with the marginal significance of the interaction between frequency, type, and embodiment, the results for the respective interaction between frequency, type, and abstractness was  $F(1, 164) = 0.194, p = 0.660$ .

**Repetition of analyses:** analyses on the data averaged by subject

The impact of embodiment, frequency, length and type of the word was measured with a Repeated Measures Analysis on data averaged by subject (i.e., eight DS children). The main effects of these factors were again estimated as significant. We obtained main effects of frequency ( $F(1, 7) = 66.714, p = 0.000$ ), of embodiment ( $F(1, 7) = 46.505, p = 0.000$ ), and also of type of the word ( $F(1, 7) = 9.239, p = 0.019$ ).

The triple interaction was also significant:  $F(1, 7) = 31.166, p = 0.001$ . The only difference was that Repeated Measures Analysis estimated as significant the interaction between frequency and embodiment:  $F(1, 7) = 12.071, p = 0.010$ .

## Discussion

According to their parents children with DS understand and use better words that involve difficult for them actions, namely the ones associated with greater posture disability and asymmetry. It seems that, while performing the difficult for them body movements, children learn better the words for these movements and the words for the objects that are typically connected to this movements. Having in mind that keeping the balance of their body is a typically difficult motor task for these children, the result is in favor of the hypothesis that the body constraints may cause systematic variations of language acquisition.

Interestingly, although both frequency and embodiment influence word understanding and production of DS children, the pattern for verbs and for nouns differs. The embodiment doesn't influence low frequent nouns. This was not due to a floor effect, as can be seen on Figure 1 and cannot be explained just by a complete misunderstanding of those words. This asymmetry raises new questions and requires further investigations.

The main effect of embodiment, however, points to an important trend in language acquisition in children with DS: the words that are related to eventual misbalance of the body were estimated as better understood and used from DS children.

The important question, however, is why this happens. We speculated at the beginning of this paper that children with DS may be recognize the situations that disturb their body posture or balance as more difficult and hence, requiring their attention. Then, their outperformance on words that are associated with such situations can be considered as a matter of attention, which is dedicated to the maintenance of body posture and balance. The extra attention dedicated to the movements that require maintaining of posture and balance may as a side effect improve the knowledge for the associated concepts. Attention, indeed, seems to be a problematic cognitive ability for DS population. Brown et al.(2003) conclusively argued that toddlers with DS has significant problems with maintaining attention to objects in the environment compared to a group of chronologically matched toddlers with Williams syndrome, a group of chronologically matched typically developing children and a

group of mentally matched typically developing children. Possibly, the extra attention and effort toward the difficult actions may overcome the reported sustained attention deficits of DS children. Instead of training the sustained attention of children with DS we may compensate it with educational techniques that back on their posture and balance difficulties.

It could be, however, that DS children recognize actions that disturb their body posture and balance as threatening ones, since at least at the beginning of their motor development these actions usually end up with incidents, associated with physical pain. Possibly, in order to avoid successfully this actions, children with DS learned better everything, associated with situations that treat their body posture and balance.

Of course, both explanations could be rephrased in a way that appreciates the role of the parents in raising their children. It is quite possible, indeed probable that parents, rather than children recognize, which are the threatening and the difficult situations for their DS toddlers and pay more attention in teaching them how to master such situations. Again, the prediction will be that children finally will learn better the words associated with such situations than with others.

Unfortunately, our study could not disentangle between those possible explanations, but we find the compensatory account the most interesting one. If extra intentional resources can be allocated to particular movements and as a side effect this extra attention can improve conceptual knowledge, we may design techniques for both native and foreign language learning appropriate for the DS peculiarities.

## Abstract

Previous studies have demonstrated that comprehension of conceptual metaphors elicits embodied representations. This finding is non-trivial, but begets the question whether alternative explanations are to be dismissed. The current paper shows how a statistical linguistic approach of word co-occurrences can also reliably predict metaphor comprehension. In two experiments participants saw word pairs with positive (e.g. *happy*) and negative (e.g. *sad*) connotations. The pairs were presented in either a vertical configuration (Experiment 1) or a horizontal configuration (Experiment 2). Results showed that response times could be explained by both the statistical linguistic approach and the embodied approach. However, embodied information was most salient in the vertical configuration and statistical linguistic information was most salient in the horizontal configuration. Individual differences modulated these findings, with female participants being most sensitive to the statistical linguistic approach, and male participants being most sensitive to the embodiment approach. These findings suggest that comprehension of conceptual metaphors can be explained by both linguistic and embodiment factors, but that their relative salience is modulated by cognitive task and individual differences.

**Keywords:** embodied cognition; symbolic cognition; linguistic context; valence words; gender differences; symbol interdependency

## Introduction

When we are happy, we are in high spirits; when we are sad, we are down in the dumps. Our mood is lifted when we are cheerful, but our enthusiasm drops when we are depressed. We have our high times and our low times. We reach for the sky, but sometimes our plans run into the ground. These are some examples suggesting that conceptual metaphors highlight associations between abstract concepts (e.g., happy, sad) and spatial properties (e.g., high, low). Lakoff and Johnson (1981; 1999) suggest that metaphors like these help automatically ground abstract concepts in bodily experiences. In this sense, metaphors inform the language user of the perceptual and biomechanical processes underlying the representation of those concepts. Such theories of embodied cognition have received an impetus in the last decade (Barsalou, 1999; Glenberg, 1997; Prinz, 2004; Zwaan, 2004) with considerable empirical support showing that cognitive processes are undoubtedly influenced by perceptual and spatial information (De Vega,

Glenberg, & Graesser, 2008; Pecher & Zwaan, 2005; Semin & Smith, 2008 for overviews). These findings allow for the conclusion that linguistic symbols are grounded in modality specific perceptual and motor systems.

If conceptual metaphors highlight associations between abstract concepts and physical or spatial properties, it is predicted that words with positive connotations are processed faster when presented higher in space, and words with negative connotations are processed faster when presented lower in space. This is indeed what a number of studies have shown, with participants being apt to process and remember matches between location and words (i.e., *joy* presented on the top of the screen) better than mismatches (i.e., *hate* presented on the top of the screen) (Meier & Robinson, 2004; Meier, Hauser, Robinson, Friesen, & Schjeldahl, 2007; Pecher, van Dantzig, Boot, Zanzolie, & Huber, 2010; Schnall & Clore, 2004; Schubert, 2005). More recently, Santana and de Vega (2011) found that matches facilitate comprehension of figurative language more so than that of literal language, suggesting that positive and negative metaphors are also processed through embodied mechanisms. Similarly, when pictures are presented in their expected spatial positions (i.e., an image of a positive concept presented on the top of screen) comprehension of such affectively salient pictures is facilitated (Crawford, Margolies, Drake, & Murphy, 2006; Meier et al., 2007). Furthermore, when participants are in a positive mood, they are more likely to exhibit upwards biases during line bisection tasks, with the opposite pattern holding true for negative moods (Wapner & Werner, 1957). Subjects even feel more successful (a positive feeling) when standing erect (a high vertical position) and less successful (a negative feeling) when slumped over (a low vertical position) (Stepper & Strack, 1993). In a review of the literature, Meier and Robinson (2008) summarized that affect is indeed understood through embodied relations, including vertical spatial representations.

However, such strong evidence supporting embodied representations diverts our attention away from other explanations for these findings. Paivio (1986) has extensively shown that both verbal and non-verbal representations play important roles in cognition. Barsalou, Santos, Simmons, and Wilson (2008) and Louwerse (2007; 2008; 2011) have similarly argued that both statistical

relationships between symbols and embodied representations work together to represent conceptual knowledge. Louwerse (2007; 2011) proposed the Symbol Interdependency Hypothesis, arguing that language encodes embodied representations. That is, embodied cues are encoded linguistically, so that language users can rely on the linguistic system as a shortcut to the perceptual system. Consequently, comprehension can be explained both by a statistical linguistic approach and an embodied approach, a conclusion supported by an increasing amount of empirical evidence (Louwerse, 2011).

Louwerse and Jeuniaux (2010) further argued that language processing relies on both linguistic and embodiment factors variably depending on the cognitive task. They showed that linguistic factors best explained response times (RTs) when participants made semantic judgments about word pairs, but perceptual factors best explained RTs when participants made iconicity judgments about pictures. Importantly, both linguistic and perceptual factors explained RTs in both semantic judgments and iconicity judgments, for both linguistic stimuli and pictorial stimuli, but their relative importance changed as a function of the task and stimulus.

In addition, Louwerse and Connell (2011) have shown that findings initially entirely attributed to embodied representations, such as the increased processing times for modality shifts, can in fact be attributed to statistical linguistic frequencies. Interestingly, faster processing can be best explained by the linguistic system, and slower processing can best be explained by the perceptual system.

In addition to cognitive tasks modifying statistical linguistic and embodiment effects on comprehension, individual differences might also play a role in how we represent information. Preexisting strategies or habits may impact an individual's propensity for processing information in different ways. For example, because embodied representations ground language through bodily experiences we could predict that those individuals with superior spatial ability are more likely to utilize such simulations. Similarly, those with enhanced language skill may show an inclination to process information in a linguistic fashion. This possibility is easily explored through gender differences, with males showing greater general spatial ability (Kimura, 2000; Linn & Peterson, 1985) and females showing greater general language ability (Kimura, 2000; Kramer, Delis, Kaplan, & O'Donnell, 1997). Based on such tendencies, we hypothesized that because males may have a greater affinity to encode information in an imagistic format, embodiment factors should better predict RTs for males. Likewise, females might be more likely to encode information in a symbolic manner, thus linguistic factors were hypothesized to better predict female RTs.

The current study had three goals. First, we aimed to investigate the extent to which a statistical linguistic approach and an embodied approach explained processing of valence words. As in Louwerse and Jeuniaux (2010) we identified embodied and linguistic factors and determined

how well each factor could explain RTs. Second, we aimed to investigate whether the effect of a statistical linguistic approach and an embodied approach is modified as a function of the cognitive task. As demonstrated by the aforementioned studies, presenting positive-negative word pairs in a vertical orientation seems to encourage subjects to perceptually simulate the words they are reading. However, we also know that positive words usually occur before negative words in texts (e.g., *plus and minus, good and bad, positive and negative*), thus if we present words horizontally (as we read them), we might expect subjects to instead rely upon statistical linguistic features. We therefore hypothesized that embodiment factors would be more salient when words were presented vertically whereas linguistic factors would be more salient when words were presented horizontally. Thirdly, we aimed to investigate whether the effect of a statistical linguistic approach and an embodied approach is modified as a function of individual differences, and more specifically as a function of participant gender. We answered these questions in two experiments whereby male and female participants responded to positive and negative valence word pairs. In Experiment 1 word pairs were presented in a vertical configuration (e.g., *happy* above *sad*) to encourage subjects to rely upon embodied features; in Experiment 2 word pairs were presented in a horizontal configuration (e.g., *happy* preceding *sad*) to encourage subjects to rely upon statistical linguistic information.

## Experiment 1

### Participants

Thirty-four undergraduate native English speakers at the University of Memphis (24 females) participated for extra credit in a Psychology course.

### Materials

The experiment consisted of 50 pairs of words that were opposites on a valence dimension (e.g., positive-negative) (see Table 1). One hundred filler items consisted of word pairs without a positive-negative relation, with half of the pairs having a high semantic association and half having a low semantic association as determined by latent semantic analysis (LSA), a computational linguistic technique that measures the similarity in meaning between word pairs, but ignores an order relation (Landauer, McNamara, Dennis, & Kintsch, 2007) (high semantic association:  $\cos = .44$ ; low semantic relation:  $\cos = .18$ ).

### Procedure

Participants were asked to judge the semantic relatedness of word pairs presented on an 800x600 computer screen running E-Prime software (Psychology Software Tools Inc., Pittsburgh, PA). Words were presented one above another, in a vertical orientation. Upon presentation of a word pair, participants indicated whether the pair was related in meaning by pressing designated yes or no keys. All word

pairs were randomly ordered for each participant to negate any order effects. Each participant saw all word pairs, but whether a participant saw a word pair in an iconic or a reverse iconic order was counterbalanced between two groups, such that all participants saw iconic and reverse-iconic word pairs, but no participant saw a word pair both in an iconic and a reverse-iconic order. To ensure participants understood the task, participants completed five practice trials before beginning the experimental task.

Table 1: Positive-Negative Critical Word Pairs

achievement – failure	add – subtract
angel – devil	angels – demons
appear – disappear	beautiful – ugly
bright – dim	birth – death
clean – dirty	confident – arrogant
day – night	dead – alive
dream – nightmare	excitement – boredom
fast – slow	freedom – slavery
friend – enemy	fun – boring
gain – loss	good – bad
grow – shrink	handsome – ugly
happy – sad	healthy – sick
heaven – hell	hero – villain
laugh – scream	life – death
love – hate	more – less
on – off	optimist – pessimist
pass – fail	plus – minus
positive – negative	pretty – ugly
progress – stagnation	protagonist – antagonist
regular – irregular	right – wrong
safe – danger	smile – frown
strong – weak	sunshine – rain
true – false	unite – split
victory – defeat	wealthy – poor
winner – loser	yes – no

## Results and Discussion

Subjects whose RTs fell more than 2.5 SD from the mean per condition, per subject were removed from the analysis, affecting 3.7% of the data.

### Linguistic and Embodiment Factors

We distinguished between a linguistic and an embodiment factor in order to determine whether a statistical linguistic approach or an embodiment approach would better explain the processing of valence words.

**Linguistic factor** The statistical linguistic factor was operationalized as the log frequency of a-b (e.g., *happy-sad*) or b-a (e.g., *sad-happy*) order of word pairs. The order frequency of all word pairs within 3-5 word grams was obtained using the large *Web 1T 5-gram* corpus (Brants & Franz, 2006).

**Embodiment factor** If conceptual metaphors are understood through embodied representations and processes (Lakoff & Johnson, 1981; 1999), then a concept must be perceptually simulated in order to determine if it is positive or negative. Therefore, we operationalized embodiment factor as a rating of how positive or negative a concept was, following previous studies (Louwerse, 2008; Louwerse & Jeuniaux, 2010). Thirty-eight participants at the University of Memphis were asked to what extent they agreed with the statement: *x is more positive than y* (e.g., *happy* is more positive than *sad* or *sad* is more positive than *happy*). Ratings were made for all word pairs (in both orders) on a scale of 1-6, with 1 being strongly disagree and 6 being strongly agree.

### Response Time Analyses

A mixed-effect regression model analysis was conducted on RTs with linguistic and embodiment factors as the fixed factors and participants and items as random factors (Baayen, Davidson, & Bates, 2008). The model was fitted using the restricted maximum likelihood estimation (REML) for the continuous variable (RT). F-test denominator degrees of freedom were estimated using the Kenward-Roger's degrees of freedom adjustment to reduce the chances of Type I error (Littell, Stroup, & Freund, 2002).

The embodiment factor was significantly related to the RTs,  $F(1, 86.93) = 10.40, p < .002$ , with higher ratings yielding lower RTs. This finding supports an embodied cognition account: the more a word pair marked a positive-negative relation, the stronger the effect on the RTs. However, the linguistic factor also explained the RTs,  $F(1, 85.511) = 70.96, p < .001$ , with higher frequencies yielding lower RTs. These findings show that the vertical configuration of conceptual metaphors can be explained by both the linguistic system and the embodied system, confirming previous findings and the claim that language processing is both linguistic and embodied.

### Gender Effects

Next, we investigated whether the linguistic and embodiment factors were modulated by individual differences. To test whether embodiment factors better predicted RTs for males, and linguistic factors better predicted RTs for females, we conducted a mixed effects analysis on RTs using the interaction between gender x linguistic factor and gender x embodiment factor as fixed factors and subject and item as random factors. The two interactions on RTs were significant, for both gender x linguistic factor,  $F(2, 113.86) = 38.68, p < .001$ , and gender and embodiment factor,  $F(2, 210.99) = 8.23, p < .001$ . Interestingly, and as predicted, the effect size was largest for females x linguistic factor, and males x embodiment factor, as shown in Figure 1.

Figure 1. The effect sizes in  $R^2$  for the interaction of participant gender x linguistic factor and the interaction of participant gender x embodiment factor on RT in vertical configuration of valence word pairs.

The results of Experiment 1 show that both linguistic and embodiment factors explain processing of valence words. The effects of either factor are modulated by individual differences. Although both male and female participants depended more upon the linguistic factor, females relied more on the linguistic factor than males, and males relied more on the embodiment factor than females.

## Experiment 2

### Participants

Forty undergraduate native English speakers at the University of Memphis (29 females) participated for extra credit in a Psychology course.

### Materials

Materials were identical to those used in Experiment 1.

### Procedure

The procedure was identical to Experiment 1 except that items were now presented next to each other (horizontal configuration) rather than above each other (vertical configuration).

## Results and Discussion

### Linguistic and Embodiment Factors

As in Experiment 1 a mixed effects regression model was conducted with RT as the outcome variable, with the linguistic and the embodiment factors as fixed predictor factors, and with both participants and items as random factors. Again, the embodiment factor was significantly related to the RTs,  $F(1, 84.93) = 7.01, p = .01$ , with higher embodiment ratings yielding lower RTs. The linguistic

Figure 2. The effect sizes in  $R^2$  for the interaction of participant gender and the linguistic factor and the embodiment factor on RT in horizontal configuration of valence word pairs.

factor also explained RTs,  $F(1, 86.01) = 94.60, p < .001$ , with higher frequencies yielding lower RTs. These findings are similar to those obtained in Experiment 1, and support the conclusion that language processing is both linguistic and embodied.

### Gender Effects

As before, to determine interactions between gender x linguistic factor and gender x embodiment factor, we conducted a mixed effects model using the two interactions as fixed factors and subjects and items as random factors. Both interactions reached significance, for gender x linguistic factor,  $F(2, 142.89) = 48.12, p < .001$ , as well as gender x embodiment factor  $F(2, 207.74) = 4.19, p = .02$ . The effect size was again largest for female participants and the linguistic factor (Figure 2). However, effect size was now also larger for females and the embodiment factor. A possible explanation for this finding is that the embodiment factor may have played a lesser role in the horizontal configuration than in the vertical configuration, an explanation that fits the idea that cognitive task modulates the relative importance of linguistic and embodiment factors. This issue was investigated next.

Next, we were concerned with the relationship between the prominence of a linguistic factor and a embodiment factor during processing. To answer this question we conducted an analysis using both the linguistic and embodiment factor, comparing their relative importance in the vertical (Experiment 1) versus horizontal (Experiment 2) configurations. Again, both participants and items were used as random factors in the mixed effects regression, and the interaction of the linguistic factor x orientation (vertical versus horizontal), and the interaction of the embodiment factor x orientation were of interest. The interaction for both orientation x linguistic factor and orientation x embodiment

factor was significant,  $F(2, 133.13) = 53.75, p < .001$  and  $F(2, 163.86) = 6.32, p < .01$  respectively. Furthermore, an interaction between orientation  $\times$  linguistic factor  $\times$  embodiment factor reached significance,  $F(2, 165.28) = 4.90, p < .01$ . Although the linguistic factor played a more important role in both configurations, the linguistic factor was more salient in the horizontal configuration than in the vertical configuration, whereas the embodiment factor was more salient in the vertical configuration than in the horizontal condition (Figure 3). These results suggest that the relative importance of linguistic and embodiment factors is modulated by the cognitive task.

Figure 3. The effect sizes in  $R^2$  for both the linguistic factor and the embodiment factor in vertical orientation of valence word pairs (Experiment 1) and horizontal orientation of valence word pairs (Experiment 2).

## Discussion

Previous studies have shown that when comprehenders process conceptual metaphors, they activate perceptual simulations (Lakoff & Johnson, 1981; 1999). The notion that metaphor comprehension is embodied is non-trivial. However, it begets the question whether alternative explanations are to be dismissed. The two experiments reported here show that both linguistic and embodiment factors explain the processing of valence words. Furthermore, the dominance of one factor relative to the other was modified differentially based on the experimental task, such that linguistic factors better explained RTs for horizontal presentations, with embodied features better explaining RTs for vertical presentations. Moreover, we found evidence suggesting that male participants typically rely more on embodied representations, whereas female participants typically rely more on statistical linguistic patterns.

The findings reported in this paper are important for theories of cognition. Although there is much evidence supporting embodied accounts of mental representations (Barsalou, 1999; Glenberg, 1997; Pecher & Zwaan, 2005;

Semin & Smith, 2008; Zwaan, 2004), there is also an increasing amount of evidence suggesting that other factors can play an important role (Hutchinson, Johnson, & Louwerse, 2011; Louwerse, 2008; Louwerse & Jeuniaux, 2010; Barsalou, Santos, Simmons, & Wilson, 2008). It is important that researchers consider alternatives contributing to metaphoric conceptual processing rather than fixating on one explanation without leaving any room for alternative explanations. Our findings do not dispute the necessity of employing embodied representations but rather we call into question their dominance during cognition. Comprehension of conceptual metaphors can be explained by both linguistic and embodiment factors, but their salience as predictors of cognitive processing is modified by cognitive task and by individual differences.

## Abstract

A knowledge-based model that emulates human behavior in a Dynamic Decision Making task is proposed. The model, MAIDEN-DSF, uses a connectionist representation of knowledge and a value function to compute the best alternative. In order to validate MAIDEN-DSF, two data sets have been used: a training set and a test set that contain the behavior of participants that performed the task with different conditions. The results suggest that MAIDEN-DSF is a considerable framework in order to model human behavior. The aim of this paper is to use MAIDEN-DSF to prove that participants do not perceive delay conditions when dealing with Dynamic Decision Making tasks.

**Keywords:** Decision Making; Computational Models; Connectionism.

## Introduction

Dynamic Decision Making lies in tasks that require a series of decisions where the state of the world changes, both autonomously and as a consequence of the decisions made (Brehmer, 1992). The Dynamic Stocks and Flows (DSF) task (Gonzalez & Dutt, 2011), emulates such situations with three elements: a single stock represented by a water tank; inflows, which increase the level of the stock; and outflows, which decrease the level of the stock. The goal of this task is to keep the stock at a certain level over 100 time periods. In every time period, a participant can control the stock adding or removing water via two inputs that represent the decision: the user inflow ( $UI$ ) and the user outflow ( $UO$ ) values. Besides, there are two external inputs that represent the environment inflow ( $EI$ ) and outflow ( $EO$ ) values, both of them are not directly controlled by the participant. The dynamics of the environment is unknown to the participant, so the  $EI$  and  $EO$  values have to be predicted using the experience acquired in previous time periods. When the participant makes a decision, the DSF determines the level of water in the tank by adding the  $UI$  and  $EI$  to the level in the tank and subtracting the  $UO$  and the  $EO$ . Then the DSF presents the resulting level, the goal level and the last  $EI$ ,  $EO$ ,  $UI$  and  $UO$  values within the following time period.

This seemingly simple stock problem is actually unintuitive and difficult. In fact, there is evidence that suggests that people do not perceive stocks and flows dynamics correctly. For example, in an experiment where graduate students were asked to sketch the evolution of the water level in a bathtub over time (given simple patterns for the environmental inflow and outflow), only 36% of the students answered correctly (Serman, 2002).

The DSF has been studied under different conditions (Cronin & Gonzalez, 2007) and there is evidence that the hardest condition for controlling the water tank is when the user inputs are delayed for three time periods (Lebiere, Gonzalez, & Warwick, 2010). Participants have some understanding about the dynamics of the tank, for example, if 1 gallon of water is added, then the level is increased 1 gallon. However, with this delay, participants seem to have incorrect beliefs about the relationship between stocks and delayed flows or participants do not perceive the delay and, therefore, they behave as if there was no delay.

The aim of this paper is to use a knowledge-based model that emulates human behavior in the DSF in order to find cues that prove that participants do not actually perceive the delay. The proposed model is based on MAIDEN, a Model of Assessment and Inference of DEcisions based on a Net of concepts (Iglesias, Del Castillo, Serrano, & Oliva, 2010).

## A knowledge-based model

MAIDEN-DSF, the implementation of MAIDEN for dealing with DSF, is divided in two main phases. The first phase lies in the estimation of  $EI$  and  $EO$  values using a connectionist representation of knowledge called decision net. In the second phase, MAIDEN-DSF uses a value function to choose the best alternative, which will be the one that sets the amount in the tank at the goal level corresponding with the estimated  $EI$  and  $EO$  values of the first phase.

## Decision net

MAIDEN-DSF is a knowledge-based model that uses a weighted net of concepts called decision net to predict the values of  $EI$  and  $EO$ . The concepts of the decision net are arranged in five layers: perception, short-term memory, working memory, deliberative and output layer. If the concepts of the decision net change, then the behavior of MAIDEN-DSF also changes. Therefore, the selection of suitable concepts is a key point in the implementation of the decision net. The decision net must be as generic as possible and the concepts of the decision net must represent general knowledge about the decision making task and the past experience.

1. The perception layer contains concepts that are directly shown by the DSF in every time period: the current level in the tank ( $Level_t$ ), the goal level ( $Goal$ ), the environment outflow and inflow in the previous time period ( $EO_{t-1}$  and  $EI_{t-1}$ ), and the last decision of the participant ( $UO_{t-1}$  and  $UI_{t-1}$ ).
2. The short-term memory layer takes into account the recent past experience and contains the last three values of the tank level ( $Level_{t-1}$ ,  $Level_{t-2}$  and  $Level_{t-3}$ ), the environment inflow ( $EI_{t-2}$ ,  $EI_{t-3}$  and  $EI_{t-4}$ ) and the environment outflow ( $EO_{t-2}$ ,  $EO_{t-3}$  and  $EO_{t-4}$ ).
3. The working memory layer provides elaborated information via concepts that represent the increase in the last environment inflow and outflow, the decrease in the last environment inflow and outflow and the positive or negative difference between the current level and the goal level.
4. The deliberative layer aggregate other concepts contained in the previous three layers. This layer is composed of two deliberative concepts.
5. The output layer contains the concepts used by MAIDEN-DSF in the value function: the estimated environment inflow and outflow ( $EI$  and  $EO$ ).

Every node of the decision net has got an associated positive activation value. The decision net propagates activation to one node by performing the weighted sum of the incoming activations from the nodes connected to it. The following expression shows how a node computes the total weighted input  $net_i$ :

$$net_i = \sum_j w_{ij} \cdot a_j \quad (1)$$

In expression 1,  $net_i$  represents the total weighted input of the  $i^{th}$  node,  $a_j$  is the activation of the  $j^{th}$  node and  $w_{ij}$  is the weight of the connection between the  $i^{th}$  and the  $j^{th}$  node. If  $net_i \geq 0$ , then the activation of a node is equal to its  $net$  value. Otherwise activation is zero.

The connections among the different nodes of the decision net have three constraints. First, nodes of the same layer are not interconnected. Second, nodes of the deliberative layer

can only propagate activation to the output layer. Third, a concept belonging to the perception, the short-term memory or the working memory layer can propagate activation to the deliberative layer or the output layer, but it cannot propagate activation to both layers according to neurophysiological evidence (Damasio, 1994; Romanski & LeDoux, 1992).

The concepts of the perception layer are easily identifiable in the DSF. The concepts of the short-term memory and the working memory layer have been extracted from interviews of participants who performed the DSF. Notice that the activation of these concepts must be updated every time period depending on the decisions and consequent outcomes up to the current time period. Figure 1 shows a graphical representation of the decision net.

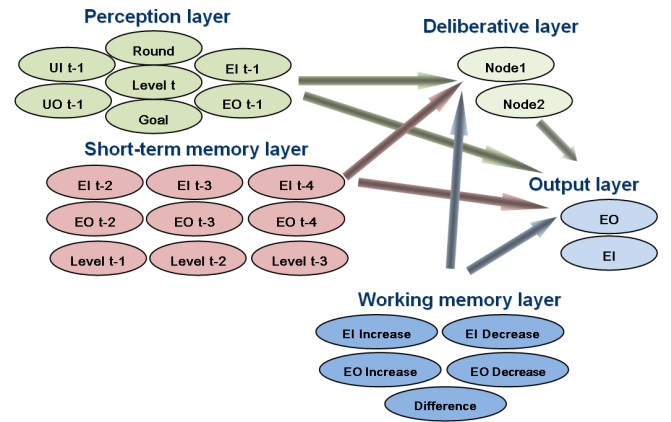

Figure 1: Representation of the decision net.

This design is coherent with Norman's definition of affordances (Norman, 1988): all action possibilities latent in the environment that are perceivable by a participant. These perceived affordances result from the mental interpretation of things based on past knowledge and experience. In MAIDEN-DSF, alternatives or actions are also evaluated based on past knowledge and experience.

## Value function

The goal of the task is to keep the water in the tank at a given level. The expression 2 represents the water level at time period  $t + 1$  ( $Level_{t+1}$ ), which depends on  $UI_t$ ,  $UO_t$ ,  $EI_t$ ,  $EO_t$  and  $Level_t$ .

$$Level_{t+1} = Level_t + UI_t - UO_t + EI_t - EO_t \quad (2)$$

The difference between the water level and the goal level at time period  $t + 1$  is calculated using the following expression:

$$Diff = Level_{t+1} - Goal \quad (3)$$

Since the best decision is the one that sets the stock at the goal level ( $Goal$ ), the value of  $Diff$  must be 0 and the best  $UI_t - UO_t$  value is given by the combination of equations 2 and 3:

$$UI_t - UO_t = Goal - Level_t - EI_t + EO_t \quad (4)$$

The expression 4 computes the best decision ( $UI_t - UO_t$ ) and requires the values of  $Goal$  and  $Level_t$ , which are known to the participant, and the values of  $EI_t$  and  $EO_t$ , which are unknown. Therefore, the value function used by MAIDEN-DSF replaces the unknown variables  $EI_t$  and  $EO_t$  with the activation of the concepts  $EI$  and  $EO$  of the decision net estimated with the information available in the current time period  $t$ , as shown in figure 2.

Figure 2: Scheme of MAIDEN's value function.

## Evaluation

The connection weights of the decision net of MAIDEN-DSF have been adjusted to model, as well as possible, the behavior of a set of participants who performed the DSF. The evaluation consists in the prediction of the behavior of another set of participants in different conditions of the DSF. The training and test data has been collected from the DSF challenge (Lebiere et al., 2010) whose homepage presents a wealth of information about the task (<http://www.hss.cmu.edu/departments/sds/ddmlab/modeldsf>). The measure used to evaluate the model fit was Pearson's linear correlation coefficient  $R$ , comparing the decisions of the model and the participants over all 100 time periods. In order to compute the decisions of MAIDEN-DSF, in each time period the activation of the concepts of the perception, short-term memory and working memory layers has been generated with the participant's actual sequence of decisions and consequent water levels up to the current time period. This method ensures that MAIDEN-DSF makes a decision with the same available knowledge as the participant whose behavior is wanted to be modeled.

The values of the connection weights that optimize the correlation of the model and the participants' decisions have been calculated by the Covariance Matrix Adaptation Evolution Strategy (CMA-ES) (Hansen, 2006), which is a kind of Evolutionary Algorithm (Goldberg, 1989; De Jong, 2006) with considerable potential for searching in complex spaces. CMA-ES has been run ten times to find the best connection weights that optimize the correlation of the decisions of MAIDEN-DSF and the decisions of the participants who participated in the training conditions. Then, the correlation of the best connection weights is presented.

## Performance in the training conditions

The DSF with the training conditions used an environment inflow that was either an increasing function or a decreasing function over 100 time periods. The function could be linear or non linear and, therefore, there were four training conditions. The environment outflow function was constant and set to zero throughout the task. The following expression shows the linear increasing function:

$$EI_t = 2.0 + 0.08 \cdot t \quad (5)$$

The goal was to maintain the level of water in 4 gallons during all 100 time periods. The initial water level in the tank was fixed to 2 gallons. The training data corresponds with the behavior of 61 participants (linear increasing = 15 participants, linear decreasing = 11 participants, non linear increasing = 17 participants and non linear decreasing = 18).

Figure 3: Correlation between MAIDEN-DSF and human decisions with the training conditions.

Figure 3 shows the correlation between the decisions of MAIDEN-DSF, whose connection weights have been optimized in order to fit the training data, and the decisions of the participants with the training conditions. All the  $R$  values are statistically significant using a Student's  $t$  distribution for a transformation of the correlation ( $p < 0.001$ ). These values correspond with the best set of connection weights found by CMA-ES after ten executions.

In the training set, the worst correlation is obtained in the non linear decreasing condition which appears to be the hardest task for the participants. The whole training set of participants has been modeled with the same connection weights. This low correlation value may be due to connection weights that model well the behavior of participants in different conditions but not in the non linear decreasing condition. Note

that CMA-ES finds the connection weights that maximize the overall correlation taking into account the four conditions.

### Performance in the test conditions

The values of the connection weights of MAIDEN-DSF were estimated to optimize the correlation of the model and the participants' decisions with the training conditions. This subsection shows the predictions made by this MAIDEN-DSF in the test conditions in order to validate the model.

The DSF with the test conditions used an environment inflow that was either a sequence-based function or a delayed function. There were three different sequence-based functions that generated a repeated sequence of length 2, a repeated sequence of length 4 and the same sequence of length 4 with noise. There were also two delayed functions where participant's decisions were delayed for either two or three time periods. Therefore, there were five test conditions. The environment outflow function was also constant and set to zero throughout the task. The goal was to maintain the level of water in 6 gallons during all 100 time periods and the initial water level in the tank was fixed to 4 gallons. The test data corresponds with 100 participants (delay 2 = 20 participants, delay 3 = 20 participants, sequence 2 = 20 participants, sequence 4 + noise = 20 participants and sequence 4 = 20 participants).

Figure 4: Correlation between MAIDEN-DSF and human decisions with the test conditions.

Figure 4 shows the correlation between the decisions of MAIDEN-DSF and the decisions of the participants with the test conditions. The  $R$  values obtained with the test conditions are all statistically significant ( $p < 0.001$ ).

It is noteworthy that the decision net of MAIDEN-DSF

does not contain any concept representing the delay; however, it models the human behavior with the delay conditions with a correlation higher than 0.4, even when the training conditions do not contain any delay. This result suggests that participants may not take into account the delay or may not understand it while performing the DSF.

In the delay 3 condition the correlation is reduced. This can be due to the high variability observed in the human decisions, for example, a participant decided to increase the level of water in  $1E + 09$  gallons.

With respect to the sequence-based conditions, the short-term memory layer of the decision net contains concepts from the previous four time periods up to the current one. A good performance in the sequence-based conditions implies the knowledge of the last two environmental inputs, if it is a sequence of length 2, or the last four environmental inputs, if it is a sequence of length 4. MAIDEN-DSF contains concepts representing the last four environmental inputs, so it may suitably model behaviors with these conditions.

### Delay conditions

The aim of this work is to find cues that prove whether participants do not perceive the delay during the DSF within the delay conditions. Although the results obtained in the previous experiment may already suggest that participants ignore delays, this section presents another cue to support the experiment.

A new version of MAIDEN-DSF with concepts that represent the delay has been also built. This new version will be denoted as MAIDEN-DSFd. The new decision net is composed of the concepts already explained in this paper with the addition of four new concepts:

- The short-term memory layer takes also into account the following user decisions:  $UI_{t-2}$ ,  $UI_{t-3}$ ,  $UO_{t-2}$  and  $UO_{t-3}$ .

Note that with the delay conditions the user inputs are delayed for two or three time periods, so the decisions relevant for the current tank level  $Level_t$  are taken in  $t - 2$  and  $t - 3$ .

The connection weights of MAIDEN-DSF and MAIDEN-DSFd have been adjusted to model the behavior of the 40 participants that participated in the delay conditions. CMA-ES has been applied ten times for each model version to estimate the connection weights that maximize the correlation between the model decisions and the decisions of the participants.

Table 1: Mean correlation (E) and standard deviation (SD) obtained by MAIDEN-DSF and MAIDEN-DSFd with the delay conditions.

Model	Delay 2		Delay 3	
	E	SD	E	SD
MAIDEN-DSF	0.54710	1.0E-06	0.43931	5.0E-09
MAIDEN-DSFd	0.54711	1.3E-06	0.43931	6.0E-09

Table 1 shows the mean correlation and the standard deviation of the ten solutions found by CMA-ES for each version

of MAIDEN. The  $R$  values obtained with both implementations are all statistically significant ( $p < 0.001$ ).

Table 2: Mean (E) and standard deviation (SD) of the root mean square error obtained by MAIDEN-DSF and MAIDEN-DSFd with the delay conditions.

Model	Delay 2		Delay 3	
	E	SD	E	SD
MAIDEN-DSF	24275.04	0.033	6227685.70	0.098
MAIDEN-DSFd	24274.98	0.036	6227685.59	0.059

Table 2 shows the mean and the standard deviation of the root mean square error obtained by the ten solutions found by CMA-ES for each version of MAIDEN. The error seems to be high due to the high variability of the human decisions within the delay conditions. In fact, in the DSF challenge (Lebiere et al., 2010) the best ranked model obtained a root mean square error of 25560.84 in the delay 2 condition and 5930065.84 in the delay 3 condition.

MAIDEN-DSF and MAIDEN-DSFd obtained similar correlations in both conditions. Within the delay 2 condition they only differ in 0.00001 and within the delay 3 condition the mean correlation is exactly the same. The standard deviation is also similar. These results point out that the behavior of the participants might be modeled without using the  $UI_{t-2}$ ,  $UI_{t-3}$ ,  $UO_{t-2}$  and  $UO_{t-3}$  decisions.

## Conclusion

A knowledge-based model that emulates human behavior in the Dynamic Stocks and Flows task has been proposed. MAIDEN-DSF operation is divided in two main phases. First, it estimates the environment inflow and outflow values using a decision net. Second, it uses a value function to choose the best alternative, which is the one that sets the water level of the tank at the goal level.

The model has been evaluated with two data sets from the DSF challenge (training set and test set). The evaluation lies in the prediction of human behavior in the test set given the training set. The results achieved support that MAIDEN-DSF is a considerable framework in order to model human behavior in the DSF. Besides, the proposed model participated in the DSF challenge and reached rank 2 regarding the ranking provided by the DSF challenge organizers based on the  $R^2$  correlation and the root mean square error.

MAIDEN-DSF has been used to find cues that point out that the behavior of the participants who performed the DSF task with the delay conditions can be modeled without taking into account any concept representing the delay. This evidence suggests that participants do not take into account or are not aware of the delay while making a decision during the delay conditions.

The results suggest that it is very difficult to configure a model in order to emulate the performance of several human beings with the same parameter values (connection weights in this case). This might lead to develop comparison procedures

focusing on individual modeling and adaptation. MAIDEN is mainly based on the knowledge acquired through past experience, the knowledge extracted from the environment and the relationships between the concepts that represent these two kinds of knowledge. A very interesting feature is that the connection weights of the decision net can show what concepts are the most important for a participant. In this experiment, the whole set of participants has been modeled with the same connection weights. A future work might consist in the individual modeling of each participant in order to study the connection weights that better fit each participant's behavior. An individual modeling may indicate which participants had realized that there was a delay in their decisions. In this experiment the connection weights of the concepts representing  $UI_{t-2}$ ,  $UI_{t-3}$ ,  $UO_{t-2}$  and  $UO_{t-3}$  in MAIDEN-DSFd affect the behavior of the model. An absence of connection between these concepts implies that the participants do not use this knowledge. However, CMA-ES seeks the best combination of connection weights that better fit the whole set of human behaviors, therefore, if there is one person that uses this knowledge, CMA-ES will find a connection weight for these concepts. This is the reason for the better suitability of individual modeling.

A global modeling is suitable for experiments where there are at least two groups: a control group and an experimental group. A future work may study the connection weights that better model the behavior of participants who performed well in the delay conditions (control group) and the participants who obtained poor results (experimental group). The connection weights can point out what concepts affect a decision for a certain participant. For instance, this information may be used to improve participants' performance by explicitly revealing relevant information that participants who obtained poor results tend to ignore but participants who performed well in the delay conditions take into account. This may lead to better understanding of dynamic decision making.

## Abstract

Oscillator models may be used for modeling synchrony between gestures and speech, or timing of backchanneling and turn-taking in dialogues. We find support for the hypothesis that oscillator networks can better predict rhythmic events on the syllable and foot level than single oscillators, but we do not find support for the hypothesis that phase resetting oscillators perform better than phase adapting oscillators. Overall, oscillators can be used to predict rhythmic events in speech, but higher level information needs to be integrated into such models to reach a satisfactory performance.

**Keywords:** speech rhythm, entrainment

## Introduction

Spontaneous speech, like music, exhibits temporal regularities, but these cannot be captured by simple descriptions. Rhythm, i.e., hierarchical structured temporal regularities, is widely believed to be an important principle for understanding both music and speech (Large, 2008; Cummins & Port, 1998). Regularity of timing greatly contributes to speech perception and understanding. Regular sequences of, e.g., inter-stress intervals in speech or tone sequences in music speed up perception by facilitating meaningful grouping and contrast within a very rich acoustic signal. The role of rhythmic expectancies both in speech and music perception has been the basis of Dynamic Attending Theory (Jones, 1990) and more specific phonological models such as PolySP (Hawkins, 2003). Humans can even perceive rhythms in music that do not directly correspond to any frequency found in a spectral analysis of the signals (Large, 2008). Similarly, the timing of speech production is coordinated via rhythmic principles. The same principles govern the neuro-physiological dynamics of all motor behavior. On the syllable level, the vocalic pulse represents the basic timing coordination of the articulatory system (Browman & Goldstein, 1992).

When measuring brain activity, one can easily find a number of prominent frequencies. Some of them are in the range of typical speech units: the theta band (3-12 Hz) corresponds to the typical duration of a syllable (100-300 ms),

whereas delta band oscillations (0.5-3 Hz) correspond to typical lengths of prosodic and metrical units. Many kinds of oscillators have the property of entraining to an externally provided periodic signal, i.e., they become phase-locked to the signal. Therefore, it seems plausible that neural oscillators might play a role in the production and perception of speech by synchronizing certain systems with the speech signal (Buzsáki & Draguhn, 2004; Ghitza & Greenberg, 2009). Previous research has also found that gestures may be synchronized with speech rhythms (Condon, 1986; Tuite, 1993; Wachsmuth, 1999; Loehr, 2007). Furthermore, listeners can become entrained to a speaker's rhythm, which helps them to provide backchanneling or take turns in a dialogue at a suitable moment in time (Wilson & Wilson, 2005).

A number of oscillator models have been proposed that can entrain to musical rhythms. Here we focus on models proposed by Large and McAuley (Large, 1994; McAuley, 1995). These have been shown to achieve entrainment to input signals not just in a period ratio of 1:1, but also in more complex ratios, which makes coupling between several levels of speech rhythm possible. Furthermore, oscillator banks have been shown to reproduce empirical findings about human perception of rhythm: they can resonate at frequencies that are not present in the input signals, but perceived by human subjects, too (Large, 2008; Large, Almonte, & Velasco, 2010).

We are interested in whether these oscillator models originally built for modeling music perception can also be used to model human entrainment to less regular speech signals. In general, we believe in the necessity to couple oscillators for different levels of the rhythmic hierarchy, so ultimately we will include this in the models discussed in this article. However, here we focus on the question what particular features might make an oscillator model more capable of correctly predicting syllable and foot onset times when considered separately from the other levels of the rhythmic hierarchy. After all, speech is less regular than music, so adapta-

tion to input signals should be very fast. Therefore, we will compare two previously proposed oscillator models and then make a number of changes to one of them to see whether prediction performance improves. In particular, we examine the following hypotheses: First, oscillators that reset their phase upon arrival of an input signal may be faster than those that adapt their phase gradually. Second, it may be better to have a bank of oscillators tuned to different frequencies than to have a single oscillator that adapts its period. This would be because period adaptation time is dependent on the amount of change necessary whereas in banks of oscillators, the time for a differently tuned oscillator to become activated is constant with regards to the amount of frequency change. To the degree these hypotheses turn out to be supported by the data, they can inform future modeling of human entrainment to speech rhythms. Besides addressing these two hypotheses, our experiments also show how much can be learned at all by oscillator models without considering the hierarchical organization of speech, i.e., from a pure low-level approach.

## The Data

The speech data comes from a corpus of spontaneous dialogue in German where one dialogue partner told a holiday story and the other was instructed to listen actively (Buschmeier, Malisz, Włodarczak, Kopp, & Wagner, 2011). The corpus was collected for the purposes of modeling entrainment in dialogue, multimodal behavior of the listener, i.e., feedback signals, head and manual gesture, as well as the prosody of the storyteller. The latter objective is addressed in the present paper.

Audiovisual recordings were made in a sound-treated studio. Participants were positioned approximately three meters apart to minimize crosstalk. Close talking high-quality headset microphones were used. The signal properties were annotated in Praat (Boersma & Weenink, 2012). Careful annotation of the acoustic signal enables to approximate emergent rhythmic phenomena (Gibbon & Fernandes, 2005). To represent the syllabic oscillator hypothesized for speech production, we first semi-automatically extracted vowel onsets from the data (Cummins & Port, 1998; Barbosa, 2006). Secondly, experts annotated rhythmic feet, representing the slower stress oscillator, where each prominent syllable is a pulse on that level. We also annotated interpausal units (IPUs) with a criterion that only minimally perceptible interruptions in the flow of speech were marked (not all acoustic pauses).

For the present simulations, two conversations (henceforth *dataset 1* and *dataset 2*) were used. Phrases (IPUs) consisting of at least two feet events were selected. Any phrase initial unstressed vowel events (anacrusis) were excluded as well as the phrase final vowel event. The trimmings were done to exclude any extra lengthening at the end of phrase and extra irregularity at the beginning of phrase that typically signal a boundary in German. The resulting phrases consist of fluent, spontaneous, uninterrupted speech with a minimal phrase length of one second. The mean duration of a syllable-sized

intervocalic interval was 125 msec in this material and 365 msec for the foot. 69 phrases each from dataset 1 and dataset 2 were provided as input to the different oscillator models, i.e., the resulting onset times for each vowel or foot event served as the input pulse.

For each conversation, a control set of regular phrases was created by generating completely regular pulses with frequencies equal to the mean frequencies of events in the corresponding individual phrases from the conversation data.

## Models of entrainment

### Phase adaptation oscillator (PAO)

This oscillator model is one of several similar models originally proposed by Large for entrainment to musical rhythms (Large, 1994). The phase of this oscillator is defined as  $\phi(t) = \frac{t-t_x}{p}$ , where  $t_x$  is the time of the last event (in the input or according to the oscillator's expectation) and  $p$  is the period of the oscillator. The phase is reset to 0.0 when it reaches 1.0. The output of the oscillator is modeled as a periodic function  $o(t) = 1 + \tanh(\gamma(\cos(2\pi\phi(t)) - 1))$ , where the output gain parameter  $\gamma$  controls the sharpness of the activity peaks. The oscillator has three adaptation rules that depend on the input signal  $s(t)$  as well as learning rates  $\eta_1$ ,  $\eta_2$ ,  $\eta_3$ . The first rule in effect adapts the phase:

$$\Delta t_x = \eta_1 s(t) \frac{p}{2\pi} \text{sech}^2(\gamma(\cos(2\pi\phi(t)) - 1)) \sin(2\pi\phi(t))$$

The second adapts the period:

$$\Delta p = \eta_2 s(t) \frac{p}{2\pi} \text{sech}^2(\gamma(\cos(2\pi\phi(t)) - 1)) \sin(2\pi\phi(t))$$

The third adapts an estimate  $\Omega$  of input variability:

$$\Delta \Omega = \eta_3 s(t) \text{sech}^2(\gamma(\cos(2\pi\phi(t)) - 1)) (\cos(2\pi\phi(t)) + 2\gamma(o(t) - 1) \sin^2(2\pi\phi(t)))$$

This estimate in turn determines the receptive field width  $\tau$  of the oscillator, i.e., the width of a window in time around its maximal activation where it is highly adaptive to input signals:  $\tau = \tau_{\max} + 0.5(\tau_{\min} - \tau_{\max})(1 + \tanh \Omega)$ . The output gain is inversely related to the receptive field width:  $\gamma = \frac{-0.416}{\cos(2\pi\tau) - 1}$ . So if there is less input variability, the receptive field shrinks, and the output peaks are sharper, whereas if there is more input variability, the receptive field grows, and the output peaks are softer. Finally, the output value  $o(t)$  is multiplied by a confidence value  $c = c_{\max} + 0.5(c_{\min} - c_{\max})(1 + \tanh \Omega)$ . Further explanations about the motivation behind these choices, and the behavior of the oscillator, can be found in the literature. The following parameter settings were also taken from the literature:  $\eta_1 = 1.0$ ,  $\eta_2 = 0.3$ ,  $\eta_3 = 0.3$ ,  $\tau_{\min} = 0.02$ ,  $\tau_{\max} = 0.5$ ,  $c_{\min} = 0.0$ ,  $c_{\max} = 1.0$ . Because we expect syllable periods to be in the range  $[0.1, 0.25]$ , and feet periods in the range  $[0.2, 0.5]$ , we set the initial periods of the period and feet oscillators to the middle of these ranges, i.e. 0.175 and 0.35.

## Phase reset oscillator (PRO)

This oscillator has been originally proposed by McAuley for the perception of music, and modified by Nerlich in the context of human-machine interaction (McAuley, 1995; Nerlich, 1998). Its output, like that of the PAO, is a periodic function modified to modulate the sharpness of the output peaks, together with a term for exponential decay of the output:

$$o(t) = \left( \frac{1 + \cos(2\pi\phi(t))}{2} \right)^{(1-\Omega(n))\gamma_{min} + \Omega(n)\gamma_{max}} \exp\left(-\frac{\beta t_x}{p_{ini}}\right)$$

The phase  $\phi(t)$  is always kept in the range  $[-0.5, 0.5]$ , and reset to 0.0 when an input event arrives. The synchrony  $\Omega(n) = (1 - \epsilon)\Omega(n-1) + \epsilon(1 - 2|\phi^r(n)|)$  is measured every time an input event arrives:  $\phi^r(n)$  is the phase of the oscillator at the reset, and  $\epsilon = 0.2$  is a parameter that weights the current impulse against the memory of earlier synchrony with input events.  $\gamma_{min} = 1$  and  $\gamma_{max} = 5$  constrain the range of output sharpening that is dependent on measured synchrony with the train of input events. The final term in the output equation dampens the output exponentially when no input arrives.  $\beta = 0.5$  is the decay rate,  $p_{ini}$  the initial period of the oscillator, and  $t_x$  the time since the last input event.

The period is adapted using  $\Delta p = \alpha \Delta t P M \frac{P}{2}$ , where  $\alpha = 1$  is the entrainment rate, the period coupling term  $P = \phi^r(n)(1 - \Omega(n))$  is dependent on the synchrony and on the phase at the last reset, and the impulse response function  $M = \frac{1}{1 + \exp(-\Gamma(\phi^r(n) \exp(-\Theta t) - 0.5))}$  (with impulse response gain  $\Gamma = 1000$  and impulse response bias  $\Theta = 2$ ) ensures that almost all adaptation is done shortly after an input event. Like in the PAO model, we set initial periods of the period and feet oscillators to 0.175 and 0.35, while all other parameters are taken from the literature.

## Phase reset oscillator network (PRN)

We use a network of 20 parallel oscillators that are similar to the PRO model. However, we let the output decay not when no input arrives as before, but when the individual oscillator is not synchronous with the train of input signals:

$$o_i(t) = \exp(c_d(1 - \sigma_i(t))) \left( \frac{1 + \cos(2\pi\phi(t))}{2} \right)^{c_s}$$

The constant  $c_s = 20$  determines the sharpness of the oscillator output signal (the more oscillators we have in the network for a given frequency range, the higher this constant should be to reduce blurring of the network output), while  $c_d = -20$  determines how much the oscillator output decays depending on its asynchrony. The synchrony is measured each time an input event arrives using  $\sigma_i(t_r) = (1 - c_p)\sigma_i(t_{r-1}) + c_p(1 - \exp(c_e\phi(t_r)^2))$ , where  $c_p = 0.2$  is a constant that weights the current impulse against the memory of earlier synchrony with input events just like in the PRO model, and  $c_e = -200$  determines how much prediction error is still considered synchronous. Using an exponential term here instead of a piecewise linear term as in the PRO model

ensures that only a few oscillators will consider themselves synchronous with the input signal, which again reduces blurring of the network output. Period adaptation is not used in the PRN model, but phase reset works just like in the PRO model.

The initial periods are logarithmically distributed in the range of  $[0.1, 0.25]$  for syllables, and  $[0.2, 0.5]$  for feet. There is an additional network output unit with a sigmoid output function  $n(t) = 1/(1 + \exp(-\sum_i o_i(t-1)))$ , where the  $o_i(t)$  are the outputs of the individual oscillators. This variant of the model is called PRN1. In the variant called PRN2, the output unit is also connected to the network input. After an input event, its output remains zero until the sum of its input has a positive slope. Because there may be high oscillator outputs immediately after an input event that could disrupt this behavior, an absolute refractory period of 5 simulation steps after an input event is enforced unconditionally.

## Results

In experiments presented elsewhere (Malisz, Inden, Wachsmuth, & Wagner, 2012), we fed event signals from the whole conversation into PAO and PRO models and measured their internal phases when an input signal arrived. In those experiments, we found a significant advantage of the PRO model over the PAO model. By contrast, here we feed data from individual phrases separately into the oscillators and measure their average output activation when an input signal arrives. We also measure average output activation when no input signal arrives and take the difference between the averages as a performance measure. As Tables 1 to 4 show, there is no significant advantage of the PRO model over the PAO model in this case. Furthermore, both are at or below random level on most of the real data sets.

As Tables 1 to 4 also show, using a bank of oscillators like PRN1 is a significant improvement over using a single oscillator (and is significantly above random level). When adding the refractory period rule to the oscillator network, performance further improves significantly for almost all datasets.

The output trajectories of the different oscillator models for an example phrase can be seen in Fig. 1.

## Discussion

Our experiments do provide some support to the hypothesis that oscillator networks may be better suited to speech data than single oscillators that adapt their period. Such insights can inform modeling of human rapid entrainment to spontaneous speech. However, the experiments provide no support for the hypothesis that phase resetting oscillators like the McAuley oscillator are better suited to the rather irregular speech data than phase adapting oscillators like the Large oscillator. This might be because performance of both models is so close to chance level when used in that way. More than anything else, these results show that the level of prediction performance that can be reached by considering just one level of speech rhythm is rather low regardless of the used oscillator models.

PRN2	0.255±0.021	0.172±0.013	0.083±0.014	0.558±0.031	0.172±0.012	0.386±0.026

Table 4: Prediction of foot events (mean oscillator output) for different oscillator models and dataset 2.

Figure 1: Example output trajectories (blue) and vowel onsets (black) for syllables in the German phrase “... eine Urlaubsreise mit meiner Familie, also ich war mit meiner Schwester und meiner Mutter dort.” (“... a vacation trip with my family, that is, I was there with my sister and my mother.”) (a) PAO model, (b) PRO model, (c) PRN1 model, (d) PRN2 model.

The parameters used for the oscillator models seem to be reasonable and have been found by looking at the literature (PAO and PRO models) or preliminary experiments (PRN model). However, it cannot be totally excluded that other parameter settings will lead to higher performance. Therefore, we searched the space of the most important parameters of the PAO and PRO models for better performance on a randomly selected subset of the data for one conversation using evolutionary algorithms (De Jong, 2006) (details and results not shown here). While the evolutionary algorithm found different parameter settings that performed better on the training set, the subsequent performance on the complete set of data was only marginally better in most cases, and did not change any of the previously mentioned conclusions.

Future work will include using coupled syllable and foot oscillators, and possibly using evidence for vocal activity rhythms, i.e., cycles in pauses and hesitations in dialogue, to model the structure of the interpausal units (McGarva & Warner, 2003; Merlo & Barbosa, 2010). Ultimately, we aim to use the output from entrained oscillators to control the timing of backchanneling and turn-taking in artificial embodied conversational agents (Kopp, Allwood, Grammer, Ahlsen, & Stockmeier, 2008; Poppe, Truong, Reidsma, & Heylen, 2010).

## Abstract

This collaborative research between a visual artist and a cognitive scientist is based on the assumption that the so-called *aha* moment actually emerges from a number of interacting micro-processes. The empirical study presented here focuses on the creative process involved in connecting two pictures by painting another picture in the middle. This technique was involved in four *Infinite Landscape* workshops conducted at Art Museums in Japan and Europe over the last five years. Based on the artist's verbal recollection of the ideas that occurred to him as he drew each of the connecting pictures, we identify the micro-processes and cognitive mechanisms underlying these ideas, and discuss their implications for modeling creativity.

**Keywords:** Creativity; emergence; perceptual features; similarity; surface features; visual art.

## Introduction

A central problem in creativity research is how new ideas are generated. In recent years, it is gradually being realized that creativity is an emergent property of many interacting micro-processes (Dunbar 1997; Sawyer 2006). These micro-processes can occur within a cognitive agent itself, or in different agents within a group or society. Our larger goal in this research is to study and model these micro-processes.

In particular, we are focusing on the creative processes in visual art. For this, one could consider the creative insights spanning over the entire career of an artist (for example, Dali 1993); or over a part of the career of an artist (for example, Okada *et al.* 2009); or across several artists (for example, Mace & Ward 2002). When a longer period is covered, it is difficult to get information about the micro-processes involved in the creation. Even when one focuses on the creation of a particular work, if the goal is too open-ended, the micro-processes are too unrestrained and divergent. For example, in the study of Mace & Ward (2002), twenty-five artists were interviewed to get data about their creative processes. But because the artists could create any work they wanted, the insights from their self-reflection are only useful for a macro-level model.

When a work is created under constraints, it often increases the level of creativity required (Stokes 2005); it also makes it easier to compare data across different works because they were created under the same constraint. With this in mind, we focused on the task of creating a picture to connect two given pictures seamlessly, as described below.

## Background: *Infinite Landscape* Workshops

This research is a collaborative effort between a visual artist [henceforth referred to as *the Artist*] and a cognitive scientist. Over the last five years, the Artist conducted four workshops at art museums in Japan and in Europe with the common theme *Connecting different spaces*. In each workshop, there were 15-19 participants, all children (8-14 years) except in one workshop there were six adults. Three workshops conducted in Japan followed the following *modus operandi*.

In the first step, the children were shown about 20 photographs of scenery from around the world, and then they were asked to draw imaginary landscapes using the building, people, animals etc. in these pictures as they liked. In the second step, the Artist brought the children's imaginary landscapes to his studio, and then he drew one picture to be inserted between every two pictures of children, so that all three pictures form a seamless scene. One such trio of pictures is shown in Fig. 1: scenes 9 and 10 were drawn by participants, and the Artist drew S9 to connect the two.

Figure 1

In the third and final step, all the pictures were connected in a ring without a beginning and an end, and the completed ring was suspended from the ceiling of the museum where the workshop was held. The ring was placed with the paintings on the inner side, so that the viewer is surrounded by the work while viewing it.

The fourth workshop conducted in Kraków was similar except for two differences. One is that the children were not shown any photographs in the first step, but half the group was asked to draw Kraków as they imagined it in the past; and the other half the future of Kraków, all based on their imagination. This was only suggested to them and the participants drew whatever they wished. The other difference was that in the final step, the completed ring was placed on a glass floor.

## Methodology

Our overall methodology for this research project is as follows. In the first step, the Artist recorded various ideas that occurred to him as he drew each of the connecting pictures. It should be emphasized that in this step, the Artist was not aware of any potential hypotheses as to what we might be looking for in this data. In the second step, we analyzed these self-reflections to identify various micro-processes and their interactions with each other that were instrumental in the creation of the macro-level connecting pictures. In the third step, we posit cognitive mechanisms underlying these micro-processes. Finally, we plan to model these mechanisms in a computational system.

The research presented in this paper focuses on Steps 2 and 3. From the self-reflection data collected about each of the four workshops, we identified instances where a new idea was generated that became a major theme in the finished picture. This identification itself is also based on the self-reflection data. In other words, we are relying on the Artist's own judgment of the novelty factor. We should emphasize here that because of the nature of the task, namely to connect the two pictures seamlessly, there were many cases where the Artist copied elements, extended texture, color or shape from one of the pictures to the middle picture, and so on. Though we have included such micro-processes in our complete analysis, they are not discussed here.

## Mechanisms of Creativity

We present here several examples of the Artist's thought processes as he sought to connect the given two pictures seamlessly. The Artist's original comments were in Japanese, and are translated here with minor editing by the other author of this paper. We have also labeled and categorized these examples based on the factor that played a key role in the overall theme and the composition of the connecting picture.

### Surface Similarity

In several instances, similarity with respect to color, shape or texture played a key role in the genesis of the connecting picture, and in such a way that a semantic construct was created. This is illustrated by the following examples.

**Similarity in shading or texture:** Consider the Artist's observations concerning Fig. 1: "These two had completely different atmosphere from each other. Sketch 9, drawn by an adult participant, is a scene set at dusk; a person looking at the artist is drawn wearing a sad expression. Sketch 10 has a bright atmosphere with flowers, fountains, buildings on a hill, and a horse. Moreover, each picture had an important character in the bottom left. The idea for connecting these sketches came to me while looking at the wonderful horse in 10. I thought of putting a parent horse running nearby. Because the background color of 9 and the body color of the horse in 10 was the same, I transformed the background of 9

into the parent horse in S9, which became a nested image structure. Then I extended the baby horse and the hill with the buildings."

Here the same shading for the horse's body in 10 and the background in 9 led to the idea that the background in 9 can be morphed into the mother horse in S9, which results in an Escher-like nesting of pictures. The same phenomenon is also seen in Fig. 2: "There was the ground and the sky in the left one-third of 11, but the sea covered the remaining part on the right. In 12, a vast meadow was drawn with rich pictorial details. Here my attention was drawn to the connection between the color of the giant bridge in 11 and the color of the sky in 12. In S11 I drew the enlarged bridge of 11 and connected it with the picture on 12, which resulted in a nested image structure."

These two examples show how texture or shading triggered an association that led to nested image structures.

Figure 2

**Similarity in shape:** In Fig. 3, it is the shape of the curves that started a chain of thought: "I felt these two could not be connected with the techniques I had used so far. Then I noticed the wall on the top-right corner of 12 and the curved ledge surrounding the fountain in 13. Using these two curves, I drew a large Mobius strip in S12. As this Mobius strip divided S12 into four sections, in each section I extended the adjacent scenery. It felt like pouring in the scenery. Accordingly, I was able to connect them without blending, and this became the first work with this technique."

Figure 3

**Surface features trigger a new concept:** In Fig. 4, surface features of an object drawn by the participant reminded the Artist of a completely different object, and that became the theme of the connecting picture: "Suddenly my attention was caught by the strange-shaped, cage-like object drawn at the corner fence in the right pencil-sketch. I thought this shape was a piano. Once I could overlap these images, the

line of fence naturally transformed into a musical staff, and I could draw the dragon playing the piano. I made the particles of light in the sky of the left picture as if they are the sound emanating from the piano.”

Figure 4

### Contrast

There were also several examples where the contrast or the opposition between the two pictures was instrumental in generating a new idea.

**Contrast in perspective:** In Fig. 5, the contrast between the viewpoints of the pictures was a major factor: “I thought it is not possible to connect 3 and 1. Picture 1 is clearly a bird’s eye-view, as if a bird is looking down towards the ground; in contrast, picture 3 has a distinct horizon with a clear separation between the earth and the sky. First I extended the broken train track and the tire tunnel. Then as I was drawing the dark blue river, I thought, ‘But where should I extend this river? Towards the top? Towards the bottom? If I extend it below, then I can connect it with the ground of 3. But...’ I felt lost. Finally, I resolved to bring the river up. It was a desperate effort. However, at that time I thought of a good way to solve this problem. In the remaining left edge of the picture, I extended the scenery from 3. Finally, to integrate the inconsistent parts of the picture, I floated a number of clouds from 3 on the river. Thus, by using clouds as intermediaries, I was able to connect a bird’s eye-view picture with a perspective picture.”

Figure 5

**Contrast in richness of details:** In Fig. 6, it was the contrast between the richness of details that lead to a very interesting result: “Because 8 was a richly detailed realistic presentation, to contrast it with the presentation in 7, I decided to stress dimensionality in the connection. The

realistic rocks and the bridge in 8 were rendered in 3-d and were connected with the bridge in 7 that was extended in 2-d. To make this connection smoother and give an accent to the picture, I drew 3 Russian onion domes from 7 into S7.”

Figure 6

Fig. 7 provides another example: “I thought about how to connect picture 5 with picture 6 that had strong green with dark lines and was rich in details. I thought I could turn the contrast of a picture rich in details and a picture low in details into a pictorial effect. On the top right of 5, there is a game-character like man standing with a trident basking in the sunlight. First, to counter that, I drew a partner woman’s figure on top left of S5. But I laid down the trident by her side. I drew most of S5 as an extension of the dynamics of picture 6. On the bottom right of 5, there is an abstract painting-like area, and I placed this dark touch on the left edge of S5. This was a pleasure to work on. When I saw all of the paintings arranged in a ring at the Art Museum in Okazaki, it was obvious that it was picture 5 that was being the heretic and bringing out the effect of difference in richness of details in paintings. This realization was the most important lesson to me from this case.”

Figure 7

### Semantic similarity/association

There were several examples where similarity at the meaning level played a key role in generating ideas for the middle picture.

**Concept retrieval based on semantic association:** In Fig. 8, the wisp of smoke coming out of the chimney of a house, suggested the idea of a steam engine: “Perhaps my worst betrayal (in a good sense) of the participants is when I changed the brown house of the robot into a steam engine somewhat arbitrarily. The thread of smoke coming out of the chimney made me do this.”

Figure 8

**Similar objects:** Two objects, both trains, but with surface-level dissimilarities played a major role in Fig. 9: “I first noticed the train in 1 and 2. I admired that even though they both had drawn the same train, their drawing styles were very different, and I felt a strong urge to connect the two trains. First I connected the two train tracks that were cutting across 1 and 2, and then drew the gradual transformation of one train into the other. On the bottom left I drew a swan from 1, and on the top right I drew the water fountains and trees from 2, and then connected the backgrounds of the two pictures.”

Figure 9

### Deliberately Ignoring Meaning

Figure 10

Fig. 10 provides an interesting example where the Artist deliberately chose to ignore the meaning and focused on the surface features only: “At first Sketch 4 was filled-in completely black, and then brightened by eraser. It had no earth and sky, but an ambiguous space from a dark fantasy. Normally, a picture like this cannot be connected with any picture. I decided to connect this dark picture with 3, which had a child-like pictorial space. However, it would be impossible to connect the two in an ordinary way. Here, I decided to ignore all the meanings in these pictures, but instead focus on the pattern of light and dark. I said to myself, ‘it is just a blotch’. The only connecting point in

both pictures was the street in 3 and the bridge on the bottom left of 4. I could connect this street and the bridge. Luckily, bottom left of 4 looks like the sea, and bottom right of 3 also looks like a body of water. In S3, I extended the road in 3 in S-shaped curve and connected it with the bridge in 4. Continuing, I also extended the sea. Until here it was traditional technique. The problem was what to do on top of this. On the left part of S3, the only possibility was to extend the street-side houses on 3, so I did that in the same touch. Then I gradually changed the color of houses from gray to black, while introducing spatial distortion, and changing them from solid to liquid. I floated a swan in the dark pond that the buildings were turned into.”

This example also illustrates the role of surface features (similarity between the shapes of the road and the bridge) and semantic association based on functionality (roads and bridge are both used for travelling.)

### Metaphor

In Fig. 11, an overarching metaphor was generated in trying

Figure 11

to connect a picture with two neighboring pictures. We include a long quote here to familiarize the reader with the context and the thought processes of the Artist: “The child who drew this seemed (and it is my personal impression) emotionally repressed, and who is not accepted as himself by the surroundings. I had decided to not consider the psychological problems of the children, but focus only on the expression of form and color. However, when I was confronted with this work that expressed intense psychological problem, I instinctively thought, ‘What can we do to help this heart?’ But I am well aware that the most I can do is to finish the work and by having the participants view it as an aesthetic experience send them some kind of message. I placed on both sides of 11 two of the brightest pictures, 10 and 12, and started to connect it with them. The sky in 10 is clear, but the top portion is dull and grey. Even more than that, the colors of gloomy 11 seem to entirely reject any possible connection. In S10, losing to this strong feeling of rejection, I connected the pictures rather abruptly and formally. As a result, I gave angel wings from the globe in the middle of 11 to the swan in the red area of S10. Continuing with connecting 11 with 12, on the spur of the moment, I thought of mixing the color of the water surface. In other words, in the middle of the blood red lake of 11, I poured in a stream of bright blue from 12. I was hoping that the same effect would also occur in the heart of the child who drew 11. I felt relieved instinctively when this work was finished. Furthermore, as a cheering party for the child

who drew 11, I added on the top right of S11 the street lamps and the acorn decorations of 12.”

### Influence of Other Ongoing Projects

Fig. 12 illustrates a case when an idea was borrowed from another ongoing project of the Artist: “In S6, I first drew the remaining portion of the cow in 6, and then the remaining portion of the cliffs of Cappadocia. Moreover, to connect the complex-shaped terrain in 7 with the savannah meadow of 6, I extended the grey building on the right edge of 6 and transformed the terrain. Incidentally, at the same time I was working on my ‘Moiré’ series, so I made the shape of the grey buildings like the silhouette of Mt. Saint Michel. This became an example of my incorporating a concept of my own in the scene through my pro-active involvement.”

Figure 12

## Discussion and Related Research

Having gleaned these bits of insights, we now identify four major themes underlying creativity that are highlighted by this study. We comment below on each theme and also discuss previous research related to it.

### Role of Surface Features

It has been widely recognized that similarities play a key role in the generation of new ideas (Kokinov *et al.* 2009; Ward 2011.) Although surface similarities are often found to influence memory access and recall (Barnden & Holyoak 1994), most of the research has focused on semantic aspects of the similarity, like structural alignment, for these are considered to be more helpful in problem solving and learning. In fact, surface similarities are often thought to be distracting (Faries & Sclossberg 1994). Our data, however, indicates that surface features can have a significant influence on creation of new ideas in at least two different ways.

**Surface similarities between two objects:** Here noticing surface similarities between two different objects triggers an exploration for a possible deeper meaningful relation between them, as we saw in many examples above. This is consistent with the results of our earlier studies (Indurkha *et al.* 2008; Ojha & Indurkha 2009), where we found that similarities with respect to color, shape, texture etc. facilitate generation of conceptual associations.

### Surface features of an object recall a different concept:

We saw above how the perceptual features of a cage-like object in Fig. 4 triggered the concept of piano, which became the motif of the connecting picture. This is consistent with a model of perceptual metaphors we had proposed in our earlier work (Indurkha 2006), where we argued that certain metaphors rely on a perceptual resonance between the images corresponding to the source and the target.

### Role of Contrast or Opposition

We found several instances where new ideas or perspective emerged in trying to connect contrasting elements. Many previous studies of creativity have also found that opposition can be a key to generating new insights. For instance, Schön (1963) emphasized that in order to get a new insight about a concept, it needs to be *displaced*, that is, put in the context of other unrelated concepts. Koestler (1964) emphasized that the pattern underlying a creative act is the perception of a situation or an idea in two self-consistent but habitually incompatible frames of reference. More recently, Shapira and Liberman (2009) suggest *psychological distance* as a mechanism for enhancing creativity. They and their colleagues (Jia, Hirt and Carpen 2009) have demonstrated that psychological distance can be induced by such simple devices as taking another person’s perspective or thinking of the problem as if it is unreal.

### Deliberate Deconstruction of Meaning

We presented one example above where the Artist deliberately chose to ignore the meaning, and focused on the perceptual features like shade and texture. This mechanism is also often acknowledged as a useful heuristic for creativity. For example, Gordon’s (1961) *making-the-familiar-strange* is essentially the process of deconstructing the familiar meaning associated with the problem. Similarly, the first step in one of the creativity mechanisms proposed by Rodari (1996) is *estrangement*, where you are asked to see the object as if for the first time, without associating familiar meanings with it.

### Interaction of Top-down and Bottom-up Influences

The metaphor and the moiré series examples (Fig. 11 and 12) illustrate the top-down influences in the creative processes. What we mean here is that the psychological state of the artist and her or his past experiences can also influence the particulars of a creative insight. There have been several accounts of creativity that emphasize the interaction of top-down and bottom-up processes (Fauconnier and Turner 2002; Hofstadter 1995; Indurkha 1997).

## Conclusions and Future Research

We analyzed data from the Artist’s verbal recollection of his thoughts as he drew the middle pictures to connect pairs of pictures seamlessly. From this analysis, we identified a

number of micro-processes that led to the *big picture* idea. In particular, we found that *surface features*, *contrast*, and *meaning deconstruction* play major roles in the generation of new ideas.

There are two lines of research that we are pursuing from here onwards. One is to develop a meme-based approach to formalize these micro-processes, and implement a computational model of them (Ogawa, Indurkha and Byrski 2012). Besides, we are also interested in studying the cognitive processes of the viewers as they look at the trio of pictures. The term creativity is generally restricted to the artist or the person who generates the work, design or the artifact; and one does not attribute it to the reader or the viewer. However, we have argued before that in some situations at least, some creativity is required from the reader or the viewer as well (Indurkha 2007). Moreover, our past research has shown that surface-level perceptual similarities influence how viewers connect pairs of images and relate them conceptually (Ojha and Indurkha 2009; 2012). It would be interesting to see how this process is affected when there is an intervening picture in the middle; and we would like to study the effect of contrast as well. We plan to conduct behavioral and eye-tracking experiments to measure the viewers' response and incorporate those observations in our model.

### Acknowledgments

We are grateful to the Meguro Museum of Art, Tokyo, the National Museum of Art, Osaka, Okazaki Mindscape Museum, Aichi, and Museum of Contemporary Art, Kraków for hosting these workshops. We are also thankful to all the participants for their efforts and contributions.

## Abstract

The creation of a work of art has been indicated to result from 'expressive awareness', achieved as the artist matches images and methods. This study examines how novices, who tend to express reproductively, acquire such expressive awareness over several weeks of practice of photography. We conducted case studies with two conditions: 1) one participant reflected only her own creative activities, and 2) one participant imitated eminent works of creative expression in the domain. As a result, the participants acquired expressive awareness in both conditions, though the contents of the expressive awareness were different. The imitation participant started to practice creative expressions and tried to control her creation consciously, while the reflection participant started to focus on precision of methods of expression. The findings of this study are useful for developing educational practice in art schools.

**Keywords:** artistic creativity; expertise; imitation; reflection; artistic expression

## Introduction

Artistic creation has been one of the most significant activities of human beings. Recent psychological studies have focused on the process of artistic creation. Such studies provide useful insights for understanding creative cognition and have implications for creativity education. Previous studies on the cognitive processes of artistic creation have indicated that artistic creation consists of processes for generating ideas or concepts, and processes for externalizing them into artwork (e.g., Mace & Ward, 2002; Yokochi & Okada, 2005). These studies have also suggested that coordination of these two processes is important. In other words, when creating artworks, artists pay attention to whether or not their artwork matches with their art concepts, and whether or not the strategies that they choose are effective in actualizing their ideas as a form of art. The process of coordinating their intentions and actions to achieve artistic expressions is a type of monitoring process, i.e. a metacognitive process (Flavell, 1976). Though it is known that these processes feature in artistic creation by experts, they have rarely been seen in creation by novices (Fayena-Tawil, Kozbelt & Sitaras; 2011).

This sense of matching of images (hereafter *expression contents*) and methods (hereafter *expression methods*) to externalize them, referred to in this paper as *expressive awareness*, plays an important role in artists' creation (c.f. Gantner, 1979). However, no empirical research has been done to examine how novices acquire this expressive

awareness in the process of achieving artistic expertise. This study focuses on such an acquisition process of expressive awareness as an initial form of monitoring ones' own creative process. The findings from this study offer new insight for the development of education programs for art schools.

When we examine the process of artistic expertise, we first need to explain what artistic expression is. Before the modern era, expression meant giving a plausible impression of motifs relating to religion or history (Diderot, 1980). In contrast, after the modern era, the concept of artistic expression came to mean turning the creators' experiences, emotions and subconscious experiences into an entity with reality and impact (Croce, 1902; 1990). Nowadays both views of expression exist in society. This diversity of views of expression may affect the process of artistic expression itself. Therefore, in this study, we classify artistic expressions as *reproductive expression*, the contents of which are intended to represent real entities such as landscapes or still lifes, and *creative expression*, the contents of which are intended to represent the creators' ideas or emotions.

Novices who have no knowledge of artistic creation generally prefer realistic works (Cupchik & Gebotys, 1988; Kozbelt, 2006). Also, Ishibashi & Okada (2009; 2010) reported that novice subjects drew realistic drawings when they were asked to draw original works with natural materials as motifs. According to these findings, art novices tend to appreciate and create reproductive expressions.

What are the important factors affecting novices' acquisition of expressive awareness? One of the candidate factors is continuing participation in expressive activities. People use *self-explanation* (Chi et al., 1989) and *reflection* (Schön, 1983) on their own artwork and on their process of creation during such expressive activities. These processes can lead to the acquisition of expressive awareness. Therefore, it is assumed that novices are able to acquire expressive awareness if they have continuing opportunities to create artworks and reflect on their own creations.

However, in order to become expert in a domain, such an action-reflection cycle may not be enough. Csikszentmihalyi (1999) suggested that creativity is dependent not only on the creators' activities, but also relates to domain rules, representations and methods in the field of expertise. Hence, it might be assumed that profound encounters with existing artwork in an artistic domain play an extremely significant role in the acquisition of expressive awareness in addition to

reflection on the artist's own creations. In fact, it has for a long time been considered that copying masterpieces (i.e. a profound type of encounter with masterpieces) is a very efficient way to learn drawing techniques and the painters' intentions represented in masterpieces.

Ishibashi & Okada (2009; 2010) empirically examined the effects of imitation on artistic creation. They conducted psychological experiments that entailed novices copying unfamiliar abstract drawings. While copying, they speculated on the intentions and processes behind the drawings and acquired new perspectives for drawing. As a result, using new representations, participants who copied abstract drawings drew more creative pictures than those who did not. Though their study produced pioneering work that empirically examined the effect of a profound encounter with the artwork of others on creative drawing, they did not focus on the issue of expressive awareness described above.

Therefore, we decided to conduct empirical case studies focusing on the question of how profound experiences (such as imitation) of existing artworks affect novices' acquisition of expressive awareness. To elucidate this question rigorously, it would have been better for us to conduct experiments with a greater number of participants, as done by Ishibashi & Okada (2010). However, conducting experiments with many participants to observe such a long-term cognitive change would be extremely time-consuming. Finding at least twenty participants who were willing to spend seven weeks on this experiment was practically impossible for us. Since our main goal is to investigate how expressive awareness is acquired during a fairly long-term process of the mastery of art, we decided to conduct exploratory case studies analyzing the data in detail from various aspects. Such a case study method with a long-term span has been used to examine the process of acquisition of knowledge or strategies in cognitive psychology (e.g., Siegler & Jenkins, 1989).

We used artistic photography as the target domain for research to answer our question, because photography is one of the most familiar genres of artistic expression in our ordinary lives. Photography also has a very distinctive feature that people can take photographs in a very short time span; a photo is usually taken in less than a second. These features of photography enabled us to study the early process of artistic expertise easily, because novices have a low barrier to participation in this artistic activity.

It is important to note that photographs can express the creator's intentions or ideas even if the photographs realistically represent the motifs. For example, a famous photographer, Henri Cartier-Bresson introduced the concept of '*The Decisive Moment*' by creating artwork matching with a theme. Hence, it is possible for us to understand photographers' intentions deeply through viewing their photographs.

Although novices in photography may usually tend to appreciate or create reproductive expressions, they acquire expressive awareness through the process of repeated

practice of photography. Specifically, novices gradually acquire creative expressive awareness and try to control relationships between expression contents and methods consciously if they imitate photographs with creative expression. In contrast, they acquire reproductive expressive awareness if they only repeat photo taking and reflection. They pay more attention to expression methods to express precisely the reproductive contents, because they have less necessity to develop expression contents than in the case of the creative expression style. These considerations lead to the following two hypotheses. The first hypothesis: Novices in the domain of artistic photography acquire expressive awareness, through just repeating photo taking and reflection or by imitating eminent artistic photographs of creative expression. However, the former acquire reproductive expressive awareness and the latter acquire creative expressive awareness. The second hypothesis: Novices with creative expressive awareness try to control relationships between expression contents and methods consciously in the following creations. In contrast, those with reproductive expressive awareness emphasize the importance of expression methods.

## Method

In this study, we conducted two case studies that examine the changes in artistic creation over a period of several weeks. Each case study included four tests [a pre-test and post-tests 1-3] and three interventions [interventions 1-3]. The tests and interventions were repeated alternately.

**Participants and the period of observation** Two female students at the University of Tokyo volunteered for this study. One participant was 23 years old and an undergraduate student in science, and was assigned to the imitation condition. The other participant was 24 years old and a graduate student in pharmacology, and was assigned to the reflection condition. The length of the case study period of the former was 86 days from 28 October 2010 to 21 January 2011, and that of the latter was 46 days from 30 September to 14 November 2011. The reason why the participant in the imitation condition spent a longer time than the other one was because the Christmas holidays fell within the case study period and she stopped her photography for a while.

Both of the participants showed an interest in artistic photography before participation in this study, and the imitation participant visited an exhibition including photographic works just before participating in the study. However, they had never had any professional training in artistic photography. They took photographs mainly when they travelled or attended special events, and were not in the habit of visiting photo galleries or exhibitions to see collections of photographs.

Also they had never used a single-lens reflex camera. Therefore, the first author taught them the basic method of use of a digital single-lens reflex camera, such as the mechanism of the camera and how to use the diaphragm,

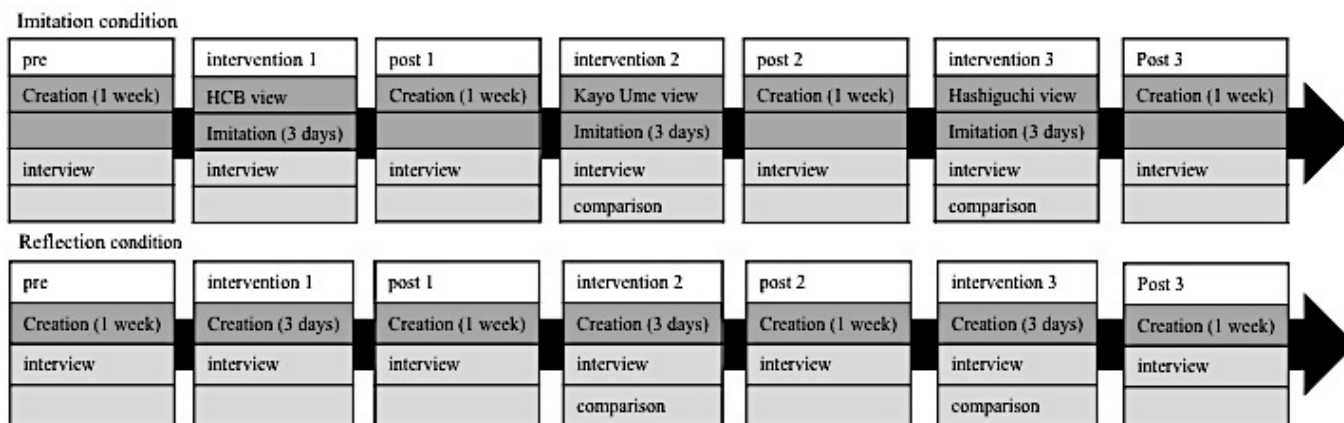

Figure 1 Procedure of case studies in each condition

shutter speed and exposure. They then practiced taking photographs with the first author.

**Procedure** The participants were required to take at least 40 artistic photographs per week during their own free time in each of the four test sessions: the pre-test and the post-tests 1-3. The three interventions were different in the two conditions. In each intervention session of the imitation condition, the participant first saw a collection of artworks by a proficient photographer, selected the one photograph that she liked the most, and then was given the following instructions, “Think about what the photographer pays attention to when taking this photograph and try to take the same style of pictures yourself.” The participant in the reflection condition continued to create artistic photographs of her own in the intervention sessions. Both of them took at least 20 photos in each intervention session (see Figure 1).

All of the photographs were taken with a digital single-lens reflex camera (Canon EOS KissX3 / EF-S18-55mm F3.5-5.6IS). The participants were directed to use only three modes of exposure that enable the user to control expression to a large extent: Manual Mode, Shutter Priority AE and Aperture Priority AE. They were not allowed to use Program Mode, since not much room is left for users to control the photographic expression if they use such an automated mode. All of the photographs taken were preserved for analyses.

After each session in the two conditions, the first author interviewed the participants. The interviews for the imitation condition took about 1 hour, and for the reflection condition took about half an hour. They were recorded by IC recorders and a video camera. In the interviews, the participants selected the ten best photographs in the session after each test, and the five best photographs in the session after each intervention. If there were any other photographs that the participants selected, they also reported on these. In addition, we interviewed them about their views on photography in each session. The participants were directed to reflect on their photographs in the session by comparing them with photographs taken in previous sessions.

**Imitation tasks** The photographs used for the imitation tasks were of styles different from those about which the

imitation participant had prior knowledge, as indicated in the interview after the pre-test. This was because it has been shown by Ishibashi & Okada (2009; 2010) that the copying of unfamiliar pictures stimulates the production of creative artwork. In order to identify styles of expression unfamiliar to the participant, the first author interviewed her about her favourite photographs, favourite photographers, and her own photographs taken in the pre-test. Her favourite photographer was Mika Ninagawa and her favourite photograph was one from ‘SHADOWS: Works from the National Museums of Art’. As their characteristics, she mentioned ‘colours’ and ‘shadows’. In addition, there were no photographs in which people were the main motif in pre-test sessions in either of the conditions. Therefore, photographs that depicted people as the main motifs and were not characterized by ‘colours’ or ‘shadows’ were selected for the imitation sessions.

**Data** The main data are protocols in interviews.

First, we checked in the interview data whether or not the imitation participant actually practiced imitation. Second, in order to examine the first and second hypotheses, we checked whether expressive awareness was observed and if so, how this awareness developed in the answers to the questions about the participants' views of photography and the interviews about each photograph taken by them.

**Expressive awareness and the process of expertise** To examine the first hypothesis, with the interview protocols on views of photography and of each photograph taken by the participants, we checked whether expressive awareness was acquired by the participants.

In the verification of the second hypothesis, we also checked whether the features of the process of expertise appear in the interview protocols on the views of photography and of each of the photographs taken by the participants. In addition, we also investigated the changes in expression methods, expression contents, and matching of them in chronological order in each condition.

**The changes in the participants' views of photography** The interviewer asked the participants, ‘What do you think is good photography?’ and ‘What should we do to take good photographs?’, in order to investigate their views on

photography in each session. In this protocol, we checked whether they mentioned ‘Expression contents’, ‘Expression methods’ and ‘Matching between the expression contents and methods’. ‘Expression contents’ are further divided into ‘Reproductive expression’ and ‘Creative expression’.

In this analysis, ‘Matching of expression contents and methods’ indicates expressive awareness. If the ‘Expression contents’ were ‘Reproductive expression contents’, we regarded the expressive awareness as ‘*Reproductive expressive awareness*’. Also, if the ‘Expression contents’ were ‘*Creative expression contents*’, we regarded the expressive awareness as ‘*Creative expressive awareness*’.

**The changes in expressive awareness in the interview protocols for each photograph** The data are interview protocols about the 10 best photographs of their choice (in total 40 photographs) taken by the participant in pre-test and post-tests 1, 2, 3, in both conditions. We identified the interview protocols about matching of expression contents and methods as expressive awareness. Then we examined how each protocol changed in chronological order in each condition.

## Results

We first checked whether imitation was actually practiced. The results showed that in the imitation participant’s reflection on her own photographs taken in the interventions, characteristics of imitation tasks appeared. We do not explain this result in detail in this paper due to limitations of space. (The detailed results are reported in Ishiguro, Okada & Ishibashi, 2011.)

For testing the first and second hypotheses, we checked interview protocols about views of photography and about

reflection on each photograph. As a result, statements about expressive awareness appeared after intervention 1 in both conditions. The reflection participant mentioned reproductive expressive awareness and the imitation participant mentioned creative expressive awareness (supporting the first hypothesis). However, the reflection participant occasionally stopped mentioning this in the interview on her view of photography, and statements about the matching of expression contents and methods were less frequent in her reflection on each photograph than that of the imitation participant.

The process of expertise of expression differed in the two conditions. The imitation participant always paid attention to expression contents, methods and matching of them after the acquisition of expressive awareness. In contrast, the reflection participant sometimes reported no matching of expression contents and methods after the acquisition of expressive awareness, and emphasized the importance of expression methods (supporting the second hypothesis). The specific results are the following.

**The views of photography** Both the participants mentioned expressive awareness after intervention 1 (see Table 1, 2). Additionally, the imitation participant, who experienced imitation of multiple varying artworks, showed a stronger interest in creative expression contents and mentioned the matching of expression contents and methods after intervention 2. In contrast, the reflection participant, who repeated only photo taking and reflection, emphasized reproductive expression contents from the pre-test, and acquired reproductive expressive awareness in intervention 1. However, she had a tendency to pay attention to precision of expression methods after post-test 2.

Table 1 The view of photography in the imitation condition

The imitation participant		pre	intervention1	post1	intervention2	post2	interventions3	post3
Expression contents	Reproductive contents	○						
	Creative contents		○	○	○	○	○	○
Expression methods			○	○	○	○	○	○
Matching of expression contents and methods (Expression awareness)	Reproductive expression awareness							
	Creative expression awareness					○	○	○

Note. ○ open circles mean that participants mentioned about each item

Table 2 The view of photography in the reflection condition

The reflection participant		pre	intervention1	post1	intervention2	post2	interventions3	post3
Expression contents	Reproductive contents	○	○	○	○			○
	Creative contents							
Expression methods			○	○	○	○	○	○
Matching of expression contents and methods (Expression awareness)	Reproductive expression awareness	○	○	○				○
	Creative expression awareness							

Note. ○ open circles mean that participants mentioned about each item

NB: The two graphs show the number of photographs mentioned in connection with each of the items on the vertical axis and sessions on the horizontal axis.

Figure 2 Expression awareness in the imitation condition

Figure 3 Expression awareness in the reflection condition

**Protocols for each photograph** We examined the interview protocols for each photograph from the aspect of ‘matching of expression contents and methods’ in order to check whether or not expressive awareness was actually utilized in each photograph (see Figure 2, 3). The results indicated that ‘matching of expression contents and methods’ was focused on more strongly in the imitation condition than in the reflection condition. The imitation participant seemed to be interested in creative expression because from the pre-test to post-test 1, she mentioned ‘No artistic concept’, which is defined as a statement indicating a lack of the concepts necessary for artistic photographs. However, she increasingly mentioned ‘Failure to use an appropriate method for a concept’, which means failure to take photos using appropriate methods despite having a certain expression content, and ‘Success in the use of an appropriate method for a concept’, which means success in taking photos using appropriate methods for a certain expression content. These results imply that the imitation participant had creative expressive awareness when taking each photograph, and such awareness became higher in the subsequent sessions. By contrast, in the reflection condition, statements about ‘Success in the use of an appropriate method for a concept’ increased in post-test 1, in which expressive awareness appeared for the first time in interview protocols about the views of photography. However, the number of the statements about the matching of expression contents and methods in this condition was less than in the imitation condition. Also, it was implied that she had less interest in creative expression contents, because there were no statements about ‘No artistic concept’.

## Discussion

Through two case studies, we have examined how novices acquire expressive awareness that controls expression contents and methods in a creation process when they continue to participate in artistic expression for a number of weeks. We have also investigated whether there are differences in expressive awareness and the process of

expertise between those who employ reproductive expression, repeating photo taking and reflection, and those who practice photography based on imitations of eminent works of creative expression.

Expressive awareness was acquired in both conditions after interventions. Creative expressive awareness was acquired in the condition of imitating eminent artworks, and reproductive expressive awareness was acquired in the condition of reflection (supporting the first hypothesis). Additionally, the result that in the reflection condition there were fewer statements about reproductive expressive awareness indicates that reproductive expression was not as consciously achieved as creative expression.

The two conditions differed in the process of expertise. The imitation participant paid attention to the matching between expression contents and methods after the acquisition of expressive awareness. By contrast, the reflection participant paid attention to expression methods very precisely (supporting the second hypothesis).

Given these results, it is suggested that novices are able to acquire reproductive expressive awareness by only repeating creation and reflection. However, through imitating eminent works of creative expression, their expression style changes to creative expressions and they become conscious of the matching of creative expression contents and methods.

In this study, we provide new findings in the study of expertise as follows. Previous studies of expertise have indicated that experts have structured domain specific knowledge and utilize their metacognition (Glaser & Chi, 1988), such as self-monitoring skills (Ericsson et al, 1993) or reflection in action (Schön, 1983) in various expert practices. Such knowledge and cognitive processes are acquired in the long-term processes of expertise.

This study defines expressive awareness as indicating the emergence of control of ones’ own creative process, and examines how this occurs. The results indicate that expressive awareness is acquired after continuous participation in creation. However, it is important not only

to repeat creation and reflection but also to have profound encounters (like imitation) with eminent creative expression works in the domain so that creators can utilize these actively. These findings support the claim that creators have to learn domain specific knowledge in order to create original works (Csikszentmihalyi, 1999).

**Limitations of this study and future work** We were not able to conduct experiments with a large number of participants. Therefore, we have to be careful in generalizing our findings. Also, for various practical reasons, this study failed to control differences in the academic backgrounds and photographic experience of the two participants. Therefore, the possibility that differences in critical thinking or motivation for photo taking between them affected the results of this study still remains. However, each of them was intelligent enough to secure a place at a highly prestigious university in Japan, and they both told us that they were highly motivated to take pictures. Future studies are required to exclude such confounding variables more carefully, by increasing the sample size of both the imitation and reflection condition and controlling variables that might affect differences in the conditions.

## Abstract

In this research, we investigated cognitive processes while playing Mini-Shogi through fMRI and cognitive experiments. Mini-Shogi is a Japanese chess-like game that uses a small board. In our cognitive experiment, the group of stronger Mini-Shogi players the stronger group's total thinking time shortened and their total number of eye movements decreased. However, our investigation of search depth revealed different results from those of past research. The results of our fMRI experiment revealed that after learning, activity in the caudate nucleus increased among stronger players. The results of our experiments suggested that intuitive ability and the capacity for careful consideration are not independent.

**Keywords:** Expertise; Mini-Shogi; Intuition; fMRI; Eye movement.

## Introduction

Since developments in measurement apparatus have recently made it easier for physiological data to be measured more correctly (and in greater detail), the amount of research comparing cognitive data with physiological data is increasing. One type of such research, research on learning, not only clarifies the mechanism of intelligence but will also be useful for education.

In the field of cognitive science, research examining the difference between beginners and experts using chess and puzzles has been executed. In chess, the most famous cognitive experiments have involved memorizing positions and were performed by de Groot (de Groot, 1965; de Groot & Gobet, 1996). The results of those experiments revealed that experts can memorize more chess pieces of a position quickly than beginners.

As a follow-up to de Groot's work, Chase and Simon introduced the theory of chunking to explain why expert game players perform so well in memory tasks (Chase & Simon, 1973). Chunking is the process of dividing a chess position into smaller parts that have meanings. Chase and

Simon showed that stronger players have bigger chunks of chess knowledge than do weaker players.

Ito and others have observed cognitive differences between experts and beginners in Shogi (Japanese chess) as a follow-up to research on chess (Ito, Reijer and Matsubara, 2004). In that research, they compared the thought processes of beginners, club players, and experts during the next move task. The results are shown in the following table (Table 1). The results suggested that there were not only spatial clusters (spatial chunks) but time clusters (time chunks) involved in the experiments on chess.

Table 1: The results of cognitive research on Shogi

	Beginners	Club players	Experts
Recognition of a position	slow	fast	very fast
Area of eye movements	wide	narrow	very narrow
Thought time	short	long	short
Generation of a candidate move	a few	many	a few
Depth of search	shallow	deep	more deep

This topic has also been researched in the field of brain science. With technological progress, measurement of brain activity came to be accomplished less via PET (positron emission tomography) and more via fMRI (functional magnetic resonance imaging). Paolo and others measured the active parts of the brain by using PET while subjects were solving chess-related problems (Paolo et al., 1994). The frontal lobes, the occipital lobes, and the left premotor area were activated when chess-related problems were considered.

Atherton, Chen, and others measured which parts of the brain were activated by solving problems in chess and Go using fMRI (Atherton et al., 2003; Chen et al., 2003). The

premotor area of the frontal lobes, the parietal lobes, and the occipital lobes are activated when solving both types of problems.

Wan and others have observed a physiological difference between amateur and expert Shogi players (Wan et al., 2011). They observed changes in brain activity by using fMRI. They found new brain activity.

When professional Shogi players saw the Shogi problem during the experiment, selective activity was observed in a part of the caudate nucleus; this activity was not seen in amateurs. On the basis of that peculiarity, we guess that this activity is related to expertise.

Much research using eye trackers has been executed in the field of cognitive science since the development of eye movement tracking devices.

Law and others analyzed the eye movements of beginners and experts in the use of training equipment for laparoscopic surgery (Law et al., 2004). Experts looked at the affected part, but beginners looked at the operating instruments. We can understand this by analyzing experts' eye movements and comparing the difference between experts and beginners. Much past research has separately measured experts and beginners and observed the differences between them.

Few studies have observed the learning process from beginner to expert. Therefore, in this research, we planned an experiment that makes the beginner learn and generates an expert. We also examined whether experts shared the features of expertise seen in past experiments.

In this research, we measured both cognitive and physiological changes. The physiological experiment was carried out at RIKEN. In this report, we explain the cognitive experiment and discuss the results of both the cognitive and physiological experiments.

## Mini-Shogi

### What is Mini-Shogi?

*Shogi* is a Japanese chess-like game. Mini-Shogi is also called 55-Shogi; it is similar to Shogi, but uses a  $5 \times 5$ -square board. Almost all rules are inherited from Shogi. Therefore, Mini-Shogi can be said to be "small-board Shogi."

Figure 1: Initial position of Mini-Shogi

The aim of the game is to checkmate the opponent's king. The initial position of the game is shown in Figure 1. There are six kinds of pieces: *fu* (Pawn), *kin* (Gold), *gin* (Silver), *kaku* (Bishop), *hisha* (Rook), and *ou* (King). Rook and Bishop can be promoted to Dragon and Horse, respectively,

as in Shogi rules, in case these pieces move to the end line of the board. Pawn and Silver can be promoted to Gold. The "drop rule" states that a taken piece can be reused, as in Shogi.

Since Shogi is a complicated game, a long period of time is taken to learn it. However, Mini-Shogi can be learned to a fixed level in a short period. In this research, since subjects needed to learn within a limited period, we found Mini-Shogi to be more suitable than Shogi for efficient acquisition of expertise.

## Experiment

### Subject

The subjects were 2<sup>nd</sup>- or 3<sup>rd</sup>-year students at the University of Electro-Communications, and 26 people became subject candidates. The contents of a questionnaire given to prospective subjects examined their experience with Shogi, Mini-Shogi, and Shogi terms. Six people whose questionnaires reflected too much expertise were excluded. After the experiment started, one person dropped out on his personal reasons. Finally, 19 people became subjects.

### Learning Environment

The learning term of this experiment lasted three months. The cognitive experiments were executed three times: the 1<sup>st</sup> period lasted from the start of the study to one week later, the 2<sup>nd</sup> period lasted from one week later to one and a half months later, and the 3<sup>rd</sup> period began after the end of the learning term. The experiments using fMRI were carried out in the early stage and the last stage of learning at RIKEN.

We gave the subjects the "K55" Mini-Shogi software package during the experimental period. "K55" was developed by Yoshikazu Kakinoki, who is a famous Shogi programmer. K55 was the champion program at the UEC Cup 55-Shogi Championship from 2007 to 2009 and the 2<sup>nd</sup> place program in 2010. Therefore, it is strong enough for beginners, and some of its interfaces are suitable for learning. It can be set to a difficulty level of 1–14, so it can be pitted against opponents of various ability levels. It is easy to operate the software, as positional evaluation by K55 can be displayed numerically, and it has a hint mode that can be used effectively for learning.

Moreover, we created an environment on which human players can play on the Internet. This system is called "55-floodgate." After a player completes 30 games, he/she receives a computed rating; we thought that these ratings would be useful for improving subjects' motivation. We asked subjects to learn about the game as much as possible (and for at least one hour each day). The duty to present a report was imposed upon the subjects once per week. The contents of this report were the following: time spent learning during the week, things noticed, winning rates against K55, etc.

In order to maintain a subject's motivation for learning during the experimental period, a lecture about Mini-Shogi was given to the subjects one month after the start of the

experiment. The contents of the lecture ranged from fundamental to strategic topics, such as the effective usage of each piece, the value of each piece, and advantageous openings. A collection of Mini-Shogi next move problems was distributed to two months after the start of learning, and subjects were made to answer these. Furthermore, a tournament was carried out at the end of the experimental period, and many prizes were awarded on the basis of the results. This tournament was thought to increase subjects' motivation.

## Cognitive Experiment

**Method** We showed the next move problems to subjects and asked them to speak freely regarding their thought processes. Eye movements were recorded simultaneously with verbal data using an eye tracker (QG-PLUS, Ditect, Inc.). We used a liquid crystal display monitor at a resolution of  $1280 \times 1024$  pixels (96 dots per inch). We recorded verbal protocol data according to the traditional cognitive science approach. We instructed the subjects that there were no time limits for thinking. We prepared 11 next move problems devised by an expert Mini-Shogi player. The next move problems shown to subjects used difficult positions from which multiple candidate moves can be considered. The order of presentation was randomized for each subject. The same problems were shown during each period, but the order of presentation was changed. (Incidentally, no subjects realized that the same problems were used.) A time interval was set between each problem, and the subject could decide to take breaks freely.

**Results** We selected six subjects for whom we obtained good verbal protocol and eye movement data in the cognitive experiment.

We executed three experiments: one each in the first period, the second period, and the third period of learning. In order to clarify the differences between subjects' mental processes before and after learning, we decided to compare the data from the first and third periods.

We classified verbal protocol data by categories of contents. We used the same classification system as did previous research, using five categories: "recognition of the position," "generation of the candidate move," "prediction," "evaluation," and "decision" (Ito, Reijer and Matsubara, 2004). On the basis of this analysis, we examined what kind of thinking was performed when the subject thought about the problems. The "depth of search" means the longest moves for which they searched, as reflected by verbal data.

The results are shown in Table 2, which displays the average changes between the 1<sup>st</sup> period and the 3<sup>rd</sup> period. Each entry in Table 2 consists of data averaged among six subjects. Statistical significance was assessed via t-tests of correlations between two samples.

Table 2: Changes between 1<sup>st</sup> period and 3<sup>rd</sup> period

	1 <sup>st</sup> period	3 <sup>rd</sup> period
Recognition of a position [s] *	37.8	52.1
Amount of eye movement [pixels] *	21089	27963
Thought time [s]	137.4	149.8
Generation of candidate moves [number] *	2.0	1.7
Depth of search [depth]	2.6	2.5

$p < 0.05$  (\*)

**Discussion** Subjects generated fewer candidate moves during the 3<sup>rd</sup> period than they did during the 1<sup>st</sup> period. This result corresponds with those of previous research.

However, other aspects of the results were different from those of previous research. We considered that the reason for these discrepancies may have been that the six subjects did not learn enough.

## fMRI Experiment

**Method** Brain activity was investigated using an fMRI scanner owned by RIKEN. The stimuli were 180 easy original next move problems (one-move checkmates, etc.).

One hundred sixty of the problem stimuli were between the early stage and the last stage of learning, and 20 of the problems were identical during the early stage and the last stage of learning. In the interrupt task used for initialization of brain activity, if a Gold piece appeared, subjects were instructed to press a button. Moreover, a task of reporting the King's position was set as the control task. The control task was used in order to check whether the subject understood the board position correctly.

We explained that a next move problem or a control problem were displayed for 2 seconds and required to answer it within 3 seconds.

**Results** In the experiment using fMRI, data from all 19 subjects were analyzed. Ten subjects were sorted into a low-rank group and nine subjects, into a high-rank group on the basis of the percentage of correct answers in the experiment conducted during the last stage of learning.

Figure 2: Correct response rates during the 1<sup>st</sup> and 2<sup>nd</sup> fMRI experiments

Figure 2 expresses the percentages of correct answers in the early stage and the last stage. The high-scoring group's data are represented by circles, and the low-scoring group's data are represented by diamonds.

Figure 3 expresses the percentage of correct answers in the last stage of learning and the strength of caudate nucleus activity. The high-scoring group's data are represented by circles, and the low-scoring group's data are represented by diamonds. Strength of activity expresses the ratio of activation in the last stage to that in the early stage. The activity was seen in the high score group. Figure 4 shows the region of enhanced activity.

Figure 3: Strength of activity and correct response rate at the 3<sup>rd</sup> time point

Figure 4: Region of enhanced activity

Figure 5: Size of caudate nucleus and correct response rate at the 1<sup>st</sup> time point

Figure 6: Size of caudate nucleus and correct response rate at the 3<sup>rd</sup> time point

Figure 5 expresses the rate of correct answers and the size of the caudate nucleus at the early stage. Figure 6 expresses the rate of correct answers and the size of caudate nucleus at the last stage. The high-scoring group's data are represented by circles, and the low-scoring group's data are represented by diamonds.

**Discussion** It is possible that good early learning rates could be caused by large caudate nuclei, as a correlation between the percentage of correct answers in the early stage and the size of the caudate nucleus was found.

The size has a weak correlation with the percentage of correct answers in the last stage.

The subjects whose percentage of correct answers was good have a tendency for caudate nucleus activity to be strong in the last stage. This result suggests that everyone can learn regardless of the size of the caudate nucleus.

## Additional Analysis

### Group analysis

The results of our cognitive experiment may have differed from the previous research because our subjects did not become strong enough. Therefore, we decided to take the subjects' strength into consideration.

As the scale that measures subjects' relative strength, we decided to use a combination of the rankings of the tournament held at the end of the experiment and the rate of correct answers to problems in the fMRI experiment performed at RIKEN. Figure 7 displays the subjects; the subjects who were used in the cognitive experiment are expressed as larger points.

Figure 7: Correct response at the 3<sup>rd</sup> time point and competition ranking

The correlation coefficient between the competition rankings and the percentage of correct answers was -0.712. We divided the two groups on the basis of competition rankings. The high-scoring group was composed of the subjects placing 3<sup>rd</sup>, 4<sup>th</sup>, and 7<sup>th</sup> in the tournament, and the low-scoring group placed 15<sup>th</sup>, 17<sup>th</sup>, and 18<sup>th</sup> out of 19 participants.

### Results

Table 3 displays the performance characteristics of the high-scoring group when the subjects are placed and analyzed in these groups.

Compared with Table 2, recognition of a position, amount of eye movement, and thought time have decreased.

Table 3: Changes in the high-scoring group during the study

	1 <sup>st</sup> period	3 <sup>rd</sup> period
Recognition of a position [s] **	31.5	21.1
Amount of eye movement [pixels] *	15560	12411
Thought time [s] *	137.4	88.7
Generation of candidate moves [number]	2.2	2.0
Depth of search [depth]	3.2	2.9

$p < 0.05$  (\*)  $p < 0.01$  (\*\*)

**Discussion** It seems that these are the features of expertise, as our results corresponded with those of previous research on certain points, such as reduction of time necessary to recognize a position, reduction of the amount of eye movement, and reduction of thinking time obtained in the high-scoring group.

A different result from previous research was obtained regarding whether searching deeply implies that skill is high. Although the tendency for search to be deep was seen as subjects became experts in previous research, this tendency was not seen in our results.

This result indicates that deep searching ability was not acquired by learning.

The items that differ between the high- and low-scoring groups at the 1<sup>st</sup> time point are the following:

Table 4: Difference between low score and high score

	low	high
Recognition of a position [s] **	44.1	21.1
Amount of eye movement [pixels] **	26616	12411
Thought time [s]	137.5	88.7
Generation of a candidate moves [number] *	1.7	2.0
Depth of search [depth] **	2.0	2.9

$p < 0.05$  (\*)  $p < 0.01$  (\*\*)

We expected that these differences might express variation in ease of learning. Bransford suggested that there is a type of beginner called an intellectual beginner (Bransford et al., 1982). He compared an efficient learner with an inefficient learner by stating that an inefficient learner did not notice the difficulty of a study subject and did not change his/her strategy when study subjects changed. The difference seen in this experiment may support the existence of the intellectual beginner.

### Analysis of Cognitive and fMRI experiment

The cognitive data obtained in the cognitive experiment and the brain imaging data acquired in the fMRI experiment are set and examined. Percentage of correct answers, size of the

caudate head, playing strength, and cognitive activity data are mainly compared.

**Results** Figure 8 expresses the percentage of correct answers to the problem used in the cognitive experiment in the 1<sup>st</sup> period and the percentage of correct answers to the problem used in the fMRI experiment at the early stage. The high-scoring group's data are represented by circles, and the low-scoring group's data are represented by diamonds. Correlations were not seen between the two variables.

Figure 8: Relationship between fMRI and cognitive experiment at the 1<sup>st</sup> time point (at the early stage)

Figure 9: Relationship between fMRI and cognitive experiment at the 3<sup>rd</sup> time point (at the last stage)

Figure 9 plots the percentage of correct answers to the problems used in the cognitive experiment in the 3<sup>rd</sup> period and the percentage of correct answers to the problems used in the fMRI experiment at the last stage. The high-scoring group's data are represented by circles, and the low-scoring group's data are represented by diamonds. There was a correlation between the two variables.

Table 5: Correlation coefficients between results of the cognitive experiment and the fMRI experiment

	Strength of activity	The size of caudate nucleus
Recognition of time positions [s]	0.021	0.746
Amount of eye movement [pixels]	-0.292	0.436
Thought time [s]	0.103	0.807
Generation of candidate moves [number]	-0.534	-0.424
Depth of search [depth]	0.538	0.282

Table 5 shows correlations between the differences of results in the cognitive experiment and the fMRI experiment. Correlations were found a little at a time in order to recognize the position and size of the caudate nucleus. Correlation was also found a little at a time between thinking time and the size of caudate. However, correlations were seldom seen among other items. Moreover, no correlation was seen when activity at the 1<sup>st</sup> and 3<sup>rd</sup> time points, brain activity, and the size of the caudate head were compared.

**Discussion** Figure 8 shows that there was no difference between the two groups' rates of considering carefully or answering problems intuitively in the 1st period of study. However, Figure 9 shows the relationship between the percentage of correct answers on problems that were considered carefully and the percentage of correct answers that were answered by intuition in the last stage of the study. It is therefore possible that intuitive and deliberative thinking abilities are not totally separate, and that these two types of thinking have mutually influenced one another. Table 4 shows that there is a relationship between the time to understand positions and the volume of the caudate nucleus. Since there is a close relationship between time to understand positions and thinking time, it is thought that the relationship was caused by both types of thinking. Since there is no relationship between cognitive change and change of brain activity in other areas, it is suggested that the changes are independent.

In the fMRI experiment, we investigated what happens to brain activity when a subject solved a problem by intuition. Some subjects described intuition in the reports that they presented once per week. A certain subject reported the following description during the 10<sup>th</sup> week of the experiment:

***"A move may flash by intuition or not flash."***

Moreover, another subject gave an analogous description:

***"If I encounter an important point in the game, I generate a move by intuition and search deeply."***

Both of the subjects seem to have considered (in light of the fact that they gave such descriptions at the end of the experiment) that intuitive ability is supported by prolonged learning.

## Conclusions

In this research, changes of expertise in Mini-Shogi were investigated in a cognitive experiment and an fMRI experiment. In the cognitive experiment, the results were analogous to those of previous experiments in terms of the difference between beginners and experts, showing reduction in thought time and reduction of eye movement upon position recognition with increasing expertise while obtaining almost the same level of skill in the subject. In the fMRI experiment, the high-scoring group displayed higher caudate nucleus activity, as seen in previous work.

Comparing the results of the cognitive experiment and the fMRI experiment, a correlation was found between the time

to understand positions and the size of caudate nucleus. However, correlation was not seen among other variables.

On the basis of this report and the results of our experiments, we suggest that subjects' intuitive ability and deliberation ability are not completely independent and that they may mutually influence each other.

## Abstract

How do people manipulate their environment when balancing trade-offs between probability of success and payoff? Individuals in a city park played a simple lottery using a small set of marbles placed in an urn. Participants had the ability to actively improve their chances of winning but only by reducing the amount of money that they could possibly win. Hence, participants controlled the lottery's intuitive trade-off between probability of success and potential payout. Across four different lottery structures, participants, on average, behaved systematically *safer* than the optimal strategy that maximizes expected gain. We explore two different accounts of this sub-optimal choice behavior: probability distortion, and intrinsic utility of winning.

**Keywords:** decision making; one-shot lottery; probability distortion; intrinsic utility of winning.

## Introduction

Typical decision making studies offer participants choices between two fixed alternatives. Sometimes the prospects are explicitly described: "Would you prefer to draw from Deck-1 which awards \$2 with .8 probability or from Deck-2 which awards \$6 with .3 probability?" Other times the prospects must be learned from experience: "After sampling repeatedly from both decks and observing the outcomes, you will choose which deck to draw from for the trial that counts." Dissimilar results from these two kinds of experimental paradigms have led to an explosion of research concerning the description-experience gap in decision-making under risk (for a brief review, see Hertwig & Erev, 2009).

While this dichotomy has gathered considerable focus, some decisions are not clearly descriptive or clearly experience-based. We think of these situations as intuitive "everyday" decisions that implicitly select one out of many choices available. A key feature of such decisions is that people need not consider explicitly every possible alternative to make a decision.

In the present study, participants manipulated their environment to choose between a large number of different prospects that weren't explicitly described and weren't directly experienced. The experimental task was a one-shot lottery whose parameters (probability of winning and magnitude of monetary prize) were partially under participants' control. Critically, the lottery was carefully designed so that increasing the probability of winning automatically decreased the potential monetary prize, and increasing the potential monetary prize automatically decreased the probability of winning (an inverse relationship typical of many real-world lotteries).

Our goal in this study was three fold. First, we were interested in how people approach situations where they have

control over a potentially rewarding stochastic environment (see also Juni, Gureckis, & Maloney, 2011). In particular, do people manipulate their environment to maximize their expected gain? Second, we were interested in intuitive "everyday" decision-making where a large number of prospects must be discerned. Finally, we were interested in taking some of our recent decision making research out of the laboratory to consider a more diverse population of decision makers.

## Taking decision research out of the lab

The majority of psychological research in cognitive science on decision making is conducted using laboratory studies with college undergraduates. However, a number of recent arguments have been presented for why such populations may not be representative of the general human population (Henrich, Heine, & Norenzayan, 2010). In addition, a large percentage of decision making research is conducted in the laboratory on computers for either real or hypothetical amounts of money. One concern about computer-based studies is that participants may suspect that the odds or payouts are being manipulated as part of the study design.

To address these concerns, we ventured outside of the laboratory and into the streets of a large US city to elicit choice behavior from randomly chosen pedestrians who were posed with a single, non-hypothetical problem that was played out for real, in person. Those who agreed to participate were informed that the lottery would be played only once and that they would receive real money if they won. The lottery was performed using a physical urn and marbles that the participant could see and touch. This guaranteed that participants could be certain that there was no manipulation of the odds (e.g., by a computer program).

## The "marbles" game

The one-shot lottery we implemented is very intuitive. The urn initially contains several black marbles and no white marbles. After agreeing to participate, the subject is handed several white marbles. To win the lottery, the participant must, without looking, pull out a white marble from the urn. Thus, the participants must put at least some of the white marbles into the urn so that they have a chance of winning the lottery.

Of course, one strategy might be to place all the white marbles in the urn (to maximally increase the odds of successfully drawing a white marble). However, the monetary prize for pulling out a white marble from the urn is determined by the number of white marbles that the participant chooses to *not* put into the urn but rather set aside as potential prize money.

Each white marble that was not placed into the urn represents \$1 in prize money, which is only awarded if the marble that the participant pulls from the urn turns out to be white.

Four different conditions were tested which varied the number of black marbles that were first placed in the urn: 1, 2, 8, or 25. In all conditions the participant was handed 10 white marbles. If the participant were to put zero white marbles into the urn, they have no chance of winning. On the other hand, if they were to put all 10 white marbles into the urn, they win nothing even if they draw a white marble. Thus, the experimental design restricted participants to put anywhere between 1 and 9 white marbles into the urn. This number becomes our primary dependent measure (i.e., “how many white marbles do participants put into the urn as a function of the number of black marbles in the urn?”).

Figure 1 shows how the different probability structures of the four conditions affects the respective expected gain functions. The figure also shows the respective number of white marbles that should be put into the urn to maximize expected gain in each condition. As is visible, the lottery was deliberately designed so that the normative ideal rule regarding how many white marbles should be put into the urn is different for each condition. When there is one black marble in the urn, the participant can maximize expected gain by putting two white marbles into the urn. When there are two black marbles, expected gain is maximized by putting three white marbles into the urn. When there are eight black marbles, expected gain is maximized by putting four white marbles into the urn. And, finally, when there are 25 black marbles in the urn<sup>1</sup>, expected gain is maximized by putting five white marbles into the urn.

The basic question asked in our study is if people combine information about probability and reward to maximize their expected gain in this intuitive one-shot lottery.

## Methods

**Subjects** Data was collected from people walking through Washington Square Park in New York City. 120 people (65 males and 55 females) participated in the experiment (30 per condition). Ages ranged from 18 to 75 years, with an average age of 29.77 years ( $SD=14.65$ ) and a median age of 24 years. Participants were not compensated for their time, but they did receive the prize money (anywhere between \$1 and \$9) if they won their lottery.

**Materials** To conduct the lottery we used transparent cups, an opaque urn, 10 white marbles, and a varying number of black marbles (1, 2, 8, or 25). The black and white marbles were identical except for color and could not be identified through touch.

<sup>1</sup>In the limit, as the number of black marbles grows very large, the rule that maximizes expected gain is to put half of the white marbles into the urn and set the other half aside as prize money. Given that participants were given 10 white marbles to work with, it is impossible for the optimal rule to dictate placing more than five of them into the urn no matter how many black marbles there are in the urn. We thank Hang Zhang for pointing this out to us.

Figure 1: Experimental design. The participant decides how many white marbles to put into the urn and how many to set aside as the potential prize for winning the lottery. The black dashed diagonal shows the prize money that the participant receives if the marble that she pulls out from the urn turns out to be white. It starts at \$9 when only one white marble is put in the urn and declines to \$1 when nine white marbles are put into the urn. The colored dashed curves show the probability (p) of winning the lottery as a function of the number of black marbles in the urn and the number of white marbles that the participant chooses to put into the urn. Each probability function is multiplied by the gain function (i.e., the black dashed diagonal) to generate an expected gain function. The colored solid lines show the discrete expected gains of the lottery as a function of the number of black marbles in the urn and the number of white marbles that the participant chooses to put into the urn. The vertical colored lines show the maximum expected gain for each of the four experimental conditions.

**Procedure** The lottery was conducted next to a bench in Washington Square Park. On the bench there was an empty urn, a cup with white marbles, and a cup with black marbles. The experimenter handed the participant the cup with the white marbles and said the following:

“To conduct the lottery we will be using marbles. You are in control of the white marbles. There are 10 white marbles and each represents \$1. I am in control of the black marbles. There are (1, 2, 8, 25) of them.”

The experimenter then showed the participant an envelope with a large number \$1 bills and emphasized that if the participant won the lottery they would receive real money. Next, the experimenter poured the black marbles into the urn and said the following:

“I have poured the black marbles into the urn. To perform the lottery, you will be placing your hand into the urn and pulling out a single marble without looking. If the marble

that comes out is black you win nothing. If the marble that comes out is white you will win the number of white marbles that you chose not to put into the urn but rather set aside as your potential prize money. This lottery will be performed only once.”

Next the experimenter held the urn in one hand and an empty cup in the other hand and said the following:

“Take your white marbles and decide how many you want to put into the urn for the lottery and how many you want to set aside in this cup as your potential prize money if you win the lottery. Remember, each white marble is worth \$1.”

Once the participant divided up the white marbles between the urn and the prize cup, the experimenter asked the participant to confirm verbally what the monetary prize would be if they pulled out a white marble from the urn to ensure that there weren’t any misunderstandings.

Next the experimenter held up the urn above the participant’s eyes and asked the participant to pull out a single marble from the urn. If the participant pulled out a black marble they received no money; if they pulled out a white marble they were paid \$1 for each white marble that they set aside in the prize cup.

## Results

Each of the four experimental conditions had 30 different participants. Each participant provided one data point. We report how many white marbles they chose to put into the urn. The outcomes of the lotteries are irrelevant to our study and so we do not report them.

Figure 2 shows a box and whiskers plot for the number of white marbles put into the urn in each experimental condition. The colored asterisks mark the optimal number of white marbles that should be put into the urn to maximize expected gain in each condition. For each of the four conditions we used a single-sample t-test with the null hypothesis set to the optimal number of marbles for the given condition. The stars indicate the level of significance (see Figure 2 caption).

The number of white marbles that participants, on average, tended to put into the urn increased systematically with an increase in the number of black marbles in the urn. Furthermore the results indicate that, on average, participants systematically put one more white marble into the urn than dictated by the normative rule that maximizes expected gain (i.e., people, on average, are sub-optimal with respect to the normative rule, preferring a \$1 decrease to their potential prize in exchange for an increase to their probability of winning the lottery).

## Discussion

Our results seem to indicate that participants, on average, did not maximize expected gain. Curiously though, the number of white marbles that they tended to put into the urn was one more than the normative ideal rule irrespective of the experimental condition. This systematic tendency led us to explore possible explanations to account for their sub-optimal manipulation of the lottery’s parameters.

Figure 2: Box and whiskers plot showing the results in all four conditions. The colored asterisks mark the corresponding optimal number of white marbles that should be put into the urn to maximize expected gain. Participants, on average, tended to put “one too many” white marbles into the urn with respect to optimal. Two stars indicate that this was significant at the .01 level, while one star indicates that it was significant at the .05 level. The non-significant condition had a  $p = .08$ .

Figure 3: Expected utility functions if we take into account an additional utility of \$4 for winning the lottery. Compare this figure to Figure 1 that shows the expected gain functions without taking into account any additional utility of winning. Notice that the maximum expected utilities under this scheme are shifted one marble to the right in all four conditions relative to the maximum expected gains in Figure 1.

Figure 4: S-shaped probability distortion.

The first possibility we explored is that participants might have had an intrinsic utility for winning the lottery in addition to their utility for the actual money that they receive if they win (Parco, Rapoport, & Amaldoss, 2005). We explored this possibility by putting a fixed dollar value on the intrinsic utility of winning (a free parameter).

Figure 3 shows the expected utility functions when the intrinsic utility of winning is valued at \$4. Notice that the maximum expected utilities shift rightward one marble relative to the normative rule that maximizes expected gain. This rightward shift persists if the intrinsic utility of winning is anywhere between \$3.10 and \$4.60.

This analysis suggests that participants' sub-optimal behavior could be accounted for if they have an intrinsic utility for winning the lottery that is in addition to their utility for the actual money that they receive if they win.

The second possibility we explored is that participants might have had a distortion in subjective probability. A standard single-parameter model for distortion of probability in decision-making under risk is written as follows (Tversky & Kahneman, 1992):

$$w(p) = \frac{p^\alpha}{(p^\alpha + (1-p)^\alpha)^{1/\alpha}} \quad (1)$$

As our task resembles a decision from description more than a decision from experience, we hypothesized that an Inverse-S-shaped probability distortion might be more likely to account for the data than an S-shaped probability distortion (Ungemach, Chater, & Stewart, 2009; Wu, Delgado, & Maloney, 2009). In other words, we expected that participants' average behavior might be accounted for with an  $\alpha < 1$  as is commonly found in decisions from description, and not with an  $\alpha > 1$  as is commonly found in decisions from experience (but see Glaser, Trommershäuser, Mamassian, & Maloney,

Figure 5: Expected gains based on the S-shaped probability distortion depicted in Figure 4. Compare this figure to Figure 1 that shows the true probabilities and expected gain curves. Notice that the maximum expected gains under this scheme are shifted one marble to the right in all four conditions relative to the maximum expected gains in Figure 1.

2012). However, the only way to shift the maximum expected gain one marble to the right in all four conditions is by having  $1.69 < \alpha < 1.92$ .

Figure 4 shows an S-shaped probability distortion with  $\alpha = 1.8$ . Figure 5 shows the consequent expected gain functions based on this distorted probability function with the maximum expected gains shifted one marble to the right.

This analysis suggests that participants' sub-optimal behavior could be accounted for if they have an S-shaped probability distortion, a form only rarely encountered in decisions from description tasks.

## Conclusion

Participants in typical decision making experiments select among a small number of lotteries each with fixed probabilities and rewards. In the experiment reported here we considered a task where participants could manipulate their environment to improve their chances of winning the lottery but only by reducing the amount of money that they could possibly win.

While a simple and preliminary study, our results may prove useful to researchers interested in how people balance risk and reward in simple, intuitive decision tasks. Our experiment is unique in a couple of ways that are worth pointing out.

First, participants could actively manipulate the odds of successfully winning the lottery (by placing more or less white marbles into the urn). While the literature on risky decision making is immense, we are unaware of previous studies

that considered this *active* manipulation of the decision environment (one exception is a related study we reported last year in Juni et al., 2011).

Second, the decision environment was set up to be intuitive, fast, and easy to conduct with everyday people walking through a park. As a result, we collected a more diverse sample than is typical for research on judgment and decision-making.

Our primary results are that participants, on average, did not maximize expected gain. In particular, participants, on average, tended to put one additional white marble into the urn than dictated by the normative ideal rule. By doing so they slightly increased their probability of winning relative to ideal, but also decreased their expected winnings slightly.

We considered two different accounts for participants' sub-optimal choice behavior. Participants in decisions from description typically over-weight small probabilities and under-weight large probabilities (Inverse-S-shaped probability distortion). However, we found that we could account for the results obtained only if we assumed that participants under-weighted small probabilities and over-weighted large probabilities (S-shaped probability distortion). While such a tendency has been found in decisions from experience, our task resembles a decision from description more than a decision from experience, making an S-shaped probability distortion surprising.

A second account for our data is that participants have an intrinsic utility for winning the lottery that is in addition to their utility for the actual money that they receive if they win. If this account of participants' behavior is correct, it would seem that their intrinsic utility of winning is approximately \$4.

Future studies could tease apart these two accounts of participants' behavior by keeping the objective probabilities of the lotteries the same and simply scaling up the value of each white marble. According to the probability distortion account we should see no change in participants' average behavior. But according to the intrinsic utility of winning account we should see participants' average behavior shift toward optimal as the intrinsic utility of winning is diluted relative to the increased potential winnings that the lotteries afford.

# Children's acquisition of fraction knowledge from concrete versus generic instantiations

## Abstract

The goal of this experiment was to investigate elementary school children's ability to acquire basic fraction knowledge. The degree of concreteness of instantiations of proportions was varied between subjects. First-grade children learned to label proportions of objects with fraction. Proportions were presented either as concrete, colorful flowers or as generic black and white circles. Following instruction, participants were given a test of learning and an immediate or delayed test of transfer involving proportions of novel objects. Those who learned with the generic materials scored higher on learning and transfer than those who learned with the concrete materials. Differences between learning conditions were attenuated for the delayed transfer test. These findings suggest that concrete, perceptually rich instantiations of fractions may hinder children's acquisition of basic fraction knowledge in comparison to simple generic instantiations of fractions.

**Keywords:** Psychology; Education; Learning; Transfer; Relations, Mathematics Education.

## Introduction

Mathematical concepts are often difficult for children to acquire. One response to this challenge is to introduce concepts to students through concrete instantiations which include perceptually rich, familiar material. The use of concrete material is widespread in education (see McNeil & Uttal, 2009 for discussion). Concrete instantiations of mathematics may involve familiar contexts and can be visually appealing and engaging. For example, simple arithmetic concepts are often instantiated through sets of familiar objects, such as two apples plus three apples equals five apples. Such material may spark interest in the learning task and maintain attention on the learning material.

However, a primary goal of learning mathematics is the ability to apply mathematics to new situations. Therefore, successful acquisition of mathematical knowledge implies that the learner has not only acquired knowledge of the mathematical relations in the context of learning, but also has the ability to transfer the mathematical knowledge to novel isomorphic situations. There is evidence that concrete instantiations can hinder transfer of learning. Adults who learned a novel mathematical concept from a generic, perceptually sparse instantiation were better able to transfer

this knowledge to a novel isomorph than those who learned the same concept from a concrete instantiation (Kaminski, Sloutsky, & Heckler, 2008; Sloutsky, Kaminski, & Heckler, 2005; see also Goldstone & Sakamoto, 2003; Goldstone & son, 2005 for related findings).

In comparison to more abstract, generic instantiations, concrete instantiations of a given concept communicate more extraneous information. For example, a photograph of a person communicates more nonessential information than a simple stick figure drawing (see Kaminski & Sloutsky, 2011 for a discussion). Similarly, instantiating addition as the sum of apples communicates more information than instantiating it as the sum of tally marks. This additional information (e.g. the appearance, taste, etc. of apples) is extraneous to the mathematics and may present an obstacle for learning for the following reason. Mathematical concepts are defined by relational structure. Relations are less salient than objects (e.g. Gentner, 1988). Instantiating mathematical concepts through concrete material, in comparison to a more generic format, may increase the salience of superficial aspects of the learning material and consequently divert the learner's attention from the to-be-learned relational structure (see Goldstone, Medin, & Gentner, 1991 for a similar argument regarding similarity judgments), thus hindering learning.

Therefore, it appears that generic instantiations of mathematical concepts have an advantage over concrete instantiations with respect to transfer. However it could be argued that this advantage is limited to older learners. After all, in educational practice, older students are expected to learn and reason with abstract instantiations including symbols, equations, and other standard notation. It may be that younger learners (e.g. elementary school students) may need concrete instantiations to begin to acquire abstract knowledge.

In addition to the notion that concrete material may be more engaging for the learner, support for the use of concrete instantiations to teach abstract concepts to young children is often tied to theories of learning and development. Some developmental theories (Montessori, 1917; Piaget, 1970) posit that young children's thinking is inherently concrete and that they are not capable of reasoning about abstract concepts using symbols. According

to these theories, children proceed through developmental stages in which their reasoning becomes more abstract and less dependent on concrete material. Other theories (e.g., Bruner, 1966) tie the ability to reason about abstract material not to developmental stages but to levels of knowledge. From this perspective, all novices, regardless of age, would need concrete instantiations to begin to acquire knowledge of an abstract concept. Both accounts suggest that learning should begin by instantiating the mathematical concept through concrete, familiar material.

However, if the difficulty transferring knowledge from concrete instantiations is due to extraneous information diverting attention from the relevant relational structure, then concrete instantiations may be at least as detrimental for children's learning as they are for adults. Children have difficulty controlling their attentional focus and filtering irrelevant, potentially distracting information (Kemler, 1982; Shepp & Swartz, 1976; Smith & Kemler, 1978, see also Hanania & Smith, 2010). For example, Shepp and Swartz (1976) instructed 6- and 9-year-olds to sort items according to shape, with color being an irrelevant dimension. It was found that 6-year-olds (but not 9-year-olds) were slower when color varied independently of shape than when color co-varied with shape or did not vary at all. Therefore, the task-irrelevant dimension affected performance of younger, but not older participants.

There is also evidence that concrete, perceptually rich material can hinder preschool children's ability to perform simple relational tasks in comparison to performance with generic material. One line of evidence comes from studies of children's early symbol use. Successful symbol use requires the detection and transfer of common relations. For example, to effectively use a map as a symbol for a real location, one must recognize the common relations between entities on the map and their real-world analogs. Two- and three-year-old children are more successful transferring location information from a picture to the real world than from a 3-dimensional scale model to the real world (DeLoache, 1995a, 1995b). These findings suggest that preschool children have difficulty using concrete, perceptually rich objects as symbols than using less concrete objects as symbols.

In addition, preschool children are better able to detect relations of monotonic increase and monotonic decrease in size between displays that involve simple perceptually sparse objects than concrete, perceptually rich objects (Gentner, Ratterman, Markman, & Kotovsky, 1995; Kaminski, & Sloutsky, 2010). It has also been demonstrated that kindergarten children are better able to recognize common proportions across displays of different objects when first given instruction with generic, perceptually sparse objects than when given instruction with concrete, perceptually rich objects (Kaminski & Sloutsky, 2009). Taken together there is evidence that concrete, perceptually rich material may hinder the recognition of relational structure for kindergarteners and preschool children.

Less is known about how concreteness affects young school-aged children's acquisition of relational knowledge that is part of standard mathematics content. While concrete instantiations of mathematics may communicate distracting extraneous information, it is possible that school-aged children have developed sufficient inhibitory control to focus on the relevant relations and not be distracted by extraneous aspects of concrete material. If this is the case, then concrete instantiations will not hinder learning of mathematical concepts and may even facilitate learning by making the material more interesting for children. However, while executive function is maturing throughout childhood, the complexity of the relations we expect children to learn is increasing.

Higher-order mathematical concepts involve more complex relations than simpler mathematical concepts. For example, the concept of addition is relationally more complex than the concept of set cardinality (i.e. the use of a natural number to represent the number of elements in a set). Preschool children learn the concept of set cardinality, while school-age children learn the concept of addition which entails determining the cardinality of the union of two sets. Similarly, the concept of multiplication is relationally more complex than the concept of addition because multiplication is defined as repeated addition. It may be that when children reach a level of development at which they are capable of attending to some relations in the context of extraneous information, they may not be able to attend to more complex relations in the presence of the same extraneous information. As a result, the acquisition of more complex relations from concrete instantiations may be more susceptible to diverted attention than acquisition of simpler relations. Therefore, we propose that concreteness in the presence of more complex relations, such as arithmetic relations, can hinder knowledge acquisition in comparison to more generic instantiations of the same concepts.

## Overview

The purpose of the present research was to test the hypothesis that concreteness of the learning material will hinder young school-aged children's acquisition of mathematical knowledge. The present study examined initial learning and subsequent transfer of basic fraction knowledge when instruction involved either a concrete, perceptually rich instantiation versus a generic, perceptually sparse instantiation. First-grade students were taught to label proportions of discrete objects with fractions. Transfer was measured as students' ability to label proportion of novel objects with fractions. For half the participants, transfer was tested immediately after instruction. For the other half of participants, transfer was tested after a two-week delay.

## Experiment

### Method

**Participants** Participants were 64 first-grade students recruited from middle-class, suburban schools in the Columbus, Ohio area (34 girls and 30 boys,  $M = 7.3$  years,  $SD = .40$  years).

**Materials and Design** The experiment had a 2 (Learning condition: Concrete vs. Generic) by 2 (Transfer Test: Immediate vs. Delayed) between-subjects design. Participants were randomly assigned to one of the two learning conditions and one of the two transfer test times. The timing of the transfer test was a between-subject factor to control for any potential testing effects on delayed transfer.

The task was to label proportions of discrete objects with fractions. The experiment had two phases. The first phase consisted of training and a test of learning. Training consisted of four examples of how to label a proportion of objects with a fraction, followed by six questions with corrective feedback. In the Generic condition, all training examples were proportions of black circles out of black and white circles. In the Concrete condition, all training examples were proportions as purple flowers out of purple and orange flowers. Figure 1 presents one of the examples used in training for both the Generic and Concrete conditions.

Following training, participants were given an eight-question test of learning which presented novel proportions in the same format as the training (i.e. circles for the Generic condition and flowers for the Concrete condition). Questions were multiple-choice. Four questions presented a proportion and participants were asked to select a fraction that described the proportion. The remaining four questions presented a fraction and participants were asked to select a collection of objects for which the proportion matched the fraction. Four response choices were given: (1) the correct response, (2) correct numerator, but incorrect denominator, (3) correct denominator, but incorrect numerator, and (4) incorrect numerator and incorrect denominator. The order of the answer choices was counterbalanced across question trials.

**Figure 1:** Example of labeling a proportion with a fraction from the training phase (Generic condition on left, Concrete condition on right).

The second phase of the experiment was a transfer task in which participants were given 24 multiple-choice questions involving novel objects. For half of the participants the transfer test was given immediately after phase 1 (i.e. training and testing of learning) and for the other half of participants the transfer test was given two weeks after phase 1. Twelve questions presented a collection of objects and participants selected a fraction that described a specified proportion of the objects (see Figure 2); the other twelve questions presented a fraction and participants selected a corresponding collection of objects that showed a proportion matching the fraction (see Figure 3). For each question, there were four possible response choices, as described for the training questions. The questions involved proportions with denominators (i.e. total number of items in a display) ranging from 2 to 10. Many different items were used for response choices and included: red and blue cars, blue and green shoes, red and green fish, green and red bugs, bears with and without flags, cupcakes with and without sprinkles, slices of pizza (present or missing), light windows and dark windows of a house, partially full bus seats, partially full pencil box, partially full paint bucket and partially remaining chocolate bar.

**Procedure** All training and test questions were presented on the computer. During training, the experimenter gave a definition of proportion and explained that fractions can describe proportions. For example, in the Generic condition when showing the example of  $2/5$  (see Generic condition of Figure 1), the experimenter stated while gesturing to the circles, “The proportion of black circles in this group is  $2/5$  because there are five circles all together, 1, 2, 3, 4, 5, and two of them are black, 1, 2”. Explanations in the Concrete condition were completely isomorphic to those of the Generic condition. Participants proceeded through the test questions at their own pace. The experimenter recorded their responses through the computer.

**Figure 2:** Example of a transfer test question for which participants needed to choose a fraction that matched the proportion shown.

**Figure 3: Example of a transfer test question for which participants needed to choose a proportion that matched the fraction shown.**

## Results

Two participants, one from the Concrete Delayed condition and one from the Generic Immediate condition, were removed from the analysis because their learning scores were more than 2.5 standard deviations below the mean score in their conditions.

In both the Concrete and Generic conditions, children successfully learned. Learning scores in both conditions were well above a chance score of 25% (see Figure 4), one-sample *t*-tests,  $t_s > 18.0$ ,  $p_s < 0.001$ . However, participants in the Generic condition scored significantly higher than those in the Concrete condition ( $M = 92.1\%$ ,  $SD = 10.1\%$  for Generic and  $M = 81.2\%$ ,  $SD = 17.7\%$  for Concrete), independent samples *t*-test,  $t(60) > 2.93$ ,  $p < .006$ , Cohen's  $d = .752$ .

Transfer test scores were also above chance in both learning conditions (Concrete and Generic) and transfer test time conditions (Immediate and Delayed) (see Figure 4), one-sample *t*-tests  $t_s > 13.0$ ,  $p_s < 0.001$ . However, there was a significant difference in transfer scores between the learning conditions on the immediate transfer test, independent samples  $t_s(29) > 2.39$ ,  $p < .024$ , Cohen's  $d = .895$ . Participants in the Generic condition scored higher than those in the Concrete condition. The difference in transfer scores attenuated considerably on the delayed transfer test, independent samples  $t(29) = .704$ ,  $p = .487$ , Cohen's  $d = .200$ . An analysis of variance was performed with transfer test score as the dependent variable, learning condition and transfer test time as fixed factors and learning score as a covariate. The results reveal a significant effect of learning score,  $F(1, 57) = 24.2$ ,  $p < .001$ ,  $\eta_p^2 = .298$ , and no significant effect of learning condition,  $F(1, 57) = .366$ ,  $p = .548$ , and no effect of transfer time,  $F(1, 57) = .815$ ,  $p = .371$ . There was a moderate interaction between learning condition and transfer time  $F(1, 57) = 2.90$ ,  $p = .094$  (see Figure 4). For both immediate and delayed testing, transfer scores were

**Figure 4: Mean Test Scores (% Correct).**

Note: Error bars represent standard error of mean.  
Chance score is 25%.

positively correlated with learning scores, Pearson Correlations,  $r(29) = .600$ ,  $p < .001$  and  $r(29) = .554$ ,  $p < .002$  respectively. These findings suggest that transfer is a function of learning such that higher levels of learning result in higher levels of transfer.

Taken together the results of this experiment suggest that learning basic fraction knowledge from a concrete instantiation, in comparison to a more generic instantiation, can hinder initial learning which may in turn hinder subsequent transfer to novel material. With time, the negative effect of concreteness on transfer appears to be attenuated.

## General Discussion

This research considered first-grade children's ability to acquire basic knowledge of the concept of fraction. Participants were instructed on how to label proportions of objects with fractions. Instruction presented proportions either through generic black and white shapes or through colorful, familiar objects. Participants were tested on their ability to label proportions of novel objects with fractions. Participants who received instruction with either type of material successfully learned and applied their knowledge to novel objects. However, those who were instructed with the generic instantiation scored 10% higher on tests of learning and immediate transfer to novel objects than those who were instructed with the concrete instantiation. The difference in transfer scores due to instruction with the concrete versus generic learning material diminished when the transfer test was delayed for two weeks. Yet both immediate and delayed transfer test scores were strongly correlated with learning scores.

The results of this study support the hypothesis that concreteness of the learning material can hinder children's acquisition of mathematical knowledge. In particular, it appears that instruction involving concrete instantiations of proportions hinders initial learning and consequently hinders subsequent transfer in comparison to instruction involving generic instantiations of proportion. Instruction of basic fraction notation using generic material may help students gain a solid knowledge foundation which may in

turn benefit them when learning more advanced mathematical concepts involving fractions. Although concrete instantiations are often colorful and visually appealing, bland, generic instantiations are learnable by children and can offer an advantage for learning and subsequent transfer of mathematical knowledge.

These findings suggest that although aspects of executive function, including the ability to control attentional focus and inhibit irrelevant information, mature considerably in the preschool years, extraneous information included in concrete educational material may be difficult for elementary school children to ignore. Learning of mathematical concepts may be hindered because less attentional resources have been allocated to the relevant to-be-learned relations.

With respect to actual pedagogical practice, mathematics instruction is generally not limited to using only one instantiation of a concept and frequently involves multiple instantiations, including formal symbolization as well as familiar contextualization. Concrete and abstract instantiations of mathematical may both have advantages. However, it is not clear a priori when and how to include concrete instantiations and generic instantiations in instruction. For example, there appears to be a trade-off between grounded, concrete instantiations and abstract, symbolic instantiations when solving algebra problems where grounded, concrete formats facilitate solving simple problems and abstract, symbolic formats facilitate solving more complex problems (Koedinger, Alibali, & Nathan, 2008; Koedinger & Nathan, 2004). The results of the present study provide evidence of an advantage for generic material for acquiring knowledge of basic fraction notation. The challenge for researchers and educators is to develop a theoretical basis for the timing and use of both concrete and generic instantiations in instruction of mathematical concepts in general.

## Abstract

Knowledge construction requires both perceptual information from external sources and our active interpretation of that information. Thirty one 5<sup>th</sup> grade elementary school students were asked to move plates in a Tower of Hanoi (TOH) task, which was displayed on a screen monitor. When the students were asked to respond to the weight of the plates, both imagination and non-imagination groups reported that they felt weight of the plates which actually had no weight. Also, students in imagination group reported that they felt the plates heavier than did those in non-imagination group. The result shows that haptic information can be created without providing any information through haptic channel. In addition, the result implies how knowledge is constructed based on previous knowledge and suggests that children create their own imaginary world even at a perceptual level. Also, it was discussed why imagination experience can maximize and help learning in embodiment activities.

**Keywords:** Imaginary world; Haptic illusion; Embodied cognition.

In Buddhism, it is said that “Everything depends on our mind.” This sentence can be interpreted as humans’ perceiving an object, or a given environment, depending on what we expect to perceive or interpret. According to Ungerleider and Pasternak (2004), when constructing knowledge we not only accept spatial and visually-guided action information (dorsal process stream), but process information of shape, form, and object identity (ventral process stream). This insight has been scientifically tried in studies about illusion in perception (Lee & van Donkelaar, 2002) and in memory (Roediger, 1996; Roediger & McDermot, 1995). Also, especially according to optical illusion studies, what we see does not always match what is actually visible. Our visual perception is influenced by our past experience and current expectations (Gregory, 1997; Gregory, 1998; Pendlebury, 1996).

According to Kant (1965), our knowledge is elicited from two fundamental sources of the mind: the capacity of receiving representations and the power of knowing an object through these representations. Intuition and concepts constitute the elements of all our knowledge, so that neither concepts without an intuition in some way corresponding to

them, nor intuition without concepts, can yield knowledge (Kant, p.92). Also, Kant mentioned that “...all perceptions are grounded a priori in pure intuition, association in pure synthesis of imagination, and empirical consciousness in pure apperception...” (Kant, p.141). This also can be interpreted as that perceptual information received via different modalities, becomes knowledge by our active cognitive process. This can be called knowledge construction. Therefore, by using this nature of human perception, it is possible to create perceptual illusions. In terms of knowledge construction from perceptual information, while previous studies have dealt with people’s creation of additional perceptual information or distortion based on what was given (Day, 1990; Ellis & Lederman, 1993; Fermüller & Malmb, 2004; Mack, Heurer, Villardi, & Chambers, 1985; Suzuki & Arashida, 1992; Otto-de Haart, Carey, & Milne, 1999), this study seeks to investigate knowledge construction from a certain activity which enriches memory representation. In other words, we argue that perceptual knowledge can still be created through another perceptual channel even if no perceptual information has been delivered.

While many studies have explored visual illusion, what has rarely been investigated is how perceptual information from other modalities is created. Furthermore, while the literature offers a handful of studies about haptic illusion (Gentaz, Camos, Hatwell, & Jacquet, 2004; Robles-De-La-Torre & Hayward, 2001), these studies have limitation that they were administered under situations where haptic information was already provided to participants.

## Knowledge construction by imagination

It is assumed that when we process information from text, we go through a perceptual process where spoken or written messages are originally encoded (Golden, 1986; Hubel & Wiesel, 1977; Kuffler, 1953; McClelland, 1976; Syrdal & Gopal, 1986). Then the words in the message are transformed into a mental representation of the combined meaning of the words (Graf & Torrey, 1966). At higher level of comprehending of a text, readers use the mental representation of the sentence’s meaning. According to

Kintsch (1998), this level of understanding adds inferences made from the reader's knowledge and these inferences come from semantic memory, knowledge about objects, events, people, goals, beliefs, etc. However, Black and Bower (1980) argued that there is another level of text comprehension, which they called the Story World because they were only discussing stories. This level of comprehension requires a representation of the world being referred to in a story, how it is laid out visually and spatially, and how it functions. We can generalize this beyond stories by calling this level of comprehension and representation an Imaginary World. For example, after reading one or more Harry Potter fantasy books, if one has reached this "imaginary world" level of comprehension, one would have some ideas about Harry Potter's world, such as how it looks, how it is laid out, and how it functions (information which actually may not be provided in the books). Then, when seeing a Harry Potter movie, one can judge to what extent it matches this Imaginary World. Black, Turner, and Bower (1979) already showed evidence of readers creating their own imaginary world when reading a story. In their study, when people read sentences like *John was working in the front yard, then he went inside*, they read them faster than when they read *John was working in the front yard, then he came inside*. The 'came' in the second sentence creates a switch in point of view and causes a longer reading time (and change in memory and change in comprehensibility ratings) because the reader has to switch the perspective from which they are watching the action in the imaginary world.

In imaginary world, people make plausible inferences or create a story that was not actually given. This is further activated when a goal is added, which results in a more coherent, interesting and memorable text. For example, Owens, Bower and Black (1979) had one group read an unsurprising script-based story just containing the expected actions of scripts, while another group had an introductory sentence that introduced a goal structure (the girl in the story wondering if she were pregnant). Adding this introduction, which allowed the readers to infer a goal structure with many linked story statements, leads to better recall of the story. Black (2008) took this a step further when he mentioned that learners can construct elaborate mental representations of Imaginary Worlds with minimal input such as text plus a floor plan. This implies that learners create imaginary worlds based on given information, place themselves into that situation, and retrieve a plausible story by filling out story gaps that are not given to them.

These findings can be linked to research on embodied cognition. Barsalou (1999) supports the idea that thoughts stem from dynamic interactions between the physical world and the body. These interactions, described as part of "grounded cognition," are not limited to bodily states, but are also found in situated action, social interactions, emotional states, the environment, and perceptual simulations. In this sense, active interaction can also be

realized in imaginary world, since one can situate himself in a given situation and enact what is given in that imaginary world. According to proponents of embodied cognition, acknowledging these interactions is the first step towards understanding human cognition.

Research on embodied cognition reveals that when people place their bodies and move around in physical space, they create references for understanding concepts. This is evident in a study by Glenberg and Kaschak (2002). The authors found that subjects, after hearing the command "open the drawer", responded faster when the response action was a pulling motion instead of a pushing one. Likewise, work by Spivey et al. revealed that during an experiment that measured eye movement, participants were more likely to look up upon hearing a description about the top of a building (Spivey, Tyler, Richardson, & Young, 2000).

These discoveries about human cognition and space are complimented by the seminal research of Shepard and Metzler on mental rotation and imagery in the 1970s. The researchers showed participants images of 3-D geometric figures. The participants were later shown similar yet rotated images and were asked to interpret the uniformity, or lack thereof, of the two images. Results revealed that participants rotated visual mental images in much the same way that the actual objects would be manipulated in an actual physical space. The research also revealed a proportional relationship between the degree of the rotation and the time it took participants to mentally rotate and respond (Shepard & Metzler, 1971).

Glenberg and colleagues have found that physical manipulation and imagined manipulation help children learn (Glenberg, Gutierrez, Levin, Japuntich, & Kaschak, 2004). Specifically these researchers have conducted experiments using a narrative of a farmer and his farm animals. The narrative is accompanied by a set of toys in the likeness of the story's characters. Participants (1<sup>st</sup> and 2<sup>nd</sup> graders) were asked to use the toys to re-enact the sentences they read. The children are then asked to imagine manipulating the toys. What resulted was an increase in reading comprehension and a more positive attitude about reading (Glenberg et al., 2004).

In the same vein, researchers on grounded cognition suggest that how people act influences how they think by grounding perception, affect, and even language comprehension in the sensorimotor systems used to interact with the surrounding world (Beilock, Lyons, Mattarella-Micke, Nusbaum, & Small, 2008; Glenberg & Robertson, 2000; Niedenthal, 2007; Zwaan, 1999). For example, learning to produce specific walking movements (without visual feedback) aids one's ability to later visually discriminate these movements, presumably because discrimination becomes tied to the sensorimotor systems used in moving (Casile & Giese, 2006). Therefore, perception and action lead to conceptual understanding. In addition, this process requires a representation of what is being referred to, how it is laid out visually and spatially,

which finally leads to the creation of “Imaginary Worlds” (Black, 2008).

Based on this “Imaginary World” concept, this study starts with a question about if learners can create their own imaginary world on a perceptual level. For example, readers develop their own mental images of a story while reading the story (Black et al., 1979) and learners can also build their own mental representation while learning from either a text, a text with floor plans plus static pictures, or a text with floor plans accompanied by a virtual tour picture (van Esselstyn & Black, 2001). In this study, we try to test that creating an imaginary world is possible on a perceptual level, which, in turn, enables us to see why imagination activity helps children more involved in embodiment activity.

So far, few empirical studies have been done to test the role of imagination in children’s perception and knowledge construction. Being that this study seeks to encourage children to create perceptual information which was not initially given to them, this study is different from previous perceptual illusion studies that showed how perceptual information is distorted or how illusion is created by sensory information which is transmitted via the same modality. Throughout this study, we try to observe how children, while in the process of constructing knowledge, represent knowledge which does not exist through modality and synthesize it into knowledge.

## Method

**Participants** Thirty-one (18 boys and 13 girls) 5<sup>th</sup> grade elementary school students from the New York City public schools district participated in this study and were divided into two groups: imagination group ( $n = 15$ ) and non-imagination (control) group ( $n = 16$ ). The study was IRB approved.

Children of this age were chosen because they were almost at the end of concrete operational stage. Therefore, they are expected to use the appropriate level of inductive logic, such as transitivity, decentering, ability to eliminate egocentrism, and etc. (Piaget, 1977).

**Apparatus** The Kinect sensor for the Microsoft Xbox 360 video game console (hereafter referred to as Kinect) was connected to an HP laptop through which an interactive Tower of Hanoi problem was displayed onto a Dell 19 inch LCD monitor with speakers attached. Kinect is a motion sensing input device by Microsoft for the Xbox 360 video game console. Based around a webcam-style add-on peripheral for the Xbox 360 console, it enables users to control and interact with the Xbox 360 without the need to touch a game controller, through an infrared natural user interface using gestures and spoken commands. However, in this study, we manipulated Kinect without Xbox 360. As a way of communicating with the Kinect, FFAST (Flexible Action and Articulated Skeleton Toolkit, version 0.07) software was used. FFAST is middleware which facilitates integration of full-body control with games and VR

applications. The toolkit relies on software from OpenNI and PrimeSense to track the user’s motion using the PrimeSensor or the Microsoft Kinect sensors. FFAST includes a custom VRPN server to stream the user’s skeleton over a network, allowing VR applications to read the skeletal joints as trackers using any VRPN client. Additionally, the toolkit can also emulate keyboard input triggered by body posture and specific gestures. This allows the user add custom body-based control mechanisms to existing off-the-shelf games that do not provide official support for depth sensors (Suma, Lange, Rizzo, Krum, & Bolas, 2011). Also, the interface of the TOH game was programmed using Scratch. Scratch is a programming language developed by the MIT Media Lab Lifelong Kindergarten Group.

**Experimental Design and Procedure** The experiment was administered in a quiet classroom with one student at a time. A student was guided and asked to stand in front of the Kinect and a screen monitor that was connected to a laptop computer. Firstly, the experimenter verbally explained how to move the plates in the TOH problem set on the screen. The children were told: “Your job is to move two plates from the first pole to the third pole. You can move only one plate at a time. Also, while moving the plate, you can put the small plate on top of the large one, but you cannot put a large plate on top of the small one.” The plates in TOH were created to look like real steel (Figure 1).

Figure 1. Snapshot of TOH problem used in the task

Afterwards, the experimenter demonstrated how to move plates on the screen. The student was then allowed to participate in a practice session of moving plates from one pole to another until he/she felt comfortable controlling the game using only hand gestures. Students were then given a challenge of two plates for the TOH problem. Unlike the practice session, in the experiment session, audio speakers attached to the LCD monitor were turned on, so as to provide students with the sound of plate being dropped (in this case, the sound of a heavy metal plate dropping to the ground).

Figure 2 shows a student moving a plate in the problem-solving task. All 31 students completed the given task. During the experimental session, children completed the TOH problem by carrying plates without touching any

objects such as a monitor screen, a keyboard, or a laptop computer. Immediately after they solved the problem, short survey questions were given.

All the procedures were identical for both imagination group and non-imagination group except that at this stage, students in imagination group were prompted to imagine how they moved the plates before answering how heavy the plates were. Non-imagination group received exactly the same survey except an imagination prompt, “Imagine how you moved the plates.” in question 1.

As dependent measure variables, students’ responses to the survey questions were compared. Students were asked to choose a number that best described what they felt while playing the game. The survey intended to measure the perceived weight the participants felt from moving the virtual plates, the level of interest in the activity, and the amount of difficulty encountered in controlling this Kinect-based embodiment tool. As they answered the questions, the experimenter read aloud each question and response options (i.e., labels of a Likert-scale). After the survey, students were sent back to their class. Totally participation time for one student amounted to about 15 minutes for the entire session.

## Results and Discussion

Students’ responses in two groups for plate weight, level of motivation, and amount of difficulty in controlling the plates were compared and analyzed.

First, to find out whether students in each group felt the weight of the plate or not, one sample t-test was administered for responses asking how heavy the plate felt. In the analysis, it was found that students in both imagination group ( $M = 2.87$ ,  $SD = 1.36$ ,  $t(14) = 5.33$ ,  $p < .01$ ) and non-imagination group ( $M = 1.94$ ,  $SD = 1.12$ ,  $t(15) = 3.34$ ,  $p < .01$ ) reported that the virtual plate they moved indeed had a tangible weight.

Also, students in both groups reported that it was relatively easy to use their hands to move the plates. Average response was 2.27 ( $SD = 1.22$ ) in imagination group and 2.81 ( $SD = 1.47$ ) in non-imagination group. In

addition, students in both groups showed strong interest in the game task. All students in imagination group responded that they enjoyed the game very much ( $M = 5.00$ ,  $SD = 0.00$ ). Similarly, average response in non-imagination group was 4.94 ( $SD = 0.25$ ).

In group comparison analysis, independent sample t-test was administered. The students in imagination group felt the plates significantly heavier than non-imagination group,  $t(29) = 2.08$ ,  $p < .05$ ,  $d = 0.75$ . Figure 3 shows response averages of feeling of plates’ weight in two groups.

In terms of students’ interest, there was no difference between two groups ( $p = .34$ ). Also, in a question of asking how easy it was to use hands to carry the plates, there was no group difference in difficulty of carrying the plates ( $p = .27$ ).

Figure 3. Response average of feeling of weight. Error bars represent standard errors of the means.

This study shows how children develop and organize perceptual information, and create their own imaginary world based on an experience. Surprisingly, children in both groups felt the weight of plates which actually had no weight. In this case, it would be a haptic illusion that falls at the intersection of perceiving and remembering.

It is even more surprising that children in imagination group weighted the plates heavier than non-imagination group. It is assumed that the memory of what plates would feel like was drawn into the procedure as expectancies and then affected performance, and the feeling of weight would be augmented by the imagination employed during the embodied activity. It may be like the case when someone thinks he is about to pick up a heavy object (e.g., a brick) but then he lifts it way too high too fast because it turns out to be light (e.g., styrofoam). According to Winograd, Peluso, and Glover (1998), self-reports of high degrees of vivid mental imagery correlate with enhanced false recall and false recognition. In our study, it is possible that, with a prompt, “imagine,” students in imagination group further developed haptic information than those in non-imagination group. As a result, children in both groups reported the weight of plates by activating what they expected to feel. This is realistic when considering that upon judging a situation, value, or an object, individuals rely more on

reasoning, which, in turn, is based on their prior knowledge or experience. Nonetheless, participants should not have responded that the plate had a weight in this situation.

What is interesting is that, even though the activities in this study were obvious and physically concrete, children in this study reported their haptic experience which was not provided to them. Based on our observations, it seems that when it comes to deciding the characteristics of a given object, children evolve into relying more on their own representation of the concept which was created by synthesizing subjective sensation and representation, rather than relying on pure sensation.

Another plausible explanation is that children might mistake a plate's supposed weight with the feeling of fatigue from arm movement caused by moving. Yet, considering that controlling plates was relatively easy and that activity was enjoyable, it is assumed that illusion of a plate's purported weight was created by the embodied activity and it was further augmented by the participants' imagination.

In our case, with imagination, children who acted out using their body added new perceptual information, creating their own representation of the TOH game and the plates in the task. This also corresponds to grounded cognition studies. It is maintained that new representation is based on individual actions and action plays an important role in the emergence of new representations (Beilock & Goldin-Meadow, 2010; Boncoddio, Dixon, & Kelley, 2010).

Children used information available to fill the knowledge gap with information that was not actually provided. In other words, as Black and Bower (1980) mentioned, children's representation of an object when derived from an imagined activity has information implicit in it beyond that which is available in the propositional listing of the scene. It is assumed that embodied cognition in a learning environment must first be physically enacted. Then, the learning activity is maintained through imagined embodiment, and is finally used within a task where transfer of learned content can occur.

Again, this study showed that by having children imagine, unsupplied information can be derived not only in text understanding, but also in perceiving an object's property which was not provided via any sensory channel. The study result implies that having children imagine activities that they involved or acted out can enrich their experience. The phenomenon we observed here has many implications of how teachers can use imagination in teaching concepts, such as ones that have information which is implicit or hard to be captured with a visually aided material.

Also, in our study, to observe how children construct knowledge from perceptual information, interactive media technology was used. Interactive media technology carries with it the benefit of enhancing students' comprehension across several frames of reference because of its ability to present information in varying ways. This ensures success for all types of learners: visual, active, auditory, and tactile. There are many technologies at use today that take

advantage of these varying styles of presentation and each caters to one or several simultaneous types of learners at once. With a help from these characters of technology, we could capture the moment at which children construct knowledge from perceptual information. The motivation observed in this study is also unprecedented and will no doubt enlighten pedagogical methods in future classrooms.

In future studies, by investigating how information in other modalities affects level of embodiment, we will learn more about the role of imagination and the interaction of imagination and perceptual channel in knowledge construction.

## Abstract

Cognitive dysfunction caused by some neurodegenerative diseases is associated with an increased risk of traffic accidents. Previous studies have reported inconsistent results for prodromal and early stages of dementia. Few studies have directly compared the effects on driving performance of amnesic subtype of mild cognitive impairment (aMCI) with those by normal aging in elderly drivers. The present study examines the association between cognitive decline and driving ability in elderly drivers with aMCI. The participants were 19 healthy young adults (HYA), 26 healthy elderly adults (HEA), and 12 elderly patients with aMCI. All performed a road-tracking, a car-following, and a harsh-braking task on a driving simulator (DS). Elderly participants also completed cognitive assessment tasks including measures of memory performance. All MCI participants showed a well-defined memory decline, and demonstrated significantly decreased performance on the car-following and road-tracking tasks as compared with the HYA group. However, the aMCI group also demonstrated significantly decreased performance on the car-following task as compared with HEA. In elderly participants, the car-following performance was positive correlated with the score on the Trail Making Test-B. This evidence indicates a difference for driving ability between individuals with symptomatic memory impairment and the

aging-related memory of normal controls. This difference may be associated with flexibility of visual attention and executive function.

**Keywords:** mild cognitive impairment, driving simulator, Trail Making Test, elderly driver, normal aging.

## Introduction

Driving is a specialized and complex action that requires the use of extensive cognitive abilities. Age-related dysfunction of the central nervous systems in people with dementia, such as symptoms caused by Alzheimer's disease, may influence driving. Studies have found that drivers with dementia have 2.5 to 4.7 times the risk of an automobile accident compared to cognitively intact elderly drivers (Cooper, Tallman, Tuokko, & Beattie, 1993; Molnar, Patel, Marshall, Man-Son-Hing, & Wilson, 2006). Fatal motor vehicle crash rates (per miles driven) show a U-shape curve with the highest rates among the youngest and oldest drivers (Hakamies-Blomqvist, Sirén, & Davidse, 2004).

Cognitive limitations not only from some age-related neurodegenerative diseases but also from aging-related normal changes are associated with an increased risk of being involved in a traffic accident. Epidemiological studies demonstrated that elderly patients with mild dementia are

high-risk drivers, as a group, compared with cognitively intact drivers (Man-Son-Hing Marshall, Molnar, & Wilson, 2007). However, there is little evidence showing the difference in the actual driving behaviors of individuals in these two groups (Iverson et al., 2010). A substantial number of patients with a Clinical Dementia Rating Scale (CDR: Morris, 1993) scores of 0.5-1.0, which are in the preclinical or early stage of dementia, were still able to drive safely in an on-road driving test (Brown et al., 2005). Iverson et al. recommend that studies are needed to identify the appropriate predictive factors for risky driving in patient with prodromal and mild dementia, and then to develop a composite system of rating risk for drivers in the early stages of dementia.

“Mild cognitive impairment (MCI)” is conceptualized as a transitional state between normal cognitive aging and clinical dementia, with amnesic and non-amnesic subtypes of MCI have been defined (Petersen & Morris, 2005). The amnesic subtype of MCI (aMCI) is characterized by memory impairment, and is often operationalized as the Clinical Dementia Rating Scale score of 0.5. People with aMCI progress to Alzheimer’s disease (AD) at a rate of 8-15% per year, as compared to the normal aging with a dementia progression rate of 1-2% per year (Petersen et al., 2001). Therefore aMCI is considered a prodromal syndrome of AD, and often precedes the onset of dementia.

Individuals with MCI may be at risk for decline in everyday complex functions, including driving. However, we have limited information about the crash risk and driving behaviors of individuals with clinical MCI (Man-Son-Hing et al., 2007). Recently, Frittelli et al. (2009) reported that MCI had a limited effect on driving performance on a driving simulator, and that AD patients’ unsafe driving behavior was not predicted by their MMSE scores. They compared patients with mild AD and with MCI and age-matched neurologically normal controls. However, it is not clear which cognitive characteristics of individuals with MCI do endorse safer driving performance or which do not.

O’Connor, Edwards, Walley, and Crowe (2011) reported associations between driving behaviors, assessed by a self-report questioners, and classification of MCI. Their sample was a subset of the mobility data ( $n = 2381$ ) in the Advanced Cognitive Training for Independent and Vital Elderly (ACTIVE) study ( $N = 2802$ ), and the subset included 82 individuals with the aMCI, 140 individuals with the non-amnesic subtype of MCI, and 82 individuals with multi-domain subtype of MCI, and normal controls. They investigated psychometrically well-defined MCI at baseline as a predictor in a five years follow-up of changes in driving behaviors. Their results suggested that MCI status predicted declines in driving frequency and increases in driving difficulty. The classification of MCI subtypes predicted different trajectories of changes for driving frequency and driving difficulty. The amnesic and non-amnesic groups showed greater declines in driving frequency than the multi-domain group and the normal controls. The amnesic and non-amnesic groups showed increases for driving difficulty

in common situations, whereas the multi-domain group showed a greater increase for driving difficulty only in complex situations. The aMCI showed decline in driving frequency but did not self-report driving difficulty. The authors discussed these findings from the viewpoint of self-regulation and risk perception in their groups’ driving behaviors. They suggested that these findings may reflect impaired risk perception related to amnesia. Objective assessment data of driving performance is still need to determine actual risk assessment.

In the present study, we considered these remaining problems, and examined individuals with clinical aMCI and age-matched memory-intact individuals and normal young adults to evaluate driving performance using a driving simulator (DS). Although many consider road testing to be the gold standard to evaluate driving competence, road tests are costly and can be dangerous when the driver is incompetent. The DS appears to be a safe and cost-effective method for the objective evaluation of driving performance.

In order (1) to examine how cognitive state may impair driving performance in patients with a prodromal stage of dementia, and (2) to identify cognitive variables explaining the deterioration of driving performance in the aMCI group, we designed a case-control study to compare the driving performance decline between adults with clinical aMCI and elderly adults with an intact memory, based on the performance of normal young adults.

## Method

### Participants

We recruited 19 healthy young adults (HYA: 39.3 years old,  $SD = 6.5$ ), 26 healthy elderly adults (HEA: 70.0 years old,  $SD = 6.1$ ), and 12 elderly patients with aMCI (71.8 years old,  $SD = 7.6$ ). The participants were naïve with regard to this study, and were paid for their participation. All were active drivers with more than 10 years of driving experience. They all had normal or corrected-to-normal vision, and no history of cerebral vascular events.

The Nagoya University Graduate School of Medicine and Nagoya University Hospital ethics review committee approved this study. Written informed consent was obtained from all participant prior to their participation.

All participants were examined by an experienced psychologist who used the same task order. They had no history of psychiatric problem as assessed by the Structured Clinical Interview for DSM-IV (SCID: First, Spitzer, Gibbon, & Williams, 1997). The HYA and HEA individuals were recruited in non-clinical setting, and had no impairment in activities daily living (ADL) and no evidence of dementia on the Clinical Dementia Rating Scale (CDR = 0.0). They showed no evidence of cognitive decline on enrollment screening questionnaire. The patients with aMCI were recruited in clinical setting. All were diagnosed according to the criteria for MCI, provided by the Petersen group. All of the aMCI group had a CDR = 0.5.

**Amnesia confirmation** The confirmation of amnesia was identified using psychometric methods. All elderly participants were assessed using structured neuropsychological tests, including the Mini-Mental State Examination (MMSE: Folstein, Folstein, & McHugh, 1975), to their confirm general cognitive state, and the Logical Memory delayed recall subtests of the Wechsler Memory Scale-Revised (WMS-R: Wechsler, 1987) to confirm memory function.

**Cognitive functions** Additional neuropsychological measures, which have been used in previous studies related to complex driving tasks, were also used. The digit span subtests of the Wechsler Adult Intelligence Scale-Revised (WAIS-R: Wechsler, 1981) and the Trail Making Test (TMT) -A were used to assess simple attention and concentration function. The TMT-B and the Modified Stroop Test were used to assess attention flexibility and executive function. The Clock Drawing Test (CDT) was used to assess visuospatial function.

## Tasks

**Driving performance** Daily driving skills associated with traffic accidents were measured by a road-tracking, a car-following, and a harsh-braking task. These tasks were run on a DS manufactured by Toyota Central R&D Labs., Inc. (Nagakute, Japan).

The car-following task involved a straight two-lane road with no other traffic, except for a single preceding car. When the preceding car decelerated, its brake lights came on. As the preceding car accelerated (to 60 km/h) or decelerated (to 40 km/h), the participant was required to maintain a distance between the cars as close to 5 m as possible. The car-following distance (m) was recorded every 20 ms. Performance was measured as the coefficient of variation (CV) obtained by dividing the standard deviation of the distance between the cars by the mean value (see Uchiyama, Ebe, Kozato, Okada, & Sadato, 2003). Therefore, a smaller distance CV value (DCV) indicated better performance. The test duration was 5 min.

The road-tracking task required the participant to drive at a constant speed of 100 km/h, while stabilizing the vehicle at the center of a gently winding road. The standard deviation of the lateral position (SDLP; in cm), which indicates weaving, was used as performance measures. Recordings were made every 20 ms during the test, which lasted for a period of 5 minutes.

The harsh-braking task included a straight two-lane road with no traffic, but with humanoid models on either side of the left lane. The humanoid models randomly ran onto the road as the participant's car approached. The participant was instructed to maintain a constant speed of 50 km/h and to avoid hitting the humanoid models by harsh braking as quickly as possible. The brake reaction time (BRT; in ms) was used as a measure of the cognitive psychomotor performance, including attention efficiency (see Ridout & Hindmarch, 2001). Each test consisted of 7 BRT trials over

a 5-min period, and the mean BRT was calculated from these results.

The driving performance evaluation using the DS was performed after the neuropsychological testing was complete. Before starting the evaluation, each driver was familiarized with the DS in three practice driving trials. During the practice, the driving performances of the HEA participants had plateaued (Kawano et al., in press). Within one week of the practice session, the test session was performed for each DS task, in the following order: the road-tracking, car-following, and harsh-braking task.

## Statistical analyses

To compare the demographic data including age, education, and the neuropsychological test performances among the groups, Kruskal-Wallis tests were carried out. Post hoc multiple comparisons were computed by the Mann-Whitney U test with the ordinary Bonferroni adjustment. DS values were compared among groups by one-way ANOVAs, after applying log transformations to normalize the data. Post hoc multiple comparisons were computed by the Tukey HSD. To analyses the relationship between the performance of DS task and some neuropsychological values, correlational analyses based on the Spearman's  $\rho$  and multiple linear regression analyses were carried out.

All Statistical analysis was performed with the SPSS. A  $P$ -value of less than 0.05 was considered to indicate statistical significance.

## Results

The characteristics of participant group are shown in Table 1. No significant differences were shown in age and education level between NEA and aMCI groups. There were significant differences between the two elderly groups for the MMSE and the Logical Memory delayed recall subtests of the WMS-R. All NEA individuals had MMSE scores over 26, and Logical Memory delayed recall performances over 11. On the other hand, all individuals with aMCI had a score of 9 or below on the Logical Memory delayed recall task.

To examine whether aMCI affected DS performance, the performance on each of the three DS tasks were compared among the groups. Figure 1 displays the groups' mean performance for each driving task. For the car-following task, the ANOVA revealed a main effect of group ( $F(2, 54) = 16.61, p = 0.00, \eta^2 = 0.38$ ). Multiple comparisons by Tukey HSD tests showed significant differences among all groups. The performance of NYA was significant higher than aMCI and NEA ( $t = 5.76, p = 0.00, r = 0.73; t = 2.69, p = 0.03, r = 0.38$ ), and NEA was significant higher than aMCI ( $t = 3.76, p = 0.00, r = 0.53$ ). For the road-tracking task, the ANOVA revealed a main effect of group ( $F(2, 54) = 17.62, p = 0.00, \eta^2 = 0.40$ ). Multiple comparison by Tukey HSD tests showed significant differences between NYA and aMCI. The performance of NYA was higher than aMCI and NEA ( $t = 5.53, p = 0.00, r = 0.71; t = 4.51, p = 0.00, r =$

Table 1: Characteristics of each group: Mean (Standard Deviations)

	aMCI		NEA		NYA	
Sex (female/male)	2/10		11/15		1/18	
Age (years)	71.8	(7.6)	70.0	(6.1)	39.3	(6.5)
Education (years)	13.4	(3.5)	14.4	(2.8)	16.6	(1.7)
<i>Cognitive characteristics</i>						
Mini-Mental State Examination	25.5	(2.9)	28.5	(1.4)		
WMS-R Logical Memory: delayed recall	4.6	(3.7)	20.0	(5.3)		

*Note.* aMCI = amnesic type of mild cognitive impairment, NEA = normal elderly adults, NYA = normal young adults, WMS-R = Wechsler Memory Scale-Revised.

0.56), but there was no significant difference between NYA and aMCI ( $t = 1.95$ ,  $p = 0.14$ ,  $r = 0.31$ ). For the harsh-braking task, 12 persons had missing values caused by technical problems or the participants. A one-way ANOVA was performed for 10 aMCI participants, 19 NEA participants, and 16 NYA participants. The analysis revealed no main effect of group ( $F(2, 42) = 3.21$ ,  $p = 0.05$ ,  $\eta^2 = 0.13$ ). There were no significant differences between groups.

Correlational analyses were conducted to examine the relationship between the performance on the car-following task (DCV) and some neuropsychological values in elderly groups. In the elderly group mixed NEA and aMCI, there were significant positive correlations between the DCV on the car-following task and TMT-A, TMT-B, and the Modified Stroop Test ( $\rho = 0.47$ ,  $p = 0.00$ ;  $\rho = 0.54$ ,  $p = 0.00$ ;  $\rho = 0.38$ ,  $p = 0.02$ ). No significant correlations were found between DCV and CDT ( $\rho = -0.18$ ,  $p = 0.30$ ), or DCV and the WAIS-R digit span subtest ( $\rho = -0.31$ ,  $p = 0.06$ ). In the aMCI group only, there were significant positive correlations between DCV and TMT-A, TMT-B, and the Modified Stroop Test ( $\rho = 0.47$ ,  $p = 0.00$ ;  $\rho = 0.54$ ,  $p = 0.00$ ;  $\rho = 0.38$ ,  $p = 0.02$ ). No significant correlations were found between DCV and CDT ( $\rho = -0.18$ ,  $p = 0.30$ ), or DCV and the WAIS-R digit span subtest ( $\rho = -0.31$ ,  $p = 0.06$ ). In addition, to confirm whether these variables, which are significantly associated with DCV, predicted the car-following performance more than just memory impairment

did, multiple linear regression analyses were carried out. Adjusting for the delayed recall performance on the WMS-R Logical Memory, the predictive strength of TMT-A, TMT-B, and the Modified Stroop Test was confirmed using log transformation DCV as an independent variable. Results of multiple linear regression analyses are displayed in Table 2. The results showed that the TMT-B performance significantly predicts the car-following performance after adjusting for the severity level of amnesia ( $\beta = 0.40$ ,  $p = 0.04$ ,  $R = 0.63$ , adjusted  $R^2 = 0.40$ ).

## Discussion

This study has provided clear evidence that late-life amnesia harms driving performance. An elderly sample with these characteristics showed that significantly decreased performance on the car-following and road-tracking tasks as compared with the normal young adults. However, the results showed a difference between individuals with symptomatic memory impairment and normal aging-related characteristics for driving abilities. There was no significant difference among the elderly groups on the road-tracking task. In contrast, there was a significant difference between groups on the car-following task. These results indicate that aMCI affects driving performance in patients with a prodromal stage of dementia, but normal aging also affects performance.

Note. TMT = Trail Making Test, WMSR = Wechsler Memory Scale-Revised: Logical Memory.

Second, the different findings may be due to sample characteristics of MCI group and age matched control group. We checked that all the MCI participants showed a well-defined memory decline, and that all the normal elderly controls had intact memory and normal cognitive characteristics. In the present study, we examined these elderly people with amnesia and age-matched memory intact controls to evaluate driving performances using driving simulator, and compared their performance with normal young adults. Frittelli et al. (2009) compared among mild AD patients, people with MCI, and age-matched neurologically normal controls. We considered the problems involved with normal aging, and we found that not only aMCI but also normal-aging impaired driving performance. Our results indicated that MCI impaired car-following accuracy.

Simulated driving was found to be significant impaired in participants with aMCI. To identify cognitive variables explaining the decrement in car-following performance in late-life, correlational analyses were conducted. Although car-following performance was significantly related to performance on the TMT-A, TMT-B, and the Modified Stroop Test in our study sample, the correlations with the MMSE were not significant. These results are in agreement with previous studies showing that the MMSE, a widespread dementia screening tool, is limited as a predictive instrument. A few studies have reported a significant relation of MMSE scores to driving simulator and on-road driving performance (e.g. Fitten et al., 1995), but many studies have indicated that MMSE scores did not discriminate unsafe drivers from elderly drivers with unimpaired performance (Brown et al., 2005; Fox, Bowden, Bashford, & Smith, 1997; O'Neill et al., 1992). Also, general cognitive decline assessed by the MMSE is not found at the start of brain degeneration disease, and the aMCI operational criteria are conditional on a normal score on the MMSE. Thus, our elderly sample had less variability in MMSE scores. For patients with a prodromal stage of dementia, the MMSE is not useful as a predictor of safe driving, which has been shown in our results and numerous other studies with inconsistent results.

We found a linear relationship between performance on the TMT-B and the car-following task, and this relationship

remained after adjusting for the degree of symptomatic memory impairment. It is possible that the TMT-B is a useful tool for classifying elderly drivers as to whether they would pass or fail on the car-following task. The TMT is associated with attention flexibility and executive function (Lezak, 2004). The difference between unsafe drivers and persons with unimpaired performance may be associated with the flexibility of visual attention and executive function. Particularly, the TMT-B assesses more precisely the ability to alternate between two cognitive sets of stimuli, while the TMT-A of the test provides useful information concerning attention, visual scanning, speed of eye-hand coordination and information processing (Zalonis et al, 2008). These results suggest that persons with MCI who not only have memory impairment but also have difficulty gathering and processing information in parallel should drive under close supervision.

According to a cybernetic model of driving output, driver psychopathology is only one of a multitude of factors to consider (Moller, 2011). However, factors of driver psychopathology, normally limitations of psychological and neurophysiologic functioning, are associated with driving performance. Future studies need to evaluate the appropriate weighting of these risk factors in people with MCI, and develop criteria for re-evaluation of competency to drive.

**Limitation** The results of this study are constrained by certain limitations that are outlined below. Although we concluded this experiment based on the premise that participants in the three experimental groups were homogenous, there may have been differences in participants within each group. These differences may have been caused by misclassification of the amnesia status as a result of differences in age, educational level, or chronic physical disorder, although, the age and education level of the sample were not correlated with DS performance. We also did not consider the possibility that individuals with aMCI may have other impairments (a multiple-domain subtype) or not (amnestic single-domain subtype), because of the small sample size. Future studies need to consider these details of individuals in amnestic subtypes, non-amnestic subtypes, and multi-domain subtypes of MCI. Finally, whereas it is generally considered that road testing is the gold standard by which to evaluate driving

competence, we used the DS. There is a definite difference between on-road testing and DS tasks provide. The former can provide information on daily habits related to driving, whereas the latter provides objective assessment of competence. Future studies need to conduct longitudinal investigations of traffic incidents and compare them with changes in DS performance.

### Acknowledgments

Funding for this study was provided by research grants from the following: the Ministry of Health, Labor and Welfare of Japan; the Chiyoda Mutual Life Foundation; the Hori Sciences and Arts Foundation; the Conference for Expressway-related Social Contribution Activities; the Japan Health Foundation; the Suzuken Memorial Foundation, the ZENKYOREN, and the General Insurance Association of Japan.

## Abstract

To achieve a full, theoretical understanding of a cognitive process, explanations of the process need to be provided at both symbolic (i.e., representational) and sub-symbolic levels of description. We argue that cognitive models implemented in vector-symbolic architectures (VSAs) intrinsically operate at both of levels and thus provide a needed bridge. We characterize the sub-symbolic level of VSAs in terms of a small set of linear algebra operations. We characterize the symbolic level of VSAs in terms of cognitive processes, in particular how information is represented, stored, and retrieved, and classify vector-symbolic cognitive models in the literature according to their implementation of these processes. On the basis of our analysis, we speculate on avenues for future research, and suggest means for theoretical unification of existent models.

**Keywords:** Vector symbolic architectures; Holographic reduced representations; cognitive modelling; symbolic modelling; sub-symbolic modelling.

## Introduction

To achieve a full, theoretical understanding of a cognitive process and how it relates to the physical world, explanations of the process need to be provided at both symbolic (i.e., representational) and sub-symbolic levels of description. The classic symbolic approaches to modelling do not account for how the symbol manipulations described in the model could arise from neural tissue, or account for how the symbols themselves come into existence. Classic connectionist approaches are more concerned with neural plausibility, but are notoriously opaque, doing little to aid our understanding of the cognitive processes modelled. By contrast, the vector-symbolic approach to modelling explicitly provides an account at both levels of description.

Vector Symbolic Architectures (VSAs), a term coined by Gayler (2003; but see also Plate, 1995), are a set of techniques for instantiating and manipulating symbolic structures in distributed representations. VSAs have been used to successfully model a number of different cognitive processes (e.g., analogical mapping in Eliasmith & Thagard, 2001; letter position coding in Hannagan, Dupoux, & Christophe, 2011; semantic memory in Jones & Mewhort, 2007). It has been argued that VSAs provide a bridge between conventional symbolic modelling and both connectionist modelling (Rutledge-Taylor & West, 2008) and more realistic models of neural processing (Eliasmith, 2007). However, if we are to take the bridging metaphor seriously, it is important to clarify which parts of a VSA are symbolic in nature and which are sub-symbolic. We will

attempt to lay out a simple system for understanding VSAs in terms of basic operations and symbolic/sub-symbolic decisions, and thereby provide a comprehensive and comprehensible introduction to VSAs for newcomers, and a common frame of reference for those already using VSAs. By providing a high-level overview that integrates the techniques of existent VSA-based cognitive models into a coherent picture we hope to highlight as yet unexplored avenues of research and sketch what a VSA-based account of cognition as a whole would look like.

In this analysis, the vectors represent symbolic information. These vectors, or symbols, can be combined and manipulated using a small number of operations, which can be understood as sub-symbolic processes. However, the information processing models built from these operations are themselves, best characterized at a symbolic level of description. Importantly, the modelling decisions made at the sub-symbolic level are to some degree independent of the modelling decisions made at the symbolic level. This paper is divided into two parts to reflect these two levels of description, symbolic and sub-symbolic.

## The Sub-Symbolic Level

VSAs are closely related to the better-known tensor product representations (Smolensky, 1990), but unlike tensor product representations, VSAs can compactly represent symbolic expressions of arbitrary complexity. A number of VSA techniques exist in the literature, including Holographic Reduced Representations (HRRs; Plate, 1995), frequency-domain HRRs (Plate, 1994), some earlier forms of holographic associative memory (Eich, 1982; Murdock, 1982), as well as binary spatter codes (Kanerva, 1992), Multiply-Add-Permute coding (Gayler, 2003), and square matrix representations (Kelly, 2010).

Each VSA technique uses the same set of basic operations, but implements the operations differently. Thus the choice of a particular VSA dictates how symbols are instantiated and manipulated and defines the model at the sub-symbolic level. To ground the discussion, we mainly discuss Holographic Reduced Representations (HRRs) (Plate, 1995), as HRRs are the most widely used VSAs in the cognitive modelling literature. Also, HRRs are used as the basis for the Neural Engineering Framework (NEF; Eliasmith, 2007) and thus demonstrably have a clearly defined and plausible neural implementation. However, the other VSA techniques are similar and most anything that can be done with an HRR can be done with any VSA technique.

## ***n*-Space and Similarity**

In a VSA, a symbol, or representation, is an  $n$ -dimensional vector: a list of  $n$  numbers that defines the coordinates of a point in an  $n$ -dimensional space. VSAs work best for values of  $n$  in the hundreds or thousands (Plate, 1995).

A vector can be understood as a line drawn from the origin (the zero coordinates) to the coordinates specified by the vector. The length of the line is the vector's magnitude. The direction of the vector encodes the meaning of the representation. Similarity in meaning can thus be measured by the size of the angles between vectors. This is typically quantified as the cosine of the angle between vectors. The cosine of vectors **a** and **b** can be calculated as:

$$\text{cosine}(\mathbf{a}, \mathbf{b}) = (\mathbf{a} \cdot \mathbf{b}) / ((\mathbf{a} \cdot \mathbf{a})^{0.5} (\mathbf{b} \cdot \mathbf{b})^{0.5})$$

where  $\cdot$  is the dot product. A cosine of 1 means the vectors are identical, -1 means they are opposites, and 0 means they are completely dissimilar. If each vector has a magnitude of one, the cosine is just the dot-product of the vectors. Thus, some systems rescale all vectors to a magnitude of one after vector operations. In memory systems where new memories are superimposed on old memories, such re-scaling causes a recency effect and rapid forgetting because new memories will make-up a fixed fraction of memory, regardless of the quantity of previous experience.

While the cosine measures the *angle* between two vectors, the cosine is often described as a measure of *distance*. As it is more intuitive to describe similarity as a measure of distance than as a measure of the angle, for convenience, we can imagine the vectors as describing points on a *hypersphere*, such that the size of the angles are the distances between them.

## **Atomic versus Complex representations**

Representations in a VSA are either atomic or complex. An atomic representation is a unique representation, a symbol that cannot be broken down into sub-symbols. In an HRR, values for an atomic representation are typically generated by random sampling from a standard normal distribution. By assigning random values to the vectors, atomic representations will be uniformly distributed across the surface of the hypersphere, such that the atomic representations will have little to no similarity to each other.

Complex representations can be created by either combining atomic representations or recursively combining complex representations. Critically, in a VSA, a complex representation has the same dimensionality as an atomic representation, allowing representations both atomic and complex to be compared, or combined together to create representations of arbitrary complexity. VSAs have two operators for combining representations: superposition and binding. In HRRs, superposition is vector addition and binding is circular convolution. We denote vector addition by  $+$ , and circular convolution by  $*$ . Binding and superposition, along with random permutation, are the basic operations used to create complex representations in VSAs.

## **Superposition (+) versus Binding (\*)**

The key difference between superposition and binding is their effect on similarity. Superposition is similarity-preserving: the sum of two vectors is a vector that falls in the angle between them. Conversely, binding is similarity-destroying: the circular convolution of two vectors is roughly orthogonal to the two original vectors. The purpose of superposition is to combine representations to create a new representation that is similar to all of the combined representations. The purpose of binding, on the other hand, is to create "chunks": unique identifiers for combinations of representations.

Most VSA use a form of vector addition for superposition. Vector addition is computed by adding together the corresponding elements of the two vectors. So, for example,  $\{1,4,7\} + \{5,4,2\} = \{6,8,9\}$ .

To bind, HRRs use circular convolution,  $*$ , which can be computed rapidly using element-wise multiplication,  $\circ$ , and the fast Fourier transform,  $\text{fft}$ , and its inverse,  $\text{fft}^{-1}$ :

$$\mathbf{a} * \mathbf{b} = \text{fft}^{-1}(\text{fft}(\mathbf{a}) \circ \text{fft}(\mathbf{b}))$$

Essentially circular convolution is a lossy way of scrambling the information of the two vectors together to produce a new vector of the same dimensionality.

Consider the problem of learning the meaning of the phrase "kick the bucket", a colloquial euphemism for death. Suppose the cognitive model has a vector representation of the concept *kick* and a vector representation of the concept *bucket*. The sum (superposition) of those two vectors will produce a vector that is close to both *kick* and *bucket*, indicating that the phrase "kick the bucket" has a meaning similar to *kick* and to *bucket*. But in order for the cognitive model to be able to learn that the phrase "kick the bucket" has a distinct meaning that is not a function of its parts, the model needs to be able to assign to "kick the bucket" a distinct identifier. Binding is the operation that performs this function in VSA-based models. The vector  $\text{kick} * \text{bucket}$  is dissimilar to the vectors *kick*, *bucket*, and  $\text{kick} + \text{bucket}$ .

Binding and superposition can also be used jointly to address the binding problem (Gayler, 2003), that is, the question of how to couple sets of attributes together such that the attributes of one object are not confused with the attributes of another. For example, given a *small red square* and a *large blue circle*, the complex representation  $(\text{small} * \text{red} * \text{square}) + (\text{large} * \text{blue} * \text{circle})$  creates a single vector that distinctively represents the knowledge that the *square* is small and red and the *circle* is large and blue.

## **Unbinding**

Unbinding is an inverse of binding that allows vectors that have been bound together in a complex representation to be unpacked and recovered. Circular correlation,  $\#$ , is the unbinding operator for HRRs. Given a pair of vectors bound together, and one of the pair, referred to as the probe, unbinding produces an approximation of the other vector, referred to as the target, i.e.,

$$\mathbf{p} \# (\mathbf{p} * \mathbf{t}) = \mathbf{a} \approx \mathbf{t}$$

where  $\mathbf{p}$  is the probe,  $\mathbf{t}$  is the target, and  $\mathbf{a}$  is an approximation of the target.

Unbinding can be understood as binding with the inverse of the probe. The *inverse* of any vector  $\mathbf{x}$  is a re-ordering of the elements of  $\mathbf{x}$ , i.e. a permutation of  $\mathbf{x}$ , such that,

$$\mathbf{x} \# \mathbf{x} = \mathbf{x} * \text{inverse}(\mathbf{x}) \approx \delta$$

where  $\delta$  is the identity vector for binding, i.e. for any vector  $\mathbf{x}$ ,  $\mathbf{x} * \delta = \mathbf{x}$ . Thus binding with the inverse of a vector unbinds what that vector has been associated with:

$$\mathbf{a} \# (\mathbf{a} * \mathbf{b}) = \text{inverse}(\mathbf{a}) * (\mathbf{a} * \mathbf{b}) \approx \delta * \mathbf{b} = \mathbf{b}$$

In HRRs, the inverse of any vector  $\mathbf{x} = \{\mathbf{x}_1 \dots \mathbf{x}_n\}$  is:

$$\text{inverse}(\mathbf{x}) = \{\mathbf{x}_1, \mathbf{x}_n, \mathbf{x}_{n-1}, \dots, \mathbf{x}_3, \mathbf{x}_2\}$$

Circular convolution,  $*$ , is commutative, i.e., the order of binding does not matter when using circular convolution. Given vectors  $\mathbf{a}$  and  $\mathbf{b}$ , their association  $\mathbf{a} * \mathbf{b} = \mathbf{b} * \mathbf{a}$ , and likewise, when unbinding,  $\mathbf{b} \# (\mathbf{a} * \mathbf{b}) = \mathbf{b} \# (\mathbf{b} * \mathbf{a}) \approx \mathbf{a}$ .

## Permutation

Gayler (2003) describes random permutation as an operation used "to quote or protect the vectors from the other operations". Permutation of the numbers  $1 \dots n$  defines a unary function that can transform a vector. A randomly chosen permutation of a vector is unlikely to be similar to the original vector, but the permutation is also reversible. Given  $p$ , there is a permutation  $p^{-1}$  such that,  $p^{-1}(p(\mathbf{a})) = \mathbf{a}$ . When permuted, the information within a vector is essentially hidden and protected from being affected by other vector operations.

For example, as noted above, circular convolution is commutative, that is,  $\mathbf{a} * \mathbf{b} = \mathbf{b} * \mathbf{a}$ . This property of circular convolution can be useful, but it can be a hindrance in situations where the order of items matter, e.g. "dog feed" and "feed dog" are phrases which carry different meanings by virtue of differences in word order.

A non-commutative variant of circular convolution can be defined using a random permutation  $p$  and its inverse  $p^{-1}$ . By always randomly permuting one of the arguments before convolution, one defines a binding operation that is non-commutative, i.e. while  $\mathbf{a} * \mathbf{b} = \mathbf{b} * \mathbf{a}$ ,  $p(\mathbf{a}) * \mathbf{b} \neq p(\mathbf{b}) * \mathbf{a}$ . Unbinding then uses the inverse permutation  $p^{-1}$ , e.g.

$$\begin{aligned} \cosine(p^{-1}(\mathbf{a} \# (p(\mathbf{a}) * \mathbf{b})), \mathbf{b}) &\approx 0.71 \\ \cosine(p^{-1}(\mathbf{b} \# (p(\mathbf{a}) * \mathbf{b})), \mathbf{a}) &\approx 0 \end{aligned}$$

Non-commutative binding is used by the BEAGLE model (Jones & Mewhort, 2007) to bind vectors that stand for words in sentences in order to construct representations of the semantics of each of those words. For a variety of other uses of random permutation in VSAs, see Gayler (2003), Sahlgren, Holst, and Kanerva (2008), and Kelly (2010).

## The Symbolic Level

When making a vector-symbolic model, decisions need to be made at both the symbolic and sub-symbolic levels. At the sub-symbolic level, the modeller needs to decide how to instantiate symbols as vectors and symbol-manipulation as vector algebra. Conversely, at the symbolic level, the modeller needs to make decisions about how to structure, manage, store, and retrieve those symbols. Choosing to use HRRs rather than another kind of VSA can define the sub-symbolic level, but this choice is largely independent of the decisions to be made at the symbolic level.

In fact, we have already seen two examples of manipulations at the symbolic level. The first was combining binding and addition to create a vector that encodes information about bound entities (e.g., *small red square* and *large blue circle*). The second was combining permutation and binding to create a bound entity that maintained information about order. Essentially, all VSA systems work in the same way. Vectors encode the desired information according to some sort of scheme (i.e., by combining the operations discussed above), and then, when needed, the information is retrieved from the vectors.

## Encoding and Storage

BEAGLE (Jones & Mewhort, 2007) and DSHM (Rutledge-Taylor & West, 2008) use the terms *environmental vectors* and *memory vectors*. We extend the use of this terminology to other vector-symbolic models. An *environmental* vector is a vector that stands for atomic perceptions from the environment (e.g., a *red circle* needs two environmental vectors, one for *circle* and one for *red*). Environmental vectors are fixed and do not change. A *memory* vector is a complex representation stored by the model and used to produce behaviour. In some systems, memory vectors change with experience. Additionally, we use the term *experience vector* to refer to a representation that stands for the model's current experience of its environment created by combining environmental vectors (e.g., an experience vector could represent the perception of a *red circle* by convolving the environmental vectors of *circle* and *red*).

By examining the relationship between environmental, experience, and memory vectors across vector-symbolic models, we distinguish between three main approaches to storage. In a *many-to-one* vector model, all experience vectors are summed into a single memory vector for storage. In a *one-to-one* vector model, each experience vector is stored as a separate memory vector among an ever-growing number of memory vectors. In a *many-to-many* vector model, there are a fixed number of memory vectors, and incoming environmental vectors are used to update them. Each of these approaches has strengths and weaknesses.

**Many-to-one** In a *many-to-one* vector model, such as TODAM (Murdock, 1983) or CHARM (Eich, 1982), memory is modelled as a single, high-dimensional vector. All experience vectors are added to the memory vector. There is a limit to how much can be stored in the vector before mistakes start to be made. Mistakes are, of course, of interest to psychologists, and the pattern of mistakes made

by a *many-to-one* vector model allow it to mimic human forgetting in list-recall tasks. If the goal is to model how people store a small amount of recently learned or closely related information, a single memory vector suffices.

*Many-to-one* vector models also have the advantage of a clear neural implementation. In the Neural Engineering Framework (NEF; Eliasmith, 2007) binding, unbinding, and and superposition can all be implemented through neural connectivity. In the NEF interpretation, a *many-to-one* memory is a neural group with self-recurrent connections that acts as a working memory or buffer, and many such buffers could exist in the brain.

**One-to-one** In a *one-to-one* vector model, such as MINERVA (Hintzman, 1986), the Iterative Resonance Model (Mewhort & Johns, 2005), and the Holographic Exemplar Model (Jamieson & Mewhort, 2011), each experience vector is represented as a separate memory. While this approach to modelling memory is both simple and successful, the ever growing number of vectors that need to be stored and accessed by the memory system is both neurally implausible and computationally impractical for modelling tasks in which very large amounts of knowledge are relevant, e.g., semantic priming tasks (Jones & Mewhort, 2007). However, these models are able to reproduce a wide variety of memory effects, providing a unitary account of episodic, semantic, and implicit memory, indicating that, although their warehouse-style management of vectors is implausible, their processes of storage and retrieval provide a good analogue for biological memory.

**Many-to-many** *Many-to-many* vector models, such as BEAGLE (Jones & Mewhort, 2007) and DSHM (Rutledge-Taylor, 2008), can be understood as a hybrid of the earlier *many-to-one* and *one-to-one* approaches. In *many-to-many* memory, for each item of interest, there is a randomly generated environmental vector and a specially constructed memory vector. In BEAGLE the items of interest are words: the environmental vector stands for the word's orthography or phonology and the memory vector stands for the word's meaning. In DSHM, the items are objects relevant to the experimental task: the environmental vector stands for the percept of the object and the memory vector stands for the concept of the object.

Like the one-to-one models, the management of the vectors in many-to-many systems is computationally expensive and, at this point, neurally implausible. However, the ability to generate memory vectors that stand for particular concepts is very powerful (e.g., Rutledge-Taylor, Vellino, & West, 2008) and allows these systems to capture numerous different phenomena (e.g., Rutledge-Taylor & West, 2008) and represent vast quantities of data (Jones & Mewhort, 2007).

For example, to create an association between *keyboards* and *computers*, each time a computer and keyboard co-occur a copy of the environmental vector for keyboard can be added to the memory vector for computer and a copy of the environmental vector for computer can be added to the memory vector for keyboard. The effect to this would be to move the memory vector for computer closer to the

environmental vector for keyboard and move the memory vector for keyboard closer to the environmental vector for computer. Over time, the result of this is to organize the space so that memory vectors are clustered around environmental vectors that they co-occur with so that the distance between the vectors equals strength of association.

Another, more complicated example involves binding and the use of the *placeholder vector*. The placeholder vector is an atomic (i.e., random) vector, but it is used to encode all associations, and thus can be used as a universal retrieval cue. Consider the phrase or stimulus *blue triangle*. Without using the placeholder, we could update memory as follows:

$$\begin{aligned}\text{memory}_{\text{blue}} &+= \text{blue} * \text{triangle} \\ \text{memory}_{\text{triangle}} &+= \text{blue} * \text{triangle}\end{aligned}$$

By binding together the environmental vectors for **blue** and **triangle** and adding the result to the memory vectors for *blue* and *triangle* (an operation denoted by  $+=$ ), we move the two memory vectors towards the point in space described by the vector **blue \* triangle**, and thereby move **memory<sub>blue</sub>** and **memory<sub>triangle</sub>** closer together. But people almost *never* get the concepts *blue* and *triangle* confused with each other. This is because *blue* is a colour (or an adjective), and *triangle* is a shape (or a noun), i.e. they are different sorts of thing.

Conversely, consider updating using the placeholder:

$$\begin{aligned}\text{memory}_{\text{blue}} &+= \text{placeholder} * \text{triangle} \\ \text{memory}_{\text{triangle}} &+= \text{blue} * \text{placeholder}\end{aligned}$$

This moves **memory<sub>blue</sub>** towards **placeholder \* triangle**, i.e. towards all properties of triangles, and moves **memory<sub>triangle</sub>** towards **blue \* placeholder**, i.e. towards all things that are blue. Thus, by using a placeholder, the memory vectors for nouns will cluster together in one region of space, and the vectors for adjectives will cluster together in another region of space, and things that are *colours* will cluster separately from things that are *coloured*. This is a subtle distinction but Jones and Mewhort (2007) have shown it to be very important and very powerful.

## Retrieval

There are two categories of information retrieval processes used in vector-symbolic models: *unbinding*, which retrieves information from a particular vector, and *resonance*, which allows information to be retrieved from the entire library of vectors in memory. *Many-to-one* models, such as TODAM (Murdock, 1982) only use unbinding. *One-to-one* models that do not use binding to encode associations, such as MINERVA (Hintzman, 1986), only use resonance. In *many-to-many* systems, these two retrieval processes are complementary. For example, resonance can be used to retrieve a vector, which can then be unbound.

**Unbinding** Consider a simple example where the agent is given a set of coloured shapes to remember: *blue triangle*, *green square*, *red circle*. In a *many-to-one* vector model this could be encoded by binding (\*) the vectors for the shapes to the colours, then summing to create a memory vector:

$$\text{memory} = \text{blue} * \text{triangle} + \text{green} * \text{square} + \text{red} * \text{circle}$$

The colour of any one of these shapes could then be recalled by unbinding (#) using the shape to probe memory:

$$\text{triangle} \# \text{memory} \approx \text{blue}$$

In a *many-to-many* vector model, unbinding may use the *placeholder* as the probe. The placeholder is a special, randomly generated atomic vector that acts as a key to all of memory. The placeholder is initially used in binding:

$$\begin{aligned} \text{memory}_{\text{blue}} &= \text{placeholder} * \text{triangle} \\ \text{memory}_{\text{triangle}} &= \text{placeholder} * \text{blue} \end{aligned}$$

The placeholder can then be used in unbinding:

$$\text{placeholder} \# \text{memory}_{\text{triangle}} \approx \text{blue}$$

**Resonance (*one-to-one*)** The term resonance comes from MINERVA (Hintzman, 1986), but it is implemented differently across different models. In MINERVA, the process of resonance begins by measuring the similarity (cosine) of each vector in memory to the probe. Then resonance computes a weighted sum of all vectors in memory. This sum, termed the *echo*, is what the model retrieves from memory. Each vector in the sum is weighted by its similarity to the probe raised to an exponent.

For example, the three shapes might be represented as:

$$\begin{aligned} \text{memory}_1 &= \text{triangle} + \text{blue} \\ \text{memory}_2 &= \text{square} + \text{green} \\ \text{memory}_3 &= \text{circle} + \text{red} \end{aligned}$$

If the probe is **triangle**, then the echo would approximate:

$$\begin{aligned} \text{echo} &\approx 0.5^b \text{memory}_1 + 0.0^b \text{memory}_2 + 0.0^b \text{memory}_3 \\ \text{echo} &\approx 0.5^b (\text{triangle} + \text{blue}) \end{aligned}$$

such that the memory system would remember that the triangle is blue. The exponent  $b$  is a small, positive integer that is odd-numbered so as to preserve the sign of the similarity. Note that the similarity values of 0.5 and 0.0 are approximate. Random vectors in a high dimensional space have an expected cosine of 0, but the actual cosine between any two random vectors will be a little more or a little less.

The exponent  $b$  critically allows *one-to-one* vector models to function even when there is a very large amount of data in memory. If the exponent  $b$  is 1, the result of resonance roughly imitates decoding in a simple associative memory, such as a Hopfield network. With an exponent greater than one, resonance increases the signal to noise ratio in the echo by increasing the relative weighting of the memory vectors most similar to the probe. If  $b$  is too low, a large number of partial matches in memory could easily overwhelm an exact match to the probe, resulting in a poor echo. With a high  $b$ , the echo will essentially just be the most similar vector in memory to the probe. In MINERVA, a  $b$  of 3 is standardly used, but a  $b$  of 3 may be too low when modelling a larger

sum of knowledge than what is typically necessary to model a psychology experiment (e.g., in modelling word pronunciation, such as in Kwantes & Mewhort, 1999).

In the Iterative Resonance Model (IRM; Mewhort & Johns, 2005), resonance is iterated, and with each iteration  $b$  is increased until a decision to stop iterating is made, resulting in either successful retrieval or a failure to retrieve. This approach has two benefits: (1) the number of iterations can be used to predict response time in memory tasks, and (2) it eliminates  $b$  as a tweaking parameter by introducing a theory-driven approach to setting its value.

**Resonance (*many-to-many*)** Although the term *resonance* is used to describe retrieval in *many-to-many* vector models, the implementation is different and simpler: Essentially, the memory vector most similar to the probe is retrieved. This can be understood as a kind of spreading activation (Rutledge-Taylor & West, 2008). The probe and memory vectors can be understood as points on a hypersphere, such that the cosine measures the distance between them. One can imagine a ripple of activation spreading out from the probe across the surface of the hypersphere. The memory vectors closest to the probe become active in working memory, with the closer vectors becoming active sooner. This model of resonance allows BEAGLE (Jones & Mewhort, 2007) to make semantic priming reaction time predictions (e.g., that *doctor* is recognized faster when preceded by *nurse* than when preceded by an unrelated prime such as *stapler*) and to model the fan-effect in DSHM (Rutledge-Taylor & West, 2008).

## Conclusions

We hold that, in order to bridge the gap between human experience and neural connectivity, explanations at both the symbolic and sub-symbolic levels of description are necessary parts of theory in cognitive science. As we illustrate in this paper, cognitive models that use vector-symbolic architectures intrinsically operate at both of these levels of description and thereby provide a needed bridge between the two kinds of explanation.

At the sub-symbolic level is the vector-symbolic architecture itself, and the linear algebra operations on vectors that comprise the architecture: *similarity*, *superposition*, *binding*, *unbinding*, *permuting*, *unpermuting*. All of these operations are easily amenable to neural implementation, as in the NEF (Eliasmith, 2007).

At the symbolic level, we have the cognitive model itself, and the cognitive processes that define it. On the basis of their storage and retrieval mechanisms, we classify existing vector-symbolic cognitive models into *many-to-one*, *one-to-one*, and *many-to-many* vector models. This classification scheme highlights stark differences between these models.

*Many-to-many* vector models differ from the other two classes of model in two important ways. First, *many-to-many* models use a *placeholder* vector to stand for "this item I am thinking about". The placeholder acts as a symbol with an important functional role but no perceptual or conceptual meaning. It may be useful to incorporate other kinds of function vectors in future models, e.g., a *wildcard* vector to

stand for "that item that I'm not thinking about", vectors to stand for emotional states, for truth values, et cetera.

Secondly, in *many-to-many* models, memory vectors are labelled and stand for particular concepts, whereas in *one-to-one* models concepts are an emergent phenomenon produced by the echoes retrieved using resonance (Hintzman, 1986). While the conceptual representations in *many-to-many* models are powerful, having a predefined number of concepts is implausible and limiting.

*Many-to-one* vector models can be constructed in NEF as self-recurrent neural groups and are understood as working memory buffers. By contrast, *one-to-one* and *many-to-many* models are best understood as models of long-term memory, but as yet lack a neural explanation.

Finding a means of translating *one-to-one* and *many-to-many* vector models into neural models may provide a route to a unified, vector-symbolic account of memory storage and retrieval. As we noted earlier, a *one-to-one* model behaves somewhat like a Hopfield network when the resonance exponent  $b$  is set to 1. To implement a *one-to-one* model as a network, one needs to find a mechanism analogous to  $b$  that can act to increase the signal to noise ratio in the echo. We speculate that the vector-symbolic intersection circuit proposed by Levy and Gayler (2009) might provide a start for developing such a mechanism.

We suspect that the memory vectors that stand for concepts in *many-to-many* vector models are, in fact, the echoes in *one-to-one* vector models. That is to say, we agree with Hintzman (1986) that concepts are an emergent property of retrieval. Using a *one-to-one* model to do the kind of large scale modelling in *many-to-many* models is impossible because *one-to-one* models store all experiences without any form of compression. However, a neural implementation of a *one-to-one* model would naturally be lossy in its storage, and so could provide a plausible account of concept formation over a lifetime of experiences.

Unification in other areas, such as representation, is important too. Incorporating a vector-symbolic model of string encoding (Hannagan et al., 2011) into the BEAGLE model of semantics (Jones & Mewhort, 2007) could, for instance, allow BEAGLE to model how shared orthography can help and hinder in understanding the meaning of words.

Eventually, we hope to see developed a vector-symbolic cognitive architecture, which not only presents a unified and neurally plausible approach to representation, storage, and retrieval, but also extends the vector-symbolic account beyond its roots in memory theory, and integrating it into accounts of emotions, attention, perception, and consciousness. As cognitive scientists, it is important to keep in mind our ultimate, lofty, and collective goal of a theory that unifies not only all aspects of the cognition, but all relevant levels of description.

## Abstract

This study examined sex differences in the discrimination of minimal pairs of foreign language (non-native) tonemes. Adult native speakers of English (237 women and 177 men), with no prior exposure to a tonal language, performed an AX-task, which required them to discriminate between rising and falling-rising Norwegian tonemes. When controlling for nonverbal intelligence, prior exposure to foreign languages, and age, sensitivity measures ( $d'$ ) showed a clear male advantage. Thus, the sex differences previously observed in non-linguistic temporal processing tasks appear to extend to the discrimination of unfamiliar non-native speech sounds. These sex differences in auditory processing may be due to anatomical differences between men and women in the ratio of white to grey matter in the left hemisphere, which, in turn, might affect speed of neural transmission. These findings contribute to the ongoing debate on cognitive effects of putative sex differences in intra- and inter-hemispheric connectivity.

**Keywords:** non-native speech perception; tonal contrast; sex differences; adult L2 learning; auditory processing.

## Introduction

Auditory processing of temporal sequences underlies the neural representation of speech and has been implicated in impairments in language development; e.g., dyslexia and Specific Language Impairment (Goswami et al., 2002; Talcott et al., 2000; Tallal, 1980). However, little is known about individual differences in auditory processing in the non-clinical adult population, and, specifically, individual differences in the ability of adults to discriminate the speech sounds of foreign (non-native) languages. Illuminating the basis of individual differences in non-native speech processing may help to explain some of the considerable variance in outcomes observed among adult foreign language (L2) learners (Johnson & Newport, 1989). So far, only a few studies have explored individual differences in the processing of non-native speech sounds (Bradlow, Pisoni, Akahane-Yamada, & Tohkura, 1997; Golestani & Zatorre, 2009). Thus, we know very little about which factors, besides age of first exposure (Flege, MacKay & Meador, 1999), make an adult more or less successful in processing non-native speech sounds.

Research on temporal processing as a predictor of psychometric intelligence (Rammsayer & Brandler, 2007) and working memory capacity (Troche & Rammsayer, 2009) has revealed a sex difference, with men outperforming women in temporal order judgments (Szelag et al., 2011; Wittman & Szelag, 2003) and temporal discrimination tasks (Rammsayer & Troche, 2010). Factor-analytical approaches have traced the male advantage to a latent variable – temporal resolution power, which has been linked to neural oscillation rate determining speed and accuracy of neural transmission (Jensen, 1982). The male advantage is not confined to the auditory modality, however, but has also been observed for tactile temporal processing (Rostad, Mayer, Fung & Brown, 2007), suggesting that it affects general temporal processing in the sub-second range.

In addition to sex differences in pure temporal information processing tasks, there is evidence for a male advantage in the discrimination of pitch contours of computer-generated waveforms, comprising a fundamental frequency and two formants, which were presented binaurally (McRoberts & Sanders, 1992). Pitch contour discrimination requires sensitivity to changes in pitch over time and therefore relies on temporal processing. Rapidly changing values of one or several acoustic parameters (e.g., formant transitions) play a crucial role in distinguishing different speech sounds—for example, notoriously difficult phonological contrasts like the dental-retroflex contrast (for English speakers) or the r/l contrast (for Japanese speakers) require sensitivity to rapid spectral changes. The present study therefore aims to examine whether a male advantage can also be found in the ability to discriminate natural non-native speech contrasts. Natural speech sounds differ from synthetic stimuli in their greater variability within speech sound categories and in the complexity of their acoustic characteristics.

We chose to examine sensitivity to lexical tones as one example of such a non-native speech contrast. We used Norwegian tonemes as many dialects of Norwegian have a simple tonal system with pitch accents that distinguish otherwise homophonous bisyllabic words. Detecting these tonal contrasts requires tracking temporal changes in pitch

contours of bi-syllabic words. We tested adult native English speakers' sensitivity to the tonal contrast between rising and falling-rising tonemes, which are illustrated in Figure 1.

If sex differences in non-linguistic temporal processing extend to linguistic stimuli we would expect to see a male advantage in the processing of an unfamiliar Norwegian tonal contrast by native English speakers.

Figure 1: Illustrations of the different pitch contours of minimal pairs of Norwegian tonemes. The upper panel shows the rising tone for the word ‘Hammer’ [a proper noun]. The lower panel shows the falling-rising tone for the word ‘hammer’ [the tool]<sup>1</sup>.

### Method

We pooled data from six experiments on non-native discrimination of Norwegian tonal contrasts that were conducted over a period of five years (Kempe, Thoresen & Brooks, 2007, 2008; Kempe, Brooks, Marronaro & Thoresen, 2010; Kempe, Thoresen, Kirk, Brooks & Schaeffler, 2011). These experiments tested native speakers of English differing in dialectal background (American, English and Scottish), and varied with respect to other cognitive abilities tested (e.g., verbal working memory capacity) and other speech sound contrasts presented in addition to the tonal contrast. All six experiments controlled for nonverbal intelligence and prior exposure to other languages. It is necessary to control for nonverbal intelligence because of the well-established link between

processing speed and temporal processing on the one hand and psychometric intelligence on the other hand (e.g., van Raavenzwaaj, Brown & Wagenmakers, 2011; Rammsayer & Brandler, 2007; Sheppard & Vernon, 2008). It is also important to make sure that any observed differences cannot be accounted for by prior exposure to tonal contrasts.

**Participants:** A total of 458 participants (197 men) were tested in various locations in the United Kingdom and in the United States (New York City). Participants’ mean age was 22.8 years (range 17-61 years). Of the participants, 282 (117 men) were native speakers of American English and 176 (80 men) were native speakers of Scottish English.

An additional ten native speakers of Norwegian (four men), aged 20 to 22 years, were tested to confirm that the chosen tonal contrast can reliably be discriminated by native speakers of the language.

**Materials:** To capture the within-category variability characteristic of natural speech sounds, a male native speaker of Norwegian recorded two different instances of each of 16 bisyllabic Norwegian words comprising 8 minimal tonal contrast pairs. In half of the pairs, the first stressed syllables contained short vowels (mean length 80 ms); in the other half they contained long vowels (mean length 144 ms). These eight minimal pairs are listed in Table 1. Stimuli were recorded at a sampling rate of 44.1 kHz and presented to participants through Sennheiser headphones.

Table 1: Minimal pairs of Norwegian words used for tone discrimination. Note that the members of a pair are homophones despite differences in spelling.

rising tone	falling-rising tone
short vowel	
<i>bønder</i> [farmers]	<i>bønner</i> [beans]
<i>lammet</i> [lamb]	<i>lamme</i> [to paralyze]
<i>sulten</i> [hunger]	<i>sulten</i> [hungry]
<i>verket</i> [creation]	<i>verke</i> [to ache]
long vowel	
<i>bøter</i> [fines]	<i>bøter</i> [to repent]
<i>laget</i> [team]	<i>lage</i> [to make]
<i>suget</i> [suction]	<i>suge</i> [to suck]
<i>været</i> [weather]	<i>være</i> [to be]

To establish whether pitch contours were indeed sufficiently distinct between the two tonemes, we measured pitch of the steady-state part of the vowels in the first and second syllable. As Figure 1 indicates, there should be a larger difference between pitch on the first and the second syllable for a rising pitch contour than for a falling-rising pitch contour. Pitch measurements confirmed that the median pitch difference between syllables for the rising pitch contour (38 Hz) was significantly larger than the median pitch difference for the falling-rising pitch contour (4 Hz), Mann-Whitney  $U = 2.0$ ,  $p < .001$ ,  $r = .84$ , indicating

<sup>1</sup>Figure reprinted from the project Lingo resource at the Norwegian University of Science and Technology, Trondheim, [http://www.ling.hf.ntnu.no/ipa/no/tema\\_008.html](http://www.ling.hf.ntnu.no/ipa/no/tema_008.html)

a sufficiently large measurable difference in acoustic characteristics between the two tonemes.

**Procedure:** The Norwegian tonal contrasts were presented in an AX discrimination procedure requiring participants to make judgments about whether pairs of words sounded the ‘same’ or ‘different’. The 32 ‘same’ trials consisted of different instances of the same word spoken with the same pitch accent. The 32 ‘different’ trials consisted of minimal pairs of words spoken with different pitch accents. The two words in each pair were presented with an inter-stimulus interval of 200 ms.

Participants also completed the Cattell Culture-Fair Test of Nonverbal Intelligence, Scale 3, Form A (Cattell & Cattell, 1973), and a language background questionnaire, used to confirm participant status as a native English speaker and to inquire about prior exposure to languages other than English. Participants were asked to rate their reading, writing, speaking and comprehension abilities in each of their languages on a scale from 1 (rudimentary) to 6 (native-like).

## Results

**Norwegian native speakers:** Each participant’s performance was converted to an  $A'$  score, a measure of sensitivity that corrects for individual differences in bias.  $A'$  is a non-parametric analogue to  $d'$  and has values ranging from 0 and 1, with 0.5 corresponding to chance. The mean  $A'$  score for the native speakers of Norwegian was .93 ( $SD = 0.04$ ), which supports the validity of our stimuli and confirms that discrimination of the native tonal contrast did not pose any problems for native speakers.

**English native speakers:** Seventeen men and 18 women reported some familiarity with a tonal language (e.g., Chinese). A further three men and six women failed to provide proficiency ratings in the language background questionnaire. All these participants were excluded from the analyses leaving a total of 177 men and 237 women.

The mean  $A'$  score for the entire sample was 0.71 ( $SD = 0.14$ ). Table 2 presents means and standard deviations for men and women, along with results of Bonferroni-corrected t-tests comparing men and women on age, Culture Fair non-verbal intelligence test scores (CF IQ), number of learned foreign languages (L2s), and mean proficiency self-ratings for first and second L2s. If participants had not studied any L2, the corresponding rating scores were set to 0. These comparisons showed that while women had higher proficiency self-ratings in their first L2, women’s discrimination of Norwegian tonemes was significantly lower than men’s.

Table 2: Means and standard deviations (in parenthesis) of the various measurements for men and women. The last column shows the results of a t-test (\*\* indicates significance after Bonferroni correction at  $p < .01$ ).

	men	women	$t(412); p$
age	22.5 (7.1)	23.0 (7.3)	-0.56; .574
CF IQ score	25.0 (5.1)	24.0 (5.1)	1.96; .050
# L2s	1.4 (0.8)	1.6 (0.8)	-2.50; .013
self-rating 1 <sup>st</sup> L2	2.3 (1.3)	2.7 (1.5)	-2.90; .004**
self-rating 2 <sup>nd</sup> L2	0.7 (1.1)	1.0 (1.2)	-2.40; .018
$A'$	0.74 (0.13)	0.70 (0.14)	3.18; .002**

To account for potential uncontrolled effects of the different testing conditions and contexts in the six experiments, we computed standardized  $A'$  scores for each experiment separately. These standardized  $A'$  scores served as the dependent variable in a multiple regression analysis with age, Culture Fair nonverbal intelligence test scores, the various language background variables, and sex (coded as a dummy variable) as predictors (see Table 3).

Table 3: Results of a multiple regression analysis of all predictors and sex, coded as dummy variable, on standardized  $A'$  scores for toneme discrimination ability.

	$\beta$	$t$	$p$
age	-.073	-1.50	.134
CF IQ score	.161	3.24	.001
# L2s	.049	0.69	.492
self-rating 1 <sup>st</sup> L2	-.071	-1.28	.201
self-rating 2 <sup>nd</sup> L2	.076	1.04	.300
sex	-.152	-3.11	.002

The model accounted for a total of 5.8% of the variance,  $F(6,405) = 5.2$ ,  $p < .001$ , and showed men outperforming women, over and above a facilitative effect of non-verbal intelligence. A further stepwise regression analysis with all predictors entered at the first step, and sex entered at the second step, showed that sex accounted for a unique 2% of variance, cumulative  $F(1,405) = 9.7$ ,  $p < .01$ .

To check whether the effect of non-verbal intelligence was present in both sexes, we performed separate multiple regression analyses for men and women. In both analyses, the only significant effect was that of the Culture Fair test (men:  $\beta = .16$ ,  $p < .05$ ; women:  $\beta = .17$ ,  $p < .05$ ). The relationship between non-verbal intelligence and sensitivity to non-native tonal contrasts in men and women is depicted in Figure 2.

Figure 2: Correlation between Culture Fair scores and sensitivity to Norwegian tonal contrasts for men (black circles, solid line) and women (white circles, dashed line).

## Discussion

Our findings demonstrate a small but significant male advantage in non-native toneme discrimination, which cannot be attributed to sex differences in prior exposure to foreign languages or non-verbal intelligence. The lack of a link between prior language exposure and processing of non-native speech sounds is consistent with similar findings from other studies (Golestani & Zatorre, 2009). Note that the effect of non-verbal intelligence on toneme discrimination ability was independent of the effect of sex, confirming the general link between temporal information processing—which is one component of non-native speech sound discrimination—and psychometric intelligence.

The sex effect may seem unexpected because studies that employ non-native speech sound discrimination tasks or temporal auditory processing tasks typically do not compare the performance of men and women. Moreover, given that the sex effect is very small, the sample sizes in such studies are often not large enough for it to be detectable. However, recently, Bowles, Silbert, Jackson & Doughy (2011) reported a male advantage for discrimination of two Hindi consonant contrasts involving differences in Voice Onset Time in a large sample of 1,185 male and 395 female native speakers of American English. This suggests that the male advantage in temporal information processing clearly extends to the processing of difficult non-native speech sounds containing rapid spectral changes.

What mechanisms may be responsible for this sex effect? Golestani et al. (2007) have shown in a perceptual training study that faster learning of non-native speech sounds, involving rapid spectral changes, was associated with differences in brain anatomy. Specifically, faster learning was linked to larger overall white matter volumes in left Heschl's gyrus and increased degree of left > right asymmetry in white matter density in auditory cortex.

Increased white matter volume may indicate greater myelination, which would result in more rapid neural transmission crucial for perception of rapid spectral changes. It may also be due to a greater number of white matter fibers connecting language regions within and between cortical hemispheres, for example, connecting the auditory cortex with anterior and posterior language regions. Given that for these perceptual learning tasks performance at the outset was highly correlated with speed of learning (Golestani & Zatorre, 2009) it is reasonable to speculate that similar anatomical changes may also distinguish individuals who perform better in perceptual discrimination tasks when presented with a non-native speech sound for the first time. In addition, white matter volume has been shown to be negatively correlated with variability in isochronous tapping in the sub-second range (Ullén, Forsman, Blom, Karabanov & Madison, 2008) suggesting that white matter volume can be implicated in rapid temporal processing in other domains as well.

Comparisons of male and female brain anatomy and cytoarchitecture have revealed larger white matter to grey matter ratios in men than women, and less white matter asymmetry between hemispheres in women (Gur et al., 1999). Gur et al. (1999) suggested that maintaining grey matter volume consisting of somatodendritic tissue—responsible for computation—at the relative expense of myelinated connective tissue—responsible for information transmission—may be a reasonable evolutionary strategy for dealing with the smaller cranial volumes of females, where transmission occurs over relatively shorter distances than in males.

How can these conjectures about the anatomical substrate responsible for a male advantage in temporal processing be reconciled with findings of (a) somewhat higher verbal abilities in women and (b) the absence of mean sex differences in psychometric intelligence? Meta-analyses (Hyde & Linn, 1988; Lynn & Mikk, 2009) have shown a reliable albeit very small female advantage in verbal abilities, mainly related to speech production and reading and writing abilities. This seems to be at odds with the present finding of a male advantage in temporal processing which extends to the processing of non-native speech sounds. However, there is much more to verbal abilities than the processing of non-native speech sounds, making it unlikely that a sex difference in one capacity will dominate the complex interaction of skills required for the various aspects involved in language learning and processing.

Mean sex differences in general intelligence have generally proven to be elusive (Johnson, Carothers & Deary, 2009) despite sex differences in reaction times (Der & Deary, 2006) and temporal processing (Rammsayer & Troche, 2010), – parameters that have been shown to be predictive of general intelligence (Sheppard & Vernon, 2008). The present study is in agreement with these findings as the trend towards slightly higher Culture Fair non-verbal intelligence scores in men was not significant after Bonferroni correction, despite the fact that Culture Fair

scores correlated significantly with sensitivity to the Norwegian tonal contrast. A review of research on sex differences in various timed tests revealed that men are faster on reaction time and finger tapping tests while women are faster in naming and symbol copying and neither sex outperforms the other in general intelligence (Roivainen, 2011). Thus, while reaction time and temporal information processing appear to explain some of the variance in general intelligence, other performance components are also bound to play a role and these components do not necessarily favor men.

It is important to keep in mind that the observed sex effect in non-native speech sound processing was very small. Future research will have to explore to what extent the male advantage in non-native speech sound processing generalizes to other tasks; e.g., identification tasks or AXB-tasks which may be more taxing on working memory or on the ability to form long-term representations of novel speech sounds. It is even less clear whether the male advantage in non-native speech sound processing benefits other aspects of adult foreign language learning, such as morphosyntax or vocabulary acquisition. To clarify these issues, studies of individual differences in various aspects of language learning should include sex as a variable into their analyses.

Despite these limitations, the reported findings underscore the importance of studying sex differences in cognitive tasks as one of the domains that allow researchers to explore potential cognitive repercussions of neuro-anatomical differences.

### Acknowledgments

The authors would like to thank Felix Schaeffler for advice in constructing the stimuli and Neil W. Kirk and James Munro for their help in running the experiments. Parts of this study were funded by a Small Grant from the journal *Language Learning*.

## Abstract

We examine whether reasoning is improved by evaluative feedback, i.e., the information of whether a reasoner's answer was correct or incorrect, and report two studies that show that evaluative feedback increases the chances that participants will produce normatively correct responses for deductive reasoning problems. In Experiment 1, participants who were given feedback about their performance did better on problems based on disjunctions that were designed to elicit illusory inferences. In Experiment 2, participants answered difficult syllogisms with more accuracy when they were provided with feedback. We conclude by contrasting the rule-, heuristics-, and model-based accounts of deduction on their ability to explain the effects of evaluative feedback.

**Keywords:** feedback, reasoning, illusory inferences, syllogisms

## Introduction

People often receive feedback after they have drawn an inference. Feedback can manifest in a contrarian's objection, a pat on the back, a heated argument, or a grunt of disapproval. In many cases, feedback can be *prescriptive*, i.e., it can be accompanied by further instructions and suggestions for improvement, such as what one might receive in a classroom environment. In other cases, feedback can be *evaluative* and devoid of any pedagogical value, such as a final grade in a course. Prescriptive feedback has been shown to improve participants' reasoning on a wide variety of tasks (Cheng, Holyoak, Nisbett, & Oliver, 1986; Khemlani & Johnson-Laird, 2009; Leevers & Harriss, 1999). The effect is robust but unsurprising: if prescriptive feedback could not make better reasoners out of humans, it would be difficult to explain the internalization of rules, heuristics, and insights. Our investigation focuses instead on evaluative feedback, i.e., feedback that neither explains nor characterizes performance as any more than a minimal description of whether performance was correct or incorrect on a particular trial (Neth, Khemlani, & Gray, 2008). We are interested in this impoverished form of feedback because it is unclear what effect, if any, it should have on a person's future performance on similar problems (Klayman & Ha, 1987; Wason, 1960).

Suppose reasoners were told that the deduction they drew from a set of premises was incorrect. Since they have no further information on why their answers were incorrect, it is not clear that the feedback could apply to different sets of premises. Reasoners may remember the structure of the premises so that if they encounter the same problem again, they can provide a correct answer, but there is little reason

to think that the feedback should produce any systematic improvement in reasoning beyond correcting an answer to a particular problem unless reasoners directly search for an explanation of why they went wrong (Walsh & Johnson-Laird, 2009). Moreover, given multiple-choice problems in which the elimination of one answer does not identify the correct answer, evaluative feedback might produce no effect whatsoever. Since memories are susceptible to interference and decay, it is uncertain whether evaluative feedback will have any impact on the ability to solve related but syntactically different problems. Few studies have examined how immediate evaluative feedback informs reasoning (but cf. Wason, 1964), and few psychological theories of reasoning explicitly permit evaluative feedback to modulate the way individuals reason (Braine & O'Brien, 1998; Oaksford & Chater, 2007; Rips, 1994; Stenning & Van Lambalgen, 2008) though there is evidence that the first thing individuals do upon learning that their conclusion is incorrect is to check their reasoning (Johnson-Laird, Girotto, & Legrenzi, 2004).

If feedback influences the way people make deductions, theories of reasoning ought to accommodate such effects by showing how individuals make use of the additional information with which they are supplied. In the following experiments, we show that immediate, evaluative feedback improves the way individuals reason. We conclude by explaining how three prominent theories of reasoning might account for improvements in performance due to evaluative feedback.

## Experiment 1: Sentential reasoning

Experiment 1 presented participants with a set of problems that were expected to yield "illusory" sentential inferences. Sentential inferences are those based on sentential connectives such as *and* (a conjunction) and *or* (a disjunction). Illusory inferences are systematic errors that are produced when people fail to consider all of the possibilities consistent with the premises (Khemlani & Johnson-Laird, 2009). Each problem was based on a set of premises in which one disjunction was embedded within another. The disjunctions were either exclusive or inclusive; for example, consider these premises based on two exclusive disjunctions:

Suppose one of the following assertions is true and one is false:

1. You have the blue candies and the red candies.
2. You have the red candies or else the orange candies, but not both.

Is it possible to have the blue candies and the orange candies only?

Table 1: The four types of problem in Experiment 1, their premises and corresponding questions, the predicted conclusions, and the correct conclusions to each question.

Problem			Conclusion	
Type	Premises	Question	Predicted	Correct
Exclusive-exclusive	One is true and one is false: 1. A and B. 2. B or else C	Is it possible to have A and B only?	Yes	No
Exclusive-inclusive	One is true and one is false: 1. A and B. 2. B or C or both.	Is it possible to have A and B?	Yes	No
Inclusive-exclusive	One or both are true: 1. A and B. 2. B or else C.	Is it possible to have A and C only?	No	Yes
Inclusive-inclusive	One or both are true: 1. A and B. 2. B or C or both.	Is it possible to have A and C only?	No	Yes

The rubric makes clear that there is an exclusive disjunction between assertions 1 and 2. In previous studies participants tended to respond “no”, that it was not possible to have only the blue and orange candies (Khemlani & Johnson-Laird, 2009, Experiments 2 and 3). The answer is illusory, however; the premises allow for the possibility of having only blue and orange candies. The difficulty of problems that yield illusory inferences is robust; even when participants received remedial instructions that explained how to overcome the illusions, they made errors more often than not.

In the present study, participants were provided feedback about their responses. They were randomly assigned to two different feedback conditions: *feedback*, in which participants were informed about whether their answers were correct or incorrect; and *no feedback*, in which they received no information about their performance but rather continued to the next problem after a brief delay.

## Method

*Participants and design.* 53 volunteers were recruited through a platform hosted by Amazon.com through which people participate in experiments over the Internet for monetary compensation (for a discussion on the validity of results from this platform, see Paolacci, Chandler, & Ipeirotis, 2010). None of the participants had received any training in logic. They received four sorts of problems based on disjunctive premises, and all of the problems were designed to elicit an illusory inference. Table 1 presents the four sorts of problems, each of which was presented twice using different materials. We tested two groups of participants; one group received feedback on their answers and the other did not.

*Procedure and materials.* On each trial, participants received a disjunctive set of premises and a question that was intended to elicit a fallacious response. Participants then selected buttons marked “Yes” or “No”. Once the participant responded, there was a delay for 2 seconds during which feedback, if appropriate, was displayed on the

screen. In the no feedback condition, participants received just a delay before moving on to the next problem. Whenever feedback was given to a participant, it replaced the text of the premises and conclusion so that participants did not have access to the problem itself, and could not re-evaluate the premises. The materials used in the study pertained to various combinations of colored candy, and participants received each set of materials only once.

## Results and discussion

Table 2 presents the percentages of correct responses for each group of participants. Participants found the problems quite difficult, and produced correct responses 30% of the time. They made more correct responses when presented feedback than when not (Mann-Whitney test: 38% vs 21%,  $z = 3.00$ ,  $p < .0001$ ).

Table 2: The percentage of correct responses to the four types of problem in Experiment 1 as a function of the type of feedback received.

Problem Type	Received feedback?	
	Yes	No
Exclusive-exclusive	28	12
Exclusive-inclusive	28	8
Inclusive-exclusive	55	27
Inclusive-inclusive	41	35

Participants in Experiment 1 performed better when presented evaluative feedback about the correctness or incorrectness of their answers on problems designed to yield illusory inferences. Likewise, performance did not differ as a function of the order in which the problems were presented; participants in the feedback condition did not do better on the last three trials compared to the first three trials in the experiment (33% vs. 37%, Wilcoxon test,  $z = .68$ ,  $p = .49$ ).

Table 3: The premises of the fourteen types of syllogistic problems used in Experiment 2 and a set of candidate conclusions, which include: a correct conclusion that necessarily follows from the first and second premises; a consistent conclusion that does not necessarily follow from the premises; and the most common erroneous conclusion that reasoners generate.

Problem		Candidate conclusion		
First premise	Second premise	Correct	Consistent	Common conclusion
Some A are B	No C are B	Some A are not C	Some C are not A	No A are C
All A are B	Some C are not B	Some C are not A	Some A are not C	Some C are A
No A are B	Some B are C	Some C are not A	Some A are not C	No A are C
All B are A	No B are C	Some A are not C	Some C are not A	No A are C
Some A are not B	All C are B	Some A are not C	Some C are not A	Some A are C
No B are A	Some B are C	Some C are not A	Some A are not C	No A are C
No B are A	All B are C	Some C are not A	Some A are not C	No A are C
All B are A	Some B are not C	Some A are not C	Some C are not A	Some A are C
Some B are A	No B are C	Some A are not C	Some C are not A	No A are C
All B are A	All B are C	Some A are C	All C are A	All A are C
No A are B	Some C are B	Some C are not A	Some A are not C	No A are C
No A are B	All B are C	Some C are not A	Some A are not C	No A are C
Some B are not A	All B are C	Some C are not A	Some A are not C	Some A are C
Some A are B	No B are C	Some A are not C	Some C are not A	Some A are C

One alternative explanation of the results in Experiment 1 is that instead of making participants better, feedback might have slowed them down so they could read the premises more carefully. A portion of the participants might have initially sped through the study, and if the effect of feedback was to get them to pay attention and stop responding erratically, then the results could be explained without recourse to theoretical claims about performance increases. We are skeptical of such an explanation for two reasons. First, most participants did not respond randomly; they performed reliably worse than chance. Second, every participant received a 2-second delay between trials, and so at the outset they were unable to rush through the study.

Another explanation of the results in Experiment 1 is that instead of making participants perform better, feedback made participants more erratic. The percentage of correct responses was not reliably greater than what would be expected if participants chose responses at random, which could have been driven by a reduction in participants' confidence in their initial answers due to the feedback they received. Likewise, one limitation of the present study is that erroneous disjunctive inferences, while representative of sentential reasoning, come about as a result of a tendency to overlook possibilities (Khemlani & Johnson-Laird, 2009, p. 622). To overcome these limitations, we used a different task and a more diverse set of materials in Experiment 2. Instead of having participants choose between just two alternatives, we provided participants several putative conclusions for syllogistic reasoning problems, only one of which validly followed from the premises.

## Experiment 2: Syllogistic reasoning

Experiment 2 examined whether feedback could help participants discover the correct response to a syllogism from a set of alternatives. Syllogistic reasoning is logically

simple but psychologically complex, and many theories have been proposed to deal with how humans process syllogisms. Modern theories of syllogistic reasoning are based on mental models (Johnson-Laird & Bara, 1984; Polk & Newell, 1995), formal rules of inference (Braine & O'Brien, 1998; Rips, 1994), or the mood of the most informative premise (Oaksford & Chater, 2007).

Not all syllogisms are created equal; some are easy and can be solved in a matter of seconds, and others are so vexing that reasoners may spend many minutes considering their premises. Consider one such problem:

All of the brewers are accountants  
All of the brewers are cashiers  
What must be true?

Reasoners often conclude that all accountants are cashiers, or else that no valid conclusion follows from the premises. The former conclusion is false because not all accountants are necessarily brewers. The latter is false as well, because a valid conclusion exists: it follows that some accountants are cashiers. The moral of the story is that syllogisms are not always easy to solve, and in the present study, we chose those syllogisms that pose the most trouble for reasoners (see Khemlani & Johnson-Laird, in press, for a review).

Participants were once again randomly assigned to the two feedback conditions that were used in Experiment 1, i.e., they either received feedback or did not.

## Method

*Participants and design.* 56 volunteers were recruited from the same participant pool that was used in Experiment 1. All of the participants were untrained in logic, and they completed the experiment using an interface written in Ajax. They received fourteen syllogistic reasoning problems; Table 3 presents the premises of the problems and their

corresponding alternative conclusions. As in the previous study, we tested a group of participants who received feedback against a control group that received no feedback.

*Procedure and materials.* Participants took the study over the Internet, and for each problem they received two quantified premises and four alternative conclusions. The problems were taken from syllogisms identified by previous research as being the most difficult for reasoners (Bucciarelli & Johnson-Laird, 1999; Chapman & Chapman, 1959; Oaksford & Chater, 1999). One of the four alternative conclusions was correct, and the other three were distractors. The distractors consisted of a) a conclusion that is consistent with, but does not follow necessarily from, the premises; b) the most common but incorrect response that participants had spontaneously generated in previous studies (see Bucciarelli & Johnson-Laird, 1999); and c) a “null” response, i.e., “no valid conclusion”. The order in which the alternative conclusions were displayed on the screen was randomized.

Participants were told that only one of the four responses was correct. They registered their response by selecting buttons assigned to one of the four conclusions. When the participant responded, there was a delay for 2 seconds during which feedback, if appropriate, was displayed on the screen. Whenever feedback was given to a participant, it replaced the text of the premises. The materials used in the study pertained to various combinations of occupations, e.g., “All of the brewers are accountants,” and participants received each set of materials only once.

### Results and discussion

Table 4 presents the proportion of agreement to the four different types of conclusions that were presented on each trial. The problems were difficult; across the study, participants agreed to correct conclusions 39% of the time. The feedback (44%) condition yielded reliably more correct responses than the no feedback condition (44% vs. 33%, Mann-Whitney test,  $z = 2.15$ ,  $p < .05$ ), and this pattern held for 10 of the 12 syllogisms (Binomial test,  $p < .05$ ). As in Experiment 1, performance in the feedback condition did not increase steadily; accuracy on the first five trials was not reliably lower than on the last five trials (41% vs. 45%, Wilcoxon test,  $z = .48$ ,  $p = .63$ ).

Table 4: The proportion of agreement to the four types of conclusions in Experiment 2 as a function of the type of feedback received.

Conclusion type	Received feedback?	
	Yes	No
Correct	44	33
Consistent	21	20
Common	26	26
No valid conclusion	9	16

As in Experiment 1, we consider the alternative explanation that instead of making participants perform better, feedback slowed participants down and forced them to read the premises more carefully. The present results are not consistent with this account, because regardless of presence or absence of feedback participants chose the consistent conclusion about 20% of the time. If the feedback motivated them to be more careful, then they would have made fewer errors of interpretation, and we would see a difference between the extent to which they agreed with consistent answers. The uniformity of their answers suggests that in fact, participants were reading and comprehending the problems at the same level of competence regardless of the feedback they were given.

### General Discussion

Across two different paradigms calling for deductive reasoning, evaluative feedback improved performance relative to no feedback. No psychological theory of deduction is constructed to explicitly make predictions about effects of feedback. However, we conclude by examining how the principles of various theories of reasoning might be used to account for the performance gains observed in our studies.

Psychological theories of deduction fall into three broad categories: those based on formal rules akin to those in the proof theory of logic (e.g., Rips, 1994; Stenning & Van Lambalgen, 2008), those based on the processing of subjective probabilities and probabilistic heuristics (Oaksford & Chater, 2007), and those based on models akin to those in the semantic theory of logic (e.g., Johnson-Laird, 1983; Polk & Newell, 1995). Each type of theory yields a different account of how feedback might be integrated into deductive processes to improve reasoning performance.

#### *Theories of deduction based on formal rules*

Theories based on the application of formal rules of inference propose that reasoning is a process of proof in which syntactic rules are used to derive conclusions from the premises. A precursor to reasoning is accordingly the recovery of the logical form of premises to allow the application of rules. Once the logical form has been recovered, rules are applied over the formal structure of the premises to yield conclusions. Theories based on formal rules posit only those rules that allow participants to draw valid deductions, but recognize that humans often make errors in reasoning. For instance, Rips (1994, p. 386) suggests that logical errors are made more often for problems that require more steps of proof or that require complex rules to be applied to the premises. To solve a particular problem, syntactic rules must be utilized to derive a proof of its conclusion, step by step. Thus improvement in reasoning on a given problem can be explained by a) an increased tendency to recognize that a particular rule is necessary, and b) the increased frequency with which the rule is applied. Rips (1994) reports studies of such improvements. If evaluative feedback improves the way

individuals reason, then it should affect the way particular rules are recognized and applied. Thus, rules theories predict that feedback makes it easier to recover the rules relevant to the problem at hand. But it is not clear how rules theories would account for generalized performance increases based on evaluative feedback, i.e., increases in reasoning that affect many rules at once. For complex reasoning problems that require several rules to be applied, a credit assignment problem exists: a reasoner does not know, based on evaluative feedback alone, which rule has been incorrectly applied. The reasoner's performance can increase only if credit is assigned to the rule that was incorrectly applied; otherwise, it is possible that the reasoner does worse on future trials. Rules theories offer no hint at how the credit assignment problem could be overcome, but one solution is to statistically abstract the conditional relationship between the use of each particular rule in all relevant contexts and the ultimate outcome. Such a solution relies on gathering and encoding massive amounts of data, and so it is incompatible with performance increases after only a few trials.

#### *Heuristic based theories of deduction*

The theory of deduction based on probabilistic heuristics (Oaksford & Chater, 2007) assumes that individuals reason by employing simple heuristics based on informativeness and probabilistic entailment. A claim is informative if it rules out possibilities; thus, the universal statement All of the swans are white is more informative than the existential statement Some of the swans are white, because the universal rules out the possibility that some swans are not white, whereas the existential statement has no such constraint. Oaksford and Chater (2007) argue that people use heuristics based on this knowledge of informativeness to select and test conclusions along with heuristics based on probabilistic entailment, i.e., knowledge about whether one premise probabilistically follows from another. For instance, the statement All swans are white probabilistically entails the statement Some swans are white. The authors detail several ways in which individuals might apply the heuristics based on informativity and probabilistic entailment to test and derive conclusions, and show that the predictions made by the heuristics are a good fit for the difficulty of certain syllogisms, i.e., arguments with two or more quantified premises (Oaksford & Chater, 2007, Ch. 7).

Oaksford and Chater argue that for a particular syllogism, individuals construct and test conclusions based on heuristics that require the following pieces of information: 1.) a complete ordering of premises on their informativeness; 2) the quantifier of the least informative premise; 3) a complete account of probabilistic entailments; 4) the most informative premise. Oaksford and Chater suggest that (1) and (3) are immutable whereas (2) and (4) are calculated from the premises of each new problem. According to their theory, a human's departure from a normative answer provided by logic need not be suboptimal, as logic is the wrong normative baseline by which to assess

rationality. If humans "err", they do so not because they do not provide the answer sanctioned by classical logic, but because they are equipped with inexpensive heuristics that are fallible. Chater and Oaksford's (1999) analysis of difficult syllogisms suggest that to provide probabilistically valid responses to syllogistic reasoning problems, reasoners are required to apply all of the probabilistic heuristics specified in the model. As Copeland and Radvansky (2004) observe, the need to apply more heuristics taxes working memory as it requires individuals to hold in mind both the heuristics themselves as well as the results of each heuristic. Feedback may trigger improved performance by inducing reasoners to apply all heuristics instead of just a subset.

#### *Theories of reasoning based mental models*

The mental model theory of deduction (Johnson-Laird, 1983) is based on the notion that individuals reason, both deductively and inductively, by constructing representations of possibilities. The theory proposes that the process of deduction goes through three stages: individuals first use the meaning of sentences and their knowledge to envisage what is possible given the propositions expressed in the premises, and they represent the possibilities as a single mental model. Second, the model is scanned for information not made explicit in the premises, and if any such information is found it is considered a putative conclusion. Third, individuals assess the conclusion by looking for counterexamples, i.e., alternative models of the premises where the conclusion is false. If a counterexample exists, then the conclusion is dismissed and individuals return to the second stage to construct an alternative explanation. Improved reasoning as a result of evaluative feedback can be attributed to the diligence with which individuals form models and search for counterexamples. Reasoners would then use feedback as a cue to fully flesh out multiple mental models and search for counterexamples. These processes require working memory resources to hold the relevant models in mind and operate on them. Thus, increases in executive control as a result of evaluative feedback may improve the ability to consider alternatives and search for counterexamples.

In summary, we showed how three accounts of reasoning can explain why deduction is enhanced by feedback. Mental rules theories predict that feedback must affect individual rules to improve general performance on non-identical problems; however, substantial experience would be required for the reasoner to learn the individual relations between feedback and the use of particular rules across many contexts. The probability heuristics theory holds that individuals apply a series of simple heuristics based on approximations of statistical calculations. Regardless of the normative baseline used, feedback for a particular problem should cue participants to apply all relevant heuristics instead of a subset. Mental models theory posits that individuals flesh out models and search for counterexamples in order to obtain correct answers, and can make mistakes

when they fail to do either. Thus, feedback may prompt the reasoner to search for counterexamples more assiduously, and could lead to general increases in performance across many types of problems.

The results we report demonstrate that feedback and reinforcement can improve the efficacy of conscious reasoning. Theories of reasoning can be extended to handle feedback effects explicitly in the ways we outlined above, and doing so may allow future studies to identify and test the ways in which feedback information implicitly changes reasoners' representations and inferential processes.

## Abstract

We designed an experiment to explore the learning effectiveness of three different ways of practicing dance movements. To our surprise we found that partial modeling, called *marking* in the dance world, is a better method than practicing the complete phrase, called practicing *full-out*; and both marking and full-out are better methods than practicing by repeated *mental simulation*. We suggest that marking is a form of practicing a dance phrase aspect-by-aspect. Our results also suggest that prior work on learning by observation and learning by mental practice may not scale up to complex movements.

**Keywords:** Dance practice; Marking; Mental Simulation; Aspect-by-Aspect.

## Introduction

We report here on a surprising finding in an experiment that compared the relative effectiveness of three different ways of practicing dance phrases. We found that 1) partial modeling of a dance phrase by *marking* the phrase, as it is called in the dance world, is a better method than practicing the complete phrase, called practicing *full-out*; and 2) both marking and full-out are better learning methods than practicing by repeated *mental simulation*. This is surprising because when a dancer marks a phrase they are literally doing the wrong thing – like humming a piece of music instead of singing it. The result raises the interesting possibility that practicing a movement in a simplified manner, or aspect-by-aspect, rather than practicing all of its components at once, may be the best way to practice. In marking, subjects intentionally practice the phrase in an improper form, with distortions, exaggerations, simplifications, even with substitutions such as using hands for legs, or gestures for entire body movements, such as pirouettes. The official reason for marking is to save energy. But we believe that when cleverly mixed, this diversity may provide a powerful method for a dancer to explore the structure of a phrase more exhaustively than regular full-out practice.

Figure 1. The three conditions in the experiment.

This idea challenges common sense and previous work on complex motor learning. It is common sense that practicing something the way it should be performed ought to be more effective than practicing it with intentional distortions, or with essential components missing. If that were not so then repeatedly drawing a face in caricature rather than drawing it realistically ought to lead to drawing the face more realistically later. Similarly, practicing tennis strokes without a ball, or using the wrong approach and form ought to lead to better shots, at times, than always practicing in proper form. It is noteworthy that experiments have shown that both these marking-like methods are, at times, better forms of practice than always practicing in an undistorted, full way. In music performance, for example, using exaggeration in rehearsal is thought to be a helpful method of practicing, delivering results that surpass repeated full-out play [Hinz, 08]. Musicians practice passages both faster and slower than written. It is standard to manipulate phrasing, dynamics, articulation, intonation, and tempo, to name a few. [Chaffin et al 2002, Friberg et al, 06]. In sports viewing, [Hill & Pollack, 00; Pollack et al 01] found that subjects have learned to recognize complex actions better, such as certain types of tennis strokes, when some of the parts of the stroke have been exaggerated. Evidently, marking may have a place in training. But as a general method, practicing *only* distorted versions of the real thing, or versions that leave out essential components, is a counterintuitive method of rehearsal. Our unanticipated result is that this counterintuitive method is effective.

Our findings also challenge work on mental simulation. In sports psychology, imagery is often referred to as cognitive enactment or visualization, and is one of the most popular performance enhancement and rehabilitation techniques. It has been shown in numerous studies that mental simulation in sports contexts can significantly improve an athlete's performance on measures of style, speed and strategy. [Weinberg 08]. In music, Pascual-Leone [2001] reported a similar finding about learning to play a five-finger exercise on a piano keyboard. After five days, the group that mentally simulated playing, performed an exercise comparably to the third day level of those who practiced physically. All these experiments showed that mental practice leads to substantial improvement. We therefore came to the experiment believing our dancers would significantly benefit from their ten minutes of mental simulation.

Failure to find this improvement from mental simulation also bears on the findings of [Cross et al, 09], who, in several experiments, found that repeated observation of a target phrase – and hence ‘practice’ in the motor resonance system – leads to comparable performance to full-out physical practice. Simulation has been shown to facilitate in much the same way as observation – by activation of covert actions via the motor resonance system, [Jeannerod, 01]. The unexpected result by Cross et al [op cit] was found to hold for learning the rhythm and steps for pieces in a game like Dance Dance Revolution (DDR), where subjects must stamp their right or left foot onto footprints on a mat in time with music. Subjects watched the video repeatedly and may have played covertly. In our experiment, the phrases to be mastered were far more complex than DDR, involving movement of the entire body, with dynamics and feeling, and not driven in response to a stimulus. And they were simulated and not observed. But if observation works so well there is reason to suspect that mental simulation should not as well.

If our results about marking are true then marking during dance practice should not be seen as a sign of fatigue or laziness, as so often it is in dance studios. Rather, it may be a strategic method for selective training. This opens the door to developing more effective methods of selectively working on ‘aspects’ of a phrase. This likely applies to domains other than dance. We speculate that the success of marking also tells us something about how the body itself can be used to help manage attention, improve focus and even facilitate simulation in a selective way. The body may well draw attention to what is important in the way a hand in speed-reading drags the eyes along so that a speed reader can move through the page faster and more effectively. It is yet another way the body itself can be involved in cognition.

**Conjecture and Method.** In designing the experiment, our conjecture was that:

- practicing a dance phrase full-out would lead to better performance than mental simulation, and
- marking would lie somewhere in the middle: better than mental simulation but worse than full-out.
- Mental simulation would also lead to better performance.

Owing to the presumed power of the motor resonance system we wanted to see if anything *extra* would be gained by adding body activity to the mental simulation and projection we thought already occurred during marking. Our belief was that dancers would learn something from marking, just not as much as from practicing full-out. To test this idea we used the dancers from Random Dance, the contemporary company we have been studying. [Kirsh et al, 09; Kirsh, 12] All are super-experts, having been chosen from an audition pool of 800 professional dancers throughout Europe and the States.

**Procedure:** The design required dividing the ten dancers into three groups: A, B, C. All three groups were then brought into the studio and taught a dance phrase new to them, lasting about 55 seconds. The dancers were taught this phrase during a 10-minute teaching period, and at the end of it, the group left the studio and the dancers returned, one by one, to the studio and performed the dance in front of the teacher. As shown in figure 1 above, there were three conditions: practicing full-out, practicing by marking the phrase, and lying still mentally simulating the phrase. After the first round the dancers changed condition and were taught a second phrase of about the same duration and complexity as the first. The experimental design is a 3 by 3 Latin Square where each group is run in each condition. Thus, if group A started by Marking, they progressed to Full-Out, and then finished in the third trial in the Simulation condition.

Each dancer’s performance was graded according to established criteria (technicality, memory, timing, and dynamics – discussed below), first by the teacher in real-time and later by two independent expert observers who reviewed the video frame by frame. Once all dancers were graded, the group returned to the same large studio and practiced the dance for 10 minutes. While practicing they were asked to face in different directions and not look at each other. Once this 10-minute practice period was over they left the studio and, as before, returned one by one to be graded by the same criteria as before. See figure 2. Learning is understood as the change in grade acquired during the 10-minute practice phase.

**Figure 2.** The temporal structure of the experiment is displayed. There were three trials.

**Measures:** In mastering a dance phrase it is customary to be evaluated on technicality, memory, timing and dynamics.

**Technicality** means the level of precision in positions and transitions. Are the forms full and well-formed (e.g. juicy, fully rounded)?

**Memory**, or level of detail, refers to the completeness of each movement. Was something left out – a hand gesture, a turn, a foot angle?

**Timing** refers to the duration of individual steps and the duration of the transitions. Our timing coder used frame-by-frame measures of timing for great precision in comparing test conditions to the target standard.

**Dynamics** refers to the force, speed and acceleration of movements. Also included are various qualities of motion – resistance, emotionality, and intentionality.

On analyzing the experimental results we found that:

- 1) Marking was the most effective method of practicing, being slightly more learning efficient than practicing full-out ( $p = .0189$ );
- 2) Both marking and full-out led to substantially more learning than mental simulation ( $p = .0001$ );
- 3) Mental simulation was not a strong form of practice; there was negligible improvement between pre and post tests in the simulation condition and in many cases it led to a decrease in performance.

Our finding both support and violate our hypotheses. We were correct that the learning achieved by marking is more effective than mental simulation (mean difference = 1.19, with  $p < .0001$ ) across the key dimensions of Memory, Technique and Timing. But we were surprised by its magnitude. We were greatly surprised that marking is more effective than Full-Out (mean difference = .31, with  $p = .0189$ ), though the difference is quite modest. We were also surprised that mental simulation did not facilitate at all. To compute these values we first performed one-way ANOVA's on all measures in all conditions and found highly significant differences throughout. We then ran pair-wise post-hoc comparisons (Tukey's HSD) and computed p values as shown in table 2. All p values were computed over z-scores to reduce noise caused by variability in dancers, measure-types, and graders.

**Table 1.** Mean improvement from practice (the learning delta), as measured on a 5-point scale. The absolute difference in delta between Marking and Full-out is 0.31, which is significant when measured by the z-score for Technicality, Memory and Timing ( $p = .0189$ ). Full is better for Dynamics but not significantly ( $p = .145$ ).

**Table 2 P values**

Measure	M>F	F>M	M>S	F>S
Memory	.7334		<.0001	<.0001
Technicality	.0029		<.0001	.0005
Timing	.0194		<.0001	<.0001
Dynamics		.145	.0003	<.0001
Mem, Tech, Timing	.0189		<.0001	<.0001

We assumed that marking would add something to mental simulation because somehow the process of marking would facilitate mental simulation rather than

interfering with it. Our main idea of a mechanism is that marking provides a physical anchor for mental simulation, thereby scaffolding imagination and leading to higher realism in simulation and increased priming of motor preparation. (See Kirsh, 10) We found qualitative support for this idea from interviews with the dancers. When asked what they think about when marking our subjects reported that they have in mind the full-out movement – though with fewer dynamics. They do not ‘see’ themselves as dancing in a distorted way, as they would if observing themselves in the mirror. They project off of their movement to the normative movement they want to be making. This is the movement they have in their mind’s eye. Marking seems to serve as a physical scaffold for projecting movement imagery. Thus, part of our conjecture was right: marking is better than simulation, though nothing we found proves our conjectured explanation of why it is better (i.e. projection). We were surprised, however, by just how much more effective marking is than mental simulation as a practice technique.

We also found that marking is better than full-out as a practice technique. This falsified our conjecture that full-out practice is the best form of practice.

**Table 3.** Marking was significantly better than Full-out for learning the aspects of a phrase related to technicality and memory and trending to significance in timing. Not surprisingly it was less effective at learning dynamics, which are rarely practiced in marking. Mental simulation was most effective (but still yielding zero or negligible improvement) for thinking about technical elements (precision in movement). It led to decreased performance – negative learning – for movement details.

**Marking vs. Full-Out Discussion:** There are a few possible explanations why marking is better than full-out. The simplest is that it is possible to mark more steps in a 10-minute period than it is to execute them full-out. To explore this idea we coded the video’ed activity of four dancers as they practiced their phrase in the experiment: two subjects in marking, were compared with two subjects in full-out, for each phrase. The results unambiguously show that the marking group performed significantly more steps and repetitions than the full-out groups. See table 4. The reason marking might be a

better way to practice, then, may be as simple as that dancers get in more trials in the same time by marking than by working full-out.

Phrase	Marking	Full-Out
I	351	275
II	317	300
III	317	188
<b>Mean</b>	<b>328</b>	<b>254</b>

**Table 4.** A simple enumeration of the number of steps executed in marking vs. full-out, matched by phrase.

Related to this number of steps argument is that marking might be a better form of practice because it is easier to fast forward or skip quickly through steps when marking, or to jump completely to new sequences. Full-out requires correct timing so there is no such thing as fast forward. Jumping to new sequences or sub-sequences is possible but it seems to be harder for dancers. From reviewing the steps that dancers practiced full-out we observed that the average sub-sequence was longer in full-out than in marking. See table 5. We observed this same phenomenon in actual dance sessions, where dancers jump to different parts of a phrase more often during marking.

**Table 5.** The string-of-steps, on average, is shorter for marking (12) than full-out (19). A string-of-steps is a sequence of steps performed in the right order. Dancers jump around within and between sequences more often when marking than when practicing full-out. In full-out, dancers alternated between very long and very short string-of-steps.

A second possible explanation of why marking is best is that in full-out practice there are more aspects to attend to at once. Not all aspects are equally in need of practice. Every step has many qualities. For instance, in Laban Movement Analysis [Newlove, 05], a distinction is drawn between ‘effort qualities’: flow (free/bound), weight (light/heavy), time (sustained/sudden), space (direct/indirect) and ‘shape qualities’: Rising/Sinking, Spreading / Enclosing, Advancing / Retreating, Growing / Shrinking. In practice, a dancer cannot attend equally to all these qualities simultaneously. Attention must be focused more narrowly. When practicing full-out,

however, dancers need to execute a movement as near to its full form as they can. This suggests that narrowing in on to a single aspect to practice will be harder because all aspects must be performed at once.

It seems, therefore, that marking offers dancers just what they want: a way of working on their movements aspect by aspect. Dancers do not think they are dancing incorrectly when they mark; they think they are dancing incompletely. They are focusing on some aspect of each step – its timing, extension, path or shape.

This ability to confine attention selectively may also explain why marking is better than full-out in remembering details. Intuitively, marking is akin to ephemeral sketching, instead of using a paper of pencil to sketch, dancers use their bodies, and the sketch is gone as soon as it made. But, ephemeral or not, dancers can still work on specific aspects of movement, the way their hands or feet specifically should move. They can cycle back to these parts while leaving everything else stationary. This is something dancers cannot do when dancing full-out. This reinforces the idea that by marking they can practice in a more incremental, piecemeal fashion than when practicing full-out. During one pass a particular aspect of a movement can be the center of attention, whereas another aspect can be the center of attention on a second pass. To be sure, the final conception of the target object requires the subject to integrate and assemble the aspects together in a unified whole. So there remains a puzzle about how a subject can come up with an effective whole movement from a set of disparate aspects that may interact in complex ways. This need for integration may impose limits on the effectiveness of marking as a learning method. But it also suggests that if aspects are relatively independent from each other, then marking can be an effective way of practicing because it facilitates a divide and conquer strategy: work on the problematic parts of a phrase and then assemble all parts into the final product. This is likely to be a more powerful method than practicing a target phrase holistically, whether through mental simulation or full-out.

**Marking vs. Mental Simulation Discussion:** Prima facie, one reason mental practice – mental simulation – is less effective than marking is that when simulating, subjects do not receive sensory feedback from the body and the environment. In marking, by contrast, there is additional information available that a subject may use to reduce error. For instance, there is input about balance, gravity, weight and inertia. These physical features are not available through mental simulation, at least not in any realistic manner. This extra input from the physical world also means that dancers can re-evaluate their movement in a different way on the basis of how they interpret their perception of their own movement. The paradox of marking, however, is that the literal feedback from the body during marking is distorted feedback. Subjects are dancing incorrectly (in a very literal sense).

So the literal feedback they might use to determine an error measure, and so to sharpen their form, is not correct.

To resolve this paradox the place to start is with the dancers' own comment that when marking they have in mind their full-out movement, that marking is the physical scaffold for projecting to this normative imagery. To explain how an imperfect model of a movement – which is what marking literally is – can behave as a physical scaffold we need to introduce a few ideas. We begin with the concepts of projection, imagination and anchoring.

Projection is akin to attaching a mental image to a physical structure. When we project onto an object, we experience ourselves intentionally augmenting the object. The object anchors our mental image, and successful projection requires spatially locking the projected image onto the anchoring structure. To spatially lock, the mental image to be attached must be the right size and be connected to a specific location on the external structure.

When we *imagine* an object, we again are dealing with mental images but we do not attach it to anything in the seen world. It has no anchor and it need have no particular size. Mental simulation is a kind of imagination.

**Fig 4.** The differences between, projection and imagination can be understood as projecting an image of X and O onto a blank tic tac toe grid versus imagining an X and O on a grid while staring at a blank sheet of paper or better still, when blindfolded.

In Kirsh [09a], the results of running 20 subjects playing tic tac toe in the projection and imagination conditions was reported. To play the game all subjects first learned to name cells using 1 to 9 for a three by three board. They then would call out their move after hearing their opponent's. The numbers 1 to 3 were used for the top row, left to right, 4-6 for the middle row and 7 to 9 for the bottom row.

The results were not simple. Subjects did not play tic tac toe faster in the 3 by 3 condition in any condition, which we had predicted. Having a grid to anchor projection did nothing in the three by three game where subjects rarely needed to recall more than 5 or 6 moves. To challenge the subjects, we then taught them to play four by four games. Here the visual memory load is greater and we found that having a grid appears to facilitate subjects. Projection > Imagination ( $p = .002$ ). As predicted a grid now serves as an understructure or scaffold for projecting moves. However, given the unhelpfulness of a 3 by 3 scaffold it seems that the value of a scaffold increases with the complexity of task. In fact, scaffolding may be necessary for successful mental

simulation of harder problems. This may explain why Cross et al found observation to be facilitative in simple dance whereas we found that mental simulation of complex dance was not facilitative.

Anchoring projection, therefore, is one possible explanation why marking helps dancers. The major limitation of this view is that anchoring and projection are themselves inadequately understood. For instance, how does anchoring a projection differ from using an external structure or process as a mediator, an idea that regularly surfaces in discussion of the effects of culture and learning [Vygotsky, 78; Wertsch, 07]?

Here's a case in point. If a musician uses his foot to keep beat, does his tapping anchor his projection (and performance) or mediate it? In this instance, the reason to call it an anchor is that the target rhythm is not a regular beat per se – the rhythm he taps – it is the musical rhythm played 'on top of the beat' (e.g. da joom da joom, daah tika daah tika). He is thinking about the rhythm and using his beating as a stable pulse to help him. This is analogous with the tic tac toe grid, because, presumably, the beat is running on an automatic oscillator, [Eck et al, 00] liberating higher motor planning centers to work on different, but coordinated, sorts of covert actions. Beating is a way of scaffolding rather than mediating the correct rhythm.

Compare tapping a basic rhythm with the gestures an orchestra leader makes as he conducts a musical piece. Once again the underlying beat is embodied, though gesturally now rather than by tapping a foot. But a conductor also adds emphasis to help instrumentalists interpret the music. By gesturing a conductor directs musicians to attend to specific musical features. Are those gestures anchoring the musicians' projection? Or are they mediating their performance, without relying on a third thing called projection to help them perform? Projection seems a mental extra, pointless. The musicians can follow the conductor's directions immediately, without a further process of projecting what they need to do.

Contrast conducting with this last case. In [Frank & Barner, 12] elementary students in Gujarat, India, were taught to add and multiply using an abacus and then asked to perform calculations without the physical abacus. This practice, known as mental abacus, involves visual manipulations of an imagined abacus. Interestingly, when students work on their mental abacus they almost always flick their fingers, miming the movement of the beads. Performance suffers when abacus users are not permitted to use their hands (Frank & Barner, *ibid*; Hatano, 77]. Apparently, gesture plays a vital role in creating, or at least sustaining, mental abacus structures. Hand motions interact with the visual system, improving mental simulation. As before we cannot say whether this process involves projecting off of gestures or is better understood as some sort of meditational process. But projection seems the simpler account. Gestures scaffold mental imagery for the human calculator.

## Conclusion

In this study we set out to test whether marking is a more effective form of practice than mental simulation. It is. We also found that marking seems to be a better form of practice than the standard method of dancing full-out, and that mental simulation did not facilitate learning as it typically does.

When looking for the cause of marking's power we speculated that marking might function as the understructure for projection. When marking, a dancer creates a physical scaffold that facilitates projection. This would explain what 'extra' dancers get by physically marking a phrase rather than mentally rehearsing it. They get an external structure they can extrapolate from. This enables them to generate a conception of the final target that is more vivid, complete, and requiring less mental effort than the targets they imagine when they mentally rehearse without the support of overt movement. So it is not that a dancer is either marking or mentally simulating: marking is way to do mental simulation better.

We speculated further that mental simulation performed poorly because the target structure was a complex dance phrase about 1 minute long and this level of complexity exceeds most studies of the use of simulation.

Lastly, we conjectured that dancing is more effective than full-out because it allows dancers to focus on aspects of their movement rather than on all aspects at once, which is what is required during full-out. In music and most sports, it is customary to work on aspects of one's performance rather than working on everything all at once. Marking is tailor made for that purpose.

The success of marking warrants rethinking the best ways to practice motor activities.

## Abstract

The question of under what conditions conceptual representation is compositional remains debatable within cognitive science. This paper proposes a well developed mathematical apparatus for a probabilistic representation of concepts, drawing upon methods developed in quantum theory to propose a formal test that can determine whether a specific conceptual combination is compositional, or not. This test examines a joint probability distribution modeling the combination, asking whether or not it is factorizable. Empirical studies indicate that some combinations should be considered non-compositionally.

**Keywords:** conceptual representation; compositionality; context; probabilistic tests

## Conceptual Representation

Within cognitive science, the question of how to represent concepts is still being debated. Different positions have been put forward (e.g. the prototype view, the exemplar view, theory theory view), and Murphy (2002) contrasts some of these positions. He asks which is most supported by the various aspects of cognition related to conceptual processing, but concludes somewhat disappointingly, that “there is no clear, dominant winner”. Here, we take the position that it is possible to progress by asking a broader question about the nature of concepts; can they *always* be modeled compositionally? Or do they sometimes take a non-compositional form?

Some arguments for compositionality center around the systematicity and productivity of language; there are infinitely many expressions in natural language and yet our cognitive resources are finite. Compositionality ensures that this infinity of expressions can be processed, as it allows an arbitrary expression to be understood in terms of its constituent parts. Since compositionality is what explains systematicity and productivity, Fodor (1998) claimed that concepts *must be* compositional, however, this is at odds with prototypicality effects (Frixione & Lieto, [In Press]; Fodor, 1998). For example, consider the by now well known conceptual combination PET FISH. A “guppy” is not prototypical PET, nor a prototypical FISH, and yet a “guppy” is a very prototypical PET FISH (Hampton, 1997). Therefore, the prototype of PET FISH cannot result from the composition of the prototypes of PET and FISH, and so the characterization of concepts in prototypical terms is difficult to reconcile with compositionality (Hampton, 1997; Fodor, 1998). This supports a view put forward by Weiskopf (2007) when he observed that conceptual

combinations are “highly recalcitrant to compositional semantic analysis”.

Here, we take a novel approach to this debate, by providing a mathematical test which determines whether a conceptual combination can be considered compositionally, or not. We start with a consideration of what compositionality might mean probabilistically.

## Probabilistic Models of Compositionality

Figure 1 represents a basic probabilistic scenario involving a ‘black box’ composed of two proposed subsystems,  $A$  and  $B$ . What would it mean if this system was declared to be compositional? Acknowledging that it is the experiments which can be performed upon this system (and their likely outcomes) that will define this notion allows us to move beyond philosophy and into the realms of a mathematical definition.

Figure 1: A potentially compositional system, consisting of two identifiable sub-components  $A$  and  $B$ . The system can perhaps be understood in terms of a mutually exclusive choice of experiments upon those sub-components, one represented by the random variables  $A1, A2$  (pertaining to an interaction between the experimenter and component  $A$ ), and the other by  $B1, B2$  (pertaining to an interaction between the experimenter and component  $B$ ). Each of these experiments can return a value of  $\pm 1$ , representing yes and no.

We define a compositional system as one which can be validly decomposed in such a manner that different experiments can be carried out upon each of its sub-systems, and that these will answer a set of ‘questions’ regardless of the experimental behavior of any other sub-systems. For the sake of simplicity, we shall assume that the answers to these questions are binary, they might be termed ‘yes’ and ‘no’, but are for generality labeled as  $+1$  and  $-1$ .<sup>1</sup> Standard probabilistic reasoning suggests that

<sup>1</sup>This assumption is more reasonable than it might at first appear: it is always possible to break a complex question into a set of simple binary questions, as the popular game

it is possible to describe this behavior in terms of four random variables representing the bivalent outcomes:  $\{\mathbf{A1}, \mathbf{A2}, \mathbf{B1}, \mathbf{B2}\}$ . What analysis can be brought to bear upon such a situation? As with many systems, the outcomes of our experiments will have a statistical distribution over all available outcomes, and it is possible to develop a set of probabilistic arguments about this scenario. For example, it is possible to consider the joint probability  $\Pr(\mathbf{A1}, \mathbf{A2}, \mathbf{B1}, \mathbf{B2})$  describing the likely behavior of our experimental black box, however, this very formulation forces us to consider what exactly a non-compositional probability distribution *would look like*. This paper is devoted to answering this question, but in order to approach the answer, we must first provide a model of non-compositional behavior, and this is not an easy task; almost all of our mathematical formalisms are based upon a notion of compositionality (Kitto, 2008). However, one mathematical model is widely accepted as non-compositional, Quantum Theory (QT), and so we take this formalism as the basis of our formulation of non-compositional behavior. Our reasons for this choice will become clearer from a psychological perspective as our argument progresses.

## Senses and Concepts

Our model takes Gärdenfors (2000) conceptual space as its starting point, extending this notion through the use of a vector space representation of concepts. For the purposes of this paper, we shall construct this representation through reference to the word association networks and vocabulary of the human mental lexicon, although this is not a necessary step for the formalism proposed; any sensible vector space construct would suffice if it has a similar structure to that discussed below. The Univer-

Associate	Probability	Associate	Probability
<b>ball</b>	<b>0.25</b>	<b>fighter</b>	<b>0.14</b>

animal	0.02		
...	...		

(a)

(b)

Figure 2: The free association data for two words, (a) bat, and (b) boxer. Both cases show a clear division of each concept into a sport sense (highlighted in bold), and an animal sense.

sity of South Florida (USF) word association data maps the strength of word associations displayed by a large sample of psychology students over a period of 30 years

of 20 questions illustrates. Quantum theory has provided a more sophisticated proof of this result using the Spectral Decomposition Theorem (Isham, 1995).

(Nelson et al., 2004). In Figure 2 we see a set of association strengths for two words, “boxer” and “bat”. Note the manner in which both words can be attributed a meaning that belongs to one of two *senses*; an animal sense and a sporting sense. Thus, we claim that the concepts BOXER and BAT are both ambiguous. Despite this ambiguity, humans are adept at recognizing the sense that is intended for an ambiguous word. They do this through reference to the context in which the word is being used, and this context might depend upon a wide range of factors (e.g. the co-occurrence of other words spoken before and after, the history of a conversation, the social context of the speaker). We note at this point that even our simple scenario has far more ambiguity than has appeared in the USF data (e.g. some people would interpret boxer as a pair of shorts, and someone could bat their eyes etc.), indeed, there are a wide range of very fine gradations in meaning that might be attributed to even these simple concepts. This added complexity can be dealt with in our model through an extension of the state space to higher dimensions, and through the use of a more sophisticated set of data<sup>2</sup> to construct the vector space model that we shall present.

In the next section we shall show that it is possible to construct a simple model of this ambiguity and its contextual dependency through use of the quantum formalism.

## A Quantum-Like Model of Word Associations

Figure 3: (a) A concept  $w$ , for example *bat*, is represented in some context  $c$  which takes the form of a basis  $\{|0\rangle, |1\rangle\}$ . (b) Changing the cue might change the chance of recall.

A simple model of the manner in which context might affect the interpretation that a subject ascribes to an ambiguous word can be constructed through the use of a *superposition state*, which is a novel concept of a state arising in Quantum Theory (QT). In Figure 3(a), an ambiguous word  $w$  is represented in some context  $c$ , as a superposition of recalled,  $|1\rangle$  and not recalled  $|0\rangle$  within the mind of a subject. When presented with a cue (rep-

<sup>2</sup>Such as the one being collected here: <http://www.smallworldofwords.com>

resented by the context  $c$ ) the subject might return word  $w$ , or not, with some probability. These probabilities can be estimated through reference to the online USF data,<sup>3</sup> which, in the context of a cue word “ball” suggests that a subject will recall the concept BAT with a probability  $Pr(BAT|ball) = .19$ , or they might recall something else ( $Pr(\overline{BAT}|ball) = .81$ ). We put this data into the quantum superposition state of Fig. 3(a) and so represent the cognitive state of our subject in the context of being presented the cue word “ball” as

$$|BAT\rangle_{ball} = \sqrt{0.81}|0\rangle_{ball} + \sqrt{0.19}|1\rangle_{ball}. \quad (1)$$

Figure 3(a) represents these probabilities *geometrically* using the measurement postulate of QT (Laloë, 2001; Isham, 1995), but this same state can be easily obtained through use of the Pythagorean theorem.

This simple model is made more interesting in Figure 3(b), where we have represented the fact that a different context (in this case a cue, but context could be a more complex semantic component) might result in a different set of recall probabilities. Thus, we could represent BAT as the superposition in the cognitive state of a subject when presented with the cue “cave”:  $\sqrt{0.94}|0\rangle + \sqrt{0.06}|1\rangle$  so giving a 6% probability that the word “bat” will be recalled by a subject who is presented with this different cue (or context). We see that the word “bat” is more likely to be retrieved from memory when a subject is presented with the cue “ball” than the cue word “cave”, and this change in probability can be obtained from the *same initial cognitive state* through a shift (i.e. a rotation) in the basis vectors representing the context in figure 3(b).

How should we consider the combination of two words in this model? While it is possible that a simple tensor multiplication of the two superposition vectors might suffice, this is not necessarily the correct mechanism (Bruza et al., 2009). Indeed, it seems possible that not all senses of a word remain accessible during conceptual combination. Thus, it might prove to be the case that a BOXER BAT is only ever interpreted by human subjects as “a small furry mammal with boxing gloves on”, or “a toy bat that a boxer dog chews on”, which would imply a case of perfect anti-correlation in the senses attributed by a subject to the combination. That is, considering the interpretation of the novel (i.e. non-lexicalized) conceptual combination BOXER BAT in the context of two priming conditions, one applied to each of the concepts in the combination (e.g. BOXER primed by “dog” and BAT by “ball”) we denote a concept which is recalled with the same sense as that for which it was primed as 1 and a failure to return in this sense by 0. For this scenario we might find that not all possible combinations of

the two senses in the combination can be realized. For example, we might find that a subject’s cognitive representation of BOXER BAT should be represented as

$$|BOXER\rangle \oplus |BAT\rangle = a|01\rangle + b|10\rangle, \text{ where } |a|^2 + |b|^2 = 1. \quad (2)$$

denoting a scenario where either BOXER has a sporting sense and BAT an animal sense ( $|01\rangle$ ) with probability  $|a|^2$ , or BOXER an animal sense and BAT a sporting sense ( $|10\rangle$ ) with probability  $|b|^2$ .

Such a cognitive state has profound consequences for the notion of compositionality. Indeed, QT has consistently shown that similar states *cannot* be interpreted compositionally (Isham, 1995; Laloë, 2001). Thus, if a similar set of experiments can be found that apply to human language processing, then this would give strong support for the claim that language cannot always be considered compositionally. The remainder of this paper will briefly sketch out recent work which attempts to test for such non-compositional conceptual behavior (Kitto et al., 2010, 2011; Bruza et al., 2012).

## Tests of (Non-)Compositionality

QT has a well developed suite of tests that can be applied to systems of the form shown in Figure 1, and these can be quickly adapted towards the the analysis of compositionality in language. For example, it is possible to construct a variation of the Clauser–Horne–Shimony–Holt (CHSH) inequality (Isham, 1995; Laloë, 2001), using an analysis derived from Cereceda (2000), which tells us that a system of this form can only be described as a combination of it’s subcomponents if:

$$\begin{aligned} 2 \geq \Delta = & |2(\Pr(\mathbf{A1} = +1, \mathbf{B1} = +1) \\ & + \Pr(\mathbf{A1} = -1, \mathbf{B1} = -1) + \Pr(\mathbf{A1} = +1, \mathbf{B2} = +1) \\ & + \Pr(\mathbf{A1} = -1, \mathbf{B2} = -1) + \Pr(\mathbf{A2} = +1, \mathbf{B1} = +1) \\ & + \Pr(\mathbf{A2} = -1, \mathbf{B1} = -1) + \Pr(\mathbf{A2} = +1, \mathbf{B2} = -1) \\ & + \Pr(\mathbf{A2} = -1, \mathbf{B2} = +1) - 2)| \quad (3) \end{aligned}$$

This formula (and a number of variations of it) has a substantial history in the physics and philosophy literature (Laloë, 2001; Shimony, 1984), and lack of space prevents a detailed explanation, however, we can briefly motivate its usage through a discussion of figure 1 and of the potentially compositional nature of the system it describes. Each subsystem  $A$  and  $B$  is represented by random variables:  $\{\mathbf{A1}, \mathbf{A2}\}$  and  $\{\mathbf{B1}, \mathbf{B2}\}$ , denoting whether a particular sense was observed (+1), or not (−1) under a given experimental arrangement. For this system, compositionality is expressed in terms of a *factorizable probability distribution*:  $\Pr(A, B) = \Pr(A) \Pr(B)$ . The syntax of this equation clearly shows how the model of the combined system is assumed to be expressed a product of the distributions corresponding to the individual subsystems  $A$  and  $B$ . When the inequality in (3) is violated, such a

<sup>3</sup>These numbers are obtained by finding the value for “bat” in the “cave” matrix that is depicted at <http://web.usf.edu/FreeAssociation/AppendixC/>.

compositionality assumption does not hold. Thus, the  $\Delta$  value in (3) gives us a clear criterion for deciding whether a given concept combination should be considered compositional or not. In a set of recent work (Kitto et al., 2010, 2011; Bruza et al., 2012), we have performed a number of experiments aimed at testing our formulation of the compositional hypothesis, and we shall now briefly discuss these results.

## Empirical Evaluation

We utilized four different priming regimes in order to generate the four different experimental scenarios required by Fig. 1. These experiments start by biasing subjects towards a particular interpretation of a non-lexicalized conceptual combination through exposure to words that have a particular *sense* representing the underlying concept. They then ask subjects to interpret the conceptual combination, and to designate the senses that they used in that interpretation. If conceptual combinations such as BOXER BAT are genuinely compositional, then it seems reasonable to assume that “vampire” primes BAT but has no priming effect on BOXER. A probabilistic analysis using (3) was performed upon the data obtained to test this assumption.

Table 1 lists the set of ambiguous conceptual combinations chosen, as well as the primes used to bias subjects towards each of two senses for the respective concepts. Primes were selected from the USF norms (Nelson et al., 2004) and the trials were composed of six phases.

**Phases 1-2:** Two consecutive double lexical decision tasks were carried out, where participants were asked to decide as quickly as possible whether two strings, a prime and the concept to be presented as a part of the compound given in Phase 3, were legitimate words, or if one of the strings was a non-word. Participants responded by pushing a button on the keyboard, labeled ‘word’ or a button labeled ‘non-word’ (left arrow and right arrow keys respectively). For instance, if given the strings “coil” and “spring”, then participants were expected to decide that both strings are words and so push the ‘word’ key, whereas if given “grod” and “church” then participants were expected to decide that they had been shown a non-word combination and to push the ‘non-word’ key. Each lexical decision consisted of the the two letter strings presented in the center of screen, one below the other. They were presented in this arrangement to discourage participants from interpreting the two words as a phrase. As soon as the participant responded, the screen was replaced by a blank screen for 800 ms, which was then immediately followed by the second lexical decision phase. The participant’s second lexical decision was followed by a 800 ms blank screen, and then immediately followed by phase 3. For example, one lexical decision task exhibited “coil” and “spring”, and was designed to prime the mechanical sense of the concept SPRING in

the conceptual combination SPRING PLANT. The order of the two double lexical decision tasks was counter-balanced, so that half were presented in the same order as the compound words (e.g., “coil” and “spring” are first presented, then “factory” and “plant”) and half were presented in the reverse order (e.g., first “factory” and “plant” are presented for lexical decision, followed by “coil” and “spring”). **Phase 3:** A bi-ambiguous conceptual combination was presented in the center of the screen (e.g. “spring plant”). Participants were asked to push the space bar as soon as they thought of an interpretation for the compound. Filler compounds were included for the filler (i.e. non-word) trials so as not to disrupt the participant’s rhythm in making two lexical decisions followed by an interpretation. **Phase 4:** Participants were asked to type in a description of their interpretation. **Phases 5-6:** Two disambiguation tasks were carried out, where participants choose what sense they gave to each word from a list (e.g., plant = A. ‘a living thing’; B. ‘a factory’; C. ‘other’). The order of test and filler trials were randomized. Participants completed 24 test trials and 24 filler trials, and the full procedure took 20-30 minutes. Experimental subcomponents utilizing non-words were discarded during the analysis presented here.

## Results

Table 1 lists a number of  $\Delta$  values, some of which violate equation (3). Confidence intervals around the CHSH value  $\Delta$  were computed using the bootstrap method that both removed and added data points that corresponded to interpretations that were either not present or added, and for each iteration, a pseudo  $\Delta$  was computed. Confidence intervals were computed using:  $\text{mean}(\text{pseudo}) \pm t_{0.975, n-1} \sqrt{\text{var}(\text{pseudo})/n}$ .

These results imply that there is good reason to believe that some conceptual combinations must be analyzed in a non-compositional framework. However, it is still possible to provide further details about *how* exactly the joint probability behaves during such a violation. In what follows, we shall analyze three specific examples from the three different categories of result: BOXER BAT (where  $\Delta < 2$ ); APPLE CHIP (where  $\Delta = 2$ ); and BANK LOG (where  $\Delta > 2$ ).

## Further Analysis

It is possible to write the joint probability in a form that starts to explain how violations of (3) occur. To do this we represent the four different random variables  $\{\mathbf{A1}, \mathbf{A2}, \mathbf{B1}, \mathbf{B2}\}$  in a matrix where each random variable contribution is split into a set of possible outcomes. This allows us to break down the results from Table 1 into a form that allows for a consideration of the underlying structure required for violations (or not) of (3). In this representation we can write the data gathered from the above experiments out as a set of joint distributions,

	Concept A		Concept B		Results	
Combination	Prime 1 ( <b>A1</b> )	Prime 2 ( <b>A2</b> )	Prime 3 ( <b>B1</b> )	Prime 4 ( <b>B2</b> )	$\Delta$	n
boxer bat	<i>dog</i>	<i>fighter</i>	<i>ball</i>	<i>vampire</i>	0.91 [0.74,1.09]	64

Table 1: Results of the CHSH analysis:  $\Delta$  denotes the CHSH value with an associated confidence interval ( $\alpha = 0.05$ ),  $n$  the number of subjects. Conceptual combinations that significantly violate the CHSH inequality are bolded.

which allows for a further understanding of the resulting behavior.

For example, under this analysis, the joint probability of BOXER BAT can be written as (Bruza et al., 2012):

$$\begin{array}{c} \text{boxer} \end{array} \begin{array}{cc} & \text{bat} \\ & \begin{array}{cc} \mathbf{B1}(ball) & \mathbf{B2}(vampire) \\ +1 & -1 \\ -1 & +1 \end{array} \\ \begin{array}{cc} \mathbf{A1} & +1 \\ (dog) & -1 \end{array} & \begin{pmatrix} 0.43 & 0 & 0.1 & 0.2 \\ 0.28 & 0.28 & 0.1 & 0.6 \end{pmatrix} \\ \begin{array}{cc} \mathbf{A2} & +1 \\ (fighter) & -1 \end{array} & \begin{pmatrix} 0.13 & 0 & 0.31 & 0.06 \\ 0.33 & 0.53 & 0.31 & 0.31 \end{pmatrix} \end{pmatrix} \quad (4)$$

Here, we see no particular ordering or patterns when we compare equations (3) and (4). We can see that the data gathered does not center the distribution in such a way that it can violate the CHSH inequality.

In contrast, APPLE CHIP leads to a joint distribution that has a far more interesting structure:

$$\begin{array}{c} \text{apple} \end{array} \begin{array}{cc} & \text{chip} \\ & \begin{array}{cc} \mathbf{B1}(potato) & \mathbf{B2}(circuit) \\ +1 & -1 \\ -1 & +1 \end{array} \\ \begin{array}{cc} \mathbf{A1} & +1 \\ (banana) & -1 \end{array} & \begin{pmatrix} 1 & 0 & 0.73 & 0 \\ 0 & 0 & 0 & 0.27 \end{pmatrix} \\ \begin{array}{cc} \mathbf{A2} & +1 \\ (computer) & -1 \end{array} & \begin{pmatrix} 0.69 & 0 & 0.53 & 0 \\ 0 & 0.31 & 0 & 0.47 \end{pmatrix} \end{pmatrix} \quad (5)$$

In this case, we see a complete correlation between the subject responses. Thus, whenever a subject interprets APPLE as a fruit they decide that CHIP is a food, and when APPLE is interpreted as a computer then CHIP is

interpreted as an electronic device. This complete correlation of the senses attributed to the bi-ambiguous words leads to a value of  $\Delta = 2$ . This is still a compositional concept combination.

Finally, if we consider conceptual combination BANK LOG then we can see how a non-compositional value of  $\Delta > 2$  is obtained:

$$\begin{array}{c} \text{bank} \end{array} \begin{array}{cc} & \text{log} \\ & \begin{array}{cc} \mathbf{B1}(journal) & \mathbf{B2}(tree) \\ +1 & -1 \\ -1 & +1 \end{array} \\ \begin{array}{cc} \mathbf{A1} & +1 \\ (money) & -1 \end{array} & \begin{pmatrix} 0.94 & 0 & 0.53 & 0 \\ 0 & 0.06 & 0.07 & 0.4 \end{pmatrix} \\ \begin{array}{cc} \mathbf{A2} & +1 \\ (river) & -1 \end{array} & \begin{pmatrix} 0.21 & 0 & 0.8 & 0.13 \\ 0.03 & 0.76 & 0 & 0.07 \end{pmatrix} \end{pmatrix} \quad (6)$$

While this case is similar to the one illustrated in (5), it exhibits a key difference; a non-zero value has been returned by the ensemble of subjects for the off-diagonal case where  $\Pr(\mathbf{A2} = +1, \mathbf{B1} = -1) = 0.13$ , which corresponds to the case where the subjects interpret “bank log” as e.g. a financial institution made of wood. The off-diagonal term in (3) means that there is enough probability ‘mass’ for a violation. Comparing (4–6) with the set of equations typified by (3) we can understand that while it is necessary to for a system violating such inequalities to have some correlation in the random variables, it is just as important to have an anti-correlation.

## Conclusions

There is nothing in equation (3) that restricts its domain of application to quantum theory. Indeed, there are many systems that appear to be separated in a similar way, and so should adhere to the probabilistic behavior that it requires. Indeed, an early work by Aerts et al. (2000) proposed that the formalism of quantum theory could be widely applied to the description of a broad class of nonseparable systems, and this paper further contributes to this stream of work. More recently Bussemeyer et al. (2011) have applied the formalism of quantum theory to obtain a unified description of human decision making and the way in which it violates many of the axioms of standard probability theory. Together with the work presented here, these and many other results suggest that the formalism of QT is widely applicable to the analysis of psychological problems. We suggest that this is due to the ability of the formalism to incorporate a complex notion of *context* into its models, a significant advantage in cognitive modeling.

More specifically, the work presented here has considered only two possible senses for each word, and a very simple priming procedure, but we claim that this is not a limitation of the model *per se*. Firstly, the *spectral decomposition theorem* (Isham, 1995) implies that any measurement can be decomposed into a sum of projection operators. Secondly, more complex primes and cues can possibly be modeled through the use of a vector space approach that extracts the meaning of proceeding sentences, phrases and part word cues.

In summary, it seems likely that a broad class of systems which exhibit strong contextual dependencies among their subcomponents can be well modeled in this approach, and future work will seek to further clarify the conditions under which such systems become non-compositional.

## Abstract

Previous studies have shown that emphasizing the goal state could facilitate insight problem solving (e.g. Chronicle, MacGregor, & Ormerod, 2004). In these studies, the goal states were given by the experimenters and the participants were instructed to reach them. In the present study, we investigated whether the same facilitative effect could be obtained when the participants were forced to find the goal state by themselves. We used the 6-coin problem and compared the performance between the self goal setting condition and the control condition. The results showed that the participants in the self goal setting condition could solve the problem less often than those in the control condition when they were not allowed to reach the other goal state. It, however, slightly facilitated the insight problem solving if the participants were allowed to change the goal. The results indicated that self goal setting is effective in finding emergent goals.

**Keywords:** Insight problem solving; Goal setting, Plan

## Introduction

Problem solving is defined as an activity in which one tries to fill the gap between the initial and the goal state. It is well known that we adopt some heuristics in order to solve the problems. The hill climbing heuristic is one of the most common ones. It is the way of selecting operators so that the distance between the present state and the goal states can be minimized. To apply the heuristic, we need to know or at least to infer what goal state is. Although no one denies that goal plays a critical role in problem solving, it seems remain a matter of debate what roles the goal plays. In the present study, we investigate what roles the goal plays in insight problem solving.

## Importance of Goals in Insight Problem Solving

Although what processes underlies insight problem solving is still open (e.g. special process view vs. business as usual view), there is agreement that the goal plays an important role in insight problem solving. Kaplan and Simon (1990) applied the information processing framework to understand the process of insight problem solving. They argued that one uses some heuristics to narrow the problem space. MacGregor, Ormerod, and Chronicle (2001) have proposed the progress monitoring theory. They argued that hill climbing heuristic underlies the selection of moves to solve

the nine-dot problem. Ormerod, MacGregor, and Chronicle (2002) applied the theory to the 8-coin problem.

Hiraki and Suzuki (1998) proposed the dynamic constraint relaxation theory to explain the processes of insight problem solving. They hypothesized three types of constraints working during insight problem solving: object-level, relational, and goal. The object-level constraint is our natural tendency to encode objects at a basic level, although there are numerous other ways of interpretations. The relational constraint is a tendency to choose specific relations among innumerable alternatives. The word “relation” is defined as the manner in which objects are related to each other. The goal constraint is the ideal image, which provides feedback to the other two constraints by evaluating a match between the present and the desired states. They suggested that these constraints create an impasse at the earlier stage during insight problem solving and the incremental relaxation of the constraints driven by failures probabilistically causes qualitative transitions.

Wajima, Abe, and Nakagawa (2008) proposed the chaotic neural network model of the insight problem solving. Their model was implemented the goal orienting mechanism by which the model selects operators to minimize the gap between the present and the goal state. By comparing the models with and without the goal-orienting mechanism, they showed that the goal-orienting mechanism is necessary.

## Effects of Goals on Insight Problem Solving

The models mentioned above hypothesized that the goal plays a role as a criterion in evaluating the current states. When the goal state is explicitly shown, one can evaluate the present state easier and more accurately than when not. It can be expected that emphasizing the goal state facilitates the insight problem solving.

Suzuki, Miyazaki, and Hiraki (1999) examined whether emphasizing the goal state could be effective in solving the insight problem using the T-puzzle. The task was to arrange the four pieces such that they formed a T-shape. The goal state is essentially included and is explicitly shown in the original task instruction. In order to emphasize the goal state, they provided the T-shape template with the participants and asked them to match the pieces to it. The results showed that the solution rate in the template condition was higher than that in the control condition. It implied that reinforcing the goal constraint can be effective in insight problem solving.

Kojima, Ito, and Matsui (2008) investigated whether emphasizing the goal state could facilitate insight problem solving using the F puzzle. The F puzzle is to arrange the four pieces so as to make the F-shape. Along with the T-puzzle, the goal state is essentially included and is explicitly shown in the original task instruction. In order to emphasize the goal state, they provided the F-shape template with the participants and asked them to match the pieces to it. In addition to the template condition, they introduced the instruction condition, in which the participants were not provided any external aid and were required only to imagine the F-shape. The results showed that the solution rate in the template condition was higher than those in the instruction condition and in the control condition. Kojima et al. (2008) concluded that giving the template was effective in emphasizing the goal state and facilitating the top-down processing and that the top-down processing can be effective in insight problem solving.

Because these studies used the insight problem having a fixed goal, the participants had to reach it. However some insight problems, for example, the 6-coin problem, have more than one goal states. What roles does goal information play in solving the multi goal states problem? Chronicle, MacGregor, and Ormerod (2004) addressed the question using the 6-coin problem. They showed that the participants could reach the solution more often when they were given the visualized goal state than when were given only the original instruction.

### Purpose of the Present Study

Previous studies have shown that emphasizing the goal state could facilitate insight problem solving. In the previous studies, the information of the goal states were given by the experimenters and the participants were instructed to reach the goal state. In the present study, we investigate whether or not the same facilitative effect can be obtained when the participants are asked to find the goal state by themselves before performing the tasks. If emphasizing the goal state facilitated insight problem solving, we expected that self goal setting could be effective in insight problem solving as long as they set the goal state appropriately.

## Experiment 1

### Method

**Participants** Fifty-two undergraduates from Chubu University participated in the experiment and received a course credit following the completion of the experimental session. None have seen the 6-coin problem. They were randomly assigned to one of the two conditions: self goal setting and control. Twenty-eight participants were assigned to the self goal condition and 24 to the control condition.

**Task** The 6-coin problem (Chronicle et al., 2004) was used. The task was to rearrange the coins from the initial state

Figure 1: The initial state of the 6-coin problem cited from Chronicle et al. (2004). The numbers in the circles were not shown the participants.

Figure 2: An example route to the ring goal state cited from Chronicle et al. (2004).

shown in Figure 1 such that each coin touched exactly two others following these four rules: (a) one can have three moves, no more and no fewer. (b) In each move, they have

Figure 3: An example route to the 2-group goal state cited from Chronicle et al. (2004).

to slide one coin only. (c) When they slide a coin, it must not disturb any other coins. (d) At the end of each move, the moved coin must be touching two other coins. There could be the following two goal states: ring and 2-group. According to Chronicle et al. (2004), there are only two paths to the ring goal state and 176 to the 2-group one. An example solution path to the former goal state is shown in Figure 2 and the latter in Figure 3.

**Procedures** Participants were tested individually and their solution attempts were videotaped. For both conditions, participants were shown the initial state of the problem using 6 Japanese 500-yen coins. The participants in the self goal setting condition were asked to draw the goal state on a paper in three minutes and then to reach the goal state in 12 minutes. They were allowed only to reach the goal state they drew. The participants in the control condition were asked only to solve the problem in 15 minutes. The

experimental session was terminated when the participants found the solutions or when the designed time elapsed.

## Results and Discussions

Because a participant in the self goal setting condition was not able to draw the goal state within three minutes, the data was not included into analyses. As a result, 51 data was used for further analyses.

Firstly, we compared the performance between the self goal condition and the control condition. The performance in each condition is shown in Figure 4. The results showed that the participants in the self goal setting condition could solve the problem less often than those in the control condition (*Chi-square* ( $df=1$ ,  $N=51$ ) = 6.24,  $p < .05$ ).

Next, we examined the relationship between the goal states the participants depicted by themselves and the performance in the self goal setting condition. As shown in Table 1, 44.4% of the participants envisioned the inappropriate goals. Because the participants were restricted to the goal states they set, they could not reach the correct goal in principle. None of the participants who set the ring goal could reach the goal.

The participants in the self goal setting condition might not solve the problem because they set the inappropriate goals. Although the participants in the control condition might also search any paths to some inappropriate goals, they were able to change the goals if they wanted. On the other hand, those in the self goal setting condition were not allowed to change the goals even when they found the goal states inappropriate during problem solving. It might put them disadvantage situation.

Figure 4: The performance in each condition.

Table 1: The relationship between the self set goals and the performance.

	Solved		Unsolved
	Ring	2-group	
Ring	0	-	10
2-group	-	3	2
Other	-	-	12

Another reason why those in the self goal setting condition could not solve the problem might be because it is more difficult to find any paths to the ring goal than the 2-group goal. Chronicle at al. (2004) have shown that there were only 2 routes to the ring goal whereas 176 to the 2-group goal. Thus, it was more difficult for those who could draw the ring goal state to find the routes to it.

## Experiment 2

Contrary to our expectation, in Experiment 1, self goal setting could not facilitate but disrupt the insight problem solving. Because some participants set the inappropriate goals and they were not allowed to change them, the situation might have negative effects on insight problem solving. If the inappropriate goal setting is cause of the disruptive effects, the disruptive effect will be diminished when the participants can change the goal state. In Experiment 2, we examine the effects of self goal setting on insight problem solving when the participants are allowed to change the goal state.

## Method

**Participants** Fifty-five undergraduates from Chubu University participated in the experiment. They received course credit for participation. None have seen the 6-coin problem. Twenty-seven participants were assigned to the self goal condition and 28 to the control condition.

**Task and Conditions** The task and conditions were the same as in Experiment 1, except that the participants in the self goal setting condition were allowed to reach not only the goals they set but also any other goals.

## Results and Discussions

Because a participant in each condition inappropriately finished the experimental session, these two data were excluded from the following analyses. As a result, 53 data was used for the analyses.

We compared the performance between the self goal condition and the control condition. The performance in each condition is shown in Figure 5. The results showed that the participants in the self goal setting condition could solve

Figure 5: The performance in each condition.

Table 2: The relationship between the self set goals and the performance.

	Solved		Unsolved
	Ring	2-group	
Ring	4	4	4
2-group	0	5	1
Other	0	3	4

the problem more often than those in the control condition (*Chi-square* ( $df=1$ ,  $N=53$ ) = 3.18,  $p=.07$ ).

Next, we examined the relationship between the goal states the participants set by themselves and the goals they actually reached in the self goal setting condition. As shown in Table 2, 29.2% of the participants drew the inappropriate goal states. Unlike Experiment1, they were allowed to change the goals and 42.9% were able to reach the 2-group goal. Most of the participants who drew the 2-group goal state could find the paths to the 2-group goal. One-third of those who set the ring goal also reach the 2-group goal.

## General Discussion

In Experiment 1, self goal setting disrupted the insight problem solving contrary to our expectation. The results

were interpreted that because the participants could not set appropriate goal by themselves or because self goal setting itself disrupted the insight problem solving. In Experiment 2, self goal setting slightly facilitated the insight problem solving. However, many participants in the self goal setting condition reached the different goals from those they depicted. Self goal setting can be effective in insight problem solving when the goal works as a working hypothesis, but detrimental as a fixed criterion.

The theory of situated cognition predicted that we can find emergent solutions even when they search for a pre-defined goal. Suchman (1987), for example, argued that when a person takes a canoe in a rapid river, he/she may abandon his/her plan of how to go down in face of rapid currents, but the plan still has a role of orienting actions towards particular courses. It seems very similar to the processes observed in the self goal setting condition of Experiment 2. The participants who depicted the ring goal state at first tried to find the route to the ring goal and after some attempts they might found it too difficult to do. In the midst of the search, they might find another goal state, that is, the 2-group. As shown in Figure 2, the second step seems similar to the 2-group goal state. It might hint the participants that there can be another goal state and they might change the goal state. It can be said that the present study provided evidence supporting the notion the situated cognition theory pointed out.

The question to be addressed further is why the ring goal state set by themselves did not facilitate the insight problem solving whereas did when the experimenter gave the goal state in the Chronicle et al. (2004). The difference in effects of the goal on insight problem solving might be caused by source attribution effects. Several studies have shown that source of information has some effects on the performance. Schunn and Klahr (1993) investigated the effects of other-generated hypotheses on rule discovery. The results showed that giving the other-generated hypothesis led participants to investigate the plausibility of hypotheses more thoroughly and less false terminations with incorrect solutions. Kiyokawa, Ueda, and Okada (2004) experimentally clarified whether assessing other-generated hypotheses could facilitate hypothesis revision using a rule-discovery task. The results revealed that the participants who assessed the other-generated hypotheses before generating and assessing their own hypotheses performed better than those who generated their own hypotheses and assessed them thoroughly. Osman (2008) showed that seeing learning history of another participant facilitated transfer of acquired knowledge during the first task to the second one in implicit learning situation. In addition, she also showed that the facilitative effects was obtained even when the participants were provided with their own learning history in fact, only if they were told that they were derived from another participant. The results suggest that source attribution has the effect on transfer in implicit learning.

## Conclusion

The goal plays an important role in insight problem solving by directing the solvers' search. When it is not fixed, that is can be flexibly changed, emphasizing the goal state can facilitate insight problem solving. Even though the content of the goal state is the same, who set the goal can have effects on what effects is emerged: self or the other.

## Abstract

Eye movements of twelve Caucasian participants were measured whilst they performed a recognition test of same (Caucasian) and other race (Indian) faces. We observed a standard other-race effect, with more items recognised correctly, fewer false alarms, and reduced reaction time to same-race than other-race faces. Additionally, a differential pattern of eye movements between races emerged. During the study phase, same-race faces were fixated more than other-race faces, whilst other-race faces resulted in a greater proportion of fixations to internal face features than same-race faces. At test, whilst no differences between races emerged in the number of fixations or in the proportion of fixations made to internal features, a significantly greater level of fixations were made to the left hemispace for other-race faces for both previously studied and lure faces. These differences in the pattern of fixation plausibly reflect the greater effort in the processing of other-race than same-race faces.

**Keywords:** other-race effect, eye-tracking, face recognition, same-race faces.

## Introduction

The other-race effect refers to the phenomenon that individuals are less proficient at recognising faces from a different race to their own. This is typically characterised by a 'mirror effect', whereby same-race faces attract a higher proportion of hits and a lower proportion of false alarms compared with other-race faces (Meissner & Brigham, 2001). As well as its theoretical importance, the other-race effect has considerable practical significance. In particular, it is well established that minority races in a community are more likely to be wrongfully convicted of a crime on the basis of erroneous eyewitness testimony (Meissner & Brigham, 2001). For instance, Scheck, Neufeld, & Dwyer (2000) found that most cases of mistaken eyewitness identification in the United States were of Caucasian victims misidentifying non-Caucasian suspects.

One explanation for the other-race effect is that individuals process other-race faces in a qualitatively different way to same-race faces. In particular, same-race faces are believed to rely on configural processes to a greater extent than other-race faces. Support for this comes

from the composite face effect (e.g., Michel, Rossion, Han, Chung, & Caldara, 2006) in which recognition of the upper half of a face was more disrupted by the bottom half of a different face for same-race than other-race faces. Furthermore, there is greater benefit for same-race than other-race faces from the whole face context when processing individual facial features (the whole/part effect, e.g., Tanaka, Kiefer, & Bukarch, 2004). Additionally, there is evidence that the face inversion effect is more pronounced for same-race than other-race faces (Rhodes et al., 1989; but see Valentine & Bruce, 1986). The greater exposure that people typically have to same-race faces (e.g., Chiroro & Valentine, 1995) may be one reason for the increased use of configural processes (Gauthier & Tarr, 2002). Similarly, perceptual learning (e.g., Gibson & Walk, 1956; McLaren & Mackintosh, 2000) may lead to same-race faces being less tightly clustered in multidimensional space than other-race faces, resulting in easier discrimination of same-race faces (as in "face-space" models, e.g., Byatt & Rhodes, 2004).

Eye movements provide an index to the allocation of visual attention towards facial features (Findlay & Gilchrist, 2003). As such, the pattern of eye movements can provide direct insight into cross-race processing differences. To date, however, eye tracking has seldom been used to explore the other-race effect. One exception is a study by Goldinger, He, & Pappas (2009) which examined eye movements to various features together with pupil dilation (an index of mental processing load in visual attention) for Caucasian and Asian faces, recruiting participants from both these races. Both Caucasian and Asian participants fixated more to same-race than other-race faces, and more to the eyes and hair for same-race faces and more to the nose and mouth for other-race faces. Pupil dilation was greatest for other-race faces, indicating the recruitment of greater resources. A separate study conducted by Blais, Jack, Scheepers, Fiset, & Caldara (2008) found a slightly different pattern of results, with Caucasians focussing on the eyes and East Asians focusing on the nose and mouth, regardless of the race of the faces viewed. As Goldinger et al. (2009) note, this discrepancy may be partially due to the fact that in their study they used faces with neutral emotions, whilst the faces presented in Blais et al. (2008) varied in expression.

Our study directly examined differences in the processing of internal features, relative to external features, for same-race compared to other-race faces. We also asked whether there would be cross-race differences in fixation

lateralization. These questions were not directly assessed by Goldinger et al. (2009) but have been investigated in studies tracking eye movements to famous/nonfamous faces (a familiarity benefit similar to the same-race advantage has been robustly established; see Johnston & Edmonds, 2009). For instance, Althoff and Cohen (1999) found that a greater proportion of fixations were delivered to nonfamous than famous faces in fame and emotion judgment tasks. Additionally, they showed that nonfamous faces evoked a greater proportion of fixations to the left hemispace than famous faces. Stacey, Walker, and Underwood (2005) showed that famous faces resulted in greater internal processing than nonfamous faces only under relatively restricted conditions (a matching-faces task). These findings are surprising given that behavioural work suggests that internal features are more important for familiar than unfamiliar face recognition (e.g., Ellis et al., 1979). Althoff and Cohen (1999) suggested that the greater processing of internal features for unfamiliar than familiar faces may reflect the necessity for more efficient sampling of information when viewing unfamiliar faces given that internal features are particularly useful for identifying people. They proposed a similar explanation for the greater left hemispace bias for nonfamous than famous faces - asymmetric viewing is more efficient due to the general symmetry of faces.

Our predictions were somewhat open-ended due to the lack of direct empirical investigation of these issues in the context of the other-race effect. However, given that internal features are regarded as more diagnostic and have greater involvement in configural processing than external features, more fixations to same-race than other-race faces would provide an explanation for the same-race recognition advantage. Nevertheless, this reasoning also applies to the face familiarity effect, yet Althoff and Cohen (1999) observed greater internal feature processing for nonfamous than famous faces. On these grounds, if one assumes that other-race faces can, on the whole, be regarded as less familiar than same-race faces, a greater reliance on internal features for other-race than same-race faces might be anticipated. For similar reasons, the results of Althoff and Cohen would suggest a greater reliance on left hemispace processing for other-race than same-race faces.

## Method

### *Participants*

Twelve Caucasian students (3 males, 9 females) from the University of Exeter, ranging in age from 18-39 ( $M = 22.92$ ,  $SD = 4.91$ ) participated. No participants had visited Asia for an extended period of time (i.e., over one month). Participants were tested individually in a testing cubicle.

### *Apparatus*

The experiment was run using E-Prime (Psychological Software Tools, 2002) on a Dell PC with a 22-inch color monitor and a standard computer keyboard. Participants sat 0.5 metres away from the screen.

The Eye link II system recorded movements in the right eye using a video-based eye tracker with a head movement compensation system connected to a Dell PC with a 17-inch TFT monitor. Eye movements were sampled on the recording computer at 500Hz. Pupil position was monitored via a miniature infrared CCD video camera mounted on an adjustable headband. The display computer initiated and terminated eye tracking recording on each trial.

### *Stimuli*

Stimuli consisted of forty colour photographs of male faces. Twenty Caucasian (taken from O'Toole et al., 2005) and twenty Indian faces (taken from Jain & Mukherjee, 2002) were used. All faces were full-face view, had neutral expressions, and no distinctive features (e.g., glasses, facial hair). Images were of comparable quality. Pictures were edited using Adobe Photoshop to achieve a resolution of 300-pixels wide; the height was constrained by the natural proportions of the face (average: 370.3-pixels). Faces were cropped, to remove the background of the image. The resulting images were presented centrally on a white background on a screen with a resolution of 800x600 pixels.

### *Procedure*

Our basic procedure was modeled on Experiment 2 of Stacey et al. (2005) with the difference that we manipulated the race of the faces rather than their familiarity. In the study phase, twenty faces were presented. Ten of these faces were Caucasian and ten Indian. Trials began with a black fixation cross for 500ms, followed by a blank screen for 500ms. A face was then presented for 5 seconds. No response was required but participants were instructed to remember the faces.

After a break of around 2 minutes, the test phase began. Here, forty faces were presented: the twenty studied faces (ten Caucasian, ten Indian) and twenty "lure" faces (ten Caucasian, ten Indian) which had not previously been seen. Faces were presented in a random order. Trials began with a black fixation cross lasting 500ms, followed by a blank screen for 500ms. A face was then displayed for 5 seconds. During this time, participants indicated whether they had seen the face previously (by pressing z on the keyboard) or if the face was new (by pressing m). If participants did not answer in time, no response was recorded and participants were encouraged to respond quicker.

In both the study and test phases, stimuli were presented in a random order. Eye movements were recorded in both phases, with corrections for drift conducted every 5 trials.

### *Analysis*

#### *Eye Movements*

Eye movements were analysed using EyeLink Data Viewer Software, which automatically detects saccadic eye movements and analyses these movements into individual fixations using a combined position/velocity/acceleration criterion (a saccade was defined as a period where eye velocity was greater than 30°/sec, eye acceleration was

greater than  $8000^{\circ}/\text{sec}^2$  and the eye had deviated at least  $0.1^{\circ}$  from its starting position). Fixations were defined as periods between saccades. Blink artefacts were automatically removed from the data.

Eye movements were analysed for the entire stimulus presentation period in the study phase. In the test phase, eye movements were analysed up until participants made their response. Using the EyeLink Data Viewer Software, Region of Interests (ROI) were created for internal (i.e., eyes, nose and mouth) and external (e.g., hair, ears) features. Furthermore, ROIs were created for the left and right hemispaces (including both internal and external features). ROIs were drawn separately for each face (c.f., Figure 1). The size of the ROI's between races was closely comparable. Fixations falling outside of the ROIs were excluded from subsequent analyses. In the analyses reported, for ease of exposition, we focus on the pattern of fixations; dwell measures showed a similar pattern.

Figure 1. An illustration of how face regions were defined in terms of internal/external and right/left ROI for each face independently.

## Results

### Behavioural Results

#### Test Phase

A paired-samples *t*-test revealed that the hit rate for studied faces was significantly higher for same-race (Caucasian;  $M = .85$ ,  $SD = .14$ ) than other-race (Indian;  $M = .70$ ,  $SD = .18$ ) faces,  $t(11) = 2.51$ ,  $p = .029$ . Furthermore, the false alarm rate was higher for other-race ( $M = .35$ ,  $SD = .18$ ) than same-race ( $M = .08$ ,  $SD = .08$ ) faces,  $t(11) = 5.75$ ,  $p < .001$ . Response time was significantly higher for other-race ( $M = 1697.22$ ,  $SD = 478.65$ ) than same-race ( $M = 1407.15$ ,  $SD = 376.43$ ) faces,  $t(11) = 3.08$ ,  $p = .011$ . Time outs were minimal (on .004 of trials).

#### Eye movement data

##### Study Phase

Descriptive data of the pattern of eye-movement across the entire 5000ms study period is displayed in Table 1.

Paired-samples *t*-tests revealed that more fixations were made to internal than external features for both same-race,  $t(11) = 7.83$ ,  $p < .001$ , and other-race,  $t(11) = 9.51$ ,  $p < .001$ , faces. An additional paired-samples *t*-test, combining both internal and external features, showed that participants made significantly more fixations to same-race ( $M = 15.13$ ;  $SD = 3.71$ ) than other-race ( $M = 14.33$ ;  $SD = 3.68$ ) faces,  $t(11) = 2.78$ ,  $p = .018$ .

Table 1

*The Pattern of Eye Movements in the Study Phase Across the entire Study Period.*

	Same-race		Other-race	
	M	SD	M	SD
Number of fixations	15.13	3.71	14.33	3.68
Internal fixations	12.24	3.70	12.37	3.52
External fixations	2.88	1.31	1.97	1.25
Proportion of internal fixations	0.80	0.08	0.86	0.09
Right hemisphere fixations	7.25	3.45	6.52	3.46
Left hemisphere fixations	7.85	2.37	7.82	2.38
Proportion of left hemisphere fixations	0.53	0.16	0.56	0.16

Due to the significant difference between groups in terms of the mean number of fixations, we calculated the mean proportion of fixations to internal features (internal features/[internal features + external features]). Next, we divided the study interval into five separate 1000ms time bins to better characterise differences in the processing of other-race and same-race faces over time. This information is displayed in Figure 2. We then conducted a within-subject ANOVA with two factors, race (same-race and other-race) and time interval (0-1000ms, 1001-2000ms, 2001-3000ms, 3001-4000ms, and 4001-5000ms) to investigate this data. This yielded a significant effect of race,  $F(1,11) = 14.994$ ,  $p = .003$ ,  $\eta^2_p = .577$ , with the proportion of fixations to internal features significantly greater for other-race than same-race faces. There was, however, no significant effect of time interval,  $F(4,44) = .723$ ,  $p = .581$ ,  $\eta^2_p = .062$ , and no significant interaction between time period and race,  $F(4,44) = .070$ ,  $p = .991$ ,  $\eta^2_p = .006$ , indicating that the main effect of race remained consistent across time.

Figure 2. The mean proportion of fixations to internal face features across time intervals for same-race and other-race faces.

We calculated the mean proportion of fixations to the left hemisphere (left hemisphere/[left hemisphere + right hemisphere]) and conducted one-sample *t*-tests which

showed that fixations to the left hemispace did not differ from 0.5 (chance) for either same-race ( $M = .53$ ;  $SD = .16$ ),  $t(11) = .67$ ,  $p = .52$ , or other-race ( $M = .56$ ;  $SD = .16$ ),  $t(11) = 1.25$ ,  $p = .24$ , faces. Figure 3 displays the mean proportion of fixations to the left hemispace across the study interval for both same-race and other-race faces. A within-subject ANOVA with two factors, race (other-race, same race) and time interval (0-1000ms, 1001-2000ms, 2001-3000ms, 3001-4000ms, and 4001-5000ms) revealed that there was no significant effect of race,  $F(1,11) = 2.171$ ,  $p = .169$ ,  $\eta^2_p = .165$ . There was, however, a significant effect of time interval,  $F(1,11) = 5.783$ ,  $p = .001$ ,  $\eta^2_p = .345$ , with the proportion of fixations to the left hemispace decreasing across the study period. Furthermore, there was also a significant interaction between race and time interval,  $F(4,44) = 3.321$ ,  $p = .018$ ,  $\eta^2_p = .232$ . T-tests, assessing the nature of this interaction, indicated that other-race faces had a significantly greater proportion of fixations to the left hemispace than same-race faces for the first 1000ms time bin,  $t(11) = 2.702$ ,  $p = .021$ , but that there were no differences between face type for the other time periods (all  $Ps > .05$ ).

Figure 3. The mean proportion of fixations to the left hemispace across time intervals for same-race and other-race faces.

### Test Phase

Descriptive data for the test phase are shown in Table 2. As in the study phase, paired-samples t-tests revealed that there were no differences between same-race and other race faces for either studied,  $t = 1.399$ ,  $p = .189$ , or lure faces,  $t(11) = .466$ ,  $p = .651$ . There were more internal than external fixations for both “seen”,  $t(11) = 10.46$ ,  $p < .001$ , and “new”,  $t(11) = 8.16$ ,  $p < .001$ , same-race faces; similarly, there were more internal than external fixations for “seen”,  $t(11) = 8.37$ ,  $p < .001$ , and “new”,  $t(11) = 9.63$ ,  $p < .001$ , other-race faces.

As for the study phase, we calculated the mean proportion of fixations to the internal features. Unlike in the study phase, however, we did not partition the fixations into time intervals due to differences both within and between participants in the time spent viewing the faces. Table 2 shows the mean proportion of fixations to internal features for both other-race and same-race faces for both studied and lure faces. A 2x2 within subject ANOVA, with the factors

being race (other-race, same-race) and presentation type (studied faces, lure faces) found no significant effect of race,  $F(1,11) = .369$ ,  $p = .556$ ,  $\eta^2_p = .032$ , and no significant effect of presentation type,  $F(1,11) = .072$ ,  $p = .793$ ,  $\eta^2_p = .007$ . There was a marginal interaction,  $F(1,11) = 4.469$ ,  $p = .058$ ,  $\eta^2_p = .289$ , which did not reach significance.

Table 2

### The Pattern of Eye Movements in the Test Phase.

	Same-race				Other-race			
	Lure		Studied		Lure		Studied	
	M	SD	M	SD	M	SD	M	SD
Internal fixations	4.86	1.58	4.45	1.53	5.43	1.80	5.01	2.10
External fixations	0.66	0.78	0.66	0.49	0.77	0.68	0.55	0.64
Proportion of internal fixations	0.89	0.09	0.87	0.08	0.88	0.10	0.91	0.10
Right hemispace fixations	2.59	1.97	2.31	1.57	2.32	1.42	2.11	1.66
Left hemispace fixations	2.92	1.38	2.80	1.05	3.88	1.51	3.45	1.47
Proportion of left hemispace fixations	0.55	0.21	0.57	0.20	0.64	0.16	0.64	0.20

The mean proportion of fixations to the left hemispace for both studied and lure same-race and other-race faces are shown in Table 2. One sample t-tests showed that fixations to the left hemispace were reliably greater than chance (0.5) for both studied,  $t(11) = 2.551$ ,  $p = .027$ , and lure,  $t(11) = 2.960$ ,  $p = .013$ , other-race faces. There was no significant asymmetry, however, for either studied,  $t(11) = 1.200$ ,  $p = .256$ , or lure,  $t(11) = .768$ ,  $p = .459$  same-race faces. In terms of the proportion of fixations made to the left hemispace, a 2x2 within-subject ANOVA, yielded no significant main effect of presentation type (studied, lure),  $F(1,11) = .980$ ,  $p = .344$ ,  $\eta^2_p = .082$ , and no significant interaction between face type and race,  $F(1,11) = .148$ ,  $p = .708$ ,  $\eta^2_p = .013$ , but there was a significant main effect of race,  $F(1,11) = 8.619$ ,  $p = .014$ ,  $\eta^2_p = .439$ . Paired-samples t-tests revealed that the effect of race was significant for both studied,  $t(11) = 2.404$ ,  $p = .035$  and lure,  $t(11) = 2.274$ ,  $p = .044$ , faces with a greater proportion of fixations to the left hemispace for other-race than same-race faces.

## Discussion

We investigated the pattern of fixations of Caucasian participants while they performed a recognition task on a group of Caucasian (same-race) and Indian (other-race) faces. Consistent with previous studies, we found evidence for a “mirror-effect” (Meissner & Brigham, 2001); participants had fewer hits (recognising “seen” faces), more false alarms (incorrectly recognising “new” faces), and a longer response time for other-race than same-race faces.

In the study phase, we found, consistent with Goldinger et al. (2009), that participants made more fixations to same-race than other-race faces. Additionally, participants made a greater proportion of fixations to internal features for other-race than same-race faces. We divided the study period into five time periods to examine whether the nature of this effect changed over time. However, there was no indication of a time x face type interaction, which indicates that this

effect remained consistent throughout the study period. We also directly examined the lateralization of the fixations that participants made to same-race and other-race faces. Whilst there was no overall effect of race type, there was a significant effect of time with fixations becoming more equally divided between the left and right hemispace over time. Furthermore, we also found that there was a significant interaction between race and time, with a greater proportion of fixations made to the left hemispace for other-race than same-race faces for the first 1000ms time interval but not for the remaining four time intervals.

At test, stimuli were divided into those seen in the study phase, and “lure” stimuli which were only presented at test. For both types of faces there was no difference in the proportion of internal fixations to same-race or other-race faces. However, there was a significant effect of race for both studied and lure faces in terms of the proportion of fixations made to the left hemispace. Specifically, we observed a greater left hemispace bias for other-race than same-race faces.

The demonstration in the study phase that a greater proportion of fixations were made to internal features for other-race faces than same-race faces is consistent with previous work (e.g., Goldinger et al., 2009). In this regard, an explanation similar to that proposed by Althoff and Cohen (1999) to account for the greater proportion of internal fixations to nonfamous than famous faces seems applicable to our results. Specifically, Althoff and Cohen (1999) argued that there was greater need to effectively process the internal features, which are critical to face recognition, for nonfamous than famous faces. Our finding may, therefore, be due to the less efficient extraction of the internal features for other-race than same-race faces. The fact that participants made fewer fixations to other-race than same-race faces whilst trying to remember them supports the assumption that other-race face information is processed less easily (see also Goldinger et al., 2009). The more efficient processing of internal feature information for same-race faces would, consequently, provide greater opportunity to focus on external feature information, which still has informational value for recognition. This explanation is also consistent with Goldinger et al. (2009) who found greater pupil dilation for other-race than same-race faces, indicating greater processing effort for other-race faces.

Given this, it is striking that the internal feature bias for other-race faces appears relatively transient – this effect did not come close to reaching significance in the test phase. One might have reasonably expected a greater reliance on the more diagnostic internal features would also have been present in the test phase where the behavioural differences between same-race and other-race faces emerged. Instead, the effect was only detectable when participants were explicitly asked to encode the stimuli rather than when the requirement was to retrieve the stimuli. As such, this pattern of findings is in line with the idea that the greater bias to internal features for other-race than same-race faces reflects an encoding related perceptual process rather than a

retrieval-based process (for related behavioural evidence see Lindsay, Jack, & Christian, 1991; Tanaka et al., 2004; but see also Papesh, & Goldinger, 2009).

One caveat to the idea that the internal feature bias for other-race than same-race faces reflects an encoding rather than a retrieval process is that, as is common in face recognition studies (e.g., Goldinger et al., 2009; Stacey et al., 2005) the same picture of each face was shown at both study and test. This may have increased the reliance on pictorial codes during recognition rather than structural (abstracted memory representations) codes (Longmore, Liu, & Young, 2008), which are assumed to underlie face recognition outside the lab. This may, therefore, account for the difference between phases rather than the differing requirements of the study and test phases. However, as Longmore et al. (2008) note, if recognition was purely picture based, one might have expected equivalent recognition performance on other-race and same-race faces which was not the case in our study. Nevertheless, this potential issue could be addressed in future work by showing different photographs at study and test.

The pattern of fixations across the study and test phases was somewhat different to the internal feature effect. In the study phase, there was evidence of a greater bias to the left hemispace for other-race faces on first viewing the stimuli but this effect was not detectable over the remainder of the study period. In contrast, we found a left hemispace bias for other-race than same-race faces for both studied and lure faces in the test phase. Broadly speaking, therefore, these results indicate a greater lateralization asymmetry for other-race than same-race faces which was most marked in the test phase than the study phase. This may reflect that whilst the internal features effect appears to be due to encoding processes, the lateralization effect may reflect retrieval processes and is present only in the initial stages of encoding the stimuli. The demonstration that a greater proportion of fixations were made to the left hemispace for other-race than same-race faces during recognition is again similar to Althoff and Cohen’s (1999) finding of greater left hemispace viewing for nonfamous than famous faces. This finding can also be explained by postulating greater processing requirements for other-race than same-race faces. Under high processing demands, it appears efficient to focus primarily on the most diagnostic regions. This would mean a greater focus on one side of the face, given that faces are generally symmetrical (Althoff & Cohen proposed a similar explanation). We note that the limitations that Althoff and Cohen identified in their study concerning assessment of laterality effects (e.g., possible differences in texture or luminance between sides) similarly apply to our experiment. Future work could assess the generality of our effect by flipping one half of the face in a counterbalanced design such as in Rhodes (1985).

Previous work indicates that familiarity effects in face processing are influenced by task demands (Stacey et al., 2005). Our findings should, therefore, be generalised to different paradigms as well as to different races. Future

work should also include participants from different races to investigate cross-over interactions between recognition performance and the race of the participants. This would ensure that our findings are due to differences in cross-race face processing rather than factors such as the properties of the stimuli themselves. One issue with this sort of study, however, is that due to the extensive media exposure to Caucasian faces which means such faces are highly familiar to most populations, it might be preferable to carry out follow-up cross-over studies with non-Caucasian races. Nevertheless, our findings provide compelling evidence for processing differences between same-race and other-race faces. They also indicate that there may be overlap in the processes that underlie the same-race benefit and the familiarity advantage. Much remains to be understood, and this study should only be seen as a first step, but we hope that our experiment will help motivate future eye tracking work in this important area.

## Abstract

To reveal the differences between intra- and inter-personal systems in terms of the perceptual effect on the stability of inter-limb coordination, the present study conducted a finger-tapping experiment in in-phase and anti-phase mode. We investigated a between-subjects factor (the intra-/inter-personal condition), and a within-subject factor (the phase mode). In the intra-personal condition, participants bimanually tapped their index fingers, paced by a metronome, with the frequency gradually increasing from 1 Hz to 3 Hz. In the inter-personal condition, pairs of participants were asked to perform the same task, but to use their right or left index finger, while sitting side-by-side and looking at each other's fingers moving. Analysis showed that the average number of phase transitions, average time-to-transition and standard deviation of the relative phase differed between the intra-personal system and inter-personal system. Some results do not agree with the predictions of theoretical model proposed in previous studies on inter-limb coordination.

**Keywords:** Inter-limb coordination; Finger Tapping Task; Perceptual Effect; Dynamical Systems Approach

## Introduction

To reveal the differences between intra- and inter-personal coordination systems, a finger-tapping experiment was conducted in which two phase modes (in-phase and anti-phase) were manipulated as a factor. The present study had two objectives. One objective was to reveal the role of perceptual information in inter-limb coordination. For this, we conducted a finger-tapping experiment, comparing the intra-personal condition with the inter-personal condition. Because the tapping task required participants to utilize visual, auditory, and haptic information (e.g., looking at a moving finger, listening to auditory metronome stimuli as well as the sounds of tapping, and touching the surface of the desk), the effect of multi-modal perceptual information could be examined (Kodama and Furuyama, 2010). We

investigated not only the intra-personal system, which involves neural and mechanical coupling between limbs, but also the inter-personal system, which involves visual coupling through watching the other's movements. We could thus focus on the perceptual effect on inter-limb coordination. The other objective was to see how generally the existing model on human inter-limb coordination, called the Haken-Kelso-Bunz (HKB) model, could be applied to human inter-limb coordination in the intra-personal system and in the inter-personal system.

The first application of self-organization theory to human inter-limb coordination was attempted by Scott Kelso (Kelso, 1984) and his colleagues (Haken et al., 1985). Since then, research on this topic has developed tremendously. In this approach, called *the dynamical systems approach*, the general findings are that bimanual coordination is more stable in the in-phase mode than in the anti-phase mode; one of the most important observations is that phase transitions take place unidirectionally from the anti-phase mode to the in-phase mode when the required oscillation frequency reaches or exceeds a critical point. These findings led to the proposal of a theoretical model, called the Haken-Kelso-Bunz (HKB) model (Haken et al., 1985).

The above findings have been confirmed for inter-personal coordinated movement (e.g., swinging of pendulums or legs) (Schmidt et al., 1990, 1998). Phase transitions in inter-personal systems indicate that visual information involves coordinated movement because inter-personal systems do not involve mechanical or neural couplings between limbs, unlike intra-personal systems. Schmidt et al. (1998) suggested that the self-organization principle of intra-personal systems governs inter-personal systems as well but that the coupling strength between limbs is stronger in intra-personal systems.

However, most studies on coordinated movement have dealt with either intra- or inter-personal coordination of a pair of oscillators (fingers, legs, pendulums, etc.) wiggling or swaying in the air; that is, these studies did not address

the effect of haptic information in terms of contact on a surface of an environment.

On the other hand, in finger tapping studies, Mechsner et al. (2001) conducted an intra-personal four-finger tapping experiment in which the perceptual bias on bimanual coordination was investigated in terms of symmetry defined in visual, perceptual space. Although they found a perceptual bias on bimanual finger tapping, they did not reflect upon the implications of their findings on the HKB model. Some researchers (e.g., Takenaka and Ueda, 2003) conducted tapping experiments both in intra- and inter-personal conditions. These studies, however, did not compare the in-phase and anti-phase modes and did not investigate the frequency effect on the stability of movement.

As far as we can tell from a survey of the literature, no studies have compared intra-personal and inter-personal coordination in finger tapping from the perspective of dynamical systems as regards the in-phase mode and anti-phase mode and none has investigated the frequency effect as a *control parameter*. Therefore, we conducted a finger-tapping experiment to reveal the differences between intra-personal system and inter-personal system in terms of how multi-modal perceptual information affects the stability of tapping movements.

## Method

### Participants

A total of 30 healthy right-handed participants (15 males and 15 females) took part in the experiment, with 10 participants in the intra-personal condition and 10 pairs of participants (i.e., 20 participants) in the inter-personal condition. All participants were between 21 and 47 years of age (average age=26.9). The procedure was approved by the ethics committee at the National Institute of Informatics, where the experiment was conducted.

### Apparatus

A computer-generated metronome produced beeps, each lasting 85 msec. The metronome frequency was increased gradually from 1 Hz to 3 Hz over a 30-s trial after an initial 3-s period at 1 Hz. The metronome was run on a personal computer (Apple MacBook2130/13.3), and the beep sounds were conveyed to the participants through headphones (Sony MDR-NC600D) at a comfortable volume adjusted for each participant. A camcorder (TK-C1380; Victor), as part of the motion analyzer system DKH Frame-DIAS II, videotaped the movements of the participants' index fingers at 60 fields per second through the two-dimensional motion capture function of the Frame-DIAS II. The tapping movements and auditory stimuli were recorded on a hard disk drive (HDD) (Sony HVR-DR-60).

## Experimental Design and Procedure

The experiment was designed as a  $2 \times 2$  factorial with one between-subjects variable, i.e., the intra-/inter-personal condition (Figure 1), and one within-subject variables, i.e., the phase mode (in-phase and anti-phase) (Figure 2).

Participants were each seated at a desk in front of the camcorder. The task was to tap either in in-phase mode (two fingers tapping in synchronization) or anti-phase mode (two fingers tapping alternatively) at a pace dictated by the auditory metronome. The participants were instructed to keep their eyes open and watch their tapping movements during a trial, and to complete one full movement cycle, an extension-and-flexion cycle, for each beat of the metronome. They were also instructed to maintain the initial mode of coordination as much as possible, but not at the expense of losing pace with the metronome, and not to resist if they felt a change in the coordination pattern as a result of the increased tapping frequency. In the anti-phase mode, they tapped alternatively: the left finger was tapped in synchronization with the metronome beat while the right finger was in syncopation. Each condition was repeated four times, and the order of the trials was arranged randomly.

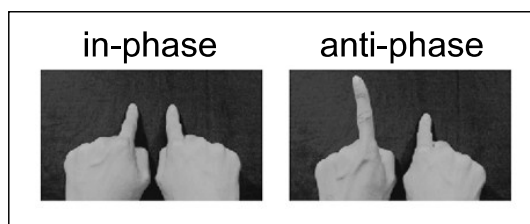

Figure 2: Phase mode.  
(left; in-phase mode, right; anti-phase mode)

## Data Analysis

In order to assess the stability of the tapping movement, we had previously analyzed the average number of phase transitions and average time-to-transition (Kodama and Furuyama, 2011). These indices, however, revealed only the total stability across a trial, i.e., *how many times* or *when* a phase transition occurred. In the present study, besides these two indices, we conducted a quantitative analysis of relative phase through a trial, to assess how progressively and how much fluctuation of movement increased or decreased. Relative phase is considered as an *order parameter* or, in other words, a *collective variable*, which represents the stability of a system. Thus, the phase transition should be described as a change in the relative phase from the perspective of the dynamical systems approach. In the present study, to assess the effect of frequency on performance, the relative phase was calculated and the standard deviation of the relative phase was obtained with respect to six 5-sec intervals.

**Average number of phase transitions** To measure the stability of movement in terms of temporally global stability, the average number of phase transitions was obtained as follows. When the right and left index fingers tapped together within a time window of 67 msec, derived from the video camera's frame rate, the tapping was categorized as being in the in-phase mode. When the time interval between one finger's peak of flexion (tap) and the other finger's peak of extension was within a time window of 67 msec, the tap was considered to be in the anti-phase mode. We considered that a phase transition would take place only if the taps in the opposite phase mode occurred at least five times in a row. The average number of phase transitions was obtained by counting the number of phase transitions in each of the phase mode conditions for each participant and each pair of participants.

**Average time-to-transition** We calculated the average time-to-transition in order to measure the temporally global stability, following a previous study's method (Riek and Wooley, 2005). The time-to-transition of a trial in which a phase transition occurred was defined as the interval from the start of the trial to the first tap in the opposite phase mode. The time-to-transition of a trial in which no transition occurred was defined as 30 s.

**Relative Phase Analysis** Besides two temporally global indices, we also calculated the relative phase between taps using standard procedures (e.g., Carson, 1995), in order to measure the temporally local stability of movement. To assess the effect of frequency on performance, each trial was separated into six equal time intervals of 5 s each (Riek and Wooley, 2005). The standard deviation of relative phase ( $SD \phi$ ) was calculated in each time interval.  $SD \phi$  reflects the stability of performance.

## Results

### Average number of phase transitions

Figure 3 shows the average number of phase transitions as a function of the intra-/inter-personal condition and phase modes. In the intra-personal condition, no transition was observed in the in-phase or anti-phase mode conditions; that is, there was no difference in the average number of phase transitions between two phase modes. In the inter-personal condition, no transition was observed in the in-phase mode condition, but it occurred an average of 2.5 times in the anti-phase one; that is, the transition occurred more often in the anti-phase mode than in the in-phase mode. In the anti-phase mode condition, transitions occurred more often in the inter-personal system than in the intra-personal condition.

Figure 3: Average number of phase transitions.

### Time-to-transition

Figure 4 plots time-to-transition as a function of the intra-/inter-personal condition and phase modes. In the intra-personal condition, the time-to-transition was 30 sec in both modes; that is, the time-to-transition between the two modes had no difference. In the inter-personal condition, the time-to-transition was on average 29.9 s in the in-phase mode and 26.7 s in the anti-phase one; that is, it was shorter in the anti-phase mode than in the in-phase one. In the anti-phase mode condition, the time-to-transition was revealed to be shorter in the inter-personal system than in the intra-personal one.

Figure 4: Average time-to-transition.

Figure 5: SD of relative phase.

## SD $\phi$

Figure 5 shows the standard deviation of the relative phase as a function of elapsed time of the trial (grouped into six five-second duration), equivalent to the frequency of movement. A three-way ANOVA (intra-/inter-personal condition (2)  $\times$  phase mode (2)  $\times$  frequency (6)) conducted on the SD  $\phi$  confirmed the main effect of the intra-/inter-personal condition ( $F(1,9)=48.186, p<.001$ ), phase mode ( $F(1,9)=34.097, p<.001$ ), and frequency ( $F(1,9)=100.841, p<.001$ ). It also revealed significant interactions: intra-/inter-personal  $\times$  phase mode ( $F(1,9)=14.338, p<.005$ ), intra-/inter-personal  $\times$  frequency ( $F(1,9)=16.996, p<.001$ ), phase mode  $\times$  frequency ( $F(1,9)=19.863, p<.001$ ), and intra-/inter-personal  $\times$  phase mode  $\times$  frequency ( $F(1,9)=28.746, p<.001$ ).

The simple main effect test for the intra-/inter-personal  $\times$  phase mode interaction revealed that there was no significant difference in SD  $\phi$  between in-phase mode and anti-phase mode in the intra-personal condition ( $F(1,9)=2.107, N.S.$ )

## Discussion

### Intra-personal condition

In the intra-personal condition, neither the average number of phase transitions, average time-to-transition nor SD  $\phi$  differed between the in-phase and anti-phase modes. This result did not agree with the prediction of the HKB model (Haken et al., 1985) that the stability of movement is higher in the in-phase mode than in the anti-phase one. It is possible that the range of the metronome frequency did not cover the critical frequency. But this is not the only possibility that contributed the result. We need to consider the contribution of 1) haptic feedback and 2) dynamical relation between inter-limb coordination systems and posture. On the basis of these two possibilities, we suggest two hypotheses to explain why such an unexpected result was obtained.

The first hypothesis concerns perceptual information (e.g., haptic information). Unlike the inter-limb coordination task that many previous studies conducted, e.g., wiggling fingers or swinging pendulums and legs, the participants in this study were required to tap on the surface of a desk, so haptic information was available at the time of the tapping. Kelso et al. (2001) reported that haptic information can stabilize finger extension-and-flexion movement; therefore, we suppose that this kind of haptic information may help to stabilize the anti-phase mode tapping movement.

The second hypothesis is that the posture may stabilize the finger tapping movement. In the tapping task, participants could support their postures by touching a desk, and cancel their body sway each time they tapped, so both the posture and limb movement might be less affected by each fluctuation. On the other hand, in the wiggling task, they could not cancel the body sway caused by the limb extension-and-flexion movement, and the instability of the posture might cause the phase transition in the anti-phase movement.

### Inter-personal condition

In the inter-personal condition, all indices of the average number of phase transitions, average time-to-transition, and SD  $\phi$  showed that the stability of movement was higher in the in-phase mode than in the anti-phase one. This result was in agreement with the results of the previous study (Schmidt et al., 1998); that is, visual information might involve organization and stabilization of coordinated finger tapping movements. Moreover, as in the previous study (Schmidt et al., 1998), one participant in the inter-personal

tapping experiment can always perceive the metronome beats as auditory information; that is, “on the beat” situation. On the other hand, the other participant must always tap at the midpoint between the metronome beats; that is “off the beat”. The possibility still remains that the “off the beat” participant might couple with not visual information, i.e., the partner’s finger’s motion, but rather auditory information, i.e., the metronome beats. Further experiments have to be done in order to reveal which kind of perceptual information (e.g., visual or auditory) is involved in organization and stabilization of the inter-personal coordination systems.

### Future direction

Recently, some researchers have referred to social coordination or joint-action in the inter-personal coordination paradigm from the cognitive perspective and the behavioral dynamics perspective (Schmidt et al., 2010). The cognitive perspective supposes there is a common coding of perception and action; that is, the same representations are used to perceive and perform an action. Additional evidence for such a common coding comes from discovery of mirror neurons in monkeys (Iacoboni et al., 1999), and mirror system in humans (Calvo-Merino et al., 2005). Although such mirror/common coding systems might be important for forming simple inter-personal coordination or imitating another’s behavioral patterns, it is difficult to explain how such a coordination or synchronization occurs *in time*. Even if perception and action coding occurs in mirror systems in the brain, we cannot share those representations directly, because the central nervous systems are not connected to each other. Therefore, we suppose that not only cognitive approaches based on neuroscience but also behavioral dynamics perspectives inspired by the dynamical systems approach are needed to reveal the coordination mechanisms in inter-personal systems. To do this, it will be important to identify which kind of perceptual information is involved in organization and stabilization of inter-personal coordinated movement. Recently, Ulzen et al. (2010) tried to apply the HKB model to inter-personal coordination during a treadmill walking task and confirmed that the dynamical model for rhythmic inter-limb coordination does not readily apply, at least not generically or robustly, to inter-personal coordination when people are walking side-by-side on a treadmill. These results suggested the possibility that the HKB model does not necessarily apply to every system.

As important as identifying the perceptual information available in the inter-personal system, it is also important to compare the intra-personal and inter-personal coordination systems. Coey et al. (2011) attempted to compare these two systems and evaluate the relationship between the stability of intra-personal coordination and the emergence of spontaneous inter-personal coordination. However, against their hypothesis that the stability of the intra-personal coordination patterns would affect the emergence of inter-

personal coordination in a pendulum-swinging experiment, the stability of the intra-personal coordination patterns did not affect the emergence of inter-personal coordination, and the emergence of inter-personal coordination did not affect the stability of the intra-personal coordination patterns (Coey et al., 2011). The present study did not clarify whether or not the stability of the intra-personal coordination patterns and the emergence of inter-personal coordination influence each other in the finger-tapping task. In the future, we should evaluate the possibility of such influences by means of analyzing the stabilities of both intra-personal and inter-personal systems.

### Conclusions

The present study investigated the differences between intra- and inter-personal systems in terms of the perceptual effect on the stability of inter-limb coordination in a finger-tapping experiment. A between-subjects factor (intra-/inter-personal system) and a within-subject factor (phase mode) were investigated. Standard deviation of relative phase revealed that the stability of the tapping movement differed for each factor and significant interactions among these factors. The stable pattern of the intra-personal system was different from that of the inter-personal system.

These findings require us to reconsider the perceptual effect on inter-limb coordination and its theoretical model. In order to classify complicated factors (e.g., the effect of haptic information on anti-phase tapping movement in the intra-personal system), we should conduct further experiments in the future.

## Abstract

Expressing the confidence level of a system's suggestions by using speech sounds is an important cue to users of the system for perceiving how likely it is for the suggestions to be correct. We assume that expressing the levels of confidence using human-like expressions will cause users to have a poorer impression of a system than if artificial subtle expressions (ASEs) were used when the quality of the presented information does not match the expressed level of confidence. We confirmed that this assumption was correct by conducting a psychological experiment.

**Keywords:** Artificial Subtle Expressions (ASEs), Human-like Expressions, Confidence, Users' Subjective Impressions

## Introduction

Human-machine communication using speech sounds is becoming more common (Cohen, Giangola, & Balogh, 2004; Nass & Brave, 2005) because users can obtain information while engaging in their primary tasks without facing nor manually operating the information providing systems (e.g., intelligent home appliances or car navigation systems). However, due to various reasons (for example, Benzeghibaa et al., 2007), such as noise in the sensors, the incompleteness of data, immaturity of technology, and the complexity of tasks, the reliability of such systems is often limited. Cai & Lin (2010) experimentally showed how expressing the levels of confidence for such systems to indicate whether the system's represented information is accurate or not to users plays an important role in improving both the user's performance and their impressions.

When intending to express a system's level of confidence, one can easily have the idea of using human-like verbal expressions such as "probably," "definitely," or "83% confident." However, expressing levels of confidence using such human-like expressions might frustrate users when the quality of the presented information does not match the expressed level of confidence. For example, users might feel frustrated with systems (like car navigation systems) that express a higher level of confidence like "you should follow my suggested route" or "I am 80% confident," but the represented information was wrong (this is the case of being "overconfident"). Since human-like expressions make users expect higher human-like abilities from the systems (for example, Sholtz & Bahrami, 2003; Kanda et al., 2008), such inconsistent behaviors eventually make them deeply disappointed (Aronson & Linder, 1965; Komatsu & Yamada, 2010; Komatsu, Kurosawa & Yamada, 2011).

Related to the above issue, we have proposed artificial subtle expressions (ASEs) as an intuitive methodology for notifying users of a system's internal state. Actually, the ASEs only have a complementary role in communication and should not interfere with communication's main protocol. This means that the ASEs themselves do not have any meaning without a communication context. In particular, we showed that ASEs implemented as beep-like sounds succeeded in accurately and intuitively conveying a system's confidence to the users (Funakoshi et al., 2010; Komatsu et al., 2010a; Komatsu et al., 2010b). Therefore, we assume that our proposed ASEs are suitable for expressing levels of confidence in comparison to human-like expressions.

The purpose of this study is then to confirm the above assumption that expressing levels of confidence using human-like expressions gives users a poorer impression of a system than by using those expressed by ASEs when the quality of the presented information does not match the expressed levels of confidence (in particular, where the system's suggestions are incorrect/correct even though the expressed confidence is high/low) by conducting a psychological experiment to comprehend the users' subjective impressions.

Such inconsistency between the represented information and the level of confidence is inevitable due to the immaturity of the current technology used in media terminals and due to the fact that the levels of confidence are just a probability indicating how accurate the represented information is. Therefore, this study should contribute to proposing a novel interaction technique on how to handle this inconsistency without frustrating the users.

Figure 1: Driving and treasure hunting video game

## Experiment

### Environment

We used a “driving and treasure hunting” video game as our experimental environment for comprehending the participants' impressions of a system. In this game, a game image scrolls forward on a straight road as if the participant is driving a car using a navigation system with three small mounds of dirt appearing along the way. A coin is inside one of the three mounds, while the other two mounds contain nothing. The game ends after the participant encounters 20 sets of mounds (20 trials). The purpose of this game is to get as many coins as possible. The location of the coin amongst the three mounds was randomly assigned. In each trial, the navigation system next to the driver's seat (circle on top of Figure 1) told them which mound it expects the coin to be in by using speech. The participants could freely accept or reject the navigation system's suggestions. After the participant selected one mound among the three using a computer mouse, they could immediately know whether the selected mound contained the coin or not on the display (middle of Figure 1).

### Using Speech Sounds

In this experiment, the navigation system used Japanese speech sounds to suggest to the users the expected location of the coin; that is, “ichi-ban (no. 1),” “ni-ban (no. 2),” or “san-ban (no. 3).” These speech sounds were created by adding robotic-voice effects to the recorded speech sounds of one of the authors. These sounds were the main protocol (suggestion) of the navigation system. We then prepared the following three experimental stimuli (conditions) to express the levels of confidence of the main protocol.

- **ASE Condition:** One of the two ASEs was played 0.2 seconds after the speech sounds (Figure 2). These two ASEs were triangular wave sounds 0.5 seconds in duration with different pitch contours (Figure 3); that is, one was a flat ASE (onset F0: 400 Hz and end F0: 400 Hz) and the other was a decreasing ASE (onset F0: 400 Hz and end F0: 250 Hz). The suggestions with decreasing ASEs were able to inform users of the system's lower level of confidence in its suggestions while the ones with flat ASEs were to inform them of a higher level of confidence (Funakoshi et al., 2010; Komatsu et al., 2010a; Komatsu et al., 2010b).
- **Paralinguistic Condition:** As a kind of typical human-like expressions, we prepared two stimuli by modifying the paralinguistic information of the suggestions (“ichi-ban,” “ni-ban,” and “san-ban”), e.g., the rate of the utterances and intonation patterns; that is, one was an utterance with a faster rate with a falling intonation (“ichiban!”, Figure 4 (b)), while the other was a slower-rate utterance with a rising intonation (“i.chi.ba.n?”, Figure 4 (c)). We designed the latter stimulus (slower rate with rising intonation) to inform users of the system's lower level of confidence in the

form of a question, while the former stimulus (faster rate and falling intonation) informs them of a higher level of confidence.

- **Linguistic condition:** As another kind of typical human-like expressions, we prepared two stimuli by adding Japanese linguistic suffixes to the suggestions; that is, one with “desu (definitely)” 0.1 seconds after the suggestion, and the other with “dato omoi masu (I guess so).” We designed the suggestions with “dato omoi masu” to inform users of the system’s lower level of confidence, while the ones with “desu” to inform them of a higher level of confidence.

Among the 20 trials, the navigation system expressed the information with a higher level of confidence 10 times and with a lower one 10 times. The order of these two levels of confidence was counterbalanced across the participants.

Figure 2: Speech sound “ni-ban (no.2)” and decreasing ASE

Figure 3: Flat and decreasing ASEs (duration: 0.5 second)

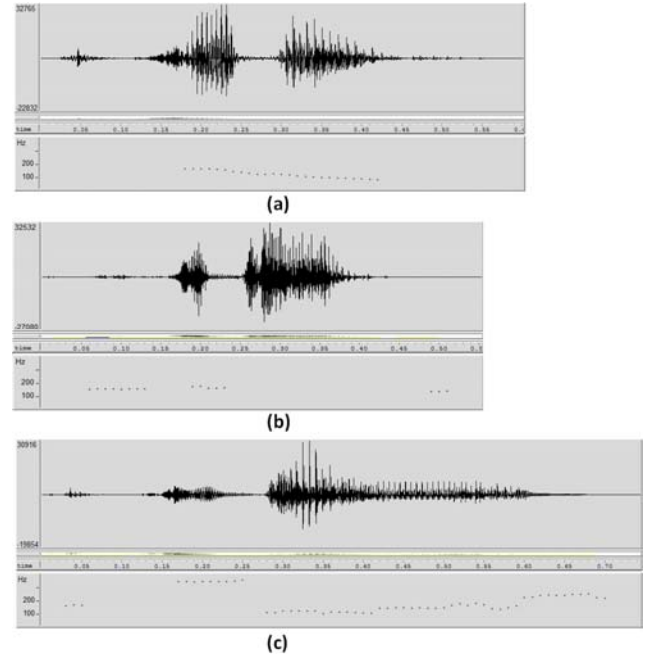

Figure 4: (a) Original wave form and pitch contour of “ichiban” used in ASEs and Linguistic conditions, (b) wave form and pitch contour of “ichiban!” and (c) wave form and pitch contour of “i..chi..ba..n?”

## Participants

Twenty Japanese university students (15 men and 5 women; 21 - 28 years old) participated. They were randomly divided into the following two experimental groups in terms of the accuracy of the navigation system’s levels of confidence.

- **Consistent Group (10 participants):** The participants in this group interacted with a system that expressed levels of confidence that were consistent with the correctness of the information it presented; that is, when the system expressed the information at a higher level of confidence, the rate of the suggested mound containing the coin was 100%, and when the system expressed the information with a lower level of confidence, the rate was 0%.
- **Inconsistent Group (10 participants):** The participants in this group interacted with a system that expressed levels of confidence that were inconsistent with the correctness of the information it presented; that is, when the system expressed the information with a higher level of confidence, the rate of the suggested mound containing the coin was 50%, and when the system expressed the information with a lower level of confidence, the rate was also 50%.

All the participants experienced all three experimental stimuli, so the experimental design was a  $2 \times 3$  mixed design; that is, the between-factor was consistent (consistent/inconsistent groups), while the within-factor was

the type of stimuli (ASEs/Paralinguistic/Linguistic conditions).

## Procedure

We used a web-based questionnaire system to comprehend the participants' impression of the navigation systems and their performances and behaviors using the treasure hunting video game in this experiment. First, the system displayed a consent form and the instructions for the experiment. Before starting the treasure hunting game, the participants were asked to listen to test sounds via a speaker or headphones and to adjust the sound volume to a comfortable level. Afterwards, they played the treasure hunting video game three times to experience all three conditions. The order of these conditions was counterbalanced among the participants.

After finishing each condition, the participants were asked to fill in a questionnaire on the navigation system, which consisted of 18 questions using a 7-point Likert scale (maximum evaluation: 7 points; minimum evaluation: 1 point). The summed points of these questions were used as the "participants' subjective impression scores" of this navigation system; that is, more points meant a better impression of the system (the highest score was 126 points and the lowest was 18). The questionnaire consisted of a modified love-liking scale (Rubin, 1970) and our original questions (Table 1: Cronbach's alpha: 0.86).

Table 1: 18 questions in the questionnaire

1. My feeling is the as usual even if I use this system.
2. This system has good adaptability.
3. This system deserves to work on responsible tasks.
4. I place complete reliance on this system.
5. This system makes favorable impressions on many people.
6. This system is always preferred among the similar systems.
7. I prefer this system because this system is similar to my way of thinking.
8. This system is human-like.
9. This system can offer good services.
10. I am satisfied with the services of this system.
11. I want to use this system again.
12. I cannot stand the mistakes made by this system.
13. This system is polite.
14. This system is a sufficiently reliable one.
15. This system is helpful for me.
16. This system is lovable.
17. I enjoy spending time with this system.
18. I feel tired when I use this system.

## Assumption

We assumed that expressing the levels of confidence using human-like expressions would give the users a poorer impression of the system than expressing these levels with ASEs when the quality of the presented information does not match the expressed levels of confidence; in particular, in the case where the systems' suggestions were incorrect/correct even though the confidence was high/low. That is, if we could observe that the participant's impression scores for the ASE condition were significantly higher than

those for the paralinguistic and linguistic conditions in the inconsistent group, we would be able to verify our assumption.

## Manipulation Check

We assumed that the types of experimental stimuli (ASEs/paralinguistic/linguistic conditions) did not affect the participants' performance and behaviors in this game but only their subjective impressions of the system. We then investigated the game scores, which indicated how many coins the participants acquired during the game (maximum: 20 coins) to clarify the relationship between the stimuli and their performance in this game (Table 2) and the acceptance rate, which indicated how many of the system's suggestions the participants accepted (maximum: 10 times for each confidence level) to clarify the relationship between the experimental stimuli and the participants' behaviors (Table 3).

The game scores were then analyzed with a  $2 \times 3$  mixed ANOVA (between independent variable: consistent/inconsistent groups, within independent variable: ASEs/paralinguistic/linguistic conditions, and dependent variable: game score). The results showed no significant difference on the main effects of the within independent variable [ $F(2,36)=0.04$ , n.s.]. The acceptance rates were analyzed with a  $2 \times 3 \times 2$  mixed ANOVA (between independent variable: consistent/inconsistent groups, #1 within independent variable: ASEs/paralinguistic/linguistic conditions, #2 within independent variable: suggestion with high/low confidence, and dependent variable: acceptance rate). The results showed no significant difference on the main effects of the #1 within independent variable [ $F(2,36)=0.04$ , n.s.].

Table 2: Game scores for each experimental condition

	Inconsistent	Consistent
ASEs	6.8	11.6
Paralinguistic	8.3	12.7
Linguistic	7	11.8

Table 3: Acceptance rate for each experimental condition according to confidence level

	Inconsistent	Consistent
ASE Low Confidence	5.4	2.4
ASE High Confidence	7.8	9.1
Paralinguistic Low Confidence	5.2	1.9
Paralinguistic High Confidence	7.8	9.4
Linguistic Low Confidence	5.1	2.5
Linguistic High Confidence	7.3	8.8

As a result of this manipulation check, we confirmed that the type of experimental stimuli did not affect the participants' performance and behaviors. Therefore, we can focus purely on the effects of the types of experimental stimuli on the participants' subjective impressions scores.

## Results

The users' subjective impression scores for each group and condition are shown in Figure 5. For the 10 participants in the consistent group, the average impression score for the ASE conditions was 58.2 (SD = 15.53), that for the paralinguistic ones was 75.1 (SD = 9.27), and that for the linguistic ones was 68.1 (SD = 11.85). For the 10 participants in the inconsistent group, the average impression score for the ASE conditions was 60.0 (SD = 11.40), that for the paralinguistic ones was 49.4 (SD = 11.94), and that for the linguistic ones was 48.6 (SD = 12.31).

These subjective impression scores were then analyzed using a  $2 \times 3$  mixed ANOVA (between independent variable: consistent/inconsistent group, within independent variable: ASEs/paralinguistic/linguistic, and dependent variable: users' subjective impression scores). The results of the ANOVA showed significant differences in the interaction effect [ $F(2,36)=11.50$ ,  $p<.01(**)$ , effect size:  $\eta^2=0.15$ ] and the main effect between independent variables [ $F(1,18)=9.99$ ,  $p<.01(**)$ ,  $\eta^2=0.22$ ]. The simple main effects of the between and within independent variables were then analyzed, and the results showed significant differences in the scores for the paralinguistic and linguistic conditions between the consistent and inconsistent groups [paralinguistic:  $F(1,18)=26.03$ ,  $p<.01(**)$ , linguistic:  $F(1,18)=11.71$ ,  $p<.01(**)$ ], and in the scores for the three experimental stimuli within both groups [consistent:  $F(2,36)=7.97$ ,  $p<.01(**)$ , inconsistent:  $F(2,36)=4.48$ ,  $p<.05(*)$ ]. A multiple comparison using an LSD test on the simple main effect of the within independent variables showed that the scores for the paralinguistic and linguistic conditions in the consistent group were significantly higher than those for the ASEs (MSe=90.4883, 5% level). In comparison, the scores for the paralinguistic and linguistic conditions in the inconsistent group were significantly lower than those for the ASEs (MSe=90.4883, 5% level).

Figure 5. Subjective impression scores for each experimental condition and group

Therefore, we clearly observed that the users' impression scores for the ASE conditions were significantly higher than those for the paralinguistic or linguistic conditions in the

inconsistent group, so we were able to verify our assumption. Moreover, we found that the scores for the ASE conditions in both groups were almost the same, while the scores for the paralinguistic and linguistic conditions significantly differed. Therefore, this also implies that the users' subjective impressions for a system expressing ASEs were quite robust regardless of the consistency between the represented information and the levels of confidence.

## Discussion

The results of this study showed that expressing confidence using human-like expressions received a higher evaluation in comparison to using such expressions with ASEs when the accuracy of the system's levels of confidence was perfect (in consistent group). However, it is almost impossible to build a user interface that can always provide correct suggestions and levels of confidence to users based on the level of current technology. Therefore, establishing a concrete methodology for handling the inconsistency between the suggestion and the levels of confidence is indispensable and worthwhile for the HCI and cognitive science domains.

We now have to investigate whether the acquired results can be used in much more realistic applications, e.g., spoken dialogue systems like an actual car navigation system. If we succeed, we can strongly argue that expressing the levels of confidence of systems by using ASEs is a reasonable methodology for avoiding frustrating users, and will contribute to the proposals for a novel interaction technique for dealing with the inconsistency between the represented information and the levels of confidence.

In this experiment, we could not clarify which kinds of users' cognitive basis significantly affected the result of this experiment. We assume that several researches such as the gain and loss of esteem (Aronson & Linder, 1965), adaptation gap hypothesis (Komatsu & Yamada, 2010; Komatsu, Kurosawa & Yamada, 2011), uncanny valley (Mori, 1970) and human's cognitive nature for anthropomorphism (Reeves & Nass, 1996) are keys to find out the cognitive basis that could clearly explain the participants' behaviors observed in this experiment. To tackle with this issue, we are now planning to conduct a consecutive experiment to investigate the further abilities of ASEs; that is, whether the ASEs could inform users of not only the higher or lower level of confidence but the other kinds of meanings? or more detailed level of confidence? We believe that this consecutive study would clarify which users' cognitive basis affect their behaviors how they intuitively interpret the ASEs.

## Conclusions

Expressing the confidence level of a system's suggestions by using speech sounds is an important cue to users of the system for perceiving how likely it is for the suggestions to be correct. We assume that expressing the levels of

confidence using human-like expressions will cause users to have a poorer impression of a system than if the ASEs were used when the quality of the presented information does not match the expressed level of confidence. We confirmed that this assumption was correct by conducting a psychological experiment. In particular, the users' impression scores for the ASE conditions were significantly higher than those for the paralinguistic or linguistic conditions in the inconsistent group.

## Abstract

This study investigated the effect of social skills on the facial movement asymmetry in facial expressions. Three-dimensional facial landmark data of facial expressions (neutral, happy, and angry) were obtained from Japanese participants ( $n = 62$ ). After the facial expression task, each participant completed KiSS-18 (Kikuchi's Scale of Social Skills; Kikuchi, 2007). Through a generalized Procrustes method, facial landmark coordinates and their mirror-reversed versions were represented as points on a hyperplane. The asymmetry of each face was defined as Euclidian distance on the plane. Subtraction of the asymmetry level of a neutral face of each individual from the asymmetry level of a target emotion face was defined as the index of "movement asymmetry" of each emotion. Correlation coefficients of KiSS-18 scores and movement asymmetry scores were computed for both happy and angry expressions. Significant negative correlations between KiSS-18 scores and movement asymmetries were found for both expressions. The results indicate that symmetric facial expressions are higher with higher level of social skills.

**Keywords:** facial expression; facial asymmetry; social skills; landmark-based 3D shape analysis.

## Introduction

Facial expressions provide various signals for social interactions. Although human faces and facial expressions are somewhat symmetrical, numerous studies have focused on facial bilateral symmetry: the degree to which one half of a face is similar to the other half. Facial asymmetry derives from two sources: structural asymmetry and movement asymmetry (Schmidt, Liu & Cohn, 2006). Structural asymmetry derives from physical variation in laterality of facial structure, while movement asymmetry derives from lateralized facial muscle movement during facial expressions. In this study, we focused on movement asymmetry in creating emotional expressions.

The primary source of facial movement asymmetry is brain lateralization in emotion processing. Several studies have shown that emotions are expressed more intensely in the left hemiface (Sackeim, Gur & Saucy, 1978; Borod, Haywood & Koff, 1997), because most facial muscles, particularly those in the lower part, are innervated by the contralateral hemisphere (Borod, 1993). Thus the dominance of the left hemiface in facial expressions has been interpreted as supporting the hypothesis of brain lateralization of emotional processing (Schwartz, Davidson & Maer, 1975; Sackeim, Greenberg, Weiman, Gur, Hungerbuhler & Geschwind, 1982). More recent studies have asserted that both hemispheres process emotion, but each hemisphere is specialized for particular types of emotion (Fusar-Poli, Placentino, Carletti, Allen, Landi, Abbamonte, Barale, Perez, McGuire & Politi, 2009) such as positive-negative emotion (Davidson, 1992; Gur, Skolnick & Gur, 1994), or approach-withdrawal (Davidson, 1999).

While the laterality in facial expressions, human face perception mostly relies on facial information contained in the right hemiface (Gilbert & Bakan, 1973; Grega, Sackeim, Sanchez, Cohen & Hough, 1988, Kanwisher, McDermott & Chun, 1997; Sergent, Ohta & MacDonald, 1992). When asked to judge the facial expression of a briefly presented chimeric face image, perceivers tend to base their decision more frequently on the expression contained within the right side of the face, i.e., the left hemiface for the viewer. Thus, the lateralization in facial expressions can lead to failure in conveying the face's real emotions to an observer. Although the role of asymmetry of facial expressions in social interactions is still unclear, asymmetric facial expression is possibly an important variable. Facial asymmetry has been proposed as a signal of developmental stability that can indicate mate quality (Grammer & Thornhill, 1994; Kowner, 1996; Penton-Voak, Jones, Little, Baker, Tiddeman, Burt & Perrett, 2001). In general, the less asymmetric a face is, the more attractive it appears (Grammer, Fink, Moller &

Thornhill, 2003; Grammer & Thornhill, 1994). This asymmetry is believed to reflect past developmental stresses and to be related to the likely quality of the individual as a potential mating partner (Fink, 2004). Such preference for symmetry may also extend to the preference for movement symmetry.

This study investigates the relationship between social skills and facial movement asymmetry in emotional expressions. Social skills are generally defined as the set of skills that enable a person to interact and communicate with others in verbal and nonverbal forms of communication. If higher social skills are related to more symmetrical facial movements in emotional expressions, symmetrical facial expressions can be considered an appropriate approach to present the face owner's emotions to receivers in social interactions.

## Method

### Facial Expression Task

Japanese undergraduate and graduate students ( $n = 62$ : 20 men and 42 women; age: 19 to 26 years, mean age = 21.3,  $SD = 1.37$ ) provided three-dimensional facial shape data of neutral, happy, and angry expressions. First, the participants were instructed to show and maintain a neutral facial expression. Then, they were asked to recall their experiences in which they had felt the target emotions (happy or angry) and to describe the experience after taking each 3D image. The participants were not instructed to pose or maintain any expression of target emotion. The order of target emotions was counterbalanced among the participants. Three-dimensional (3D) shapes and textures of facial expressions of each face were captured using a 3D picture measurement device (TRiDY-S: JFE Techno-Research Corp.) based on pattern-projection method.

### Assessment of Participants' Social Skill

After the facial expression task, each participant completed KiSS-18 (Kikuchi's Scale of Social Skills; Kikuchi, 2007), an 18-item self-report measurement of social skills with higher scores indicating high level of social skills. This scale is based on six categories of social skills proposed by Goldstein (1980); basic skills, advanced skills, emotional management skills, stress management skills, offence management skills and planning skills. Basic skills include 'talking with others', 'maintaining a conversation' and 'introducing oneself'. Advanced skills include 'asking for help', 'giving instructions', 'obeying instructions', 'apologizing' and 'persuading'. Emotional management skills include 'managing fear', 'emotional expression' and 'managing others' anger'. Stress management skills include 'managing criticism' and 'managing a contradiction in message'. Offence management skills include 'helping others', 'conflict resolution' and 'managing trouble'. Planning skills include 'staying on target' and 'taking initiative'. The scale has demonstrated high reliability and validity in previous studies (Kikuchi 2007).

## Facial Shape Measurement

Thirty-six facial landmarks were selected on the basis of our previous studies (Kamide, Komori, Kawamura & Nagaoka, 2011; Figure1, Table 1). All 3D coordinates of the landmarks were visually measured using a computer program (Rapid Form 2004: INUS Technology) by referring to each of the 3D shape data and texture.

Figure. 1: Landmark locations. Photographs were formed by warping average facial texture.

Figure 2: Schematic illustration of asymmetry. Each facial shape and its mirror-reversed version are represented as points on the tangent hyperplane. Only two axes are represented for ease of illustration. The “consensus face” is the origin of the space. Asymmetry is defined as the Euclidean distance from each original version to the mirror-reversed version.

### Facial Shape Standardization

Each face differed in location, size, and orientation. To standardize them, we performed a generalized Procrustes analysis (GPA) on the facial landmarks of all faces irrespective of the gender of the face. A GPA is an analytical method used for multivariate statistical analysis of landmark locations expressed in Cartesian coordinates. This method preserves information about the relative spatial relationships of landmarks throughout the standardization, and that has recently been applied to psychological research on human faces (Komori, Kawamura & Ishihara, 2009, 2011).

For the standardization of location and size, we used the centroid size technique (Bookstein, 1991). All facial shapes

were translated into the same origin (centroid) and scaled to the unit centroid size, which is the sum of the squared distances from the centroid to each landmark. For alignment of orientation, rotations around the centroid of the faces were performed (Dryden & Mardia, 1998) such that the sum of the squared distances among corresponding landmarks between samples was minimized. Using the GPA, each facial shape was represented as a point on a linear tangent hyperplane of 108 dimensions ( $36 \times 3$ ), which allowed us to treat the faces as multidimensional, normally distributed values.

The “Shapes” statistical package written by Dryden and Mardia (1998), which runs in an R statistical analysis environment, was employed for the analyses. In addition to the coordinates of 62 facial shapes, the mirror-reversed versions of the same faces were used in the facial shape analysis.

### Calculation of Facial Asymmetry

Through a generalized Procrustes method, each of the facial shapes and their mirror-reversed versions were represented as a point on the tangent hyperplane. We defined asymmetry (the converse of symmetry) of each facial shape as the Euclidean distance between the face and its mirror-reversed face on the hyperplane (Figure 2), according to our previous study (Komori, Kawamura & Ishihara, 2009). Furthermore, all original faces and their mirror-reversed faces were combined to create a consensus face. This was the average of all facial shapes and represented the origin of the tangent hyperplane. The distance from a given original face to the origin was the same as that from its mirror image to the origin. This distance can be regarded as an index of facial distinctiveness (the converse of facial averageness). Therefore, asymmetry and distinctiveness can be measured independently through this procedure; in other words, facial variations can be separated into distinctiveness and asymmetry.

### Calculation of Local Asymmetry

To investigate the degree of asymmetry in each facial part, such as eyebrows, eyes, and mouth, facial subspaces were constructed from the standardized landmark coordinates of eyebrows (from No. 4 to No. 12 of Table 1), eyes (from No. 15 to No. 22), and mouth (from No. 29 to No. 34). Asymmetry in each part of a face was defined as the Euclidean distance from the original version to the mirror-reversed version of each part in each subspace.

## Results

### Social Skill Score

Some studies have reported that males and females differ in facial shape (Little, Jones, Waite, Tiddeman, Feinberg, Perrett, Apicella & Marlowe, 2008) and facial muscle reactivity (Dimberg & Lundquist, 1990). It is possible that gender differences in social skills could be a potential confound in the analysis of the relationships between social

skills and facial expressions. However, the Kiss-18 scores were not significantly different between males and females ( $t(60) = -.57, p = .57$ ).

### Facial Asymmetry

The mean morphological asymmetry in each facial expression is shown in Figure 3. To examine the relationship between facial expressions (neutral, happy, and angry) and facial asymmetry levels, we conducted repeated measures ANOVA with facial asymmetry levels as the dependent variable. There was no significant effect of facial expression on the facial asymmetry levels ( $F(2,122) = .36, p = .72$ ).Local Asymmetries

The local asymmetries were calculated for eyebrows, eyes, and mouth (Figure 4). A repeated measures ANOVA was performed for each facial part, and a significant effect of

Figure 3: Mean facial asymmetry level. Error bars represent 1 S.D.

Figure 4: Mean facial asymmetry levels of facial parts. Error bars represent 1 S.D.

facial expressions on the asymmetry in mouth shape was found ( $F(2,122) = 4.10, p = .019$ ). However, there was no effect of facial expressions on the asymmetries in eyebrows or eyes (eyebrows:  $F(2,122) = .06, p = .94$ ; eyes:  $F(2,122) = .16, p = .21$ ).

### Relationship between Social Skills and Facial Asymmetry

Since there was no significant correlation between the Kiss-18 scores and facial asymmetry levels of neutral expression, facial structural asymmetry is considered potentially unrelated to social skills ( $r = .20, p = .13$ ). Thus, the subtraction of the asymmetry level of a neutral face of each individual from the asymmetry level of a target emotional face can be defined as the index of movement asymmetry that derives from facial muscle movement. Here we refer to the value as the “movement asymmetry score.”

To assess whether higher social skills are linked to facial movement asymmetry, correlation coefficients of the Kiss-18 scores and movement asymmetry scores were computed for both happy and angry expressions. Figure 5 shows the relationship between social skills and movement asymmetries. There was a significant negative correlation between the Kiss-18 scores and movement asymmetries for both expressions (happiness:  $r = -.30, p = .017$ ; angry:  $r = -.30, p = .018$ ), indicating that the higher a participant scored on the social skills test, the more symmetric their facial expressions were.

The partial correlation coefficients between social skills and movement asymmetries, using gender of the participants as control variables, were also significant for both expressions (happiness:  $r = -.30, p = .015$ ; angry:  $r = -.30, p = .017$ ). This suggests that the relationship between facial movement asymmetry and social skills was not caused by the gender differences in social skills.

Figure 5: Relationship between social skill score and degree of facial asymmetry.

The correlation coefficient of the Kiss-18 score and movement asymmetry in each facial part was calculated for each target emotion. For a happy expression, movement asymmetry of none of the parts was significantly correlated with social skills (eyebrows:  $r = -.16$ ,  $p = .21$ ; eyes:  $r = -.13$ ,  $p = .33$ ; mouth:  $r = -.02$ ,  $p = .89$ ). On the other hand, for an angry expression, only movement asymmetry of mouth was found to be negatively correlated with social skills (eyebrows:  $r = .03$ ,  $p = .82$ ; eyes:  $r = -.17$ ,  $p = .19$ ; mouth:  $r = -.26$ ,  $p = .04$ ).

## Discussion

This study provides evidence that facial movement asymmetry in emotional expressions is linked to low social skills. Some studies have shown that a spontaneous smile is symmetrical, but a posed (voluntary) smile is asymmetrical (Gazzaniga & Smylie, 1990; Frank, Ekman & Friesen, 1993), suggesting a possibility that symmetrical facial expression is recognized as spontaneous facial expression derived from the facial owner's emotion. In fact, Ozono, Watabe, Yoshikawa, Nakashima, Rule, Ambady & Adams (2010) have reported that Japanese participants rated faces with greater smile symmetry as more trustworthy. Thus, the results of this study may reflect the connection between symmetrical facial expressions and trustworthiness.

The results also show that the relationship between low social skills and facial movement asymmetry is especially observed in the lower face region. Neurologically, movements of the lower face region follows voluntary muscle control, while upper face area movements follow automatic control (Rinn, 1994; Gazzaniga & Smylie, 1990). It is possible that the different effect of social skills on the asymmetry in the upper or lower facial areas is caused by such differential motor control.

The results of the study also suggest that the asymmetry quantification method of this study is an effective method for evaluating 3D facial asymmetry.

## Abstract

Although the problems on Raven's Progressive Matrices intelligence tests resemble geometric analogies, studies of human behavior suggest the existence of two qualitatively distinct types of strategies: verbal strategies that use propositional representations and visual strategies that use iconic representations. However, all prior computational models implemented to solve these tests have modeled only verbal strategies: they translate problems into purely propositional representations. We examine here the other half of what may be a dual-process mechanism of reasoning in humans: visual strategies that use iconic representations. In particular, we present two different algorithms that use iconic visual representations to address problems found on the Advanced Progressive Matrices test, the best of which yields performances at levels equivalent to the 75th percentile for human test takers aged from 20 to 62 years-old. We discuss implications of our work for understanding the computational nature of Raven's and visual analogy in problem solving.

**Keywords:** Analogy; intelligence tests; knowledge representations; mental imagery; Raven's Progressive Matrices; visual reasoning.

## Introduction

The Raven's Progressive Matrices (RPM) test is a standardized intelligence test. The test consists of geometric analogy problems in which a matrix of geometric figures is presented with one entry missing, and the correct missing entry must be selected from a set of answer choices. Figure 1 shows an example of a matrix problem of this kind.

There are currently three published versions of the RPM: the original Standard Progressive Matrices (SPM), the Advanced Progressive Matrices (APM), developed as a more difficult test than the SPM for individuals in high IQ ranges, and the Colored Progressive Matrices (CPM), intended as a simpler test than the SPM to be used with children, the elderly, or other individuals falling into lower IQ ranges (Raven et al., 2003). The RPM tests are considered to be the single best psychometric measures of general intelligence, outside of multi-domain IQ tests like the Wechsler scales (Snow et al., 1984), and all three versions of the RPM are widely used in clinical, educational, occupational, and scientific settings.

Neuroimaging and behavioral studies suggest that humans recruit qualitatively different strategies on the RPM regarding what types of mental representations are used, specifically in terms of visual versus verbal strategies. Visual strategies use iconic mental representations rooted in the visual perceptual modality, such as mental imagery.

Verbal strategies use amodal propositional mental representations, such as linguistic description.

From factor analyses of both the SPM (Lynn et al., 2004; van der Ven & Ellis, 2000) and the APM (Dillon et al., 1981; Mackintosh & Bennett, 2005; Vigneau & Bors, 2005) as well as from fMRI data (Prabhakaran et al., 1997) comes evidence for various categories of RPM problems differentially eliciting from people either visual or verbal strategies. Studies of patients with focal brain lesions have also found linkages between brain regions associated with visual or verbal processing and successful performance on certain RPM problems (Berker & Smith, 1988; Villardita, 1985). Individuals with autism, who may exhibit a general bias towards using visual strategies over verbal ones (Kunda & Goel, 2007, 2011), tend to do particularly well on the RPM (Bölte et al., 2009; Dawson et al., 2007) and have been observed with fMRI to prefer predominantly visual strategies on the RPM (Soulières et al., 2009).

Despite this breadth of evidence for the existence of both visual and verbal RPM strategies, most computational RPM accounts have presumed to translate visual inputs into propositional representations, over which various kinds of reasoning then take place. One reason for this may be the general preponderance of propositional representations in computational accounts of cognition; in many models of visual reasoning across various task domains, visual knowledge too is represented using propositions (Carpenter et al. 1990, Lovett et al. 2010, Davies et al. 2008).

Figure 1: Example RPM Problem.

Another reason may stem from the practice of using verbal reporting protocols to study RPM problem solving. By their very nature, verbal reports are better suited to describing verbal strategies than visual strategies, which may introduce bias into the results of such protocols. Of even greater significance are findings across multiple task domains that the act of verbal reporting actually biases individuals towards using verbal strategies and/or impairs their use of visual strategies, a phenomenon known as “verbal overshadowing” (Schooler & Engstler-Schooler, 1990; Schooler et al., 1993). DeShon, Chan, and Weissbein (1995) found that a verbal reporting protocol on the APM significantly impaired accuracy on about half of the problems, and specifically on those typically solved using visual strategies.

The goal of our work is to develop computational models of a dual cognitive strategy that uses both verbal and visual representations. This first requires the development of computational models of the visual strategy itself. Once such computational models have been developed, they then may potentially be coupled with existing models of the verbal strategy. We have developed two such computational models of reasoning on the RPM using iconic visual representations. In earlier work, we tested these models against the SPM (Kunda, McGreggor, & Goel, 2010). In this paper, we apply these computational models to the APM.

In so far as we know, this work represents several firsts: it is the first report of any computational model addressing the entirety of the APM test, the first in which the problems are attempted using purely iconic visual representations, and the first to tackle the test using scanned images of each test page, without any re-rendering or representational change of inputs from those presented to a human test-taker.

## Computational Accounts of the RPM

Hunt (1974) proposed the existence of two different RPM strategies that varied primarily in how problem inputs were represented. The “Analytic” algorithm used propositions to represent problems as lists of features and logical operations to evaluate rules such as constancy and addition/subtraction. The “Gestalt” algorithm, akin to mental imagery, used iconic representations and perceptual operations like continuation and superposition. However, neither algorithm was actually implemented. All of the computational RPM models that have since been developed resemble Hunt’s Analytic algorithm in that they rely on a conversion of problem inputs into amodal propositional representations.

**Model 1** Carpenter, Just, and Shell (1990) used a production system that took hand-coded symbolic descriptions of certain problems from the Advanced Progressive Matrices (APM) test and then selected from a set of predefined rules to solve each problem. The rules were generated by the authors from a priori inspection of the APM. The rules were experimentally validated using a verbal reporting protocol, but the potential confound of a verbal overshadowing effect was not addressed. Differences between low- and high-scoring participants were modeled by developing two different versions (FairRaven and BetterRaven) of the production system; the more advanced system (BetterRaven) contained an increased vocabulary of

rules and a goal monitor. Both systems were tested against 34 of the 48 problems from the APM and solved 23 and 32 problems, respectively.

**Model 2** Bringsjord and Schimanski (2003) used a theorem-prover to solve selected RPM problems stated in first-order logic, though no specific results were reported.

**Model 3** Lovett, Forbus, and Usher (2010) combined automated sketch understanding with the structure-mapping analogy technique to solve SPM problems. Their system took as input problem entries sketched in Powerpoint as segmented shape objects and then automatically translated these shapes into propositional descriptions, using a sketch understanding system based on work by Biederman (1987). A two-stage structure-mapping process, following the theory of Gentner (1983), was then used to select the answer that most closely fulfilled inferred analogical relations from the matrix. This system was tested against 48 of the 60 problems on the SPM and solved 44 of these 48 problems.

**Model 4** The system of Cirillo and Ström (2010), like that of Lovett et al. (2010), took as input hand-drawn vector graphics representations of test problems and automatically generated propositional representations. Then, like the work of Carpenter et al. (1990), the system drew from a set of predefined patterns, derived by the authors from an a priori inspection of the SPM, to find the best-fit pattern for a given problem. This system was tested against 36 of the 60 problems on the SPM and solved 28 of these 36 problems.

**Model 5** Rasmussen and Eliasmith (2011) used a spiking neuron model to induce rules for solving RPM problems. This system took as input hand-coded vectors of propositional attribute-value pairs. While the system was said to correctly solve RPM problems, no specific results were reported.

## Our Approach

As mentioned above, despite considerable differences in architecture and problem-solving focus, all five of these computational models of the RPM have reasoned over amodal propositional representations of test inputs. We believe that Raven’s problems may be solved via computational models that use purely iconic visual representations of test inputs, and we present these models as a complementary view of reasoning on the RPM.

The two models that we have developed are the affine model and the fractal model, both of which use image transformations to solve RPM problems without converting the input images into any sort of propositional form. Previously, we described each of the models along with an analysis of their performance on all 60 problems from the SPM (Kunda, et al., 2010).

## Iconic Visual Reasoning

The affine and fractal methods differ in important ways, but share two intuitions: comparing images under a variety of transformations, and judging the similarity based upon features which arise from the images.

## Similitude Transformations

Each of our algorithms compares images (or fragments of images) under a variety of transformations. We use

similitude transformations, similarity-preserving transformations which are a subset of affine transformations. Similitude transforms are a linear composition of a dilation, an orthonormal transformation, and a translation. Our implementation presently examines images under eight orthonormal transformations, specifically dihedral group D4, the symmetry group of a square. The translation is determined as a consequence of the searching each algorithm performs. The affine method restricts dilation to a value of one, i.e. no scaling, whereas the fractal method uses a short sequence of progressively smaller dilation values. Thus, the fractal method's similitude transformations are contractive.

There is evidence that human visual processing can apply some of these types of transformations to mental images, or at least operations that are computationally isomorphic in some sense. In the theory of mental imagery proposed by Kosslyn, Thompson, and Ganis (2006), transformations of mental images include scanning (i.e. translation), zooming (i.e. scaling), and rotation, among others.

### A Model of Similarity

Our models must judge the similarity between images. The nature of this similarity may be determined by any number of means, many of which might associate visual or geometric features to points in a coordinate space, and compute similarity as a distance metric (Tversky 1977). Tversky developed an alternate approach by considering objects as collections of features, and similarity as a feature-matching process. We adopt Tversky's interpretation, and seek to derive a set of features for use in our matching process.

We desire a metric of similarity which is normalized, one where the value 0.0 means entirely dissimilar and the value 1.0 means entirely similar. We use the ratio model of similarity as described in (Tversky 1977), wherein the measure of similarity  $S$  between two representations  $A$  and  $B$  is calculated by the formula:

$$S(A,B) = f(A \cap B) / [f(A \cap B) + \alpha f(A-B) + \beta f(B-A)]$$

where  $f(X)$  is the number of features in the set  $X$ . Tversky notes that the ratio model for matching features generalizes several set-theoretical models of similarity proposed in the psychology literature, depending upon which values one chooses for the weights  $\alpha$  and  $\beta$ .

Although the same equation is used for similarity calculations, each of our models has its own interpretation of what constitutes a feature. In the affine method, a feature is defined to be a single pixel, and intersection, union, and subtraction operations are defined as the minimum, maximum, and difference of pixel values. This formulation assumes that pixels are independent features within the pixel sets represented by images  $A$  and  $B$ . While this notion of pixel independence is a strong simplification, it matches assumptions made by basic template theories of visual similarity that define similarity based purely on evaluations of the extent of overlapping figural units (Palmer, 1978), e.g. individual pixels. The fractal method uses features derived from different combinations of elements from the

fractal representation of the image comparison (McGreggor, Kunda, & Goel, 2010).

#### For each base transform $t_i$ :

- Apply  $t_i$  to image  $A$  to create image  $t_i(A)$ .
- Search all possible translation offsets between images  $t_i(A)$  and  $B$  to find single offset  $(x,y)$  yielding highest similarity between them.
- Calculate similarity  $s$  between images  $t_i(A)_{(x,y)}$  and  $B$
- For set-theoretic addition and subtraction, determine image composition operation  $\oplus$  and operand  $X$  as follows:
  - If  $\Sigma(A-B) = 0$ , then  $\oplus$  and  $X$  are null.
  - If  $\Sigma(A-B) = \Sigma(B-A)$ , then  $\oplus$  refers to image addition and  $X = B - t_i(A)_{(x,y)}$ .
  - If  $\Sigma(A-B) > \Sigma(B-A)$ , then  $\oplus$  refers to image subtraction and  $X = t_i(A)_{(x,y)} - B$ .

The composition transformation  $T_i$  is thus defined as precisely the transformation that changes image  $A$  into image  $B$ :

$$T_i(A) = t_i(A)_{(x,y)} \oplus X = B$$

#### Algorithm 1. Inducing a composite transform

### The Affine Model

Given a matrix problem, the affine model makes two basic assumptions: (a) that collinear elements are related by a composition of a similitude and/or set-theoretic transform, and (b) that parallel sets of elements share identical or analogous transforms. The model proceeds in three steps:

- 1) Induce a best-fit composite transform for a set of collinear elements in the matrix.
- 2) Apply this transform to the parallel set of elements containing the empty element; the result is a predicted answer image.
- 3) Compare this predicted image to the given answer choices for maximum similarity.

Algorithm 1 shows how, for a pair of images  $A$  and  $B$ , the "best-fit" composite transform is induced. The base unary transforms are the eight orthonormal symmetry transforms mentioned above (image rotations and mirrors), along with image addition (union of sets) and image subtraction (complement of sets). The base binary transforms are the five set operations of union, intersection, subtraction (both directions), and exclusive-or.

There are two places at which the affine model computes visual similarity, first in the induction of a best-fit composite transform, and second in the selection of the answer choice that most closely matches the predicted image. In addition to using Tversky's ratio model of similarity, as defined above, we also implemented a sum-squared-difference measure, which we converted to a measure of similarity (with minimum value of 0.0 and maximum value of 1.0) as:

$$SSDsimilarity = 1 / (1 + SSD)]$$

These two similarity measures exhibit different behaviors. The Tversky measure privileges matches that share more pixel content. In contrast, the SSD similarity measure

effectively ignores any pixel content that is shared; similarity is calculated only as a function of pixels that are different.

Once the transformation is found that maximizes similarity, the transformation is applied to the first entry or entries in the last row or column, as shown in Figure 2. The resulting image represents the algorithm's best guess as to the missing entry. This image is compared to the answer choices, and the best match is chosen as the final answer.

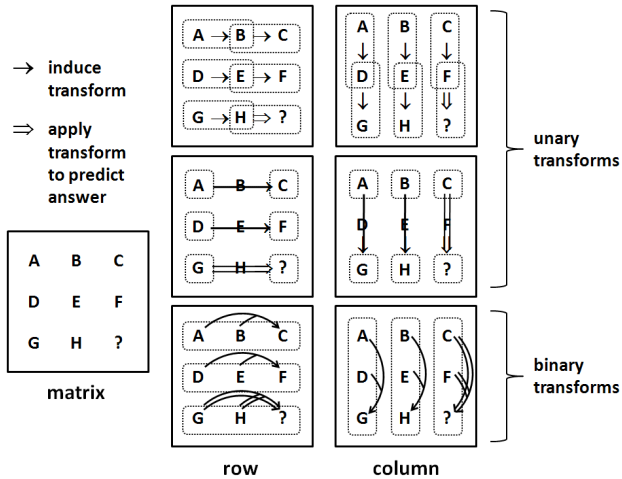

Figure 2. Sets of elements examined by the affine method

## The Fractal Method

Like the affine method, the fractal method seeks to find a re-representation of the images within a Raven's problem as a set of similitude transformations. Unlike the affine method, the fractal method seeks these representations at a significantly finer partitioning of the images, and uses features derived from these representations to determine similarity for each possible answer, simultaneously, across the bulk of relationships present in the problem.

For visual analogy problems of the form  $A : B :: C : ?$ , each of these analogy elements are a single image. Some unknown transformation  $T$  can be said to transform image  $A$  into image  $B$ , and likewise, some unknown transformation  $T'$  transforms image  $C$  into the unknown answer image. The central analogy in the problem may then be imagined as requiring that  $T$  is analogous to  $T'$ . Using fractal representations, we shall define the most analogous transform  $T'$  as that which shares the largest number of fractal features with the original transform  $T$ .

To find analogous transformations for  $A : B :: C : ?$ , the fractal algorithm first visits memory to retrieve a set of candidate solution images  $X$  to form candidate solution pairs in the form  $\langle C, X \rangle$ . For each candidate pair of images, we generate a fractal representation of the pairing from the fractal encoding of the transformation of candidate image  $X$  in terms of image  $C$ . We store each transform in a memory system, indexed by and recallable via each associated fractal feature.

**First, systematically partition  $D$  into a set of smaller images, such that  $D = \{d_1, d_2, d_3, \dots\}$ .**

**For each image  $d_i$ :**

- Examine the entire source image  $S$  for an equivalent image fragment  $s_i$  such that an affine transformation of  $s_i$  will likely result in  $d_i$ .
- Collect all such transforms into a set of candidates  $C$ .
- Select from the set  $C$  that transform which most minimally achieves its work, according to some predetermined metric.
- Let  $T_i$  be the representation of the chosen transformation associated with  $d_i$ .

**The set  $T = \{T_1, T_2, T_3, \dots\}$  is the fractal representation of the image  $D$ .**

Algorithm 2. Fractal Representation of  $D$  from  $S$

To determine which candidate image results in the most analogous transform to the original problem transform  $T$ , we first fractally encode that relationship between the two images  $A$  and  $B$ . Next, using each fractal feature associated with that encoding, we retrieve from the memory system those transforms previously stored as correlates of that feature (if any). Considering the frequency of transforms recalled, for all correlated features in the target transform, we then calculate a measure of similarity.

**Determining Fractal Similarity** The metric we employ reflects similarity as a comparison of the number of fractal features shared between candidate pairs taken in contrast to the joint number of fractal features found in each pair member (Tversky 1977). The measure of similarity  $S$  between the candidate transform  $T'$  and the target transform  $T$  is calculated using the ratio model. This calculation determines the similarity between unique pairs of transforms. However, the problems from the Raven's test, even in their simplest form, poses an additional concern in that many such pairs may be formed.

**Reconciling Multiple Analogical Relationships** In  $2 \times 2$  Raven's problems, there are two apparent relationships for which analogical similarity must be calculated: the horizontal relationship and the vertical relationship. Closer examination of such problems, however, reveals two additional relationships which must be shown to hold as well: the two diagonal relationships. Furthermore, not only must the "forward" version of each of these relationships be considered but also the "backward" or inverse version. Therefore for a  $2 \times 2$  Raven's problem, we must determine eight separate measures of similarity for each of the possible candidate solutions.

The  $3 \times 3$  matrix problems from the APM introduce not only more pairs for possible relationships but also the possibility that elements or subelements within the images exhibit periodicity. Predictably, the number of potential analogical relationships blooms. At present, we consider 48 of these relationships concurrently.

**Relationship Space and Maximal Similarity** For each candidate solution, we consider the similarity of each potential analogical relationship as a value upon an axis in a

Model	Representation	Input	Strategy	Set of APM	
				I (12 problems)	II (36 problems)
FairRaven	propositional	hand-coded propositions	prediction	7*	16*
BetterRaven	propositional	hand-coded propositions	prediction	7*	25*
Affine	iconic	scanned images	prediction	7	14
Fractal	iconic	scanned images	estimate / refine	12	26

\*out of 7 and 27 problems attempted, respectively

Table 1: Affine and fractal results on the APM compared with results of the Carpenter et al. (1990) model.

large “relationship space.” To specify the overall fit of a candidate solution, we construct a vector in this multidimensional relationship space and determine its Euclidean distance length. The candidate with the longest vector length is chosen as the solution to the problem.

The fractal method is described in more detail in McGregor, Kunda, and Goel (2010, 2011).

## Method

We tested our affine and fractal models on all 48 problems from the Raven’s Advanced Progressive Matrices test, 12 on Set I, and 36 on Set II. To obtain visual inputs, we scanned paper copies of each test at 200 dpi and manually corrected for small ( $\pm 3^\circ$ ) rotational misalignments. Thus, the input to the models was grayscale images in the PNG format, with each image containing a single problem (matrix and answer choices).

The models used a semi-automated procedure to extract individual sub-images from each problem image. Each 3x3 problem contained 8 sub-images (plus one target blank) for the matrix entries and 8 sub-images for the answer choices.

The models were run against two variations of the test inputs: raw inputs and quantized inputs. For the raw inputs, grayscale values were extracted directly from the original PNG images, and no color correction of any kind was performed. The raw inputs contained numerous pixel-level artifacts and some level of noise. For the quantized inputs, each grayscale value was rounded to be either white or black, thus turning the inputs into pure black-and-white images as opposed to grayscale.

In addition, each model considered multiple strategies when solving the problems. The affine method used two different similarity measures (Tversky and SSD). The fractal method used three different groupings of relationships (horizontal, vertical or both).

## Results

Across all input variations and strategies, the affine model correctly solved 7 of the 12 problems on Set I, and 14 of the 36 problems on Set II. These levels of performance generally correspond to the 25<sup>th</sup> percentile for both sets, for 20- to 62-year-olds (US norms) (Raven et al. 2003). Looking at input variations individually, the scores were 7 and 10 on each set for raw input, and 6 and 12 on each set for quantized input. Of the similarity measures used, the

best scores were achieved using the Tversky measure on the quantized set, with scores 6 and 12 on sets I and II respectively.

Likewise, the fractal algorithm correctly solved all 12 of the problems on Set I, and 26 of the 36 problems on Set II. This level of performance corresponds to the 95<sup>th</sup> percentile for set I, and the 75<sup>th</sup> percentile for set II, for 20- to 62-year-olds (Raven et al. 2003). Looking at input variations individually, the scores were 10 and 21 on each set for raw input, and 7 and 18 on each set for quantized input. Of the groupings used by the fractal method, the best scores were achieved by considering both horizontal and vertical groupings on raw input, at 7 and 17 on sets I and II respectively.

In comparison, Carpenter et al. (1990) report results of running two versions of their algorithm (FairRaven and BetterRaven) against a subset of the APM problems. Their results, and ours, are given in Table 2. On the ones not attempted by Carpenter et al. (1990), our methods score 4 and 5 on set I (of the 5 skipped), and 4 and 7 on set II (of the 9 skipped), for affine and fractal respectively.

## Discussion

We have presented two different models that use purely iconic visual representations and transformations to solve many of the problems on the Raven’s Advanced Progressive Matrices test. Our results align strongly with evidence from typical human behavior suggesting that multiple cognitive factors underlie problem solving on the APM, and in particular, that some of these factors appear based on visual operations. Additionally, in so far as we know, this work is the first report of any computational model addressing the entirety of the APM test, the first in which the problems are attempted using purely iconic visual representations, and the first to tackle the test using scanned images of each test page, without any re-rendering or representational change of inputs from those presented to a human test-taker.

This robust level of performance calls attention to the visual processing substrate shared by the affine and fractal algorithms: similitude transforms as a mechanism for image manipulation, and the ratio model of similarity as a mechanism for image comparison. Of course, there are many other types of visual processing that may or may not be important for accounts of visual analogy, such as non-similitude shape transformations or image convolutions, which certainly bear further investigation.

While it has been shown (Davies et al. 2008) that visuospatial knowledge alone may be sufficient for addressing many analogy problems, the representations used in that work were still propositional. In contrast, the methods described here use only visual representations. We believe the visual methods we have presented for solving the APM can be generalized to visual analogy in other domains, such as other standardized tests (e.g. the Miller's Geometric Analogies test), as well as to tests of visual oddity. We conjecture that these methods may provide insight into general visual recognition and recall. Cognitively, we hold that these strategies are a reflection of what Davis et al. (1993) referred to as the deep, theoretic manner in which representation and reasoning are intertwined.

## Acknowledgments

# Corpus-based metrics for assessing communal common ground

## Abstract

This article presents the first attempt to construct a computational model of common ground. Four corpus-based metrics are presented that estimate what facts are likely to be in common ground. The proposed metrics were evaluated in an experiment with human participants, focussing on a domain of famous people. The results are encouraging: two of the proposed metrics achieved a large positive correlation between the estimates of how widely known a property of a famous person is and the percentage of participants who knew the corresponding property.

**Keywords:** Common Ground; Common Knowledge; Mutual Knowledge; Evaluation with human subjects; Web as corpus

## Introduction

Assessing other people's knowledge is crucial in many situations. Teachers, for example, do well to highlight information that their pupils do not know. Examples in other areas abound. Suppose, for example, we want to persuade you to reduce your intake of butter. We might do this by telling you "butter gives you high cholesterol". This argument only works if you, the hearer, know that cholesterol is bad for you, as is often assumed, for instance because it raises the likelihood of heart disease. The (presumed) fact that cholesterol is bad for you happens to be well publicised, and this might be what lies behind our assumption that you know it. Similar examples obtain in advertising, where companies might persuade you to buy a toothpaste by saying it contains fluoride, because they assume that many viewers know that fluoride is good for your teeth. It is often important to distinguish between knowledge and belief, but we will focus on cases where the distinction is less than crucial.

The difference between information assumed to be "given" (i.e., known by the hearer) and "new" (i.e., privileged information of the speaker) is crucial to philosophers, logicians and linguists (Frege (1892 (1952)); Strawson (1952); Van Eijck (1993), to mention but a few) and it is highly relevant to computational linguists working on Natural Language Generation (NLG) programs (Reiter & Dale, 2000), whose output is meant to mimic human language use. A central example is the generation of referring expressions, which has been studied extensively over the last 20 years (Krahmer & van Deemter, 2012). For example, an NLG program that aims to identify a person would do well to express properties that are likely to be known by the reader. For example, the expression "the former member of Led Zeppelin" would not be very informative to a hearer who has never heard of Led Zeppelin.

To the best of our knowledge, no general computational models exist for assessing what knowledge is likely to be known. In this paper, we examine a corpus-based strategy for building such a computational model. But, before we go into the details of our approach, there are some terminological and conceptual issues to be clarified. Common and mutual knowledge have been defined in different ways. In this paper, we shall follow the terminology of Vanderschraaf and Sillari, which the authors clarified with the following example.

Suppose each student arrives for a class meeting knowing that the instructor will be late. That the instructor will be late is mutual knowledge, but each student might think only she knows the instructor will be late. However, if one of the students says openly, "Peter told me he will be late again", then the mutually known fact is now commonly known. Vanderschraaf and Sillari (2009)

Thus, mutual knowledge is knowledge shared by a group of people. Common knowledge might be informally characterised as knowledge that is *publicly* shared by a group of people. Slightly more precisely, A and B have *mutual knowledge* of p if and only if A knows p and B knows p. They have *common knowledge* of p if they have mutual knowledge of p, and A knows that B knows p, and B knows that A knows p, and A knows that B knows that A knows p, and so on, *ad infinitum* (Lewis, 1969). Logicians and game theorists have proposed various precise definitions of common knowledge (including cases with more than two knowers), typically cast in epistemic logic, which formalise the "ad infinitum" (above) in different ways (Vanderschraaf and Sillari (2009)). For reasons that will become clear later, we use a third term that is often used in this connection, *common ground*, in a loose sense, when the distinction between mutual and common knowledge is irrelevant.

The psychologists Clark and Marshall observed that, in simple situations, common knowledge is enforced by "triple co-presence", where the speaker, the hearers and entities are physically present and the speaker believes that the hearers attend to the entities (Clark and Marshall (1981)). They contrast this simple situation (which they call *personal* common ground) with *communal* common ground, which arises not from physical co-presence but from being in a shared community (e.g., people living in Paris). Speakers are frequently able to distinguish between knowledge that is available to

members of such communities or to outsiders (Jucks, Becker, & Bromme, 2008; Nickerson, Baddeley, & Freeman, 1987). Personal common ground comes from joint personal experience of the agents; communal common ground derives from a range of sources, including the likelihood of common experience. For example, suppose Paris residents see the Eiffel Tower as they travel around their city. As they have no reason to believe that others do not see the same Eiffel Tower, they can exploit the knowledge shared by the residents of Paris namely, that the Eiffel Tower is in Paris. They can use this mutual knowledge as a shared basis for the communal common ground. In this case, the community are the Paris residents.

Our purpose was not to design a new theory of common ground, but to estimate what atomic facts are likely to be in (communal) common ground, using a corpus-based method. The method is based on metrics that use the frequency of information in a corpus to predict how widely known the information is. If it is successful, the method could be used to model different communities by studying different corpora. In other words, we offer a *parametrised* model, that has a corpus (or, equivalently, a community) as its parameter.

We focus in this paper on reference to famous people, because famous people are a prime instance of something people actually have common knowledge about. The proposed metrics will be used as one of a number of heuristics for selecting the content of a description of a famous person.

## Estimating Common Ground

The proposed heuristic simplistically hypothesises that facts that often co-occur in a document are more likely to be known because of frequency and repetition effects on memory (Atkinson & Shiffrin, 1968). Additionally, if a fact occurs frequently in a very large corpus (such as the world-wide web), which has many authors, then this implies that many people (i.e., many authors) know this fact. It seems plausible that people write about what they themselves know but, to our knowledge, no one attempted to examine how much can shallow corpus methods (i.e., methods not involving semantic analysis) tell us about mutual knowledge (Vanderschraaf & Sillari, 2009).

Assessing mutual knowledge is of substantial interest, and practical use, in its own right. So, how about common knowledge? If a fact occurs frequently in a corpus, is this evidence for common knowledge (as opposed to just mutual knowledge)? Clark (1996) essentially answered this question in the affirmative. He suggested that instead of thinking directly in terms of the knowledge of others, people use evidence as a basis for common ground (as in our example of the Eiffel Tower). Nickerson et al. (1987) and a series of studies performed by R. Krauss and S. Fussell (Fussell & Krauss, 1991; Krauss & Fussell, 1991) showed that people often use their own knowledge to estimate what others know. Given that it would not make much sense for computers to use “their own” knowledge, an alternative source of knowledge has to

be utilised, and we have chosen corpora as such a source of knowledge. Corpora in combination with measures of association were previously used in distributional models of semantic representation, where the main assumption is that if words appear in a similar context they have a similar meaning (Firth, 1957). Riordan and Jones (2011) examined in detail several distributional and feature-based models and concluded that they performed similarly well. Jurafsky (2003) argued that probabilistic modelling, as used by computational linguists, can effectively model some of the phenomena observed by psychologists. Given the past success of probabilistic models applied to various tasks including distributional semantics (Baroni & Lenci, 2010), we believed that the use of these techniques as a tool for estimating common ground was at least promising.

## Measures of association

Below, we list some of the main metrics that have been proposed for measuring the strength of association between words. These metrics assume that a *context* for the words has been defined. The context is frequently defined as a limited number of words before or after the target word or a short frame such as a paragraph in which the target word occurs. These contexts are not suitable for our purpose, because a fact about a person can be mentioned further away from the person’s name, especially if the name is pronominalised in consequent paragraphs. Instead, we will use an article as a context for our search. This can be, for example, a news article or a Wikipedia article.

**Frequency** The simplest measure of association between a person and a property (a fact about a person) is the frequency of occurrence of the name and the property together in a corpus. Taking a collection of documents as a corpus, frequency corresponds to the count of articles that contain the name and the property. This association is then the value of  $count(n, p)$  where  $n$  stands for the name of an entity and  $p$  is the property in question.

**Conditional Probability** A more sophisticated measure is conditional probability calculated as (1) and (2), where (1) measures the probability of the name given a property, and (2) measures the probability of a property given the name of the person. While the former measure normalises the results by the frequency of the property, the later measure takes into account how famous each person is.

$$assoc_{prob}(n, p) = P(n|p) = \frac{count(n, p)}{count(p)} \quad (1)$$

$$assoc_{prob}(p, n) = P(p|n) = \frac{count(p, n)}{count(n)} \quad (2)$$

**Pointwise Mutual Information** (PMI) (Fano, 1961) is a measure that compares how often two events  $x$  and  $y$  occur together. PMI exploits the fact that if two terms appear together often their joint probability ( $P(n, p)$ ) will be higher than if

they were independent ( $P(n)P(p)$ ). The value of PMI is positive for terms that co-occur and negative otherwise.

$$assoc_{PMI}(n, p) = \log_2 \frac{P(n, p)}{P(n)P(p)} \quad (3)$$

One problem with PMI is that infrequent words that only appear together achieve a disproportionately high score. In order for a property to be in common ground, it also has to be frequently mentioned. To mitigate the problem, (Hodges, Yie, Reighart, & Boggess, 1996) suggest multiplying each PMI score by  $count(n, p)$ . To reduce the big difference between the numbers of documents and to take into consideration the association as measured by PMI as opposed to the mere count, we multiply the PMI scores by the square root of the count. The final formula used for calculating the association is given by (4). Our pilot experiment showed better results with the adjusted PMI metric and any subsequent reference to PMI refers to (4).

$$assoc_{PMI}(n, p) = \sqrt{count(n, p)} * \log_2 \frac{P(n, p)}{P(n)P(p)} \quad (4)$$

## Search Engine as Corpus

How do we acquire the frequencies  $n$  and  $p$  in the metrics above? Turney (2001) successfully used the AltaVista search engine to measure association between words using a variation of PMI called PMI-IR, where he used numbers of hits returned by the search engine instead of real corpus probabilities. The number of hits corresponds to the number of documents on the Internet that contain the search term. The functionality of providing the number of hits is available from other search engines. Google does not respond to queries from programs other than web browsers but offers Google Custom Search which allows programmers to achieve the same functionality upon registration. Note that each of the search engines only searches a subset of all the documents available on the Internet and these subsets can differ substantially. This is also the case for Google accessed from a web browser and from a Google Custom Search.

There has been a debate as to whether to use search engines for research purposes (Kilgarriff, 2007; Pedersen, 2008). One of the arguments against using search engines was that the queries are optimised by performing morphological adjustments such as stemming and by looking up related words or synonyms. While these issues are pertinent to lexicography, they seem to be of less importance when it comes to establishing an association between a person and a property. A property can be described by different words and so such optimisations can in fact be very useful. There can be a problem with morphological changes to names but many search engines also offer search for exact phrases that are not morphologically or semantically manipulated and so we can avoid optimisations at places where they are undesirable. This is usually achieved by embedding the searched string in quotes.

Another problem that comes with the usage of search engines is the fact that we do not know the number of searched documents. This is necessary for calculating the probabilities used by the PMI metric. We have chosen a large constant  $N = 1.0e12$  for normalising the counts (the number of search results for the word *the* is about 25 billion on Google and about 10 billion on AltaVista and Bing and 2.4 billion on Google custom search).

## Experiment

We performed an experiment to evaluate how well the different heuristics perform. Given a person and a set of properties, our heuristics produce a set of  $\langle \text{property} : \text{score} \rangle$  pairs, where the *score* for each property is calculated by one of the described measures of association. Our goal is to assign scores so that they reflect the commonality of a particular property with regard to the name. This means that properties that are often associated with a name (e.g., Isaac Newton was a physicist) should get a higher score than properties that are less frequently associated with the name (e.g., Isaac Newton was the warden of the Royal Mint).

We used hearers' individual knowledge to assess how well the proposed heuristics perform. More specifically, the participants viewed statements such as "*Andy Warhol was American*" and "*Ernest Hemingway is the author of For whom the bell tolls*" and were asked to select one of the following statements: *true*, *false* or *don't know*. Our hypothesis is that **when a metric assigned a property higher score, a higher proportion of participants should give an affirmative answer** (i.e., state that the sentence involving the property is true). The success of the metric is measured as a Spearman correlation between the output of the metric and the percentages of affirmative answers assigned to the individual statements by the participants.

## Heuristic Options and Pilot

Aside from the choice of metric, several other choices had to be made. The first choice was which search engine to use. As we had no reason to believe that a particular search engine will perform better than others, our pilot tested the metrics on the three major search engines: AltaVista (Yahoo), Bing and Google.

The second choice is what search terms to choose. Most properties can be expressed as a combination of the attribute and a value extracted from sentences such as "Alfred Nobel was born in Stockholm." Choosing the value only would lead to a loss of information, because there would be no difference between properties such as  $\langle \text{bornIn} : \text{Stockholm} \rangle$  and  $\langle \text{diedIn} : \text{Stockholm} \rangle$  (since in both cases we would only search for Stockholm). On the other hand, attributes such as *actedIn* can be expressed by many similar expressions (e.g., *starred*). In such case, using both the attribute and the value might be too restrictive. As only empirical testing can show which option is better, we tested both. In the following tables, V stands for value only (e.g., "Stockholm") and AV stands for attribute and value (e.g., "born in Stockholm").

Thirdly, there is the question what to do with synonyms. While sometimes it might help to let a metric count all synonyms of a word, as people remember concepts rather than exact words, sometimes we would prefer to look for an exact phrase. This is especially the case when the value of the property is a proper name. This means that we had the option to quote the searched term to force the used search engine to look for an exact match. Again, our pilot tested both options (i.e., quoting and no quoting).

The choices described above left us with a large number of combinations. To minimise the likelihood of type II errors, we first performed a pilot experiment. The pilot uses a different set of stimuli than the real experiment. Based on the pilot, we then selected the most promising combinations. The setup and the procedure used in the pilot experiment were similar to the actual experiment (which is described in the following sections).

Table 1: Results of the pilot study: Spearman correlation between the heuristics and knowledge of hearers.

SE + Opt	Frequency	P(n   p)	P(p   n)	PMI
AltaVista V	0.27	0.25	0.30	0.32
Bing V	0.25	0.20	0.26	0.29
Google V	<b>0.47</b>	0.14	<b>0.37</b>	<b>0.51</b>
Google AV	<b>0.60</b>	0.23	<b>0.50</b>	<b>0.64</b>

Table 1 shows the Spearman correlations between the results of the individual metrics (unquoted option) and people's judgement. The options with quoted properties proved less useful so our final evaluation used unquoted properties. The best results were achieved by using Google and expressing properties as attribute and value. Field (2009) treats values around 0.1 as indicating small effects, values around 0.3 as medium effects and values around 0.5 as large effects. This standard terminology gives our PMI and Frequency based metrics a large (positive) correlation, and our P(p | n) metric a medium (positive) correlation. To validate our results, we selected **Frequency**, **P(p | n)** and **PMI** and evaluated them on a different set of properties using the Google search engine (table 1 shows the relevant numbers from the pilot study). The results of the final evaluation can be found in the section Results and Discussion.

## Participants

71 English speakers participated in our main experiment. 5 participants were discarded because they have not finished the experiment and further 5 participants were removed because the number of errors they made was more than 4 (mean + 2 \* std. dev). The total number of participants was 61; 30 females, 29 males and 2 unspecified.

## Materials

Ten people were selected for the experiment, each of whom was famous enough that their names occurred on the BBC

Historical Figures page <sup>1</sup>. Based on the pilot, we attempted to select the 10 in such a way that they varied maximally (i.e., spaced evenly) in terms of how well known they are. We created sentences of the appropriate form from facts concerning these people mentioned in Wikipedia and the BBC Historical Figures page. We also added properties that did not hold true of the person in question to keep our participants more focused and to make it less likely that a participant answered *true* to each statement without using their knowledge. Only the true statements were used in the analysis. The false statements were used as a measure of participant's effort. Participants who answered *true* to more than 4 false statements were discarded. We used 7 true properties and 5 false (control) properties for each person. This resulted in total of 120 statements. To make the task shorter, the statements were ordered alphabetically and then split into 5 groups of 24 statements (14 true, 10 false, 2 or 3 properties of each person in a group). Participants were randomly assigned to judge the statements in one of the groups. Figure 1 shows the names that were chosen for the evaluation and table 2 shows a sample of the properties that were judged by the participants along with the percentage of agreement answers.

## Procedure

In order to find a large number of participants, the experiment was conducted online using the Amazon Mechanical Turk (MTurk). The use of MTurk can have some drawbacks, because it lets participants work from home, which makes it difficult to ensure that they are fully dedicated to the task; even worse, computer programs have occasionally been known to perform the task (instead of real people). Responses collected during the pilot experiment showed a large variability in the participants' effort, the amount of time taken to complete the experiment, and a large proportion of participants from non-English speaking countries. To mitigate some of these problems, to ensure a reasonable level of proficiency in English, and to avoid automatic responses generated by computers, participants had to successfully pass a cloze test which amounted to a very strict test of their English proficiency (Stubbs & Tucker, 1974). (Only native or highly fluent speakers tend to pass.) Furthermore, the final evaluation was advertised only to the US and UK population of the MTurk. In this way, we focussed on a particular cultural-linguistic community; the choice seemed natural

Table 2: List of properties of Ernest Hemingway, corresponding condition and the percentage of affirmative answers. Rank AV and Rank V show how the corresponding properties ranked according to the PMI metric using Google with unquoted properties.

Property	Condition	Percentage	Rank AV	Rank V
Ernest Hemingway was a writer.	true	100.0	1	2
Ernest Hemingway was American.	true	100.0	2	1
Ernest Hemingway received the Nobel Prize in Literature.	true	63.6	4	4
Ernest Hemingway is the author of For whom the bell tolls.	true	54.5	3	3
Ernest Hemingway committed a suicide.	true	50.0	6	5
Ernest Hemingway was British.	false	27.3	-	-
Ernest Hemingway was born in Oak Park.	true	25.0	5	6
Ernest Hemingway received the Italian Silver Medal of Bravery.	true	20.0	7	7
Ernest Hemingway is the author of A tale of two cities.	false	13.3	-	-
Ernest Hemingway invented dynamite.	false	0.0	-	-
Ernest Hemingway died in a plane crash.	false	0.0	-	-
Ernest Hemingway was born in Paris.	false	0.0	-	-

given that the searched pages must have been written in English in order to contain the searched terms. The inclusion of the pre-requisites (cloze test and country restrictions) greatly improved the results (e.g., less variation in the time taken to complete the experiment and fewer number of participants who made errors).

The first page showed the instructions on how to answer and how to navigate the website and also urged the participants to rely on their own knowledge and avoid using the Internet to answer the questions. The participants were then asked to fill in some information such as sex, age group and interests. The participants then viewed one statement at a time and were asked to select one of the three provided options (true, don't know, false). The participants could also provide a comment for each statement. After finishing the experiment they were given an opportunity to provide additional open comments.

The search engine queries were performed over December 2011 and January 2012. To ensure replicability of the experiment, we saved all the queries and the corresponding numbers of hits returned by the search engines. These files are available on our website <sup>2</sup>.

## Results and Discussion

Table 2 contains a sample of statements that were shown to the participants. Condition *true* means that it was a true statement and *false* means it was a false (control) statement. As previously mentioned, only the true statements were used in the analysis. The percentages of affirmative answers were correlated with the output of the metrics using Spearman correlation. All calculations were performed using the R statistical package (R Development Core Team, 2010).

Table 3 shows the final results of our experiment. We used the Google search engine and tested expressing properties as attribute and value (condition AV) and as value only (condition V). The properties were unquoted in both cases.

Our results show a large positive correlation between the PMI and the Frequency based metrics, and the knowledge of people and a medium positive correlation achieved by the

Table 3: Spearman correlation between the heuristics and the knowledge of hearers. All correlations were significant at  $p < 0.001$ .

Option	Frequency	P(p   n)	PMI
Google AV	0.639	0.437	0.664
Google V	0.632	0.475	0.662

P(p | n). This suggests that a heuristic for common ground that employs either the Frequency or the PMI metric, to large extent, agrees with the knowledge of general public.

The presented heuristic seems to work relatively well with the kinds of facts that appear in natural language generation systems. A natural question is whether the heuristic can give good results for facts that are so widely known that they are not explicitly stated. There are two kinds of these facts.

The first kind are facts such as "a person has a stomach." While it seems improbable that such a fact would be explicitly mentioned in a corpus, there are ways of implying it by statements such as "a person can get a stomach flu" or "a person can increase the risk of getting stomach cancer..." These statements include the words "person" and "stomach" and the heuristic can pick up these words without doing any semantic analysis. We tested the heuristic with a few of such statements and it seems to place them in to the well known part of common ground (i.e., assigns high scores to such facts). A proper evaluation would be needed to confirm this trend.

The second kind of facts are facts such as "Einstein had a stomach." This kind of facts requires inference, e.g. Einstein is a person and people have a stomach therefore Einstein had a stomach. As our heuristic works on the surface level of the text, it will not produce the expected results for such facts.

## Conclusion and further work

We set out to find a computation estimation of common ground, starting with mutual knowledge (in the sense of Vanderschraaf and Sillari (2009)). We hypothesised that standard co-occurrence measures could be used as an approximation of a solution to the problem and tested several of

<sup>2</sup><http://www.abdn.ac.uk/~r04rk9/cge.zip>

these measures against the knowledge of people in a particular community (cf. Clark and Marshall (1981)), as acquired in a new experiment with human participants. We consider these results to be highly encouraging. They suggest that the proposed heuristic (based on either Frequency or PMI, combined with Google search) are on the right track, at least in terms of estimating how widely known an atomic fact is (i.e., mutual knowledge); in section Estimating Common Ground we argued that this also makes it plausible that these heuristics could offer a reasonable approximation of *common* knowledge (i.e., the facts of which everyone in the community knows that everyone in the community knows them), but this was not directly investigated.

The community investigated in our experiment was comprised of native speakers of English in the UK and the USA with access to a computer. We believe it would be interesting to test to what degree different communities be modelled by different knowledge sources.

Our current work focuses on combining the metrics investigated here with other heuristics (including a discriminatory power heuristic for assessing the usefulness of a fact) to improve content selection algorithms for Natural Language Generation (e.g., Reiter and Dale (2000)).

## Abstract

Despite their importance in public discourse, numbers in the range of one million to one trillion are notoriously difficult to understand. We examine magnitude estimation by adult Americans when placing large numbers on a number line and when qualitatively evaluating descriptions of imaginary geopolitical scenarios. Common conceptions of the number line suggest a logarithmic compression of the numbers (Dehaene, 2003). Theories of abstract concept learning suggest that in situations where direct experience is unavailable, people will use the structure of notation systems as a proxy for the actual system. (Carey, 2009; Landy & Goldstone, 2007).

Evaluations across two subject populations largely matched the predictions of the latter account. Approximately 40% of participants estimated *one million* approximately halfway between *one thousand* and *one billion*, but placed numbers linearly across each half, as though they believed that the number words “thousand, million, billion, trillion” constitute a uniformly spaced count list. Very brief training procedures proved partially successful both in correcting number line placement and in shifting participants’ judgments of geopolitical situations. These results reinforce notions of abstract concepts as grounded in external notation systems, as well as having direct implications for lawmakers and scientists hoping to communicate effectively with the public.

**Keywords:** number cognition, mathematical cognition, formal reasoning, human subjects experimentation

## Introduction

Large numbers<sup>1</sup> are interesting for both practical and theoretical reasons. Many arenas of public discourse rely on an understanding of large numbers, including debates about evolutionary biology, nanotechnology, and the reliability of DNA testing. The United States is currently involved in a heated conversation about the national budget and economy. The budget, the deficit and the debt are in the low trillions, while most proposed budget changes are in the millions and billions. Americans generally exhibit poor knowledge about spending on specific programs by the federal government (Gilens 2001), and it is likely that poor understanding of large numbers contributes to this ignorance.

Number systems covering this range are also an excellent example of an abstract system: magnitudes such as *one billion* are beyond our immediate experience and yet are clearly understood in part through abstracting the concrete

process of counting (Carey, 2009; Leslie, Gelman, & Gallistel, 2008). We experience large numbers primarily syntactically, and through associations with situations (e.g., claims that the U.S. deficit is \$1.4 trillion; Facebook has 700 million users; or the human body has 100 trillion cells).

One way we understand abstractions is by studying the properties of their concrete representations (Clark, 2006; Landy & Goldstone, 2007; Kirsh, 2010). For instance, Carey (2009) proposes that when learning to count, the memorized count list orients attention to appropriate features of the environment, so that the verbal label “eighteen” cues a learner that there is *something* that “eighteen” situations have in common. In addition to the simple presence or absence of labels, however, count lists have other structural properties: for instance, counting numbers are typically stated in sequence, with accompanied rhythmic hand motions, and are constructed on a semi-regular pattern. Here, we wonder how structural components of symbolic systems impact inferences made by reasoners.

## Structure in the numerals

A student learning the English counting system must master several different lists. In addition to the numbers from 1-9, one must learn the teen words, the tens words, and –most importantly for our purposes—is the *short scale*, used in the United States and Britain. In this system, one thousand million is “one billion”. This list “thousand, million, billion, trillion, quadrillion, ...” constitutes an effective count list, which after the initial “thousand”, bears an apparent sequential structure, and clearly derives from Latin number words. North American students typically learn the short scale up to “trillion” by around 7<sup>th</sup> grade (Skwarchuk and Anglin, 2002).

There are several common notations for understanding large numbers. In this paper, we focus on perhaps the most common one, which we will call the *hybrid notation*, because it combines number words and numerals. Examples of numbers in this from include “324 million”, “426”, or “5 thousand.”

We model large number understanding by combining two conceptually separate steps: the first involves the interpretation of a number word into an abstract numerical quantity (“abstract” because we are agnostic with respect to how people would actually estimate perceived quantities in the range of millions and billions—here we mean merely the interpretation can be treated as a metric), and the mapping

<sup>1</sup>Here, roughly those between 10<sup>5</sup> and 10<sup>13</sup>.

of a quantity into a response. For brevity, we blur these distinctions here.

Of the many plausible ways that people might extract quantities from number representations, the simplest is that people might roughly correctly estimate the relative values of large numbers. We will refer to this as the *linear* or *normative* model of large number understanding.

Second, if learners use the structure of the number notations—especially the short scale—as a guide to numerical size, then a different pattern is expected. Since the number words—millions, billions, trillions, are similar and uniformly spaced in their count list, people might evenly distribute the referred quantities. Since adults generally linearly estimate numbers from 1-1000 (Seigler & Opfer, 2003), this suggests a piecewise-linear pattern, in which (roughly) values like 1 thousand, 1 million, and 1 billion are separate units, which are spaced evenly on the line, and other values (such as 500 million) are linearly interpolated between these points. We will call this the *uniform spacing* or *piecewise linear* model.

Another plausible approach is based on developmental studies of line estimation with small number ranges (Siegler & Opfer, 2003). These studies have repeatedly demonstrated that number estimation errors tend to be highly compressed at the large end of the line. Traditionally, this compression has been modeled using a logarithmic function, and a fitted linear mapping from quantities to line positions (Booth & Siegler, 2008; Siegler & Opfer, 2003). We will call this combination the *log-linear* model.

Finally, it is naturally plausible that some people would either have no interpretation of the large numbers, or highly variable or non-monotonic interpretations.

## Empirical Methodology

We used two tasks to explore the number word interpretation: Number line estimation, and situation evaluation.

In typical *number line estimation* tasks, a participant is presented a line with labeled endpoints, and a stimulus numeral. The participant makes a mark indicating their estimate of the proportion of the line that corresponds to the proportion relating the stimulus number to the specified range. In the experiments reported here, the left end was always *1 thousand*, and the right end was *1 billion*. Prior to performing estimations, participants were shown a marked number line ranging from 1 to 10, and were instructed to likewise place their numbers in a linear manner.

In *situation evaluations*, participants made qualitative judgments about attempted government actions involving short-scale quantities. In each story, one number was selected as a goal, and a number to be evaluated was selected from the preceding element of the short scale. For instance, in one question a fictional country's government had a goal to eliminate their 1.1 trillion "taler" deficit, and proposed the solution cut 100 billion talers. Participants rated the quality of the attempted solutions on a 9-point scale from "very unsatisfactory" to "very satisfactory".

## Experiment 1

### Method

**Participants & Procedure** Partial course credit or monetary compensation was given to 67 participants recruited from the University of Richmond community. Three participants gave responses that were generally non-increasing across the number range, and were extremely variable; these participants' data were removed and replaced to yield our goal of 64 participants.

Participants made 108 number line estimates, on a line ranging from 1 thousand to 1 billion. Each stimulus number was the product of an integer strictly between one and one thousand, and either  $10^3$  or  $10^6$ .

Two between-groups differences were used to rule out possible confounds in our approach. First, in Experiment 1 half of all participants viewed numbers in the hybrid notation; for half all stimuli and endpoints were presented in the pure numeral format. Second, the range of the stimulus numbers was manipulated between participants, so that we could evaluate whether people shifted their placement to fit the distribution of observed numbers. Half of the participants saw numbers only in the millions; half estimated numbers which were evenly divided between those above and below 1 million. Neither manipulation affected results qualitatively or altered significance of contrasts; similar patterns were observed across all four groups; the slight differences will not be discussed here.

After completing the experiment, regardless of condition, participants filled out a paper form prompting them to generate the numerical form for each of one billion, one million, and one thousand. All but two participants did so correctly; one participant left the "one billion" mark blank, while the other made significant errors.

### Analysis

Our primary analysis compared linear and uniform spacing model fits with the log-linear, using a hierarchical Bayesian model fitting approach.

Since both models are linear above and below one million, the primary variable distinguishing the linear and uniform spacing models is the estimated position of one million on the line ( $M$ ).  $M$  was fitted at the individual subject level; since  $M$  ranges from 0 (extreme left) to 1 (right), the population was fitted as a uninformative beta distribution. Within this framework, the linear model is the special case when  $M = 0.001$ , pure uniform spacing is produced when  $M = 0.5$ . The prior on  $M$  was uniform between 0 and 1, and 0 elsewhere.

This *segmented linear* model was compared to a log-linear model,  $y = a \ln(x)$ ; this model also has one parameter, fixing the shape of the linear component. The left intercept of both models was fixed at 0. To capture variability in responses, both models assume truncated (at 0 and 1) normal distributed deviations from the model prediction.

A hierarchical mixture model mixing both components at the group level was fit to the data using JAGS through the

rJAGS package. In this model, each subject has some probability  $\pi$  of producing split linear responses and some probability  $1 - \pi$  of producing a log-linear responses. The model thus categorizes individuals as part of the fitting procedure. The model was simulated using MCMC, with 4 chains with 100 samples per chain, a burn-in of 30,000 iterations, and a thinning of 250 iterations per sample.

## Results

Figure 1 shows the fitted values of  $M$ . Qualitatively, nearly all participants were captured very well by the segmented linear model. The logarithmic model was selected as better fitting by the model for only one participant. Three other participants produced non-monotonic fits with wide variability, and were poorly fit by both models. The remaining 61 participants matched well the predictions of the segmented linear models. Figure 2 illustrates two typical patterns of response: one group of participants ( $n = 36$ ) were fit very well by the linear model, and thus had low  $M$  values; the other group had high values of  $\pi$  with typical  $M$  values centered around 0.4 ( $n=19$ ). The few participants with intermediate  $M$  values ( $n=6$ ) between 0.1 and 0.3 seemed to switch strategies, producing responses which were sometimes close to linear, and at other times very close to the uniform spacing model.

## Discussion

Experiment 1 demonstrates that there is not a general misunderstanding of large numbers, nor a logarithmic scaling of these numbers. Instead, a single, specific misconception of large numbers predominates errors: at least 85% of substantial deviations from linear responding involved a piecewise linear behavior, in which each of the ranges of “millions” and “billions” are linearly constructed, but are each of approximately identical size. Despite the prevalence of smooth, log-like functions in theories of economic and psychological utility functions and psychological magnitudes, evaluations of large numbers appear to no more than rarely approach logarithmic scaling.

Figure 1: Histogram of individual fitted values of the position of 1 million ( $M$ ). The normative value is 0.001.

Figure 2: Number line estimates for a linear (top,  $M=0.0004$ ) and piecewise linear (bottom,  $M=0.44$ ) sample subject, along with predictions of the segmented linear model. The log-linear model predicts straight line responses on a log-scaled x-axis.

It is possible that participants in our study misconstrued the nature of the task, believing, for instance, that a segmented linear graph was requested. We believe this is unlikely for two reasons. First, although both linear and logarithmic number lines are fairly commonplace (for instance, as graph axes), segmented linear number lines—lines in which one linear number range lies adjacent to a linear range with a different unit—are vanishingly rare. Second, while piloting these materials we interviewed many individuals completing this task. While many made the error, none gave evidence having misunderstood the task. On the contrary, these individuals seemed very surprised when they realized or were told the normative location of one million.

## Experiment 2

The number line is an idiosyncratic task, involving visual and spatial components as well as number processing per se. It might be that the results of Experiment 1 result from idiosyncratic reasoning, and would not generalize well to

other kinds of number judgments. One purpose of Experiment 2, then, was to explore whether piecewise linear number line estimation would generalize to other tasks.

In studies involving smaller number ranges, learning of linear behavior can be strikingly sudden—with participants often becoming linear across an entire range from the presentation of just a single point (Opfer & Siegler, 2007). A second purpose of Experiment 2 was to explore whether similar approaches could lead to sudden reductions in misconceptions about large numbers, and such shifts in line estimation would generalize to evaluative judgments.

## Participants and Procedure

300 participants were recruited from Amazon's Mechanical Turk in exchange for small monetary remuneration. Mechanical Turk is a scalable workforce solution frequently used by psychologists to recruit subjects for online experiments (Mason & Suri, 2012). All tasks were completed remotely through a web interface.

Each participant first performed eight number line estimations (the *pretest*), followed by an intervention. Half of all participants saw an *encouragement* intervention, which simply thanked them for their hard work, and asked them to do their best on the rest of the experiment. The other half of participants saw a *training* screen, which reminded them that 1 billion was equal to 1,000 millions, and showed them the normative placement of 10 million on the number line from 1 thousand to 1 billion. Participants then completed eight more number line estimates (the *posttest*), followed by three situation evaluation questions.

In the *situation evaluation* task, participants read, in fixed order, three short narratives about how the governments of two fictional countries were dealing with various social challenges. The participants rated the quality of the attempted solutions on a 9-point scale from “very unsatisfactory” to “very satisfactory”. In each story, one number was selected as a goal, and a number to be evaluated was selected from the preceding element of the short scale. For instance, in question 3 (designed to match the U.S. budget for 2011) the goal was to eliminate the 1.1 trillion “taler” deficit, and the solution cut 100 billion “talers”. After both tasks were completed, participants reported their age, sex, and political affiliation, and briefly describing their problem-solving strategy. The strategy explanations provided an extra check that participants were in fact attempting the problems.

## Analysis and Results

**Number Line Estimation.** Estimates were modeled using a version of the model described in Experiment 1. Because the unimodal beta model at the family level did not capture the pattern of observed behaviors, in Experiment 2 data was fit only at the level of the individual. Further, the logarithmic model was not tested. Thus, the single model parameter was the estimated location of one million,  $M$ . Separate models were fit to the data before and after the intervention.

Figure 3 illustrates the shift in number line behavior before and after the intervention. An ANOVA evaluating  $M$  values as a dependent measure over time of estimation (pre vs. post intervention) and condition, indicated a significant interaction between the two ( $F(1, 298)=15.8, p<.01$ ). There was also a main effect of condition ( $F(1, 298)=4.4, p<.05$ ); considering only the pretest data, the difference was not significant ( $F(1,298)=.21, p>.0.5$ ).

As in Experiment 1, the empirical values of the  $M$  parameter were contrary to the predictions of the uniform spacing model. While the model predicts a mean value around 0.5 among the piecewise linear group, the actual mean fitted value was around 0.40.

**Situation Evaluations.** Evaluations were averaged across the three situations for analysis. These average responses were moderately normally distributed. An ANOVA of mean evaluation against pretest  $M$  and condition revealed significant effects of both ( $F(1, 298)=11.3, p<0.01$ , and  $F(1, 298)=4.3, p<0.05$ , respectively). Once behavior at posttest was included, however, it was the only significant predictor of situation evaluations ( $F(1, 298)=15.8, p<0.001$ ; see Figure 4); condition was no longer significant ( $F(1, 298)=2.4, p\sim.12$ ), suggesting that some of the effect of training on situation evaluation resulted from shifts in processes involved in number line estimation.

Figure 3: Best-estimated location of 1 million ( $M$ ) at pretest and posttest. The normative location is 0.001. The large preponderance of blue circles in the bottom right represents the efficacy of the training.

Figure 4: Situation evaluation against post-intervention placement of 1 million (M), binned into quantiles based on pre-intervention number line estimates. Errors reflect standard errors in the estimate of post-intervention values.

## Discussion

Experiment 2 demonstrated that the same strategies found in Experiment 1 are employed in a substantively different population: 45% of judgments were compatible with the piecewise linear account. However, participants were readily educable: just a single example of a normatively placed term sufficed to correct number line estimations in nearly half of error-prone estimators. Training seemed to be largely all-or-none: participants who shifted strategies halfway through the task gave responses nearly indistinguishable from those who had been following the final strategy from the beginning, judging both by number line estimations and situation evaluations.

Furthermore, Experiment 2 demonstrated that number line strategies are closely related to political judgments involving numbers in this range. People who estimate the number lines normatively are less optimistic about political situations involving numbers in this range. Furthermore, participants trained on the number line shifted their evaluations of political situations. Hence, the uniform spacing misconception does not result from reasoning specific to the number line task.

## General Discussion

Numbers picked out by the short scale—despite appearing frequently in educational contexts and public discourse—do not seem to be robustly understood by much of the population. While roughly half of our participants treated large numbers linearly, two experiments indicate that a large portion of the population—around 40 percent in the studies reported here—seems to evaluate large numbers based on the assumption that the number labels are roughly equally spaced as the numbers increase. Furthermore, people who

rely on an equal spacing heuristic when placing numbers on a line are more satisfied with poor resolutions to political problems involving comparable scales.

Currently, the people of the United States, along with many other countries, are deciding how best to handle economic debt and deficit crises. These conversations crucially involve the accurate assessment of numbers across the range of  $10^6$ - $10^{13}$ . The current results suggest that a substantial fraction of Americans are ill equipped to engage in these conversations. This conversation is of direct relevance to the practice of scientific research, which is often funded by grants in the low millions of dollars. Detractors of the government spending on science research and other programs often present funding information by contextualizing these amounts within the overall budget using short-scale labels.

Logarithmic number line behavior was rare or non-existent on this task, despite substantial prior research that has supported the hypothesis that unfamiliar number ranges are initially represented logarithmically (Siegler & Opfer, 2003; Dehaene, 2003). One possibility is that large numbers fall beyond the upper range of the approximate magnitude system (Izard & Dehaene, 2008). Another possibility is that the reasoning processes we find adults employing when estimating large numbers account for apparently logarithmic behavior in young children (Nuerk et al, 2001).

Although the hypothesis that people infer spacing on the number line from the structure of the short scale labels predicted the basic pattern of responses, it does not predict the observed structure perfectly. In particular, most people who erred in their estimate of the relative values of 1 thousand, 1 million, and 1 billion did not put 1 million halfway between the other two, but substantially close to 1 thousand. Anecdotally, people we have observed often placed 1 million more or less exactly in the middle, then ‘correct’ to approximately the 40% mark. One possibility is that this positioning reflects a compromise between uniform spacing and normative number knowledge, but the nature of such a compromise remains speculative.

These results are striking in that the actual numerical system of short scale words and place value notation is formally extremely simple, and the referent system—the natural numbers—is acquired fairly early in mathematical development. A simple induction suffices to suggest the referents of the large number words studied here, rather than a conceptual restructuring, as has been implicated in rational-number learning. These results emphasize that even when dealing with basic abstract material, accessible concrete structures play a key role in guiding the development of concepts and strategies (Carey, 2009; Goldstone & Landy, 2010). When dealing with large numbers, people rely heavily on number naming structures to fix the meaningful properties of particular number words. Instead of using the number labels as placeholders to an independently existing world, accessed via number principles, many people attend to the surface properties of number nomenclature to determine numerical properties. As

the four-year old daughter of the first author (who was at the time learning to read two digit numbers) put it “100 is just one more than 10. It’s three: one, two, three!” Magnitudes in this range are constructed by borrowing structure from the symbol systems used to represent them.

## Abstract

An important visual strategy in the visual control of driving during curve negotiation is tangent point orientation – directing gaze to the inside road edge in the area of interest (AOI) around the tangent point. Yet, while the phenomenon has been replicated in many studies at a qualitative level, and several computational models have been proposed to explain it, there is no consensus on whether the actual gaze target is the tangent point itself – or some other road point in its vicinity- and what the functional significance TP targeting (looking at the tangent point) or TP orientation (looking at a point in the TP AOI, but not necessarily the tangent point) might be. We report here a previously unobserved dependence between gaze distribution on road curvature: gaze concentrates on the part of the road where the vehicle yaw rate (local curvature) will be highest. We therefore suggest this geometric property of the future path may act as a functionally salient visual reference for the driver, and that the oft-reported “tangent point orientation” may in some cases be a side-effect caused by the spatial contiguity of the tangent point and the point of maximal path curvature.

**Keywords:** visually guided behavior, driving, eye-movements, field studies, tangent point, optic flow.

## Introduction

One of the ultimate goals in modeling eye-movements during natural behavior would be to be able to predict the whole sequences of eye movements executed during the performance of a naturalistic task, such as reading, car driving or preparing a meal (Kowler, 2011; Land 2006, 2007). This goal may not be as far off as it may seem, for as research on eye movements in naturalistic tasks during the past two decades has shown, in naturalistic tasks (as opposed to many artificial laboratory tasks) eye-movements present a picture of surprisingly stereotypical patterns, where the subjects’ gaze behavior is closely bound to the task conditions, both in spatial terms (gaze is concentrated only on task-relevant gaze targets) and in temporal terms (gaze target selection is closely coupled to the execution of different phases of a complex task, picking out targets “just in time” – i.e. selecting targets whose state needs to be verified, or which are about to be manipulated in 1-2s, so that the use of short term visual memory can be minimized). (Ballard et al., 1995). Successful modeling would thus entail (i) identifying the relevant gaze targets, (ii) specifying their relevance to the task (phases) in terms of the cognitive com-

putations the information provided by these targets could support, and (iii) testing the differential predictions of models against data collected from participants performing actual naturalistic tasks.

In the domain of car driving, one pattern in particular has been the subject of continuous research and theoretical debate, namely, *tangent point oriented curve negotiation* (Land & Lee, 1994): directing gaze in the direction of inside road edge during curve driving (Figure 1). Yet, while the basic phenomenon has been replicated in many studies (Underwood et al, 1999; Land & Tatler, 2001; Chattington et al., 2007; Kandil et al., 2009, 2010), and several computational models have been proposed to explain it (Land & Lee, 1994; Boer, 1996; Wann & Swapp, 2000; Wann & Land, 2000; Wann & Wilkie, 2004), there is no consensus on whether the gaze target is the tangent point itself – or some other road point in its vicinity- or the functional significance of this gaze pattern.

There are several models that account for the basic pattern (see Table 1). Some assume that the tangent point itself is the relevant gaze target for visually controlled steering (its eccentricity acting as a feedback control parameter), others that it is points on the forward-planned future trajectory which the driver looks at (only falling near the tangent point due to geometric reasons).

As the models are all compatible with the general observation of “tangent point orientation”, but make subtly different predictions concerning the precise spatial and temporal dynamics of gaze, more detailed on-road data is required to arbitrate between the various models. We report here a previously unobserved dependence between gaze distribution on road curvature: gaze concentrates on the part of the road where the vehicle yaw rate (local curvature) will be highest.

We therefore suggest this geometric property of the future path may act as a functionally salient visual reference for the driver, and that “tangent point orientation” may in fact – at least in some cases - be a side-effect caused by the spatial contiguity of the tangent point and this other gaze target. (This highlights the inherent problems of using AOI based measures in naturalistic environments where the experimenter has no control over the overlap of the AOI’s of different gaze targets).

Table 1: “Tangent point orientation” models of visual control of steering.

i. Land & Lee (1994)	Drivers fixate the tangent point and use the visual angle of tangent point (or gaze) relative to the locomotor axis to judge the curvature of the bend. (This model makes no specific prediction about steering).
ii. Land & Lee (1994), Wann & Land (2000)	Drivers fixate the tangent point and actively steer so as to keep the visual angle of the tangent point (and gaze) at a <i>constant horizontal direction</i> .
iii. Wann & Land (2000), Wann & Wilkie (2004)	The driver fixates a target point on their future path (i.e. a point they wish to pass through) which is near the tangent point not necessarily the tangent point, and then steers so that <i>the fixated point sweeps from its initial offset to directly in front of the locomotor axis at a constant rate</i> ..
iv. Boer (1996)	A reference point (“next to the tangent point but slightly into the road”) is chosen, although not necessarily fixated directly. Steering and speed are controlled in the following manner: The driver observes the visual angle between the vehicle’s heading and the target point, estimates the vehicle’s speed and the geometric distance to the target point, and adjusts steering and speed so that the following constraints are satisfied (1) the visual angle to the target point shall reach zero in less time than it will take to traverse the distance to the target point (2) the trajectory minimizes the maximum required lateral acceleration (i.e. minimizes the maximum steering input), and (3) the furthest deviation from the road edge remains within lane boundaries. (Active model).
v. Kim & Turvey (1996), Wann & Swapp (2000)	Visual flow is used to steer the car on a linear or locally circular trajectory: the driver fixates a target point on the road she wishes to pass through - a reference point on the future trajectory that is at rest in the allocentric reference frame, but moves in the egocentric frames of reference due to optic flow – and steers so that the visual flow lines are straight rather than curved. What is more, all those flow lines that fall on the observer's future path will now be be vertical

## Subjects

Nineteen subjects participated in the experiment (11 male, 8 female, age range 23-52 years, mean 30, s.d. 7 years. All had held a valid driving license, and could be considered experienced drivers. Participants were recruited through university e-mail lists, some through personal contacts among students and staff. Condition for inclusion in the experiment was normal uncorrected vision (qualified to drive a car without correction) and sufficient driving experience (>20 000km). All participants were naïve to the purpose of the study (the tangent point hypothesis) and were given two cinema tickets as compensation for participating. All participants gave written informed consent, and the study was approved by the local ethics committee.

## Procedure

The test road was a 3.9 km low-standard two-lane rural road with a low traffic density and no lane markings (5.4 m pavement width). All drives were carried out in daylight. Participants drove the car to the test route, which was located 34 km from the campus. A few kilometers before arriving at the test road, the instrument panel was occluded. This was in done to reduce downwards glances to the speedometer during the test run, giving us the best opportunity to record road-directed gaze patterns. The participants did not express discomfort at having to drive without a speedometer. In addition to the participant who drove the car, a member of university staff acted as driving instructor on the front seat, giving route directions and ensuring safety.

Figure 1: Illustration of some possible gaze targets in curve driving, discussed in the text. The future path of the vehicle is indicated by dotted line TP = tangent point; OP = occlusion point; point of maximum yaw rate is the point where the driver can begin to unwind the steering and accelerate out of the turn.

A research assistant acted as experiment instructor on the back seat on the driver's side. She was there to administer a cognitive secondary task on a different road section, the results of which are reported in Lehtonen, Lappi & Summala (2011). During the recording segments from which data is reported here the driver and the other persons in the car avoided any interaction. The participants drove the test route at their own pace. The driver was simply instructed to (i) drive as they normally would, but (ii) observe traffic laws and safety - in particular, they were explicitly instructed not to cut onto the lane of oncoming traffic in left-hand turns, if this was what they would do in normal driving. (This was deemed a necessary precaution because of the relatively high speed limit - 80 km/h - and the fact that many of the turns had a blind entry).

### Equipment and data preparation

The instrumented car was a model year 2007 Toyota Corolla 1.6 compact sedan with a manual transmission. The passenger side was equipped with brake pedals and extra mirrors for the driving instructor, as well as a computer display that allowed him to monitor vehicle speed, as well as the operation of the eye-tracker and the data-logging systems. The car was equipped with a two-camera (Smart Eye Pro versions 5.1 and 5.5 [www.smarteye.se](http://www.smarteye.se)) eye tracker operating at 60 Hz, a forward looking VGA scene camera, a GPS-receiver, as well as a forward looking infrared rangefinder (IBEO, [www.ibeo-as.com](http://www.ibeo-as.com)). Vehicle speed, the vehicle control signals (steering, throttle and brakes), as well as vehicle yaw rate were recorded directly from CAN-bus (all oversampled at 100 Hz). All signals were synchronized and time stamped on-line, and stored on a computer running custom MATLAB software, located in the rear luggage compartment. All subsequent data preparation, visualization and analysis was done with custom-made Python scripts, except for the final statistical analyses which were done with SPSS 18.

The data was segmented based on the time stamps corresponding to the GPS coordinates of the test route. To render different trials (drives) comparable, the data was given a distance-based representation. One trial, with no traffic or other "incidents" was chosen as a reference. The vehicle trajectory in an allocentric xy plane was computed by interpolating the GPS signal. This interpolated trajectory would then be used as the basis of a route-distance value. All participants' trials were then mapped onto this frame of reference, by first best-matching the observed GPS values to the reference trajectory, and then associating the rest of the data, with time-stamps matching the relevant GPS location.

The trajectory of the vehicle was also computed for individual trials by starting from point of gaze observation on the trajectory, and integrating the vehicle yaw rate and speed over time. This was used to estimate the point of gaze landing on the future trajectory, by finding first the point on the trajectory where the eccentricity of a point on the path-integrated trajectory corresponded with the visual eccentricity of gaze at the initial point - i.e. the point where the

line of sight would intersect the path-integrated trajectory. This gaze-landing point could then be assigned a route distance value based on the mapping of time stamps to route distances<sup>1</sup>

Tangent points were manually identified from still video frames from SmartEye's Scene camera (5 Hz frame rate), and the image coordinates of the mouse pointer and the eye-tracker coordinates were physically calibrated, using a calibration grid visible in the scene camera and the infrared rangefinder (whose coordinates were used as the native coordinate system for the car). The scene images were then associated with the rest of the data based on the time stamp of the video frame. If there was oncoming traffic in a turn (any vehicles or pedestrians visible in the forward-looking video camera), data for that turn was excluded from gaze-direction analyses (but included in the driving speed analyses). This was done in order to eliminate the effect of these potentially confounding visual targets in the road scene.

### Results

Four turns from the test route were selected for detailed analysis. The turns were chosen so that we would have two pairs of roughly similar turns, this way we could check whether any pattern of visual behaviour seen in a turn would also be seen in the other, similar, turn. The analysed turns comprised of two long left hand turns (hereafter denoted by T1 & T4), and two blind right-left sequences (T2/3 & T5/6)<sup>2</sup>. The blind sequences T2/3 and T5/6 probably resembled the roads used in Land and Lee (1994), while the faster turns T1 and T3, with a sighted approach phase, were probably more similar to the curves in Kandil et al. (2010).

#### Driver Gaze Behaviour in Relation to the Tangent Point (Tangent Point Orientation)

We first set out to replicate the commonly observed tangent point orientation. Based on the previous research reviewed above, we expected the drivers to direct their gaze towards the tangent point region, especially during the approach and

<sup>1</sup> Note that the gaze-landing point, as defined here, may not in all cases perfectly coincide with the driver's true gaze target, because it does not use pitch-information and effectively projects the trajectory and gaze directions onto a two-dimensional plane; it does, however, provide a good estimate when the road is flat - as in the present experiment. The reason we did not use the pitch information is the difficulty of measuring it reliably in the noisy environment.

<sup>2</sup> We refer to a turn as blind when both of the following conditions are met: (i) At no point during the approach phase - i.e. before the driver steers into the turn - is the exit of the turn or the exit of the entire sequence in the case of connected curves visible to the driver, and (ii) During the entire approach phase, the occlusion point falls within some angular threshold of the tangent point (the threshold used here was 10°). The *occlusion point* is defined the furthestmost part of the desired trajectory to which a continuous line of passage is visible, i.e. the point on the road where the driving line first disappears from view (Fig. 1, see Lehtonen, Lappi & Summala, 2011). Turns that are not blind by these criteria are said to be sighted.

turn entry phases. As table 2 shows, we could demonstrate a consistent pattern of tangent point orientation during curve approach and turn entry. This establishes for the curves analysed the basic pattern observed in many previous studies, which have reported drivers to direct their gaze into the tangent point region 60-70% of the time, when entering a bend (Land & Lee, 1994; Kandil et al., 2010).

Table 2: Estimated relative frequency of tangent point oriented gazes (% of all valid observations, mean and standard deviation) falling within three degrees horizontal of the tangent point during turn approach (before the driver turns the wheel) and entry into the turn (after the driver turns the vehicle). In connected curve sequences only the first turn of the sequence for which an approach phase can be defined is listed.

	<i>Approach</i>	<i>Entry</i>
T1	52 (23)	41 (28)
T2/3	72 (24)	67 (22)
T4	50 (25)	58 (24)
T5/6	71 (25)	60 (22)

### Tangent Point and Gaze Behavior in Relation to the Vehicle Frame of Reference

We next set out to investigate further the behaviour of the tangent point and the driver's gaze in vehicle coordinates. The Land & Lee (1994) model which predicts that the drivers steer so as to maintain the tangent point at a constant bearing angle. The Wann and Land (2000) model, in turn, predicts that tangent point eccentricity should decrease during turn entry (from a relatively eccentric value) when the driver begins to rotate the vehicle and to orient it towards a reference point (close to the tangent point) which he wishes to travel through.

Neither pattern was observed. Instead, as illustrated in figure 2, the observed horizontal positions of gaze and the eccentricity of the tangent point become progressively *more* eccentric during the turn-in phase of this right-left turn. The first vertical green line indicates the average point where the vehicle rotation rate exceeds one degree per second, the second indicates the point where the vehicle reaches its maximum rotation rate (the driver begins to turn the wheel back to the left) and the third green line indicates the point of maximum rotation-rate in the left hand turn (after which the driver begins to reach a maximum at towards the end of the turn-in phase).

Table 3 gives the values for tangent point displacement from the turn-in to the end of the entry phase. Although during the entry phase gaze is relatively concentrated in the TP region, the drivers nevertheless do not appear to be steering to compensate for the outward movement of the tangent point (and gaze) due to visual flow.

Figure 2: Tangent point and gaze in vehicle coordinates for the right-left turn sequence 5/6. The solid red line indicates the eccentricity of the tangent point (averaged across subjects), and the dotted line indicates the road centerline. Right is negative. Note that the tangent point (and gaze) are neither constant, nor do they sweep towards the vehicle centerline (zero eccentricity).

Table 3: Average displacement of the tangent point in the entry phase of each turn. Negative is to the right.

	N	mean
T1 entry	16	3.58
T2 entry	17	-8.68
T3 entry	16	25.1
T4 entry	16	0.66
T5 entry	15	-6.4
T6 entry	15	25.5

We could see the tangent point eccentricity (and gaze) was not constant through the turns but instead increased steadily, in step with the increase in vehicle yaw-rate as the car was entering the curve. As can be seen in Figure 2, the highest tangent point and gaze eccentricities appear occur systematically in the steepest parts of the turn (the green vertical lines indicating the parts of the trajectory where the yaw-rate values reach their maxima). This suggested that a possible relation might exist between the driver's gaze and the vehicle yaw-rate. We decided to investigate this relationship by looking at the estimated fixation density on the road, i.e. the distribution of gaze landing points where the line of sight would intersect the vehicle trajectory.

The relative frequency of gaze landings in each 10 m road segment through each curve was computed as the percentage of all gaze landings falling within the segment. This was computed first individually, and then averaged across

subjects. This distribution is shown by the histogram in figure 3 (bottom), and shows that gaze is not equally distributed on the road surface. This would happen if the drivers were, for example, fixating a point on their trajectory that would be some constant distance ahead. Instead, as shown in the top half of figure 3, while they are approaching a turn the drivers are looking further ahead – 100-150 meters up the road in this instance – but as they enter the turn, the gaze falls closer to the car. Also, when in a connected sequence of turns, the gaze moves discontinuously on the road. Here, the gaze is seen to jump further up the road (from right to left) just before the vehicle yaw rate has reached its peak and the left-hand part of the turn begins.

An unexpected pattern became evident when the relative frequency of estimated gaze landings in a specific part of the curve was compared with yaw rate at that part of the road (histogram in fig.3, bottom shows data for one curve). Gaze landings appeared to be concentrating those parts of the road where the vehicle yaw rate (and thus the road curvature as well) would be highest. I.e. there is a high correlation between the vehicle yaw rate (local road curvature) and the frequency of gaze landings. This correlation is shown graphically in figure 4, and the numerical values of the correlations are given in Table 4, showing that drivers preferentially look at segments of the road where they are going experience a high yaw rate, i.e. parts of the road with high curvature.

Table 4: Correlation (Spearman's Rho) between the median relative frequency (within a turn) with which a particular 10m road estimated as a potential gaze target, and the measured average yaw rate in that segment.

	n	Spearman's Rho
T1	41	0.811
T2/3	46	0.565
T4	53	0.717
T5/6	43	0.795

## Discussion

There are many different steering models available and all predict the same qualitative pattern of tangent point orientation (i.e. orienting gaze in the general direction of the tangent point, the TP AOI), but different predictions concerning the details of the gaze distribution pattern.

Figure 3: Horizontal axis location on the road (m from beginning of the route) Top: Estimated look-ahead distances through T5/6, i.e. distance of estimated gaze landing point from the current location, measured along the future path Bottom: Absolute value of vehicle yaw rate (continuous line) and the frequency histogram of gaze landings on each part of the curve (both variables scaled to sum to 100% within the analysed road section).

Figure 4: Top: Scatterplot of vehicle yaw rate and gaze landing density in the analysed turns. Each datapoint represents the across-subjects average for one 10m segment of all the curves analysed.

One model (Land & Lee 1994 / Wann & Land, 2000) would predict a constant value for gaze and tangent point eccentricity throughout a turn since, according to the model, the driver would make compensating steering movements (induce vehicle yaw) to cancel out the apparent horizontal motion of the tangent point due to optic flow. The prediction of the Wann and Land (2000) / Wann & Wilkie (2004) visual sweep model is that tangent point - and gaze - eccentricity should decrease during turn entry as the driver rotates the vehicle towards the reference point on the future path near the tangent point. Instead, we find that the tangent point - and gaze - become progressively *more* eccentric during the turn-in phase, without compensation or any apparent adverse effects to steering. We therefore conclude that these two steering models *which are based on the idea of using the tangent point as a visual target point which acts control parameter in set-point feedback loop* do not offer a general account for gaze/ steering behavior, at least on the kinds of turns analysed here (variable-radius curves on rural roads).

The differences of the remaining models - not based on simple negative feedback but on an *active trajectory planning strategy because they involve a predictive model of future path* – cannot be judged on the present data. It is thus not possible to pick one that would be the clear best fit for our data. However, the surprising finding that gaze was heavily concentrated on a few parts of the turn – namely, the locations where the vehicle achieved highest yaw-rate – offers some interesting possibilities. *Prima facie* none of the steering models appear to predict this high correlation between the yaw rate and probability of being selected as a gaze target, but we would consider that this pattern may be best interpreted as complementing the Wann & Swapp (2000) model or the Boer (1996) model. Both models predict that the driver should fixate *some* part of the road which he wishes to pass through, but neither specifies *which* part of the future trajectory the driver would or should look at. The location of highest anticipated trajectory curvature (max. yaw-dot) could perhaps serve as such a salient point of reference. (Note that is also behaviourally meaningful in terms of the sequencing of the driving task: this is the point where the curve/trajectory “opens up”, and the drive may begin to accelerate and unwind the steering).

There clearly exists a need for new and such accurate data on visual behaviour in curve driving – i.e. data that could speak the issue of which model or models offer the best fit to driver behavior. This study takes one steps in this direction, by presenting data that speaks directly to the *differential* predictions the models make beyond the *common* prediction of tangent point orientation (which was observed in all turns analysed). We also observed a surprising correlation between gaze landings on the road and measured vehicle rotation at that point, not predicted by any of the existing models.

It is suggested that the next generation of models be developed and empirically tested based on such detailed

quantitative basis - not only for the qualitative pattern of tangent point orientation.

## Acknowledgments

We are grateful to Mr. Juha Vepsäläinen for programming the annotation tool, and Mr. Henri Kotkanen and Mr. Harri Hiltunen for assistance in data collection.

## Abstract

In two experiments, participants were presented with a triad of morphed White and Hispanic faces paired with pseudoword labels. The meanings of these labels were manipulated to represent categorical information about the face. Labels were said to represent either the person's belief, the food s/he ate, the disease s/he had, or the person's last name. The results indicated that categorical information affects our judgments of faces. Information categories such as belief, food, and diseases were particularly strong in modifying the participants' similarity judgment of faces, whereas information characterized with last names of faces were least powerful. Previous research focuses on race face perception being affected primarily by racial indicators or racial information. Our results provide that how we perceptually analyze faces is not confined to obvious racial cues, but by non-racial semantic information as well, suggesting that category-relevant information by itself provides a strong basis for inductive generalization.

**Keywords:** Labeling; Similarity; Categorization

## Introduction

In the perception of faces, there is a tendency to pay excessive attention to salient features such as race-specific (Eberhardt, Dasgupta, & Banaszynski, 2003; Levin, 2000; MacLin & Malpass, 2003). When we see racially ambiguous faces, we shift our attention to features that signal ethnicity such as hair-style or skin color and ignore other important information. This attention shift often results in undesired psychological effects such as cross-race face recognition deficit, i.e., faces that are categorized into "other race" are recognized less than the faces that are categorized into one's own race. (MacLin and Malpass, 2003) and erroneous impression formation (Kashima, 2000; Hamilton & Sherman, 1994; Macrae, Milne, & Bodenhausen, 1994).

Additional studies show that race-based categorization modifies perception of skin color and the width of faces and mouth (MacLin & Malpass, 2003). Research further suggests that holistic face-processing is more prevalent in same-race faces than in other-race faces (Michel, Rossion, Han, Chung, & Caldara, 2006b).

Social categorization based on in-group and out-group of an observer also yield a cross-race recognition deficit, implying that categorization itself can be a mediating factor changing face perception (Bernstein, Young, Hugenberg, 2007). As long as stimuli are grouped in a meaningful way, some modification in face perception is likely to occur. For

example, incremental training or labeling of faces into arbitrary categories generates a categorical perception effect, in which faces taken across a category boundary are recognized better than faces taken within the category boundary (Kikutani, Roberson, & Hanley, 2008). Taken together, these studies demonstrate that not just racial information per se, but category information plays a substantial role in modifying perception of faces.

This explains why social categorization often accompanies faulty generalization and stereotyping. Categories are generative in nature. Categorical labeling not only accentuates features that are central to the category (e.g., prototypical features), but also help generate new features by means of explanations and justifications (Kunda, Miller, & Claire, 1990). When confronted with contradictory attributes (e.g., a rich African-American businessperson), people often make up a subtype of the category (e.g., black entrepreneur) and use it to preserve their initial stereotypical belief (Macrae, Stangor, & Hewstone, 1996). Combinations of contradictory concepts such as "Harvard-educated carpenter" create new features such as "being rebellious" or "anti-social," which were not part of each separate concept – "Harvard-educated" and "carpenter" (Kunda, Miller, & Claire, 1990). When a person is characterized categorically ("Linda is a feminist" as opposed to "Linda believes in and support feminism"), people not only think that the person possesses prototypical attributes of the category ("Linda majored in philosophy in college") but also some unrelated features are deemed likely ("Linda likes Chinese food") (Yamauchi, 2005, 2008, 2009). Categorization also helps reframe people's attention. When geometric stimuli are grouped by categories, perceptual sensitivity within the category is reduced while the differences between categories are enhanced (Tajfel & Wilkes, 1963; Yamauchi & Yu, 2008; Yamauchi et al., 2002). On this basis, we think that when labels help form categories, labeling can modify people's perceived facial similarities. The two experiments tested this idea.

## Overview of the experiments

We employed a widely used triad task (Gelman & Markman, 1986; Sloutsky & Fisher, 2004; Yamauchi Markman, 2000; Yamauchi, Kohn, & Yu, 2007; Yamauchi & Yu, 2008; Yu et al., 2008, 2010; Waxman & Booth, 2001) in which we attached pseudoword labels (e.g., "Scrakies") to face pictures and examined how these labels

Figure 1: Otherwise identical, triads of faces shown (a) without labels, (b) with labels (different-label condition; Experiment 1), and (c) with labels (same-label condition; Experiment 2). Here, the dissimilar base picture appears on the right.

influenced participants' judgments of facial similarity when the same arbitrary labels represented different kinds of semantic information.

In our experiments, participants were shown a triad of human faces (Figure 1) and judged which face, bottom left or right, was more similar to the target face on the top. The target face (top face) was an original face that was either Hispanic or Caucasian. The bottom left and right faces were morphed faces. These faces were displayed either without a label (the control condition, Figure 1a) or with a label (the label condition, Figure 1b & 1c). Each label was an arbitrary pseudoword (such as "Scrakies"), but the meaning of the label was manipulated in the instructions that the participants read at the beginning of the experiment.

In the three experimental conditions, participants were told the arbitrary labels either represented the name of the food the person regularly eats (the food-label condition), the name of the disease that he has (the disease-label condition), or the name of belief that he follows (the belief-label condition). Note that these manipulations were introduced only in the instructions participants received and all participants received the same stimuli. These three conditions were contrasted to two control conditions, in which the labels were removed entirely from the stimulus frame (no-label condition, Figure 1a) or the arbitrary labels were characterized as the last name of the person (the last-name-label condition).

We measured the proportion of trials that participants chose the face that was physically dissimilar to the target image. For example, in Figure 1a, the left base image looks more similar to the target image when compared to the right base image. We measured the proportion of participants selecting the dissimilar face pictures (the right base image in Figure 1) when face pictures had no labels (Figure 1a), and when the target and dissimilar face pictures had different labels (Figure 1b – Experiment 1) or the same labels (Figure 1c – Experiment 2).

We predicted category information would affect similarity judgments while indexical labels would not to the same degree. We commonly classify people by their habit of eating (food-labels, e.g., vegetarians, ethnic-food lovers), the disease they have (disease-labels, e.g., people with high blood pressure, people with cancer, people with allergies) or the belief that people follow (belief-labels, e.g., Christians, positive thinkers). By categorizing people in this manner,

we obtain a sense of similarity and unity among category members. In contrast, a last name is indexical; it refers to a specific person. Groups, such as families, can be formed by last names, but they do not give us a sense of coherence. A name points to a specific entity within a category and therefore should no influence judgments of similarity as strongly as categorical labels. Thus, our hypothesis that categorical labeling helps modify perception of facial similarity leads to the prediction that arbitrary labels change the perception of face similarity in the food-label, disease-label, and belief-label conditions, but not in the last-name label condition.

When items do not share category membership, differences are emphasized. On the contrary, when items are in the same category, differences are diluted (Sloutsky, 2003; Waxman & Markow, 1995). Therefore, in Experiment 1, when the dissimilar picture does not share a label with the target, the proportion of participants selecting the dissimilar base picture should be considerably smaller in the food-label, disease-label, and belief-label conditions than the no-label condition. In Experiment 2, the dissimilar base picture shares a label with the target, so the proportion of participants selecting the dissimilar base picture should be larger than the no-label condition. The proportion of participants selecting dissimilar face pictures as "similar" should be indistinguishable between the no-label and last-name-label conditions in both Experiments

## Experiment 1

### Method

**Participants** A total of 191 undergraduate students participated in this experiment for course credit. They were randomly assigned to one of five conditions: no-label ( $n=39$ ), belief-label ( $n=39$ ), food-label ( $n=35$ ), disease-label ( $n=34$ ), and last-name-label ( $n=34$ ) conditions.

**Materials** Stimuli were triads of faces that either had no label or label attached to them (Figures 1a and 1b). The target was an original picture of either a Hispanic or Caucasian face, and the two base pictures were a morph of the original Hispanic and Caucasian face (Figure 2).

In total, we photographed five pairs of original Hispanic and Caucasian faces. All expressions are neutral and no faces contained any distinguishing features, e.g., none had moles or mustaches. These photographs were morphed into

five pairs of 20 images using Morph Man 4.0 (2003) software starting from the original Hispanic face and morphing towards the Caucasian face (Figure 2). Altogether there were 100 images (10 original faces and 90 morphed images) that had varying degrees of Hispanic and Caucasian facial features.

Figure 2. One real Hispanic face (far left) is morphed gradually with one real Caucasian face (far right). In the actual experiment, there were 18 morphed images between the two original faces.

From the 90 morphed images, base pictures were selected controlling for physical differences between stimuli. Specifically we developed three levels of physical difference— low, medium and high physical difference within conditions – based on the degree of merging two of the original face pairs. In the low physical difference

Figure 3: The three levels of physical difference— low (a), medium (b), and high (c) used in the similarity judgment task. In this example, the dissimilar picture is seen on the right.

**Procedure** Participants were shown 60 triads of pictures, one at a time, and judged which base picture within the triad was more similar to the target image by pressing either the right or left arrow key on the keyboard. The order of presenting the stimuli and the left-right location of placing the dissimilar base pictures were determined randomly. The experiment took approximately 15 minutes to complete.

**Design** The experiment had a 3 (Physical Difference; low, medium, and high; within-subjects factor)  $\times$  5 (Label Condition; belief-label, food-label, disease-label, last-name-label and no-label; between-subjects factor) mixed design. All participants in the five conditions (no-label, food-label, disease-label, belief-label, and last-name-label conditions) received the identical stimuli. The labels in each condition were physically the same, but the meaning attached to the labels was altered in the instructions.

## Results

Figure 4 summarizes the results in Experiment 1. There was a significant main effect of label condition:  $F(4, 176) = 4.49$ ,  $MSE = .03$ ,  $p = .002$ ,  $\eta^2 = .09$ . Individually, the belief-label ( $M = .10$ ), food label ( $M = .09$ ), and disease label ( $M = .11$ ) demonstrated a significant effect when compared to the no label condition ( $M = .18$ ): belief label vs. no label,  $t(76) = 3.76$ ,  $SE = .02$ ,  $p < .001$ ,  $d = .85$ ; food label vs. no label,  $t(72) = 5.66$ ,  $SE = .02$ ,  $p < .001$ ,  $d = 1.32$ ; and disease label vs. no label:  $t(71) = 4.13$ ,  $SE = .02$ ,  $p < .001$ ,  $d = .97$ . The last name label condition ( $M = .13$ ), however, showed no

Figure 4. The proportion of participants selecting the dissimilar image of the base pair pictures according to label type in Experiment 1. The error bars represent two SE units calculated from each condition

significant difference when compared to the no label condition ( $M = .18$ ),  $t(71) = 1.59$ ,  $SE = .03$ ,  $p > .10$ ,  $d = .37$ .

Physical similarity played a role in judgments. Labels influenced similarity judgments of faces more in the low physical difference condition than the medium and high physical difference conditions. In the low physical difference condition, all labels produced a significant effect compared to the no-label condition,  $t_s > 2.33$ ,  $ps < .01$ ,  $d_s > .60$ . In the medium physical difference condition, the food label and disease labels produced significant effects when compared to the no label condition:  $t_s > 2.33$ ,  $ps < .01$ , while the belief and last name conditions did not,  $t_s < 2.33$ ,  $ps > .01$ . In the high physical difference condition, the disease condition was significantly different compared to the no label condition,  $t(65) = 3.16$ ,  $SE = .06$ ,  $p = .002$ ,  $d = .77$ , while other conditions were not,  $t_s < 2.33$ ,  $ps > .01$ .

## Discussion

Consistent with our hypothesis, labels attached to face pictures modified participants' judgments of similarity considerably. When the target and dissimilar face pictures had the different labels, the proportion of participants selecting the dissimilar face pictures decreased dramatically. The impact of the labels was particularly pronounced when these labels conveyed some categorical information, such as the types of food, disease, or belief that the people eat, have, or follow. When the labels represented the last names of the people, the effect of labels diminished considerably, supporting the view that the distortion of race perception occurs especially when labels are associated with categorical information.

Because such an effect was present primarily when labels conveyed categorical information, we suggest that the distortion of face perception is linked to the general mechanism of categorical perception. Experiment 2 tested this idea further.

## Experiment 2

The results from Experiment 1 suggest that labels attached to face pictures can modify people's perception of similarity. In Experiment 1, all dissimilar face pictures carried the different labels as the target picture (Figure 1b); as a result, the difference between the two face pictures (target and dissimilar base pictures) was exaggerated considerably. If, as hypothesized, the categorical labels attached to the face pictures are indeed responsible for the modified perception faces, then the labels can also create the perception of "sameness." In other words, if the dissimilar face pictures carry the same label as the target picture then the dissimilar face pictures should be perceived as more *similar* to the target picture. This was tested in Experiment 2. The only difference between Experiment 1 and 2 was the assignment of the labels. In Experiment 2, the labels of the base pictures were simply swapped so that the dissimilar face pictures and the target picture had the same label (Figure 1c). In Experiment 2, when compared to the no-label condition, the proportion of participants selecting the dissimilar face pictures should increase considerably when the dissimilar face pictures and the target picture have the same label. This phenomenon should occur primarily in the belief-label, food-label and disease-label conditions, but not when in the last-name condition.

## Method

**Participants** A total of 182 undergraduate students participated in this experiment for course credit. They were randomly assigned to one of five conditions: no-label ( $n=34$ ), belief-label ( $n=40$ ), food-label ( $n=38$ ), disease-label ( $n=33$ ), and last-name-label ( $n=37$ ) conditions.

**Materials and Procedure** The materials and procedure used in Experiment 2 were identical to those described in Experiment 1.

**Design** The design of Experiment 2 was the same as Experiment 1 except that the target face in each slide shared the same label as its least similar base face (Figure 1c).

## Results

Consistent with our hypothesis, our results show that category information, even though they were only indirectly related to race, can affect judgment of Hispanic and White faces.

Figure 5 summarizes the results of Experiment 2. There was a significant main effect of label condition:  $F(4, 177) = 4.50$ ,  $MSE = .16$ ,  $p = .002$ ,  $\eta^2 = .09$ . Specifically, the belief-label condition ( $M = .36$ ), the food-label condition ( $M = .33$ ) and the disease-label condition ( $M = .32$ ) demonstrated significant effects when compared to the no-label condition

Figure 5. The proportion of participants selecting the dissimilar image of the base pair pictures according to label type in Experiment 2. The error bars represent two SE units calculated from each condition

( $M = .17$ ): belief-label vs. no-label,  $t(72) = 4.05$ ,  $SE = .05$ ,  $p < .001$ ,  $d = .95$ ; food-label vs. no-label,  $t(70) = 3.18$ ,  $SE = .05$ ,  $p < .005$ ,  $d = .75$ ; disease-label vs. no-label,  $t(65) = 3.11$ ,  $SE = .05$ ,  $p < .005$ ,  $d = .76$ . The last name label ( $M = .22$ ), however, showed no significance when compared to the no label condition ( $M = .17$ );  $t(69) = 1.84$ ,  $SE = .03$ ,  $p = .07$ ,  $d = .44$ . There was no interaction effect between the label condition and the physical difference:  $F(8, 354) = .74$ ,  $MSE = .01$ ,  $p = .66$ ,  $\eta^2 = .02$ .

The belief, food, and disease conditions all showed significance at each level of physical difference when compared to the no label condition:  $ts > 2.33$ ,  $ps < .01$ ,  $ds > .60$ . Just as in the between subject analysis, the last-name label produced null effects across all levels of physical difference:  $ts < 2.00$ ,  $ps > .05$ .

## Discussion

As in Experiment 1, labels attached to the face pictures in Experiment 2 modified participants' judgments of similarity considerably. Again, the impact of labels was particularly

pronounced when the labels conveyed certain categorical information such as the types of food, belief and disease that people eat, follow, and have. The effect of labels was reduced dramatically when the labels were associated with the names of people. In Experiment 2, the target and dissimilar face pictures had the same labels (Figure 1c). As a result, the proportion of participants selecting the dissimilar face pictures as similar to target pictures increased dramatically. These results indicate that the effect of the categorical labels is bi-directional. Categorical labels can create a sense of difference and a sense of proximity. These changes occurred primarily when labels were associated with the types of food, disease, and belief that people have (or eat) but not when labels were associated with the last names of the people.

Together, these experiments further support the view that the meaning attached to these labels, not labels themselves, modifies our perception of similarity both positively and negatively by enhancing the sense of similarity and difference depending on whether stimuli carry the same or different labels.

## General Discussion

Our results indicate that categorical information influences the participants' judgments of similarity. In Experiment 1, participants chose the dissimilar face significantly *less often* when the target and dissimilar face pictures had different labels. In Experiment 2, participants chose the dissimilar faces *more often* when the target and dissimilar face pictures had the same labels. The impact of the labels was negligible when the labels were associated with the last names of people. These results suggest that categorical information given to these labels were indeed responsible for the modified perception of similarity. This modified perception likely arose from some general mechanism underlying the categorical perception effect (Goldstone, 1994, 1995; Livingston, Andrews, & Harnad, 1998; Newell & Bulthoff, 2002; Roberson, Davies, & Davidoff, 2000).

Previous research has focused on race-specific cues to distort racial perception (Eberhardt, Dasgupta, & Banaszynski, 2003). Other research deliberately uses racially related facial features to distort race perception (MacLin & Malpass, 2003). Our study, which uses both White and Hispanic faces, extends previous results by demonstrating that perceptions of race-oriented faces can be distorted by attributing information that is not directly related to racial cues. Meaningful categorical labels can create a sense of similarity and difference depending on whether two stimuli have the same or different labels. Some category information seems to have greater impact than others. For example, the belief labels and the food labels were relatively stronger than the disease and last-name labels. Although the reason behind these differences cannot be determined based on these experiments, we speculate that some categories of information held stronger weight because of their behavior and preference implications

Gil Diesendruck and Heidi HaLevi (2006) point out that personality traits are the primary means by which categorical distinctions and inferences are made because these traits explain behavior and preferences (Yuill, 1992). Food-labels, disease-labels, and belief-labels explicitly refer to such behaviors and preferences, while last-name-labels do not suggest that two people will behave in the same manner.

This reaction to labels and assumptions based on these traits may be related to naïve theories that people form in everyday situations (Chao, Chen, Roisman, & Hong, 2007; Gelman, 2003). It is suggested that people tend to assume there is an essence underlying observed physical characteristics of people, animals, and things (Ahn, 2001; Chao et al., 2007; Gelman, 2003; Medin & Ortony, 1989; Murphy & Medin, 1985). Such essence can be biological characteristics (diseases or DNA, Medin & Atran, 2004), core beliefs (e.g., religion, Cairns, Jenworthy, Campbell & Hewstone, 2007), or behavioral habits (Gelman & Heyman, 1999). The results of our experiments demonstrated how easily people construct naïve theory and how powerful the influence of the naïve theory is. The simple label-meaning manipulation used on our experiments was powerful enough to alter their perception of people. Our results, combined with previous research, suggest categorical information is important when makes judgments about people.

## Abstract

It is widely believed that local and global levels of visual stimuli are better processed in the left and right cerebral hemispheres, respectively. One classic explanation for this observation is the spatial frequency hypothesis proposed by Sergent (1982), which states that the left hemisphere is more efficient at processing high spatial frequencies, whereas the right hemisphere is better with low spatial frequencies. Sergent tested this by measuring RTs for laterally presented stimuli (in the left and right visual fields) composed of high and low spatial frequencies and obtained results consistent with the hypothesis. We put Sergent's findings to the test by replicating her experiment; our first experiment was a direct replication of hers, while the second used the same procedure, but with different stimuli. Our results largely corresponded with those of Sergent, and the crucial interaction between visual field and spatial frequency was obtained in Experiment 1, but was qualitatively different from Sergent's. Possible explanations are discussed.

**Keywords:** spatial frequency; global/local processing; hemispheric differences; hierarchical stimuli; visual hemifield paradigm.

## Introduction

Neuropsychological case studies with brain-injured patients, neuroimaging studies, and experimental research with healthy participants have shown that there are certain functional asymmetries in the left and right hemispheres of the human brain. (Springer & Deutsch, 2001). When it comes to visual perception, one of the most studied phenomena in the field of hemispheric asymmetries concerns the difference between the left and right hemispheres in their ability to process (1) global vs. local aspects and (2) categorical vs. coordinate spatial relationships of visual stimuli. Studies show that the left hemisphere (LH) is better at processing the details of a visual stimulus, whereas the right hemisphere (RH) is superior for processing its overall shape, patterns formed by Gestalt principles, etc. (Han et. al., 2002; Hellige, 1996; Ivry & Robertson, 1998; Van Kleeck & Kosslyn, 1989). Similarly, research has shown a LH advantage in processing distance-independent categorical spatial tasks (e.g., "Is the dot to the left or right of the vertical line?"), and a RH advantage for spatial tasks that require relative- or absolute-distance spatial judgments (e.g., "Which dot is closer to the

vertical line?"; Hellige & Michimata, 1989; Jager & Postma, 2003; Kosslyn et. al., 1989, 1994).

An early attempt to explain some of the hemispheric asymmetries was made by Sergent (1982) who proposed that the global/local effect was due to hemispheric differences in the capacity to process different spatial frequencies.<sup>1</sup> According to this hypothesis, the LH advantage for local stimuli emerges because the LH is better at processing high spatial frequencies (HSF), whereas the RH global advantage is due to its efficiency in processing low spatial frequencies (LSF). Attempts to verify or falsify this hypothesis have been rather controversial. Some neuroimaging and neuropsychological studies support the LH-HSF/RH-LSF asymmetry (e.g., Han et. al., 2001; Mecacci, 1993; Peyrin et. al., 2004, 2006a; Woodhead, et. al., 2011), whereas others show results partially or entirely inconsistent with it (e.g., Grabowska et. al., 1989; Fink et. al., 1997, 1999). Studies with healthy participants which use the visual hemifield paradigm yield similarly mixed results, with some research consistent (Hübner, 1998; Peyrin et. al., 2006b; Proverbio et. al., 1997; Van Kleeck & Kosslyn, 1989) and other inconsistent (Blanca & Lopez-Montiel, 2009; Evert & Kmen, 2002) with the hypothesis.

Yovel, Yovel, & Levy (2001) present a good meta-analysis of studies that used the visual hemifield paradigm with hierarchical stimuli. These are mostly Navon-type letters (large letters composed of small letters; Navon, 1977). The basic idea behind those studies is that when such a stimulus is presented in the left (LVF) or right (RVF) visual field, the response times (RT) and error rates should show a LVF advantage when the response is given based on the large letter and a RVF advantage when it is given based on the small letters.<sup>2</sup> Despite the theoretical predictions, Yovel et. al. found that studies confirming them are outnumbered by those that don't find a significant visual field (VF)×stimulus type interaction (i.e., more studies failed to find one or both of the LVF-LSF/RVF-HSF advantages).

---

<sup>1</sup> This hypothesis has later been used to explain the categorical/coordinate spatial relationship asymmetry as well (Ivry & Robertson, 1998).

<sup>2</sup> Visual input to one of the VFs is initially received and processed by the contralateral hemisphere (Beaumont, 1983).

Of the studies reviewed by Yovel et. al. which used the divided attention task, only Sergent (1982) found the significant interaction mentioned above. Another interesting observation is that, as a whole, the studies that reported significant results used fewer participants than those that didn't. Furthermore, the authors of this paper have previously employed Sergent's procedure along with an additional manipulation, but failed to obtain positive results. Sergent (1982) has been one of the most cited studies in the literature of hemispheric asymmetries for low and high spatial frequencies, yet, to our knowledge, there have been no attempts to replicate its findings. For those reasons, we decided that there is value in conducting a study with the same methodology, but significantly more participants, in order to gain more insight into the validity of the original study's results.

### Sergent (1982) revisited

Sergent's study used Navon-type hierarchical letters projected to the LVF, RVF, and central visual field (CVF). The stimulus material consisted of 4 letters (for a total of 16 large-small letter combinations), 2 of which were targets and 2 non-targets. Twelve participants had to press a "yes" button if either the large or small letters were target, or a "no" button otherwise. The critical finding was that in the so-called "conflict conditions" in which a non-target large letter was composed of small target letters (L+S-), or vice versa (L-S+) a VF×stimulus type interaction was observed. That is, L+S- stimuli were responded to faster in the LVF/RH than in the RVF/LH, with the opposite result for the L-S+ condition (for the full results, see Fig. 2a). These results were interpreted in light of the spatial frequency hypothesis, i.e., that the LH is superior for HSF (small letters), whereas the RH shows an advantage for LSF (large letters).<sup>3</sup>

In Experiment 1, we use nearly the same procedure but with significantly more participants.

## Experiment 1

### Method

#### Participants

Forty-one volunteers and New Bulgarian University students (21 men and 20 women, aged 19-42) took part in the experiment for course credit. All were right-handed and with normal or corrected-to-normal vision. Their visual acuity was tested by presenting 4 small letters (the same as those used in the experiment) four times each in the RVF, CVF, and LVF, which they had to identify. All participants could identify most of the letters presented, deeming them fit to participate in the study.

<sup>3</sup> Sergent proposed that since the large and small letters are of equal complexity, they should differ only on the spatial frequency dimension.

### Stimulus Material and Apparatus

The stimuli were large letters composed of small letters. The letters used were H, C, Т и P from the Cyrillic alphabet (analogues of the English letters N, S, T, and R), the combinations of which add up to a total of 16 stimuli. The letters were chosen to visually resemble the ones in Sergent's study, which were H, L, T and F (L was replaced with C and F was replaced with P). In our study the target letters were H and C (Fig. 1).

Large letters subtended visual angles of  $2.08^{\circ} \times 1.36^{\circ}$  and small letters subtended angles of  $0.23^{\circ} \times 0.16^{\circ}$ . The stimuli were black and were presented against a white background using the E-Prime software package on a 19" monitor (refresh rate of 200 Hz) of a Samsung SyncMaster 959 NF. The stimuli were presented in the LVF, CVF, and RVF. In lateral presentations, the center of the stimulus appeared  $1.4^{\circ}$  to the left or to the right of the fixation cross.

### Design and Procedure

Participants were led into an experimental booth and introduced to the experiment by signing a consent form with general information about it. They were asked about handedness and tested for visual acuity. Instructions were given with emphasis on the importance of speed and accuracy of responses. Each trial began with the appearance of a fixation cross for 1500 msec, followed by a stimulus appearing for 150 msec in the LVF, CVF, or RVF, a 2000 msec response window (which terminated when participants pressed one of the response buttons), and a 2000 msec intertrial interval. Participants had to determine whether the stimulus contained either H or C or both by pressing a "yes" key if it did and a "no" key if neither level contained a target letter. The hand for response was counterbalanced across participants.

The experimental procedure began with a practice session, consisting of 36 trials with feedback on response accuracy, followed by the experimental session, consisting of five blocks of 72 trials for a total of 360 trials. The duration of the entire session was about 35 minutes, with 4 breaks in between experimental blocks, during which participants took several seconds to rest their eyes.

Both independent variables were within-subject: (1) VF (left, central, right); (2) stimulus type (6 types; see Fig. 1). An equal number of positive (containing a target at at least one level) and negative (containing only non-target letters) stimuli were randomly presented in each VF (each of the 4 negative combinations was presented 3 times as frequently as the remaining 12 combinations).

### Results and Discussion

Before performing any analyses on the RTs for the different conditions, we removed all incorrect responses. The average accuracy was 97% and no participants were excluded from further analysis based on low accuracy. We also removed all data points above or below 2.5 standard deviations from the mean for each participant (excluding 2.6% of the data). There was no main effect of the between-subject factors sex,

$t(39) = 0.175$ ,  $p = 0.862$ , and hand for response,  $t(39) = 0.212$ ,  $p = 0.83$ , so all further analysis was collapsed over them.

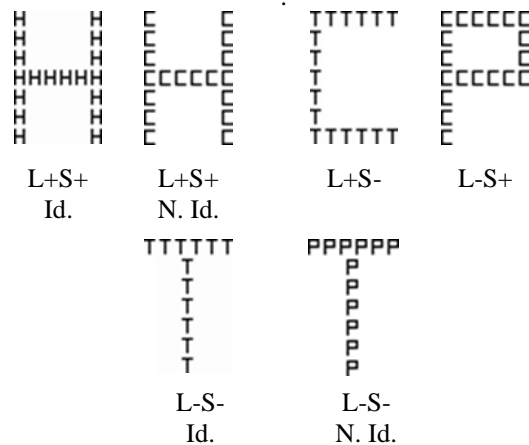

Figure 1: Sample stimuli used in Experiment 1.

Top left: positive, non-conflict stimuli with identical and non-identical large and small target letters; Top right: positive, conflict stimuli with a large target letter composed of small non-target letters, and a large non-target letter composed of small target letters. Bottom: negative stimuli with identical and non-identical non-target large and small letters. The C and P in our study replaced Sergent's L and F, respectively.

Figure 2b displays the mean RTs and standard errors for each condition. A repeated measures ANOVA revealed a main effect of VF,  $F(2, 39) = 15$ ,  $p < 0.001$ , with about 20 msec faster latencies in the LVF and CVF compared to the RVF. There was also a main effect of stimulus type,  $F(5, 36) = 37.984$ ,  $p < 0.001$ , with the L+S+ conditions having the shortest latencies, while the L-S- conditions had the longest latencies. Similar to Sergent (1982), we also found a main effect of identity,  $F(1, 40) = 41.977$ ,  $p < 0.001$ . That is, it took less time to respond to identical non-conflict stimuli (i.e., large targets made up of the same small targets and large non-targets made up of the same small non-targets), compared to their non-identical counterparts.

Next, we analyzed the conflict conditions, where we found a marginally significant difference in latencies. RTs were about 17 msec faster for L+S- than for L-S+,  $F(1, 40) = 3.548$ ,  $p = 0.067$ . This result is consistent with findings from the psychophysical literature, according to which LSFs are available to the visual system earlier than HSFs and are therefore processed faster (Breitmeyer, 1975; Breitmeyer & Ganz, 1977; Kulikowski & Tolhurst, 1973; Vassilev, Mihaylova, & Bonnet, 2001).

The conflict conditions were most interesting in regards to Sergent's hypothesis, namely, that there should be a LVH-RH advantage for the L+S- (LSF) condition and a RVF-LH advantage for the L-S+ condition (HSF). That is, when the decision is based on the large letter, there should be a RH

advantage, whereas the opposite result should hold when the decision is based on the small letters. Despite the overwhelming correspondence between Sergent's and our results, as seen in Figure 2a and 2b, we only found a LVF advantage for the large letters, but, critically, no RVF advantage for the small letters. In fact, the LVF was superior for both large and small letters. Nevertheless, we did find a significant two-way interaction between left/right visual fields and the L+S-/L-S+ conditions,  $F(1, 40) = 34.742$ ,  $p < 0.001$ . This is mainly due to the difference between the LVF and RVF being smaller for the L-S+ condition; when the decision was based on the small letters, participants were significantly slower to respond when the stimulus appeared in the LVF (but not slower than the RVF). However, we don't consider this observation to be good support for the hypothesis. First, the case may be that there is a ceiling effect when it comes to RVF RTs for the L-S+ stimuli. Second, it is very difficult to draw strong conclusions from RT interactions which don't involve change in sign of the slope of latency curves across conditions, given that the relationship between task complexity and RT is not always linear. In other words, the interaction could have simply been due to task difficulty (since small letters are more difficult to process) and not because of hemispheric asymmetries related to processing different spatial frequencies.

Given the discrepancy between our results and the results obtained by Sergent, we decided to analyze the data from individual participants separately. Another incentive for doing so was based on the controversial results obtained from other studies using similar procedures. We found 12 participants (from a total of 41) whose data had the pattern consistent with Sergent's results (i.e., shorter RTs in LVF than RVF for the L+S- condition, and shorter RTs for RVF than LVF for the L-S+ condition). Their results can be seen in Fig. 2d. A comparison of those and Sergent's results reveal remarkably similar patterns (coincidentally, she also used 12 participants).

Given the conflicting results of previous studies, combined with our findings, we consider the possibility that there might be a yet undiscovered dimension on which people differ. That is, there may be individual differences when it comes to hemispheric asymmetries for spatial frequency processing. Hence, it might have been the case that Sergent (1982) obtained positive results due to an unrepresentative sample of participants from the general population. We do not find this explanation to be particularly appealing, however, since it is done post-hoc, rather than based on empirical or theoretical reasoning. It is also possible, though less likely, given our larger sample size, that it is *our* sample that was unrepresentative. For those reasons, we decided to conduct a second experiment with different participants, using the same procedure, but slightly different stimuli. Instead of using hierarchical letters, we used hierarchical shapes. The purpose of this was also partly exploratory. It is possible that using verbal

Figure 2: Mean RTs and standard errors for the six stimulus conditions for (a) Sargent (1982); (b) Experiment 1 of this study; (c) Experiment 2 of this study; (d) The data from 12 participants from Experiment 1 with results consistent with the spatial frequency hypothesis.

stimuli is a confounding factor, since it is a well-established fact that the LH plays a bigger role in language processing than does the RH (Springer & Deutsch, 2001). We wanted to see if using non-verbal stimuli would affect the results in any direction.

## Experiment 2

### Method

The method was identical to that of Experiment 1 with a few exceptions. Compound shapes were used, instead of compound letters (squares and triangles were target, whereas circles and crosses were non-target, see Fig. 3) and they subtended visual angles of  $1.94^{\circ} \times 1.94^{\circ}$  for the large shapes, and  $0.24^{\circ} \times 0.24^{\circ}$  for the small shapes. Thirty-nine right-handed volunteers and New Bulgarian University students (18 men and 21 women, aged 19-38) took part in the experiment for course credit (none of them had participated in Experiment 1).

Figure 3: Sample stimuli used in Experiment 2

### Results and Discussion

As in Experiment 1, we excluded all incorrect responses from further analyses. The average accuracy was 97% but one participant was excluded because of a large error rate (26%). As before, we removed all data points above or below 2.5 SD from the mean (excluding 2.8% of the data). There was no main effect of the hand for response factor,  $t(36) = 1.036$ ,  $p = .307$ , but there was a marginally significant main effect of sex,  $t(36) = 1.879$ ,  $p = .068$ , with men having a small average RT (by 63 msec) than women. The latter factor and the hand for response factor did not interact with any others in a theoretically meaningful or statistically significant way, so we collapsed all further analyses over them.

Figure 2c displays the mean RTs and standard errors for each condition. A repeated measures ANOVA showed a main effect of VF,  $F(2, 36) = 32.054$ ,  $p < 0.001$ . As in Experiment 1, the latencies were about 20 msec faster in the LVF and CVF compared to the RVF. There was also a main effect of stimulus type,  $F(5, 33) = 60.144$ ,  $p < 0.001$ , with the L+S+ conditions having the fastest latencies, while the L-S- conditions had the slowest latencies. Similar to Experiment 1, we also found a main effect of identity,  $F(1,$

37) = 9.743,  $p = 0.003$ , and a large letter advantage,  $F(1, 37) = 16.605$ ,  $p < 0.001$ .

No significant visual field-stimulus type interaction was obtained,  $F(1, 37) = 1.25$ ,  $p < 0.269$ , but we still observed a LVF-RH advantage for both large and small shapes, and no RVF-LH advantage whatsoever for small shapes. As in the previous experiment, these results run counter to Sergent's findings. Unlike in the previous experiment, in this one only two of 38 participants exhibited similar patterns to the ones Sergent reported. Our results are also inconsistent with some of the studies reporting global/local or LSF/HSF interactions with VF presentations (Gier et. al., 2010; Hübner, 1998).

## General Discussion

Our experiments revealed several consistent findings. First, participants were faster as a function of both stimulus type and stimulus identity. That is, they were fastest to respond to a stimulus if both the large and small letters were target, slower when only one of the levels was target, and slowest when neither level was target; they were also faster to respond when the two levels were represented by the same letter or shape. In our interpretation, this is consistent with a model of parallel processing of the two levels where processing is facilitated when the global and local levels are composed of the same letters/shapes and when they're both either target or non-target. Therefore, when both levels are identical, it is more likely that at least one of them will evoke neural mechanisms that will lead to the proper response. Other studies have also shown evidence supporting the parallel processing of global and local levels of hierarchical stimuli (e.g., Hübner, 1997).

Another result of our experiments that is consistent with the literature is the idea that LSF are available to the visual system earlier than HSF. This phenomenon has been explained by the differences between the magnocellular and parvocellular visual pathways. They correspond to the *transient* and *sustained* channels described by Breitmeyer (1975), Breitmeyer & Ganz (1977), and Kulikowski & Tolhurst (1973). The magnocellular pathway is most sensitive to LSH and high temporal frequencies (HTF), whereas the parvocellular pathway is most sensitive to HSF and low temporal frequencies (LTF). Furthermore, the magnocellular pathway is more efficient when it comes to the speed with which it propagates information to the higher cortical structures, which explains the earlier availability of LSF.

When it comes to the central hypothesis that was tested in this study, our results are inconsistent with those of Sergent (1982). We did not observe the critical interaction between spatial frequency and the visual field of stimulus presentation. At the same time, it could be argued that our results are consistent with the general trend observed in studies using the hierarchical stimulus/visual hemifield paradigms of finding mixed results. A somewhat interesting finding of our study was that 12 participants showed RT patterns for the conflict conditions that were in line with the

hypothesis, but the remaining 29 participants did not. This might suggest that the conflicting results in the literature could be partially explained by individual differences on an unidentified dimension. Individual differences in processing time of the different levels (Evert & Kmen, 2002; Kimchi, 1992; Peyrin et. al., 2006b) are a possible candidate dimension. For example, Peyrin et. al. found that the classic hemispheric asymmetry for spatial frequency processing occurred only when the stimulus presentation time was 30 msec, whereas only a LVF/RH advantage emerged when the presentation time was 150 msec. Note that the latter is consistent with the results from our experiments. We propose that there may be between-subject, as well as within-subject, differences related to stimulus presentation time underlying these effects. Kimchi (1992) has done an overview of a variety of other factors that could influence the global/RH advantage in these studies, from the overall visual angle, sparsity, and number of local elements of the stimuli to goodness of form and attentional factors.

Finally, it is worth noting that some researchers argue that hierarchical stimuli are not a good way of manipulating spatial frequency (e.g., Peyrin et. al., 2003). Also, Yovel et. al. (2001) point to the salience of the hierarchical stimuli as a determining factor for obtaining the critical interaction. They observed a RH advantage for both global and local levels when stimuli were globally salient, as opposed to equally salient, in which case they observed a RH advantage for global letters and a LH advantage for local letters. The stimuli used in Sergent's and our study are of the globally salient type.

We conclude that, despite the large number of studies, there is still a significant amount of uncertainty surrounding the nature of hemispheric asymmetries for low and high spatial frequency processing. Further studies are needed to explore the underlying mechanisms, the different stimulus and procedural factors involved, as well as possible individual differences that are at play.

## Acknowledgments

We would like to thank our volunteers and Oksana Itkes for her assistance in finding many of the references. We also express our gratitude towards prof. Angel Vassilev and Ivan Vankov for their valuable advice and fruitful discussions.

## Abstract

Understanding episodic memory formation of real-world events is essential for the investigation of human cognition. Most studies have stressed on delimiting the upper boundaries of this memory by using memorization tasks with conditional experimental paradigms, rather than the performance of everyday tasks. However, naturally occurring sensory stimuli are multimodal and dynamic. In an effort to investigate the encoding and retrieval of episodic memory under more naturalistic and ecological conditions, we here demonstrate a memory experiment that employs audio-visual movies as naturalistic stimuli. Electroencephalography measurements were used to analyze neural activations during memory formation. We found that oscillatory activities in the theta frequency bands on the left parietal lobe, and gamma frequency bands on the temporal lobes are related to overall memory formation. Theta and gamma power of the frontal lobes, and gamma power of the occipital lobes were both increased during retrieval tasks. Furthermore, subjects' memory retrieval performance on the query task was used to clarify our experimental results. Correlation between behavioral differences and neural activation was observed in the same regions. Our results extend the previous results of neurocognitive studies on memory formation via naturalistic stimuli, neural oscillations, and behavioral analysis combined.

**Keywords:** Memory formation; Naturalistic stimuli; EEG study; Neural oscillation; Reaction time.

## Introduction

Memory processing is one of the most prominent features of human cognition. Particularly, understanding how the experience of an episode in our everyday life can be transformed into a long-term memory is a central issue in human memory research.

Episodic memory formation is a complex neurocognitive process that involves many interacting brain regions, and

enables us to store contextual (spatial and temporal) information about individual events that can be later retrieved. In contrast, semantic memory consists of isolated facts that are decontextualized and not organized into a specific experience.

Research in cognitive neuroscience thus far has focused on the human memory system, and much knowledge has been acquired via the neuropsychological examination of brain-lesioned patients (Milner, Squire & Kandel, 1998; Squire, 2004). Furthermore, noninvasive neuroimaging studies in the last decade have revealed numerous functional roles of particular brain regions related to memory phenomena (Freeman, Dennis & Dunn, 2010; Spaniol et al., 2009).

However, the vast majority of experimental protocols used to study the neural mechanisms of episodic memory formation (Schacter & Addis, 2007; Vissers et al., 2008) deal with well-controlled experimental setups in which conditional static stimuli (e.g., single words or still images) are presented for memorization. They are typically dissimilar from what the human brain encounters in everyday life, since naturally occurring sensory stimuli are continuous and multimodal. (Bartlett, 1932; Jacobs & Shams, 2010; Tulving, 2002).

In an effort to investigate episodic memory encoding and retrieval under more naturalistic and ecological conditions, we performed a memory experiment employing audio-visual movies to mimic natural stimuli.

Movies are suitable for use as naturalistic stimuli because they reflect aspects of experiences in our daily lives by fusing multimodal sensory perception with emotional and cognitive overtones (Eisenstein, 1947; Hasson et al., 2007; Morin, 2005). In fact, cinematic materials have been used to explore memory since the early days of cinema (Boring, 1916), but only recently have some neuroimaging studies used audio-visual movies as natural stimuli for the examination of brain activation induced by memory

operations (Ben-Yakov et al., 2011; Furman et al., 2007; Green, Li & Bavelier, 2011; Hasson et al., 2007; Milton et al., 2011; Sestieri et al., 2011).

In contrast to recent studies investigating memory processes with functional magnetic resonance imaging (fMRI) during the presentation of video stimuli, here we aimed to examine brain activation using electroencephalogram (EEG) recordings. Neural oscillations have been linked to various cognitive phenomena in humans. Although there is no exact mapping of neural oscillatory rhythms to specific cognitive processes, neural oscillations in a specific frequency range in each brain region may function as their own cognitive process (Başar et al., 1999; Bechtel & Abrahamsen, 2010; Kahana, 2006; Klimesch et al., 2008).

We focused in this study on gamma and theta oscillations because recent research has suggested a functional role of theta (4–8 Hz) and gamma (30–50 Hz) oscillations in episodic memory (Doppelmayr et al., 1998; Klimesch et al., 2001, 2008; Osipova et al., 2006). Other rhythms such as delta (1–4 Hz), alpha (8–13 Hz), and beta rhythms (13–30 Hz) have not been discussed because they have not been consistently reported as being related to episodic memory, and they correlate not only with episodic memory but also with semantic memory (Düzel et al., 2005; Hanslmayr, Spitzer & Bauml, 2009; Weiss & Rappelsberger, 2000).

A secondary aim of this study was to investigate memory retrieval in consideration of the subject's behavioral factors. Because the human brain can be easily affected by numerous factors that disturb the expected neural response to experimental paradigms, there may not be a specific interpretation of the acquired neuroimaging results. To alleviate this problem, we designed a 2-way analysis of brain oscillation rhythms based on subjects' memory retrieval task performance. Using this approach enables the results of our oscillatory analysis during memory formation to be supported by behavioral analyses.

## Materials and Methods

Two goals were considered when constructing the task and methodology used in this study. First, a set of memory tasks was designed to look at 2 aspects of episodic memory: encoding and retrieval. Second, we obtained EEG data on the scalp while memory tasks were being performed by subjects in order to specify the anatomical locations of brain activations associated with episodic memory formation.

## Subjects

Ten neurologically healthy subjects (mean age,  $24.0 \pm 2.7$  years; 4 women) with normal or corrected-to-normal vision (mean eyesight in left and right eyes, 0.87/0.80) were recruited from Seoul National University (Seoul, Korea). Informed consent was obtained from all subjects in accordance with the guidelines of the institutional review board (IRB) at the Clinical Research Institute of Seoul National University Hospital.

## Stimuli

The experimental stimulus used in the encoding session was an audio-visual movie containing an episode of a television sitcom (duration, 27 minutes). The spoken language in the movie was American English, and subtitles were not displayed.

We extracted 20 video clips (each of 5 seconds), taking into consideration the current of its story, and captured 40 subsequent still images from the movie. These short video clips served as retrieval cues in the retrieval session of the experiment, and the captured images were used in the query tasks.

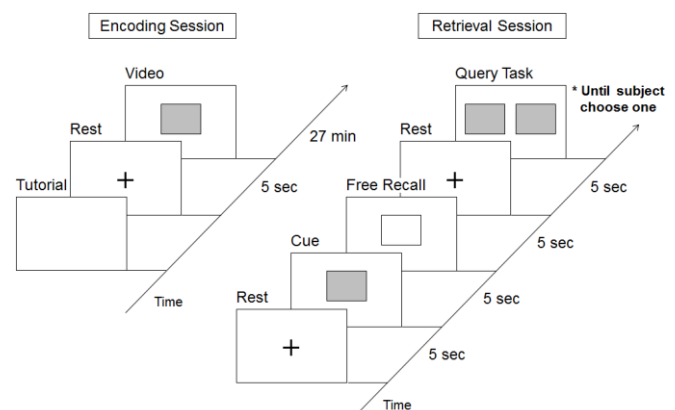

To make the experiment more accurate, we also developed a software program capable of displaying stimuli, including movies and images, sequentially following fixed time as input by an experimenter. Additionally, the program records subjects' responses and reaction times (RTs) during query tasks, so that these records could be used in EEG analysis. In the program, all the stimuli are 130 mm wide and 100 mm high, and were displayed with a black background on a 15-inch LCD monitor placed approximately 50 cm away from the subject.

## Experimental Paradigm

The entire experimental procedure is depicted in Figure 1. The memory experiment program begins with a tutorial task consisting of a concise example set of whole experiments in order to allow subjects to become accustomed to the experimental procedure.

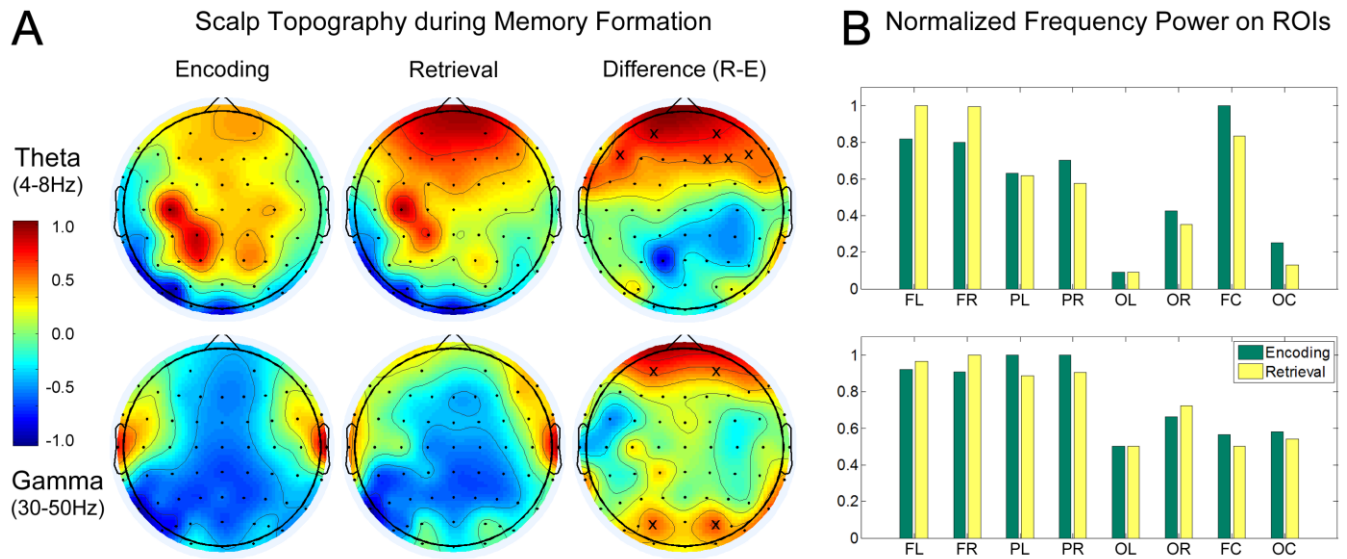

Following the tutorial, the encoding session starts, playing an episode of a television sitcom in its entirety. The subjects watched the movie without requiring any response. EEG measurement also began at this point. The EEG data were analyzed later by using the time stamps recorded by the program.

In the retrieval session, each subject performed video cue-based free recall tasks by imagining the scene immediately following the cue stimuli. Finally, as for the query task, 2 images contained in the cue video were presented in a random order. The subject was asked to decide whether the order of presentation is correct or incorrect, and press the "O

**Figure 1:** Schematic depicting the experimental paradigm.

**Figure 2:** Theta and gamma oscillatory activation during memory formation. (A) The first row indicates increased theta frequency power of the frontal lobes in the encoding task, and the second row indicates increased gamma frequency power of both the frontal and parietal lobes in the encoding task. Differences between retrieval and encoding tasks are depicted in the third column with ‘x’ markers which stand for locations showing the major differences (B) Normalized theta and gamma frequency power values on the 8 topographical regions of interest (frontal left, FL; frontal right, FR; parietal left, PL; parietal right, PR; occipital left, OL; occipital right, OR; frontal center, FC; and occipital center, OC) shows quantitative differences between encoding and retrieval sessions. In the retrieval session, theta activations on the left and right frontal regions were increased. Gamma activations on the frontal and parietal regions were increased, although other regions were decreased.

(correct)” or “X (incorrect)” button on a small keypad.

The experiment constituted 20 rounds of the retrieval task.

### EEG Measurement

Ongoing brain activity was recorded using Ag/AgCl electrodes mounted in a 128-channel Quik-cap, and a Neuroscan SynAmps amplifier (Neuroscan, El Paso, TX) in a dimly lit, soundproof, electrically shielded room at the Clinical Cognitive Neuroscience Center of Seoul National University Hospital. The ground electrode was located 10% anterior to FZ, with linked mastoids serving as references. Eye movements and blinks were monitored by a horizontal electrooculogram (hEOG) and a vertical electrooculogram (vEOG). Impedance was maintained at 5–10 kΩ or less. Throughout the experiment, EEGs were continuously obtained at a sampling rate of 1,000 Hz/channel.

### EEG Data Analysis

EEG data analysis was performed using the EEGLAB toolbox (Delorme & Makeig, 2004) developed at the Institute for Neural Computation in the University of California San Diego<sup>1</sup> using MATLAB 7.13 (MathWorks, Natick, MA). A baseline removal process was applied in order to eliminate some shift signals and to synchronize the zero levels of each channel. Eye movement artifacts were eliminated by excluding hEOG and vEOG components

extracted by Independent component analysis (ICA). All signals were then band-pass filtered between 4.0 and 50.0 Hz in order to exclude unnecessary frequencies. Some electrodes on the prefrontal area (AF7, FP1, FPZ, FP2, and AF8) were excluded to reduce any remaining chance of including ocular artifacts. A fast Fourier transform (FFT) in the frequency domain on the artifact-free EEG record was then performed. Frequency bandwidths were divided according to the following divisions: theta (4–8 Hz), alpha (8–13 Hz), beta (13–30 Hz), and gamma (30–50 Hz). From the computed FFTs, overall power averages were computed for each bandwidth.

## Experimental Results

### Oscillatory Correlates of Memory Formation

2D brain maps showing the grand-average topographical distribution of theta and gamma frequency power during the 2 experimental conditions (memory encoding session and retrieval session) are presented in Figure 2(A).

First, we observed increased theta frequency activation on the left parietal lobe (C3 and CP1), and increased gamma activation on the temporal lobes (T7 and T8) during overall memory formation.

As seen in the topographical plots showing the difference between the encoding and retrieval sessions, theta and gamma power on the frontal lobes were more increased in retrieval sessions than in encoding sessions (indicated by

<sup>1</sup> <http://sccn.ucsd.edu/eeqlab>

**Figure 3:** RT histogram for one subject. The blue line stands for the average of RTs (3754ms) and the red line stands for the sum of the average and standard deviation of RTs (5053ms). From this subject, 5 trials (1st, 15th, 16th, 17th, and 20th) were chosen for the sustained RTs, and the remaining 15 trials were considered as the instant RTs.

positive values of the difference between encoding and retrieval in Fig. 2(A)). Some of occipital theta powers in the retrieval session were also increased, but they were not significant differences. Contrarily, theta powers on the occipital center regions were decreased in retrieval sessions. Occipital gamma power was increased during the retrieval session. Independent *t*-tests verified that both differences are statistically significant for theta ( $F = 3.771$ ;  $p < 0.005$ ) and gamma frequency powers ( $F = 3.902$ ;  $p < 0.001$ ).

### Analysis based on Behavioral Factors

To clarify our finding regarding neural oscillations associated with memory formation, correlation between EEG and RT of the query task was analyzed. We classified the experimental results from 20 query tasks into 2 types: sustained RT and instant RT. Sustained and instant RT represent an RT that is longer and shorter, respectively, than the sum of the average and standard deviation of all RTs. Fig. 3 depicted RT histogram of one subject as an example. Theta and gamma oscillatory activations during the query task were then analyzed in consideration of the 2 different classes of responses on query tasks.

Interestingly, as shown in the topographical plots in Fig. 4, a correlation between neural activation and RT of subjects in query tasks were observed in the theta and gamma oscillations in some meaningful brain regions: increased theta power on the left parietal lobe, and increased gamma power on the right frontal and left occipital lobes during query tasks with sustained RT.

This indicates that memory formation, especially retrieval, is more activated when subjects make more effort on the query tasks. Additionally, this result supports the notion that regions with high theta and gamma power, including the left

**Figure 4:** Theta and gamma oscillatory activation during query task, classified according to the length of reaction time. Both theta and gamma were increased on the same regions with the former result of oscillatory activation during memory formation. In contrast to the tasks of instant RT, theta power on the left parietal lobe, gamma power on the right frontal and the left occipital lobes show greater activations in the RT-sustained tasks.

parietal lobe, right frontal lobes and left occipital lobes, are related to episodic memory retrieval.

As for other behavioral factors, the average correct response rate on the query task was 69.4% (about 14 questions were correct) and the average RT for each query task was  $7.1 \pm 3.3$  seconds. However, there was no significant effect observed in the frequency power analysis of factors such as true/false sequential order of presented pictures in the query task, correctly/incorrectly answered tasks, or the correlation between RT and these factors.

### Discussion

Recently, many functional neuroimaging studies using fMRI or positron emission tomography (PET) have shown that specific brain regions are significantly correlated with memory formation. For example, the temporal lobes have been long associated with memory retrieval (Nakamura & Kubota, 1996), and the medial prefrontal cortex (mPFC) and transverse occipital sulcus (transOCS) have been shown to play a significant role in subsequent memory retrieval (Hasson et al., 2007). Furthermore, neural oscillations in the gamma and theta frequencies have long been observed in cognitive tasks, such as those used to investigate episodic memory, and in focal lesion studies (Milner et al., 1985; Nyhus & Curran, 2010).

In consideration of using naturalistic stimuli, unlike traditional experiments that have consistently revealed memory effects for still images or words, we observed similar results in both the spatial and spectral domains. Moreover, our results link the frequency domain with each observed region (i.e., delta frequency on the frontal and left parietal lobe, and gamma frequency on the frontal and occipital lobes). This is similar to the results of several

studies that have shown greater gamma power in the posterior cortex for subsequently remembered items than for forgotten items (Hanslmayr et al., 2009; Osipova et al., 2006).

As for the individually different effects of the experimental stimuli, there is some evidence from previous studies showing the same effect in a previous experiment using similar movie narrative stimuli (Hasson et al., 2004; Wilson, Molnar-Szakacs & Iacoboni, 2008). Thus, a statistical evaluation showed that the observed brain activations in our results are significantly different from each other.

Our study has some limitations. It is not entirely unexpected that there was no significant correlation observed between correctly and incorrectly answered questions in the query task, because the subject might not care what the correct answer is at the time of the task. In addition, the paradigm of the query task is too ambiguous to determine which image has been shown earlier, because the presented images were both taken from the same scene. This problem could be addressed by choosing 2 images from different scenes, but such a paradigm might also evoke some semantic memory processes, with the subject cued by many possible different factors in the images or stories, such as actors' clothes and the scenery of each scene. Instead, RT seems to be a more appropriate factor for behavioral analysis because RT will be longer when subjects make more effort to retrieve stored memories, and thus, the brain region related to retrieval memory will be more activated at that time.

## Conclusion

In summary, we have demonstrated episodic memory formation using with an audio-visual movie as a naturalistic stimulus, and measured subjects' EEG signals throughout the task in order to reveal the neural responses involved in episodic memory operations. We also developed a memory task program designed to obtain more accurate experimental results. We identified oscillatory activities related to memory formation in the spatial and spectral domains. Different oscillatory activities in the retrieval session were also observed. A correlation between RTs and oscillatory activation during the query task was observed in the same regions. We expect that our naturalistic and behavioral factor-based analysis approach for memory investigation could help extend the range of neurocognitive research.

## Abstract

Clustering quality evaluation is an essential component of cluster analysis. Given the plethora of clustering techniques and their possible parameter settings, data analysts require sound means of comparing alternate partitions of the same data. When proposing a novel technique, researchers commonly apply two means of clustering quality evaluation. First, they apply formal Clustering Quality Measures (CQMs) to compare the results of the novel technique with those of previous algorithms. Second, they visually present the resultant partitions of the novel method and invite readers to see for themselves that it uncovers the correct partition. These two approaches are viewed as disjoint and complementary.

Our study compares formal CQMs with human evaluations using a diverse set of measures based on a novel theoretical taxonomy. We find that some highly natural CQMs are in sharp contrast with human evaluations while others correlate well. Through a comparison of clustering experts and novices, as well as a consistency analysis, we support the hypothesis that clustering evaluation skill is present in the general population.

**Keywords:** clustering; validity indices; psychophysics; visual perception; machine learning

## Introduction

Clustering is a fundamental data analysis tool that aims to group similar objects. It has been applied to a wide range of disciplines such as astronomy, bioinformatics, psychology, and marketing. Successful clustering often requires using a number of different clustering techniques and then comparing their output. The evaluation of clusterings is an integral part of the clustering process, needed not only to compare partitions to each other, but also to determine whether *any* of them are sufficiently good.<sup>1</sup>

As there is no universal clustering objective, there is no consensus on a formal definition of clustering. As a result, there are a wide variety of Clustering Quality Measures (CQMs), also known as internal validity indices, that aim to evaluate the quality of clusterings. To compare clusterings, researchers often select a CQM, which assigns a numerical value to a partition representing its quality.

Researchers rarely rely on CQMs alone. There is a deep implicit assumption running through the clustering literature that human judgment of clustering quality is quite good. Authors visually present the resultant partitions and invite readers to see for themselves that the new method performs well. To take one example, in their influential paper on spectral clustering Ng, Jordan and Weiss write, “The results are surprisingly good... the algorithm reliably finds clusterings consistent with what a human would have chosen.” (Ng, Jor-

dan, & Weiss, 2002) Up until now, clustering quality measures and human judgment were considered complementary approaches to clustering evaluation. Most papers that present novel clustering algorithms include these two types of evaluations separately.

Our study compares formal CQMs with human evaluations to determine how often they agree, and whether certain CQMs correlate better with human judgments than others. We also evaluate the consistency of human responses—if humans are very inconsistent, then it is unlikely that they are good judges of cluster quality (an ideal measure is stable on the same partition). Further, we separate our human subjects into expert and non-expert groups to determine whether clustering evaluation requires experience, and identify divergent strategies between the groups.

To sharpen our focus on a small set of CQMs, we construct a property-based taxonomy of CQMs that distinguishes them on grounds beyond their particular mathematical formulations. The CQMs selected for the study are diverse in that they each satisfy a distinct set of these properties.

Previous studies have investigated how humans choose the number of groups (Lewis, 2009) and partition data (Santos & Sá, 2005) in a clustering setting, but these approaches only show what humans think are the optimal partitions rather than how they judge partition quality in general. Our study uses a set of non-optimal partitions that humans partially order by quality, giving us more detailed quality judgments than in past work. Intuitively, in (Lewis, 2009) and (Santos & Sá, 2005) subjects took on the role of a *k*-choosing algorithm and a clustering algorithm (respectively), whereas in this study subjects are in the role of clustering evaluators.

Our main findings are as follows. Many CQMs with natural mathematical formalizations disagree with human evaluations. On the other hand, we identify CQMs whose evaluations are well correlated with those of humans. In particular, we find that Silhouette (Rousseeuw, 1987) and Calinski-Harabasz (Caliński & Harabasz, 1974) are highly correlated with human evaluations. Our findings also indicate that there is sufficient similarity between the evaluations of novices and experts to suggest that clustering evaluation is a task that does not require specific training (though it may benefit from training). This opens the door for using human computation resources such as Amazon’s Mechanical Turk to quickly solicit a large number of clustering quality judgments from novices as part of the data analysis process. Nevertheless, experts show much less sensitivity to the number of clusters and relate more closely to a greater range of clustering quality measures than novices, indicating a nuanced approach to the eval-

<sup>1</sup>If no good clusterings have been found the underlying dataset may have no good clustering (the data is not “clusterable”, see (Ackerman & Ben-David, 2009) for more on clusterability).

uation problem. Regarding consistency, we find that even novices are more consistent in their evaluations than our set of CQMs.

## Clustering quality measures

In this section we introduce the formal machinery describing the CQMs selected for our study.

Let  $X$  be a finite domain set. A *distance function* is a symmetric function  $d : X \times X \rightarrow \mathbb{R}^+$ , such that  $d(x, x) = 0$  for all  $x \in X$ . A  $k$ -*clustering*  $C = \{C_1, C_2, \dots, C_k\}$  of dataset  $X$  is a partition of  $X$  into  $k$  disjoint subsets (so,  $\cup_i C_i = X$ ). A *clustering* of  $X$  is a  $k$ -clustering of  $X$  for some  $1 \leq k \leq |X|$ . Let  $|C|$  denote the number of clusters in clustering  $C$ . For  $x, y \in X$  and clustering  $C$  of  $X$ , we write  $x \sim_C y$  if  $x$  and  $y$  belong to the same cluster in  $C$  and  $x \not\sim_C y$ , otherwise. Finally, a CQM is a function that maps clusterings to real numbers.

**Gamma:** This measure was proposed as a CQM by (Baker & Hubert, 1975) and it is the best performing measure in (Milligan, 1981). Let  $d^+$  denote the number of times that a pair of points that was clustered together has distance smaller than two points that belong to different cluster, whereas  $d^-$  denotes the opposite result.

Formally, let  $d^+(C) = |\{\{x, y, x', y'\} \mid x \sim_C y, x' \not\sim_C y', d(x, y) \leq d(x', y')\}|$ , and  $d^-(C) = |\{\{x, y, x', y'\} \mid x \sim_C y, x' \not\sim_C y', d(x, y) \geq d(x', y')\}|$ . The *Gamma* measure of  $C$  is  $\frac{d^+(C) - d^-(C)}{d^+(C) + d^-(C)}$ .

**Silhouette:** The Silhouette measure was defined by (Rousseeuw, 1987). Silhouette is the default clustering quality measure in MATLAB.

Let  $\text{dist}(x, C_i) = \text{avg}_{y \in C_i} d(x, y)$ . The *silhouette* of a point  $x$  with respect to clustering  $C$  is  $S(x, C) = \frac{\min_{j \neq i} \text{dist}(x, C_j) - \text{dist}(x, C_i)}{\max(\min_{j \neq i} \text{dist}(x, C_j), \text{dist}(x, C_i))}$  where  $x \in C_i$ . The *silhouette* of a clustering  $C$  is  $\text{sum}_{x \in X} S(x, C)$ .

**Dunn's Index:** Dunn's Index (Dunn, 1974) compares the maximum within-cluster distance to the minimum between-cluster distances. *Dunn's Index* of  $C$  is  $\frac{\min_{x \not\sim_C y} d(x, y)}{\max_{x \sim_C y} d(x, y)}$ .

**Average Between and Average Within:** The Average Between and Average Within measures evaluate the between-cluster separation and within-cluster homogeneity, respectively. The *average between* of  $C$  is  $\text{avg}_{x \not\sim_C y} d(x, y)$ . The *average within* of  $C$  is  $\text{avg}_{x \sim_C y} d(x, y)$ .

**Calinski-Harabasz:** The Calinski-Harabasz measure (Caliński & Harabasz, 1974) makes use of cluster centers. Let  $c_i = \frac{1}{|C_i|} \sum_{x \in C_i} x$  denote the center-of-mass of cluster  $C_i$ , and  $\bar{x}$  the center-of-mass of  $X$ . Let  $B(C) = \sum_{C_i} |C_i| |c_i - \bar{x}|^2$  and  $W(C) = \sum_{C_i} \sum_{x \in C_i} |x - c_i|^2$ . The *Calinski-Harabasz* of  $C$  is  $\frac{n-k}{k-1} \cdot \frac{B(C)}{W(C)}$ .

**Weighted inter-intra:** The weighted inter-intra measure is proposed by (Strehl, 2002). It compares the homogeneity of the data to its separation. Let  $\text{intra}(C_i) = \text{avg}_{x, y \in C_i} d(x, y)$  and  $\text{inter}(C_i, C_j) = \text{avg}_{x \in C_i, y \in C_j} d(x, y)$ . The *Weighted inter-intra* of a clustering  $C$  is  $(1 - \frac{2k}{n}) \cdot (1 - \frac{\sum_i \frac{1}{n-|C_i|} \sum_{j \neq i} \text{inter}(C_i, C_j)}{\sum_i \frac{1}{|C_i|-1} \text{intra}(C_i)})$ ,

where  $n$  is the number of points in the dataset.

## Methods

We ran two groups of human subjects and a group of clustering quality measures on a partition evaluation task. Our human subjects were divided into a novice group with little or no knowledge of clustering methods and an expert group with detailed knowledge of clustering methods.

Figure 1: All stimuli. Datasets are in rows; partitions are in columns.

## Human subjects and stimuli

Twelve human subjects were recruited for this project as the novice group, 9 female and 3 male, with an average age of 20.3 years. The novice subjects have no previous exposure to clustering. The expert group consists of 5 people and includes the authors of this paper. All experts have studied clustering in an academic setting, and 4 have done research on the subject.

We used 19 different two dimensional datasets to generate our clustering stimuli, drawn from (Lewis, 2009), and chosen to represent a range of dataset types including mixtures of Gaussians and datasets with hierarchical structure. In order to maintain responsiveness of the stimulus presentation interface, we subsampled 500 points randomly from each dataset. We use synthetic datasets in order to better generate a wide range of stimuli, and our datasets are 2D to facilitate visualization.

Each dataset is randomly clustered nine times in the following manner. For each of the nine clusterings, we first draw the number of partitions,  $k$ , from a uniform distribution over the integers 2 to 6. Second we choose cluster centroids using two strategies: for four of the clusterings we randomly select  $k$  centroids from the original dataset, and for five of the clusterings we select  $k$  centroids from a Laplacian Eigenmap embedding of the data. Finally we color points based on the identity of their nearest centroid in the appropriate space. The goal of this approach is to create stimuli with varied clustering quality.

Each trial consisted of all nine different partitions of the same dataset randomly arranged per trial in a 3 by 3 grid (see Figure 1 for a visualization of all the stimuli). The datasets were shown as scatter plots with colored points on a black background to reduce brightness-related eye strain. For novice subjects, trials were organized into three blocks of 19, where each dataset appeared once per block and the order of the datasets within each block was randomized. Expert subjects were tested on one block of non-randomized datasets. We instructed subjects to choose the two best partitioned displays and the one worst partitioned display from the nine available on every trial (leaving six displays implicitly chosen as neutral).

## Analysis

We analyzed our novice subjects for internal consistency of their positive and negative classifications across blocks and found that even our least consistent subject performed well above chance. We did not exclude any subjects due to inconsistency and we did not analyze internal consistency for experts as they were only tested on one block.

To analyze consistency across subjects we use Fleiss'  $\kappa$  (Fleiss, 1971) and include neutral responses. Fleiss'  $\kappa$  measures the deviation between observed agreement and the agreement attributable to chance given the relative frequency of classifications and normalized for the number of raters. Neutral classifications are twice as frequent as non-neutral, and positive classifications are twice as frequent as negative classifications, so the compensation for relative frequency in Fleiss'  $\kappa$  makes it well-suited to our data. In addition, we perform a consistency analysis on the clustering quality measures by discretizing their classifications in a manner similar to the human data.

We analyze the relationship between novice classifications, expert classifications and clustering quality measures by calculating the Pearson's correlation coefficient,  $\rho$ , between

classifications. To make the responses as comparable as possible we normalize response vectors to a length of one within each dataset. Human subjects have to classify two positive and one negative partition per dataset, even if every partition is quite bad, so by normalizing within dataset we make the CQM responses similar in structure—partitions are judged only relative to other partitions within a dataset.

Because cluster centroids are chosen randomly, increasing  $k$  is likely to increase the chance of getting an undesirable partition (e.g. a partition with very few data points). Additionally, partitions with higher  $k$  require more effort to interpret, and therefore we might expect novice subjects to be biased towards a lower  $k$ . For these reasons our correlations control for  $k$  by partialing out a vector of  $k$  values for each partition. Geometrically this is equivalent to projecting each response vector onto the hyperplane orthogonal to the vector of  $k$  values.

## Results

### Correlation

Table 1 shows correlation coefficients between all measures for both expert and novice responses, with  $k$  factored out. The correlation between expert and novice human positive classifications is higher than the correlation between any CQM and either human positive classification. The negative human classifications have a similarly high correlation. The absolute values of the correlation coefficients between CQMs and expert classifications are strictly greater than or equal to those between CQMs and novice classifications, indicating a closer relationship between expert strategies and the dataset characteristics summarized by the CQMs when  $k$  is factored out.  $k$  itself correlates very strongly with the novices and less so with the experts. Silhouette provides the best overall correlation with expert classifications, and Avg Within provides the best overall correlation with novice classifications (save  $k$ ).

### Consistency

The most undesirable form of inconsistency across subjects or CQMs is both positive and negative responses to the same stimulus. For experts, stimuli with a number of positive classifications 3 or higher never receive a negative classification, and only once does this occur for stimuli with 2 positive responses. In contrast the CQMs exhibit much more disagreement and novices seem to fall somewhere in between. The quantitative measure  $\kappa$  bears this out: CQMs score 0.128, novices score 0.183 and experts score 0.213.  $\kappa$  ranges from  $-1$  to  $1$ , with  $-1$  representing complete disagreement,  $1$  representing complete agreement and  $0$  representing the amount of agreement expected by chance. While there is no standard significance test for differences in  $\kappa$ , the rating scale suggested by Landis and Koch (Landis & Koch, 1977) would characterize the CQM and novice rater groups each as in slight agreement, and the expert raters as in fair agreement. To test whether any one measure was significantly harming CQM consistency we left each out in turn from the analysis

Table 1: Correlation coefficients between human responses and CQMs with  $k$  factored out (except for the  $k$  column). Text in bold (excluding  $k$  column) if  $p < .0025$  after Bonferroni correction for  $n = 20$  comparisons per subject group and  $\alpha = .05$ .

$\rho$	Expert Positive	Expert Negative	Novice Positive	Novice Negative	Gamma	Silhouette	Dunn	Avg Within	Avg Btw	CH	W-Inter/Intra	$k$
Expert Pos	1	<b>-.35</b>	<b>.56</b>	-.19	-.15	<b>.46</b>	<b>.40</b>	<b>-.39</b>	<b>.34</b>	<b>.44</b>	.19	-.43
Expert Neg		1	-.13	<b>.44</b>	.09	<b>-.27</b>	-.12	<b>.44</b>	-.18	<b>-.36</b>	<b>-.30</b>	.32
Novice Pos			1	-.04	-.13	<b>.39</b>	<b>.40</b>	-.20	.23	<b>.30</b>	.04	-.73
Novice Neg				1	.08	<b>-.27</b>	.01	<b>.30</b>	-.07	<b>-.25</b>	<b>-.27</b>	.71

Table 2: A summary of the number of partitions for which a high degree of agreement was achieved by the raters. If a partition is classified as negative or positive by 80% - 100% of raters, it would be added to the top row, and similarly for the 60% - 79% bucket. The total possible number of agreed upon partitions is 57 (19 datasets \* 3 possible negative/positive responses to partitions per dataset).

% Majority	Experts	Novices	CQMs
80% - 100%	19	3	1
60% - 79%	20	11	7
Sum $\geq 60\%$	39	14	8

and found values ranging from 0.098 to 0.172, which is in line with the CQM consistency with no measure left out, and in every case less consistent than the novice subjects. Finally, we left out both Avg Within and Between, since they measure quality on intentionally simple and distinct dimensions, and found a  $\kappa$  of 0.110.

In Table 2 we summarize the consistency of experts, novices and cluster quality measures. It shows how often certain percentages of raters are able to agree on negative or positive classifications for particular stimuli. Experts agree over 60% of the time on more samples (39), than do novices (14) or CQMs (8).

## Discussion

### Comparing human evaluations with CQMs

Some natural quality measures have low correlation with human evaluations. Most notably, Gamma has low correlation with both positive and negative human classifications for both novices and experts. W-Inter/Intra has low correlation with the positive classifications of both subject groups. This shows that a natural mathematical formalization does not suffice to guarantee that the evaluations of clusterings produced using the CQM will seem natural to humans.

There are also CQMs that correlate well with human evaluations. Of these the most notable are CH and Silhouette. These two popular measures correlate well with both expert

and novice evaluations, on both the positive and negative classifications.

### Comparing experts with novices

Evaluations of experts and novices have a correlation score of 0.56, higher than the correlation of any CQM with any of the two subject groups. This suggests that a cluster evaluation skill is present in the general population.

On the other hand, we observe some interesting differences between the two groups of subjects. One of the most notable differences between experts and novices is that, while both groups prefer clusterings with fewer clusters, novices rely much more heavily on this heuristic.

Experts seem to use more, and more complex strategies than novices. Positive expert classifications correlate well with two more measures than positive novice classifications. No measure considered correlates better with novice classifications than with expert classifications, and in the great majority of cases the correlation is higher with expert classifications.

With a cover of at most six domain elements on any input dataset (see Definition 5 below), Dunn’s measure is (according to this measure of complexity) the simplest measure that we explore. While positive expert evaluations correlate well with five distinct measures, Dunn’s measure is one of three measures that correlate well with novice evaluations. This further illustrates that novices rely on fewer simpler strategies, which indicates that expert evaluations may be more sophisticated and reliable.

### Consistency

Given the difficulty of knowing whether humans or CQMs do a reasonable job of evaluating clustering quality, one might hope that at least they are consistent across individuals (or measures). Consistency indicates that some repeatable process is at work and that its repeatability is minimally affected by changes in input. Of course CQMs are perfectly consistent on a within measure basis—given the same partition they will always report the same quality—and one is tempted to suggest that between measure consistency is an unfair point of comparison; aren’t all the measures using quite different evalu-

ative procedures, and didn't we select them to be distinct? We did, but CQMs purport to evaluate clustering quality in general. Insofar as they evaluate this more nebulous property they should be consistent, even if their methods differ. As it turns out, they are somewhat consistent with each other, just not as consistent as humans. Further, the consistency story did not vary when we tested all the leave-one-out subsets of CQMs, indicating that CQM consistency is not being skewed by just one divergent measure.

Human experts are the most consistent group in this study. This lends empirical support to the common practice of seeking human visual evaluations of partition quality. Novices are less consistent, and as discussed above there is evidence that the evaluations they provide are less sophisticated. Despite the unfavorable comparison to experts, it is notable that subjects with no formal knowledge of cluster analysis are able to respond more consistently than a set of CQMs. This lends credence to the notion that our ability to evaluate partitions is acquired in the natural course of visual development.

### A Property-Based Taxonomy of CQMs

In the absence of formal guidelines for CQM selection<sup>2</sup>, in particular for selecting a versatile set of CQMs, we develop a property-based framework for distinguishing CQMs based on such a framework for clustering algorithms discussed in (Ackerman, Ben-David, & Loker, 2010b) (also see (Bosagh-Zadeh & Ben-David, 2009) and (Ackerman, Ben-David, & Loker, 2010a)). The framework consists of identifying natural properties of CQMs and classifying measures based on the properties that they satisfy. For the purposes of our study we use this framework to select meaningfully versatile CQMs. This taxonomy may have independent interest for choosing CQMs in other settings. Note that these properties are descriptive only, and not necessarily desirable.

Our taxonomy of CQMs follows a line of work on theoretical foundations of clustering beginning with the famous impossibility result by (Kleinberg, 2003), which showed that no clustering function can simultaneously satisfy three specific properties. (Ackerman & Ben-David, 2008) reformulate these properties in the setting of CQMs, and show that these properties are consistent and satisfied by many CQMs. We follow up on (Ackerman & Ben-David, 2008) by studying natural properties that can be used to distinguish between CQMs.

In Table 3, we present a taxonomy of our seven clustering quality measures. Each property, defined below, aims to capture some fundamental feature that is satisfied by some measures.

#### Normed clustering quality measures

A clustering quality measure  $m$  takes a domain set  $X$ , a distance function  $d$  over  $X$ , and a clustering  $C$  of  $X$ , and outputs a non-negative real number. Some quality measures are defined

<sup>2</sup>Although there are no formal guidelines for CQM selection, some interesting heuristics have been proposed, see, for example, (Vendramin, Campello, & Hruschka, 2009).

Table 3: A taxonomy of the seven quality measures used in the study.

	Gamma	Silhouette	Dunn	Avg Within	Avg Btw	CH	W-Inter/Intra
Order-consist.	✓	X	X	X	X	X	X
Sep-invariant	X	X	X	✓	X	X	X
Hom-invariant	X	X	X	X	✓	X	X
Bounded	✓	✓	X	X	X	X	X
Constant Cover	X	X	✓	X	X	X	X
Norm-based	X	X	X	X	X	✓	X

over normed vector spaces. *Normed CQMs* take a quadruple of the form  $(V, X, C, \|\cdot\|)$ , where  $V$  is a vector space,  $X$  a finite subset of  $V$ , and  $\|\cdot\|$  is a norm over  $V$ . Normed CQMs can rely on centers-of-mass of clusters that are not necessarily in  $X$ , but are part of the vector-space  $V$ . Observe that the centers-of-mass are not defined for un-normed CQMs. We define the properties for CQMs in general, but one can apply any property to a normed CQM by using the norm to define the distance function. That is, set  $d(x, y) = \|x - y\|$  for all  $x, y \in X$ .

#### Invariance and consistency properties

Invariance properties describe changes to the underlying data that do not affect the quality of a clustering. Consistency properties describe similarity conditions under which clusterings have similar quality. We propose two new invariance properties.

**Definition 1** (Separation Invariance). A CQM  $m$  is separation-invariant if for all  $X$  and distance functions  $d$  and  $d'$  over  $X$  where  $d(x, y) = d'(x, y)$  for all  $x \sim_C y$ ,  $m(C, X, d) = m(C, X, d')$ .

A separation invariant CQM is not affected by changes to between-cluster distances. Conversely, homogeneity invariant CQMs depend only on between-cluster distances, and are invariant to changes to within-cluster distances.

**Definition 2** (Homogeneity Invariance). A CQM  $m$  is homogeneity-invariant if for all  $X$  and distance functions  $d$  and  $d'$  over  $X$  where  $d(x, y) = d'(x, y)$  for all  $x \not\sim_C y$ ,  $m(C, X, d) = m(C, X, d')$ .

Observe that separation-invariance and homogeneity-invariance can also be viewed as consistency properties. An additional consistency property, order consistency, is an adaptation of an analogous property of clustering functions presented in (Jardine & Sibson, 1971). Order consistency describes CQMs that depend only on the order of pairwise distances.

**Definition 3.** A CQM  $m$  is order consistent if for all  $d$  and  $d'$  over  $X$  such that for all  $p, q, r, s \in X$ ,  $d(p, q) < d(r, s)$  if and only if  $d'(p, q) < d'(r, s)$ ,  $m(C, X, d) = m(C, X, d')$ .

## Domain and range properties

A bounded range can aid in interpreting the results of a CQM, in particular if the bounds are attainable by some clusterings.

**Definition 4** (Bounded). A CQM  $m$  is bounded if there exist datasets  $X_1$  over  $d_1$  and  $X_2$  over  $d_2$ , and clusterings  $C_1$  of  $X_1$  and  $C_2$  of  $X_2$ , so that  $m(C_1, X_1, d_1) \leq m(C, X, d) \leq m(C_2, X_2, d_2)$  for all  $C, X$ , and  $d$ .

Our next property describes the quantity of domain elements that effect the CQM. First, we introduce the notion of an  $m$ -cover of a clustering, a subset of the domain which has the same quality as the entire set. For clustering  $C$  of  $X$ , and  $X' \subseteq X$ , let  $C|X'$  denote the clustering  $C'$  of  $X'$  where for all  $x, y \in X'$ ,  $x \sim_{C'} y$  if and only if  $x \sim_C y$ .

An  $m$ -cover of clustering  $C$  of  $X$  is any set  $R \subseteq X$ , so that  $m(X, k) = m(R, C|R)$ . We define clustering quality measures that have a constant size cover for all clusterings.

**Definition 5** (Bounded Cover). A CQM  $m$  has bounded cover if there exists a constant  $r$  so that for every data set  $X$  and clustering  $C$  of  $X$ , there exists an  $m$ -cover of  $C$  of cardinality at most  $r$ .

CQMs that have a bounded cover search the domain space for some local features, ignoring most of the information in the dataset.

## Conclusions

We perform an empirical study comparing human evaluations of clustering with formal clustering quality measures. To select a versatile set of CQMs, we develop a theoretical property-based taxonomy of CQMs. Our study shows that some CQMs with seemingly natural mathematical formulations yield evaluations that disagree with human perception. On the other hand, we identify CQMs (CH and Silhouette) that have significant correlation with human evaluations.

Our consistency analysis reveals that even novices are at least as consistent as a broad set of CQMs, and perhaps more consistent. We also find significant correlations between the evaluations of expert and novice subjects. This lends support to the common practice of seeking human visual evaluations of partition quality. If one needs to evaluate a very large number of partitions it may be reasonable to use human computation via a service such as Mechanical Turk to rank partitions efficiently (or at least throw out the really bad ones). Finally, experts appear to use more sophisticated strategies than novices, indicating that training can improve human clustering evaluation performance.

## Abstract

The field of machine learning is constantly developing useful new techniques for data analysis, but they are often ignored by researchers outside the field due to unfamiliarity and the difficulty of keeping up with a large body of work. We propose a methodology for training researchers how algorithms work through experience, such that they gain an implicit, rather than explicit, understanding of their function. Thus we combine theory from discovery learning with advanced software and a more educated target population to foster such understanding. We have developed an open source application for exploratory data analysis called Divvy that lets users quickly and visually interact with a range of data analysis techniques. Using a simplified version of Divvy, we find that undergraduate subjects are generally able to learn machine learning concepts through experience, though they have only partial success in applying them.

**Keywords:** unsupervised machine learning; clustering; discovery learning; human computer interfaces

Machine learning has a PR problem. The field has developed many techniques that cluster, classify, or reduce the dimensionality of data, and most techniques could be profitably applied to scientific data sets. Researchers that are not machine learning experts face a daunting question, however—which techniques should I use to analyze my data? Authors proposing a new technique will focus on its strengths over its weaknesses, and most researchers do not want to spend a year reading math papers and becoming a machine learning expert in order to best analyze their data. So too often the analysis technique used is the convenient one (freely available online or as part of a software package), or the traditional one. Researchers miss out on the advances in machine learning, and the machine learning field is not as valuable as it could be to the broader scientific community.

There are two fundamental problems: expertise and access. Gaining expertise is difficult—if a researcher wants to find the right technique for the job, but is unwilling to engage in the time-consuming process of learning the details of every technique, how can they be trained to apply the best one? With the right tools, we believe discovery learning has substantial potential for training researchers. Software that provides direct and intuitive access to the behavior of machine learning algorithms can support the development of a pragmatic (not mathematical) understanding of the algorithms.

As an analogy, baseball players have an excellent idea of how baseballs behave. A baseball's behavior is, of course, governed by the laws of physics and an explicit description of that behavior might be quite complex when spin, deformation, wind and field texture are taken into account. Nevertheless, through extensive experience baseball players acquire an excellent pragmatic understanding of how baseballs

behave, an understanding that one might guess is founded on an implicit learned model of baseball behavior rather than the explicit model a physicist would give. We believe that interactive experience with machine learning techniques can give rise to a similar sort of practical and implicit model of algorithm behavior, and that researchers can use such a model to make informed decisions during data analysis.

Discovery learning is particularly compelling in this context because researchers often do not have the time or inclination to seek out traditional forms of instruction while analyzing data. Tools that support learning on the job are thus necessary and expedient. In this paper we test our hypothesis using a data analysis platform called Divvy that we've developed to provide such an experience that emphasizes speed and visualization.

Gaining access to a wide variety of data analysis techniques is also tricky—it might require technical knowledge (e.g. basic programming skills in whichever languages the techniques are in), or owning proprietary software like Matlab and formatting one's data for it. To that end Divvy is a free, open source project designed around a plugin architecture where machine learning researchers can package their algorithms with intuitive custom UIs that require no programming expertise from users.

In our experiment we give undergraduate subjects interactive experience with two clustering techniques,  $k$ -means (MacQueen, 1967) and single linkage (Johnson, 1967), labeled simply as method A and method B and without any explicit instruction as to their differences. We find that after training almost every subject learns a few relevant facts about A or B or their parameters, and that some subjects appear to be able to apply this knowledge to new analysis contexts.

## Divvy

Data analysis is often a laborious process. A researcher collects data, and then loads it into a software package such as Matlab or R. To apply an algorithm to his or her data, the researcher has to write a command or fill out a dialog box and then wait for processing to finish. Finally, the researcher will use other commands to visualize the algorithm's output. To change a parameter and see the impact it has, this process must be repeated. Some researchers might write a script that runs a set of different parameters and visualizations, and then go out for a coffee and come back to see if the whole endeavor bore any fruit.

This is a tenuous kind of interaction. A baseball, by virtue of being in the real world, provides critical instantaneous

Figure 1: The full Divvy UI. Each visualization represents a different view of the same dataset (generated by combining a dimensionality reduction technique, a clustering technique and a dataset visualizer) and users can set the properties of each view using the tools to the right. A list of datasets resides in the bottom right, allowing the user to switch between them at any time, even while results are computing in the background.

feedback to those interacting with it. In the above process the algorithm does not, and the goal of the Divvy project is to close that gap and provide an interface where visualization happens instantaneously and researchers can tweak parameters and see their effect in real time. In a way, Divvy is providing the human analog to active learning (Cohn, Ghahramani, & Jordan, 1996), where learning algorithms choose which training samples to get based on what they predict to be the most informative. Divvy is similar in spirit to a tool called GGobi (*Ggobi data visualization system*, n.d.), which brings cutting edge methods in high-dimensional data visualization to a user friendly graphical interface but without the strong machine learning component Divvy provides.

Divvy supports four types of plugin: clusterers, reducers, point visualizers and dataset visualizers. Clusterers and reducers represent clustering and dimensionality reduction algorithms, respectively. Point visualizers represent single points in the dataset with visualizations, such as the image of a handwritten digit, and dataset visualizers represent the entire dataset, for example with a scatter plot. Each view of the dataset (of which a user can have a practically unlimited number) represents a combination of these four plugin types, so a user can compare, e.g.,  $k$ -means in the first two PCA dimensions with spectral clustering in the same embedding.

Divvy achieves real time responsiveness on many datasets

through parallel computing. Many personal computers (and all Macs) ship with multi-core processors (CPUs), as well as graphics processors (GPUs) that can be used for general purpose computation. High performance computing research has so far focused on how these hardware resources can make very large problems tractable (Raina, Madhavan, & Ng, 2009). With Divvy, we are using these technologies to make medium problems very fast—fast enough to feel real time, and to invite the exploratory interaction that we believe leads to learning. Even if an algorithm takes a while to run, users can continue to use Divvy to perform other analyses on the same dataset or even on others while they wait. Our UI design puts a focus on visualization, allowing users to simultaneously visualize many perspectives on their data. Algorithm parameters are controlled with standard UI elements (such as sliders or check boxes) rather than having to be specified with code. See Figure 1 for the full Divvy UI and Figure 2 for the simplified version of the UI we used in this experiment.

Divvy does not attempt to replace a user’s data analysis workflow, but rather to be a part of it. It can export data and visualizations in standard formats and import from other popular tools. Divvy, its source code, sample datasets, and R/Matlab data importers are freely available from <http://divvy.ucsd.edu> and on the Mac App Store.

## Discovery Learning

Our study represents a form of discovery learning (Bruner, 1961), also known as constructivist, inquiry or experiential learning. In discovery learning students learn material independently of explicit instruction by exploring environments, solving problems, or performing experiments. Several researchers have called into question the effectiveness of pure discovery learning, suggesting that active guidance from an instructor (Mayer, 2004), or a sufficient foundation of domain knowledge (Kirschner, Sweller, & Clark, 2006) are required for constructivist approaches to be successful.

Our target audience for Divvy differs from the traditional subjects used in studies of discovery learning. We intend for Divvy to be used by researchers such as faculty and graduate students who have a highly sophisticated understanding of their problem domain. Further, they are accustomed to self-directed learning. In this sense, though they do not have a detailed understanding of machine learning, they do have a foundation of domain knowledge with which they can determine whether the output of a machine learning algorithm is appropriate or not. In addition, Divvy provides some forms of active guidance. Divvy plugin UIs default to reasonable ranges for parameter settings and every plugin can specify a help link that takes users to a relevant resource on the web, such as a paper describing the method or a relevant Wikipedia article.

For these reasons we believe Divvy to be more likely to succeed than other examples of discovery learning that focus on elementary-, middle-, and high-school populations with less active guidance. In this study we use an undergraduate population that is generally less knowledgeable than our target population, representing a more challenging domain than that which Divvy will have in the wild. If undergraduates are able to learn machine learning concepts with Divvy then graduate students, postdocs, and faculty likely can as well.

As outlined above, we believe that guided learning is not necessarily practical or expedient for our target population. So while explicit instruction would certainly allow subjects to learn machine learning concepts, we do not compare Divvy to that form of learning in this paper. Here we focus on what, if anything, subjects are able to learn from a version of our more pragmatic approach to solving machine learning's PR problem.

## Methods

We recruited 22 undergraduate subjects for this experiment. Subjects received course credit for participation. One subject was excluded from the study after he indicated at the end during the interview segment that he must not have understood the instructions, and so we analyzed the data from a grand total of 21 subjects.

Each subject performed 36 trials, which were split into two 18 trial blocks, a training block and a testing block. In both blocks, subjects use the sliders to change the number of clusters,  $k$ , and the relative weighting of the horizontal and vertical

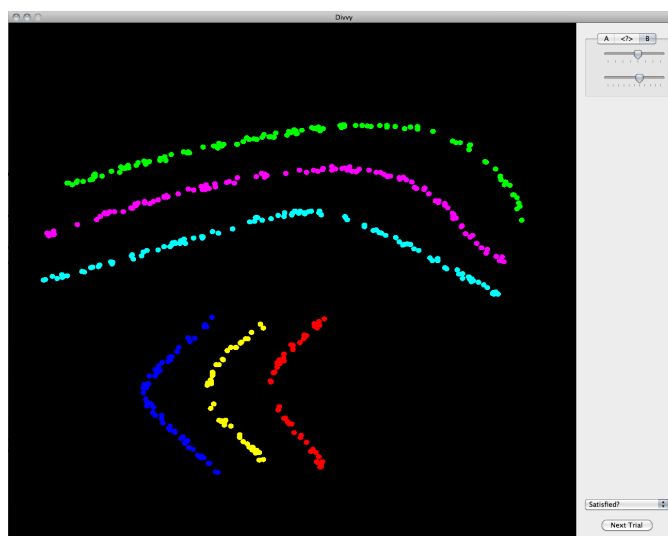

Figure 2: The Divvy UI used in this experiment. The tabs at the top right select method A ( $k$ -means) or B (single linkage), and the sliders below control the number of clusters and the relative weighting of the horizontal and vertical axes. Subjects indicate their satisfaction with a particular partitioning using the dropdown menu above the next trial button at the bottom right.

cal axes in order to best group the points in each stimulus (one stimulus per trial) and then indicate their satisfaction with the result (ranging from 1, not satisfied, to 7, very satisfied). In the training block, subjects use both A and B ( $k$ -means and single linkage, respectively) to group the points, and are required to arrive at a solution for each method. In the testing block, neither A nor B are initially selected and subjects must choose which method they want to use for that trial. Once the choice is made they cannot switch. We divided subjects into two groups of 10 and 11. One group's training set was the other's testing set, and vice versa. At the end of the two blocks, subjects filled out an interview form that assessed their knowledge. The eight interview questions were as follows (where circles means the individual data points):

1. What did you feel like method A was doing?
2. What organizations of circles was method A good for grouping?
3. What did you feel like method B was doing?
4. What organizations of circles was method B good for grouping?
5. Did you have a preference between A and B?
6. Why or why not?
7. What did the first (top) slider do?
8. What did the second (bottom) slider do?

We instructed subjects to do their best to learn what A, B and the sliders were doing in the first half of the experiment, as they would need to use that knowledge during the second half. We also made clear that not every stimulus could be ideally grouped with both A and B, and that if they did not like a solution they could just indicate dissatisfaction using the dropdown above the next trial button. We provided two helper images along with the instructions. One showed a well-separated mixture of Gaussians where each Gaussian had its own color. This was held up as a positive example. The second showed two circular groups split in half with color, which was considered a negative example. Beyond these very simple prompts (shown in Figure 3) we did not bias the subjects as to what a group should be.

Figure 3: Sample images to give subjects basic guidance on good groups (top) versus bad groups (bottom).

The 36 stimuli fall into three categories, those where A is most effective (14), those where B is most effective (15), and

those where A and B are similarly effective (7). We created all 36 stimuli by hand in order to ensure that the first two categories had sufficient membership. Stimuli ranged from complex collections of lines, rings and spirals to connected and disconnected blobs to uniform noise. While these are not real data, so to speak, they provide us with a solid foundation on which to train and judge our subjects that real data would not necessarily provide. Additionally, most meaningful real data are more than two dimensional, and while the full version of Divvy uses dimensionality reduction techniques and multiple views to visualize such data, those techniques are not relevant to our core question in this experiment concerning cluster analysis.

Divvy records every method and parameter combination subjects try over the course of the experiment, including their final grouping and satisfaction. We use these data in concert with interview responses to determine what subjects were able to learn from their experience. From the Divvy records we extract two variables per subject, the total number of different algorithm and parameter settings queried in the training period (the number of “moves”), and the percent of correct method (A or B) choices (with any parameter choice) in the testing period, out of the stimuli for which there is a preferred method. From the interviews we code for understanding of seven possible concepts. The seven possible concepts are as follows:

1. The first slider controls the number of colors (i.e. clusters).
2. The second slider controls the orientation of the boundary between clusters.
3. *k*-means works well on blobs of points (compact regions).
4. Single linkage works well on extended shapes like lines or rings (non-compact regions).
5. *k*-means can work when there is no space separating clusters.
6. Single linkage works best when there is lots of space between clusters.
7. *k*-means tends to divide the points into evenly sized groups, whereas single linkage can make large and small groups.

We hypothesize that there will be a positive correlation between understanding a greater number of concepts and selecting the correct method. We also report correlations between these measures and the number of moves subjects take. To gain an understanding of the relative difficulty of learning the concepts we report in detail the concepts learned on a per-subject basis. Finally, we compare subject satisfaction when using the correct method on a stimulus versus the incorrect method. This test indicates whether subjects recognize when the partitions are not ideal. If the subjects cannot distinguish good partitions from bad given their intuition and the instructive samples, then there is not an opportunity for learning.

## Results

In Table 1 we summarize the contents of each subject's interview, using the seven concepts described above. Nineteen of 21 of the subjects learned at least one concept, and 15 of the subjects learned at least one concept excluding the simplest one (the function of the first slider). On average subjects learned 2.4 concepts over the course of the study.

Table 1: A summary of the concepts subjects learned. Subjects in bold chose the correct method for over 70% of stimuli in the test block.

Subjects	1st Slider	2nd Slider	k-means Blobs	Single Linkage Shapes	k-means No Separation	Single Linkage Separation	k Even vs SL Uneven	Sum
1								0
2								0
3	✓				✓	✓	✓	4
4	✓	✓		✓				3
5	✓				✓			2
<b>6</b>	✓	✓		✓				<b>3</b>
<b>7</b>	✓		✓	✓				<b>3</b>
<b>8</b>	✓			✓			✓	<b>3</b>
9	✓							1
10	✓						✓	2
11							✓	1
12	✓		✓	✓				3
<b>13</b>	✓		✓	✓				<b>3</b>
<b>14</b>	✓							<b>1</b>
15						✓	✓	2
<b>16</b>	✓				✓	✓	✓	<b>4</b>

<b>19</b>	✓		✓	✓			✓	<b>4</b>
20	✓	✓						2
21	✓				✓		✓	3
Sum	17	3	5	9	5	4	7	

The number of concepts learned correlates positively, but only as a trend, with both percent correct ( $p = .29$ ,  $p < .10$ ) and number of moves ( $p = .34$ ,  $p < .07$ ). Percent correct and number of moves are not correlated ( $p = -.22$ ,  $p < .84$ ). In Figure 4 we show scatter plots of the pairwise comparisons between these variables.

For stimuli with a correct answer where the subject used the correct method, we had 470 satisfaction ratings with  $\mu = 5.88$ ,  $\sigma = 1.37$ . For stimuli with a correct answer where the subject used the incorrect method, we had 444 satisfaction ratings with  $\mu = 4.94$ ,  $\sigma = 1.77$ . A t-test indicated a sig-

nificant  $p < .01$  effect of correct versus incorrect method on satisfaction, indicating that subjects were in general able to judge some difference between good and bad partitions.

## Discussion

Almost every subject learned about cluster analysis through their experience—over half learned three concepts or more. Giving researchers expertise and access through tools like Divvy promises to encourage and improve the application of machine learning techniques in other fields.

Nevertheless, some subjects had difficulty using the knowledge they acquired to make good data analysis decisions. Though subjects explored quite a bit during the training phase (an activity that showed a trending correlation with concept learning) they did not necessarily parlay that experience into better performance. So while we are pleased that subjects demonstrated concept learning in the interviews, we would like to investigate why they had trouble applying it. The subjects were overall less satisfied when using the incorrect method, which indicates that evaluative confusion was not the primary culprit.

Given that the core audience for Divvy is composed of graduate students, postdocs, and faculty, we would like to perform a follow-up study with that audience. While undergraduates serve as a useful lower bound, so to speak, for testing learning with Divvy, our target population is likely more motivated, more familiar with data analysis tasks, and in possession of greater domain knowledge.

The process of crystallizing the implicit knowledge gained during the experiment in the interview might help subjects make better decisions. To test this, a future experiment could place the interview between the training and test blocks. If this results in better performance, it would indicate that having to articulate knowledge assists concept crystallization and application, and that the subjects are in a sense still learning when they fill out the interview.

We do not think a comparison to traditional guided learning is useful since our target population will rarely have the time or inclination to seek out explicit instruction. However, we would be interested in comparing our results to other forms of discovery learning where the interaction between subject and software is modified. We believe that self-directed exploration with instantaneous feedback is valuable and we would like to compare our results with, e.g., simply showing subjects a set of partitions and their associated methods and parameter values without allowing them to choose parameters, or putting a delay between parameter changes and result visualization. These modifications would move the experimental context closer to traditional machine learning approaches where the training data are fixed (as opposed to the active learning paradigm mentioned earlier). It would also correspond to writing a script to run through a set of parameter settings and visualizations while one goes out for coffee, and then interpreting when one returns.

Our results provide compelling evidence that undergradu-

Figure 4: Scatter plots of the three main variables. The points are colored from dark blue to dark red based on percent correct.

ate subjects can learn useful concepts about machine learning algorithms just by interacting with them. This leads one to suspect that the target population for this work, practicing researchers, will be able to do so as well. Subjects do not reliably apply these concepts when tested, and additional study is required to determine why this is, and how to better support the discovery and application of machine learning concepts.

### Acknowledgments

## Abstract

We present the results of a 100 participant study on the role of a robot's physical presence in a robot tutoring task. Participants were asked to solve a set of puzzles while being provided occasional gameplay advice by a robot tutor. Each participant was assigned one of five conditions: (1) *no advice*, (2) *robot providing randomized advice*, (3) *voice of the robot providing personalized advice*, (4) *video representation of the robot providing personalized advice*, or (5) *physically-present robot providing personalized advice*. We assess the tutor's effectiveness by the time it takes participants to complete the puzzles. Participants in the *robot providing personalized advice* group solved most puzzles faster on average and improved their same-puzzle solving time significantly more than participants in any other group. Our study is the first to assess the effect of the physical presence of a robot in an automated tutoring interaction. We conclude that physical embodiment can produce measurable learning gains.

**Keywords:** Robotics; Computer Science; Tutoring

## Introduction

What kinds of human-robot interactions benefit from the physical embodiment of a robot? For human-robot interactions that require manipulating the physical world, a physical robot is a necessity, but for those interactions where physical embodiment is optional, when is an embodied robot more useful than an on-screen agent?

In this study, we explore the differences in task performance of participants engaged in a cognitive learning task in which a robot acts as a tutor. Participants were asked to play a puzzle game while receiving strategy advice from either: a physically-present robot, a video of the same robot, its disembodied voice, a robot giving randomized advice, or no agent at all. We use the resulting data to draw conclusions about the effect of embodiment in robot tutoring tasks.

Previous work has investigated the social influence of a robot's embodiment. Does a robot engender more trust, more compliance, more engagement, or more motivation by its physical presence, more so than an on-screen agent or a video representation of a robot would? Such questions have been explored via two methodologies: self-report measures and task-performance measures. Using self-report measures, Kidd and Breazeal (2004) found that a physically-present robot was perceived as more enjoyable, more credible, and more informative than an on-screen character in a block-moving task. In Wainer, Feil-Seifer, Shell, and Mataric (2007), an embodied robot was rated as more attentive and more helpful than both a video representation of the robot

and a simulated on-screen robot-like character. Tapus, Tapus, and Mataric (2009) found that individuals suffering from cognitive impairment and/or Alzheimer's disease reported being more engaged with a robot treatment than a similar on-screen agent treatment.

Kiesler, Powers, Fussell, and Torrey (2008) used task-performance measures to find that participants who received health advice from a physically-present robot were more likely to choose a healthy snack than participants who received the same information in robot-video or on-screen agent conditions. In Bainbridge, Hart, Kim, and Scassellati (2008), a physically-present robot yielded significantly more compliance to its commands than a video representation of the same robot.

No previous work has investigated whether learning outcomes are affected by a robot's physical presence. The closest related work is in Intelligent Tutoring Systems (ITSs), which are educational computer programs that produce individualized lessons, advice, and questions usually in a workbook-style or quiz-style environment (Nkambou, Bourdeau, & Psyché, 2010). A parallel notion of embodiment called "the persona effect" exists in ITS research. (See Dehn and Van Mulken (2000) for an overview.) The persona effect is the impact, if any, that an on-screen character has on students using an ITS. The majority of research on the persona effect has shown no significant learning gains produced by on-screen agents, although many studies note that students find an ITS with an on-screen more engaging than one without (Moundridou & Virvou, 2002).

Our study is the first to assess the effect of the physical presence of a robot in an automated tutoring interaction. We use the task-performance measure of puzzle solving time in this work as well as several self-report measures.

## Methodology

### Participants

There were 100 participants in this study, between 18 and 40 years of age. The study was conducted in New Haven, Connecticut. Most participants were undergraduate and graduate students of Yale University. Each participant was assigned to one of five groups: (1) *no lessons*, (2) *randomized lessons from a physically-present robot*, (3) *personalized lessons from a disembodied voice*, (4) *personalized lessons from a video representation of the robot*, and (5) *personalized lessons from*

(b) Sample nonogram puzzle, solved.

Figure 1: A sample nonogram puzzle. The objective of nonograms is, starting with a blank board (see left figure), to find a pattern of shaded boxes on the board such that the number of consecutively shaded boxes in each row and column appear as specified, in length and order, by the numbers that are printed to the left of each row and above each column (see right figure). For a more detailed explanation see the **Domain** section.

a physically-present robot. There were approximately 20 participants in each group. Exclusion criteria for participants were lack of English fluency or prior academic experience with robotics or artificial intelligence.

## Apparatus

In this experiment, participants were asked to solve a series of logic puzzles. In the four experimental conditions with a tutor, the tutor interrupted participants several times per puzzle to deliver puzzle-solving strategy lessons. The lessons themselves were pre-recorded audio and synchronized visual aids, between 21 and 47 seconds in length, that explained and gave examples of the use of a single puzzle-solving strategy. In the experimental conditions with *personalized lessons*, the order of the lessons was determined by a skill assessment algorithm that identified skills in which participants were weak; see the **Skills & Lessons** section. In the *randomized lessons* condition, the tutor chose a random lesson among the same ones used in the *personalized lessons* conditions, such that it was immediately applicable to the current state of the game-board. We compare the puzzle solving time performance between participants in these groups to evaluate the effect of the robot's physical presence on the effectiveness of the tutoring.

**Domain** To minimize the influence of prior experience, we chose a test domain to which participants likely had little previous exposure: a grid-based fill-in-the-blanks puzzle game called “nonograms” (or “nonogram puzzles”) that resemble crossword puzzles or Sudoku. Nonogram puzzles are a difficult cognitive task, one that requires several layers of logical inferences to complete. Solving a nonogram puzzle of arbitrary size is an NP-complete problem (Nagao, Ueda, Ueda, Sato, & Watanabe, 1996), meaning that no efficient computational solution is known.

The objective of nonograms is, starting with a blank board, to shade in boxes on the board such that the number of consecutively shaded boxes in each row and column appear as

specified, in length and order, by the numbers that are printed to the left of each row and above each column. (See Figures 1(a) and 1(b) for a sample puzzle and solution.) For instance, a row marked as “4 2” must have 4 adjacent shaded boxes, followed by 2 adjacent shaded boxes—in that order, with no other boxes shaded, and with at least one empty box between the sets of adjacent shaded boxes. We refer to these contiguous sets of shaded boxes as “stretches” in this paper. For instance, the row described above requires two stretches, one of length 4, the other of length 2. One solves the puzzle when one finds a pattern of blank and shaded boxes such that all of the requirements for each row and column are satisfied.

In a typical puzzle, one cannot solve many rows or columns independently. One must infer the contents of parts of rows or columns and use previous inferences as the basis of subsequent inferences. To that end, when a player has reasoned that in some box or boxes there should not be shading, they can mark such boxes with an ‘X’ for reference.

We created a full-screen nonograms computer program that participants used via mouse and keyboard. The user interface provided a timer and a count of how many lessons (called “hints” in the interface) the participant had received and how many they would receive; see Figure 2.

Participants were asked to play four puzzles on ten-by-ten grids with a time limit of fifteen minutes per puzzle. The puzzles themselves were the same across all participants. The fourth puzzle used the same board as the first, although disguised in the fourth puzzle by rotating the board 90° (such that the column stretch requirements were swapped with row stretch requirements). This means that the first puzzle and the last puzzle are of the exact same difficulty and require knowledge of the exact same set of skills to solve. This manipulation enables us to make within-subjects comparisons about the extent to which each participant improved their skills over the course of their participation in the study. There was no indication that any participant was aware of this manipulation.

(a) Experiment apparatus in the *no lessons* condition and the *personalized lessons* from a disembodied voice condition.

(b) Experiment apparatus in the *personalized lessons* from a video representation of the robot condition.

(c) Experiment apparatus in the *randomized lessons* from a physically-present robot condition and the *personalized lessons* from an embodied robot condition.

Figure 2: Experiment apparatus by condition.

**Skills & Lessons** In the four conditions with lessons, the tutor interrupted the participant three times per puzzle, paused the puzzle, and delivered a short lesson about nonograms. The lessons ranged from 21 seconds to 47 seconds in length and consisted of a voice recording and a set of animations presented on screen during the lesson as well as a set of coordinated robot motions specific to each lesson.

When beginning a lesson the tutor would turn to face the participant (in the *video* and *physically-present robot* conditions) and say “I have an idea that might help you,” or “Here’s another hint for you.” During the lesson, the tutor bounced subtly and looked back at the screen whenever, in the course of the lesson, it would make reference to the example presented on screen. For instance, when in the audio of the lesson the robot would say “Like in this example...” or “As you see here...,” the robot would turn briefly to the screen and then back to the participant.

Ten nonogram puzzle-solving skills were identified based on the subjective experience of the authors; they are not universally identified skills or rules for nonograms. Each skill is a set of row or column states in which one can logically fill in some of the remaining empty boxes. For example, a stretch of length 9 can fit in a blank row or column of 10 boxes in only two ways. Either it fills the first box and 8 more, or it fills those same middle 8 boxes and the last box. In either case, the middle 8 boxes are shaded. One of the ten skills in this experiment is that, for an empty row or column with just one stretch requirement of  $n$  where  $n > 5$ , the middle  $(2n - 10)$  boxes are shaded. See Figure 3 for examples and explanations of this skill and two others.

There was one recorded lesson for each skill. Three lessons were delivered per puzzle, for each of four puzzles. The number of lessons was constant for all participants regardless of how long they needed to finish the puzzle. Lessons were triggered either when a participant made no moves for 45 seconds or as he or she filled the 25<sup>th</sup>, 50<sup>th</sup> or 75<sup>th</sup> box on the board

(of 100). The user interface displayed the number of lessons remaining for each puzzle at all times.

In the *personalized lesson conditions* the lessons were chosen based on a skill assessment algorithm. For each skill, a weighted sum was calculated internally consisting of: (1) the number of recent demonstrations of that skill (weighted positively) and (2) the number of recent gameboard states in which a skill could have been applied but no action was taken (weighted negatively). These assessments were updated for each skill separately throughout the game, and the skill with the lowest assessment that was applicable to the current gameboard was the skill for which a lesson was selected. In this way, participants in the *personalized lesson* conditions received lessons based on their individual performance on the puzzles.

Alternatively, in the *randomized lesson condition*, lessons were chosen among the same ten lessons at random each time, such that the lesson chosen could be applied to the current state of the gameboard. This ensures that although the lessons were randomized, they would provide actionable information every time.

**Robot** The robot we used, Keepon, is a small yellow snowman-shaped robot; see Figure 2(c). Keepon has previously been used as an emotive non-threatening communication tool (Kozima, Nakagawa, & Yasuda, 2005; Leyzberg, Avrunin, Liu, & Scassellati, 2011).

The robot operated in one of three modes. First, it refereed the puzzle game: it welcomed participants when they started, told them when they had finished or when they had run out of time, and told them when the experiment was over. Second, it “observed” the board during gameplay: the robot frequently turned its head to face the location of the mouse cursor. Third, it delivered short gameplay lessons three times per puzzle: it “spoke” to the participant by turning to face him or her and “bouncing” its body subtly while playing one of several pre-recorded spoken messages. If a lesson needed to be repeated,

the robot would first apologize for repeating itself (i.e., “I’m sorry to repeat this hint but I think it might help.”).

To simplify the potential perception problems inherent in real-world measurements, the robot in this study received perfect knowledge of the state of the game. We did not use a robotic vision system to detect state changes.

## Procedure

Participants were first asked to watch a five-minute instructional video and read a two-page instruction manual describing the rules of nonograms and how to use the computer interface. In the video and in the text, participants were encouraged to use logical reasoning to make moves in the puzzle rather than making moves by guessing. Potential questions about the rules of the puzzle game were answered by the experimenter after the instructions.

During the experiment, participants were alone in a room with the computer, the robot in conditions including the robot, and a video camera positioned behind them; see Figure 2. Participants would choose when they were ready to start each new puzzle; each round would end either when the participant solved the puzzle or when fifteen minutes had elapsed, whichever happened first.

After the conclusion of the final puzzle, participants were asked to complete a survey consisting of five Likert-scale questions with open-ended follow-up questions for each. The questions were designed to assess whether the lessons were helpful, clear, and influential, as well as the user’s perceptions of the robot. We asked participants to rate: how relevant the lessons were, how much the lessons influenced their gameplay, how well participants understood the lessons, and how “smart/intelligent” and “distracting/annoying” they perceived the robot to be.

## Results

This study investigates the role of physical embodiment in a robot tutoring system. The behavioral measure is the time in which participants were able to solve each of the four puzzles. For the purposes of calculating a mean, puzzles in which participants ran out of time were evaluated as having solved the puzzle when time ran out, fifteen minutes from the start of each puzzle. This occurred in 12.4% of all puzzles.

Table 1: Mean Solving Time

	Puzzle 1	Puzzle 2	Puzzle 3	Puzzle 4
<i>None</i>	13.6 ± 2.2	13.0 ± 2.3	12.3 ± 2.5	11.6 ± 2.7
<i>Rand.</i>	13.8 ± 1.4	12.5 ± 2.0	11.4 ± 2.3	10.3 ± 2.9
<i>Voice</i>	12.6 ± 2.4	10.7 ± 2.7	10.3 ± 3.3	9.1 ± 3.0
<i>Video</i>	12.8 ± 2.1	11.1 ± 2.6	9.9 ± 2.6	8.7 ± 2.4
<i>Robot</i>	12.7 ± 2.6	10.0 ± 3.5	9.4 ± 3.0	7.6 ± 3.1

Participants in the *robot group* performed better, on average, on the second, third, and four puzzles than participants in any other group. See Table 1 for means and standard deviations and see Figure 4(a). In the forth puzzle, the

(a) In this row, there must be one long stretch. By the process of elimination one can infer that this stretch must occupy at least the middle six boxes, no matter where in the row it is placed.

(b) In this row, the first box is already shaded. Given that, and that the first stretch must be 3 boxes long, one can infer that the first three boxes must be shaded and the fourth must be crossed out.

(c) In this row, there is only one short stretch and some boxes are already shaded. One can infer that regardless of where that one stretch is placed, it cannot occupy the first two or the last two boxes in that row.

Figure 3: Examples of nonograms skills. Displayed are the contents of a row before and after each skill is applied. Although only rows are shown here, all nonograms skills apply to columns as well.

mean solving time in the *robot group* ( $M = 7.6$  minutes,  $SD = 3.1$ ) is significantly better than in the *video group* ( $M = 8.7$  minutes,  $SD = 2.4$ ),  $t(36) = 0.03$ , and in the *voice group* ( $M = 9.1$  minutes,  $SD = 3.0$ ) as well,  $t(36) = 0.02$ . These data indicate that the robot’s physical presence made a significant learning impact on participants greater than that of an disembodied voice and a video representation of a robot.

In this experiment, the first and fourth puzzles were 90° rotated variations of the same board. Thus they required exactly the same skills to solve and the difference in their solving time is a measure of the participants’ acquired knowledge over the course of the study. Participants in the *robot condition* improved ( $M = 5.8$  minutes,  $SD = 3.5$ ) their same-puzzle solving time significantly more than those in both the *video condition* ( $M = 3.9$  minutes,  $SD = 2.3$ ),  $t(36) = 0.048$  and *voice condition*, ( $M = 3.4$  minutes,  $SD = 3.5$ ),  $t(36) = 0.04$ ; see Figure 4(b). This data indicates that participants who received lessons from the robot learned more effectively than those who received only voice- or video-based lessons.

Survey results verify the following manipulation: participants in the three *personalized advice conditions* rated the lessons significantly more relevant ( $M = 6.0$ ,  $SD = 1.4$ )

(a) Mean solving time per puzzle. Participants in the *robot condition* solved each puzzle faster than participants in any other condition. In the fourth puzzle, significantly faster ( $p \leq 0.03$ ). See Table 1 for means and standard deviations.

(b) Mean improvement in solving time between puzzles #1 and #4. These two puzzles were variations of the same gameboard, disguised in the fourth puzzle by a 90° rotation. Participants in the *robot condition* improved their solving time significantly more than those in any other condition ( $p < 0.05$ ).

Figure 4: Behavioral measure results: (a) participants who received personalized lessons from an embodied robot solved every puzzle faster on average, the fourth significantly so ( $p \leq 0.03$ ) than participants in all other conditions; see Table 1. (b) *robot condition* participants also improved on their same puzzle solving time significantly higher more than participants in all other conditions ( $p < 0.05$ ).

than participants in the *randomized advice condition* ( $M = 3.9, SD = 1.1$ ),  $t(33) < 0.001$ . There was no significant difference in how highly participants rated their understanding of the lessons between groups: ( $M = 6.0, SD = 1.4$ ) in the *random condition*, ( $M = 6.6, SD = 1.2$ ) in the *voice condition*, ( $M = 6.6, SD = 1.5$ ) in the *video condition*, and ( $6.4, SD = 1.2$ ) *robot condition*; see Figure 5. These data indicate that whatever social effect physical embodiment has on this interaction, it does not influence the participants' perception of their understanding of the lessons, despite the fact that the behavioral measure indicates better learning in the *robot condition*.

## Discussion

Our results indicate that a physically-present robot tutor produces better learning gains than on-screen or voice-only tutors. Further work is needed to identify the underlying social factors and mechanisms that cause this effect.

One such factor may be the novelty of the stimulus. Robots are an uncommon stimulus in the present day; we may expect participants to be more attentive to the agent in the physically-present condition. However, novelty can also be a distraction. The physical presence of the robot during the game may divert the participant's attention from the puzzle solving task. More work is needed to identify what effect, if any, a robot's novelty has on interactions such as these.

Physical presence may imbue the robot with more per-

ceived authority than an on-screen agent. Earlier work in this area indicates that people are more likely to comply with commands given by a physically-present robot than an on-screen video of the same robot (Bainbridge et al., 2008). Embodiment may cause participants to take the robot tutor's advice more seriously. We are accustomed to receiving lessons from teachers and authority figures who have physical bodies. Perhaps a robot's physical presence increases its authority or social standing.

Participants, however, did not report having significantly more difficulty understanding the lessons in any of the three advice conditions. In fact, all four groups rated their level of understanding of the lessons fairly highly ( $M = 6.3, SD = 1.3$ ); see Figure 5(b). This may indicate that the embodiment effect is so subtle that the participants did not notice its effect on their learning.

Another social factor is the potentially increased sense of peer pressure during the performance of the task itself. The distinction between physically-present robot and on-screen agent may parallel the way we perform tasks when we think of ourselves as alone rather than in view of another person. In person-person interactions, social presence can lead to significantly worsened task performance, especially in cognitively-demanding tasks (Short, 1976). More work is needed to compare the potential effect of peer pressure caused by a physically-present robot tutor to the peer pressure exerted by a human tutor who observes as participants perform

Figure 5: Results of self-report questionnaire measures completed after the interaction.

cognitively-demanding tasks.

Social presence effects may also be responsible for the survey result in which participants in the *physically-present robot condition* rated the robot ( $M = 4.7, SD = 1.8$ ) as significantly less “annoying/distracting” than participants in the other *advice conditions* ( $M = 6.1, SD = 1.3$ ),  $t(33) < 0.01$ ; see Figure 5(c). This may indicate that physical embodiment produces a significantly greater sense of social acceptance than an on-screen agent does.

Participants in the *robot condition* became better puzzle solvers than those in the other conditions. Further research is needed to identify the underlying social factors that contribute to this empirically-observed effect.

## Conclusion

This study investigates the role of physical embodiment of a robot tutor in a cognitive skill learning task. Participants who received personalized lessons from a physically-present robot outperformed participants who received the same kind of advice from a video representation of the same robot as well as participants who received the same kind of advice from a disembodied voice on the last three puzzles. Participants in the *robot condition* also improved their same-puzzle solving time significantly more than those in any other group, which is a direct measure of learning gains over the course of the experiment. From these data we conclude that physical embodiment can yield measurable learning gains in robot tutor interactions.

## Abstract

Systems are an important part in today's science education. Computer simulations have many advantages in teaching science systems. Our research goal is to test whether a hierarchical instructional scaffolding framework embedded in simulation-based learning environments and retrospective mental modeling task could facilitate mental model construction in learning science systems. This pilot study was conducted with a sample of adult learners who didn't have strong science background. They were asked to learn a chemical system in a simulation-based environment. The results show that participants in the hierarchical scaffolding condition performed better than the non-hierarchical scaffolding condition. The retrospective mental modeling task could enhance learning only within the hierarchical scaffolding condition; while in the non-hierarchical scaffolding condition, the task was detrimental to learning. Based on the results from the pilot study, an 8 session curriculum teaching ideal gas laws to middle school students has been designed for our future study.

**Keywords:** Science systems; simulation-based learning environments; scaffolding.

## Research Background

Systems thinking skills have become increasingly important in today's science education. Scientific explanation of mechanism is usually difficult in learning a system (Jacobson & Wilensky, 2006). Studies have demonstrated that learning systems thinking skills go through several sequential stages before learners are able to grasp a network of mechanics-function relations (Assaraf & Orion, 2005); for example, studies on the reasoning processes of complex systems show that novices focus more on the structure of the system, while experts tend to reason around mechanism and functions of the system (Jacobson, 2001).

Structure-Behavior-Function framework (SBF) provides a language to describe experts' and novices' conceptual representations of systemic knowledge (Hmelo-Silver, Marathe & Liu, 2007). Structure refers to the elements of the system, behavior refers the mechanism of how the elements act and interact leading to certain outcomes; and function

refers to the roles of the elements or the outcomes caused by the elements' behaviors (Hmelo-Silver, Marathe & Liu, 2007). Explaining mechanism and causality is usually difficult for learners especially when the systems have hierarchical levels (Duncan & Reiser, 2007). One important pedagogical implication from these studies is to provide hierarchical instructional scaffolding based on the SBF framework to help learners iteratively modify their conceptual representations (Liu & Hmelo, 2009).

## Mental Models of Science Systems

Mental models are internalized representations of the structural and functional relations of the reality (Johnson-Laird, 1983). The constructivist perspectives imply that mental model construction goes through trajectories, and iterative mental model modification could be very effective (Vosniadou & Brewer, 1992). Learning science systems usually require learners to construct mental models with various entities and a network function relations among the entities, well scaffolded step-wise learning could produce better structured conceptual representations (Clement & Steinberg, 2002).

Active mental modeling, or active rule-driven visualization, involves cognitive processes such as mentally manipulate the visual information to solve a problem (Briggs & Bodner, 2005). Learners' knowledge of a system could still be fragmented after initial learning, retrospective mental modeling around system functions with "what" and "how" questions could facilitate internal information organization, and enhance reflective thinking.

## Using Computer Simulations to Teach Science Systems

Deep understanding of a system involves constructing a mental perceptual simulation for information retrieval and reasoning (Black, 2010). Computational modeling and visualizing technology makes it possible to show the otherwise invisible mechanism of systems (Wilensky & Resnick, 1999), which could provide rich perceptual information to ground the abstract concepts (Barsalou,

2008). Multiple dynamic representations at different abstract levels could provide complimentary information, constraining interpretation of any singular representation, and support deep understanding (Ainsworth & VanLabeke, 2004). Active integration of multiple structurally and conceptually mapped representations can potentially facilitate deep learning (van der Meij & de Jong, 2006; Plass, Homer & Hayward, 2009). At different learning stage, different representation could be used for different learning purposes. For example, a concrete graphical representation can be used to depict system phenomena, and an abstract flowchart representation can be used to model symbolic systemic mechanism after sufficient perceptual information has been delivered.

Although multiple dynamic representations in simulation-based environments have the potential to facilitate mental model construction in learning difficult science systems, the instructional scaffolding should be well designed to help learners make full use of the learning environments. Our research question in this pilot study and future studies is: How to design better scaffolding in simulation-based environments teaching science systems? Pedagogical research implies that mental model construction has a hierarchical nature and goes through stages, thus the scaffolding should support sequential and step-wise learning. Additionally, retrospective mental modeling around system function might facilitate internal organization of systemic knowledge.

## Hypotheses

H1: Hierarchical scaffolding based on the Structure-Behavior-Function framework produces better learning performance.

H2: Retrospective mental modeling task facilitates internal reconstruction of the system knowledge.

## Method

### Participants

Participants for this pilot study were 36 adult learners (Mean age: 29.7, SD=7.61) from a graduate school of Education with a diversity of ethnicity. 29 of them were females and 7 were males. Most of them majored in social sciences and humanities fields, and didn't have strong background in science. One case was dropped because the participant totally misunderstood the learning goals and didn't complete the posttest. Another pilot study earlier showed that reasoning across different levels of a complex system and scientific reasoning about causality was difficult even for this population, and that was why we conducted a pilot study in this population before designing the curriculum for the junior high population.

### Instrument

Two computer-based simulations teaching three Ideal Gas Laws were used in this study. Participants were asked to

learn how Temperature, Volume and Pressure of a certain amount of ideal gas interact and reason about the relationship between lower-level molecular activity and the emergent function. One simulation was a realistic model (see Figure 1) and the other was a conceptual flowchart model (see lower part of Figure 2). These two dynamic representations are structurally and conceptually mapped, depicting and describing the system knowledge at different abstract levels. The realistic model provides rich visual information of the system phenomena while the flowchart model emphasizes the mechanism and causality in the system. The function of a realistic graphic simulation is to provide rich perceptual information grounding the abstract symbolic concepts, and the function of a conceptual model simulation is to constrain the processing of the visual information, reinforce the symbolic level of understanding.

### Design

This study employed a 2x2 factorial design testing the effect of hierarchical scaffolding based on SBF conceptual framework (HS), the effect of the retrospective mental modeling task (RMM) and their interaction effect. Regarding the procedure of the experiment, the manipulation of "RMM vs. N-RMM" came after the manipulation of "HS vs. N-HS".

### Procedure

1. Participants signed the consent form
2. Participants read through powerpoint slides which gave them an introduction to what they were going to learn
3. Participants interacted with the simulations for a couple of minutes to get familiar with the interface
4. Learning stage: participants were randomly assigned to a condition, given the worksheet which guided them through the whole learning process. They were asked to think aloud as they were learning. Eight sessions were randomly selected to be videotaped and the verbal protocols transcribed.
5. Posttest

The whole session lasted around 70-80 minutes in total for each participant.

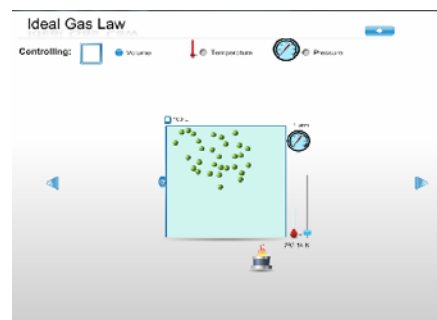

Figure 1: The realistic model simulation-an experiment

Figure 2: Two simulations displayed on the same page, and dynamically linked

## Manipulation

**Hierarchical Scaffolding.** The instruction was divided into three steps:

**Step 1.** Learners observed the higher level system function;

**Step 2.** Learners Described system lower level behaviors;

**Step 3.** Learners modeled the system causality around the system function.

In step 1, participants played with only the concrete graphic simulation (see Figure 1), and were asked to describe higher level phenomena for each ideal gas law (e.g.: how temperature and volume interact when pressure is constant). In step 2, they were asked to observe and describe lower level element behaviors (gas particle velocity, particle-container collision). In step 3, the instruction is function-centered with questions such as “when pressure is constant, why increasing temperature will lead to increased volume?” With both the concrete graphic simulation and the conceptual flowchart simulation (see Figure 2), participants were required to explain the lower level mechanism in a coherent matter for each ideal gas law. Simply speaking, in the HS condition, participants observed and described system structure and function, integrated fragmented behavior information, then connected the molecular behavior and the emergent T-V-P relationship, and explained the mechanism or causality in a coherent manner.

**Non-Hierarchical Scaffolding.** Indicated in a previous pilot study, when two simulations were displayed on the same page at the very beginning, participants tended to regard the flowchart concept model as complimentary fragmented behavior information, thus described each bar diagram separately, rather than using it as a modeling tool to explain the system causality. So for the no hierarchical scaffolding condition (N-HS), participants were given the combined simulations interface at the very beginning (see Figure 2); given the worksheet including all the questions asking about the system function and lower-level behaviors for each ideal gas law. The participants were asked to describe the structure, function and behavior knowledge for each ideal gas law, and were not guided to iteratively interrogate with the system. It was ensured that participants

in the N-HS condition had same amount of questions asking about the system functions and behaviors compared to the HS condition, while there were no structured progressive learning steps in this condition.

## Retrospective Mental Modeling & Control Condition.

There were three ideal gas laws for the participants to learn in this experiment. After a participant completed learning one ideal gas law, the other experimental variable (Retrospective mental modeling task) was manipulated. For the retrospective mental modeling condition (RMM), after learning each ideal gas law by interacting with the simulations, the participants were asked to close their eyes, describe the processes of how the phenomenon happens. For the no-retrospective mental modeling condition (N-RMM), there was simply no such a step.

## Measures

The posttest included four sections:

1. Comprehension task: participants were given three questions asking them to explain the mechanism for each ideal gas law phenomenon.
2. Four multiple-choice questions on problem solving
3. Explaining new diagrams: participants were given three new line diagrams representing the events happening from time A to time B, and they were required to visualize and describe the what happened in the system
4. Transfer task: participants were asked to explain everyday gas law problems

## Results

The posttest results indicate that the groups differ in their understanding of the lower-level molecular activity (the mechanism and processes of the system) but not higher-level structure and function of the system.

Task 1 (Comprehension task) and Task 3 (Explaining diagrams task) measured the understanding of lower-level behaviors and their functions (molecular activity). The answers for Task 1 (Comprehension task) were coded on the presence and absence of lower-level mechanism knowledge units (highest possible score: 7), by two raters blinded to the condition of the participants. The agreement was 93.2%, and the rest was resolved through discussion. The results of Task 1 are displayed in Table 1 and Figure 3.

Figure 3. Comprehension task mean scores

Table 1. Comprehension task mean scores

Group	Mean	N	Std. Deviation
HS&RMM	4.1250	8	1.72689
HS&N-RMM	3.0000	9	1.00000
N-HS&RMM	1.4444	9	1.13039
N-HS&N-RMM	2.2222	9	1.09291
Total	2.6571	35	1.55190

Significance tests show that HS has significant effect on learning lower-level element behaviors and their functions,  $F(1, 31)=16.63$ ,  $p<.001$ , no main effect is found for RMM,  $F(1, 31)=.168$ , n.s., while the interaction of HS and RMM is significant,  $F(1, 31)=5.03$ ,  $p=.032<.05$ . Post-hoc tests show that HS&RMM performed significantly better than the N-HS&RMM and N-HS&N-RMM group, and the N-HS&RMM performed the worst, which indicates that without hierarchical scaffolding, the retrospective mental modeling will do no good but interfere with the learning.

Task 3 was also coded on the presence and absence of lower-level behavior and function knowledge units (possible highest score 8) by two raters blinded to the condition. The agreement is 95.9%. Participants who described more molecular activity in explaining the abstract line diagrams were believed to notice and appreciate the importance of behavior-function interdependence. The results of Task 3 (see Figure 4 and Table 2) show a similar pattern as in Task 1.

Figure 4. Explaining diagrams mean scores

Table 2. Explaining diagrams task mean scores

Group	Mean	N	Std. Deviation
HS&RMM	4.2500	8	2.81577
HS&N-RMM	2.7778	9	2.86259
N-HS&RMM	1.5556	9	1.50923
N-HS&N-RMM	2.2222	9	2.04803
Total	2.6571	35	2.46078

The main effect of HS is marginally significant,  $F(1, 31)=4.13$ ,  $p=.051$ ; although the interaction of HS and RMM is not statistically significant, it is mostly due to a small sample size.

No difference was found in Task 2 (multiple choice questions, highest possible score 4, see Table 3). It might be because the participants tended to do abstract rule-based reasoning rather than applying their mental models in solving the problems, as indicated in the interviews with some of the participants. e.g., one question is “If you want to maintain pressure at a constant level, which of the following combination would work?” Participants will tend to draw abstract rules (e.g., Pressure constant, Temperature increases, Volume increases) and then make the judgment for each choice, without visualizing the molecular activity and the processes of the system.

Table 3. Multiple choices task mean scores

Group	Mean	N	Std. Deviation
HS&RMM	2.7500	8	1.16496
HS&N-RMM	2.6667	9	.86603
N-HS&RMM	2.7778	9	1.09291
N-HS&N-RMM	2.8889	9	1.26930
Total	2.7714	35	1.05957

In task 4, although participants were originally expected to describe lower-level system behaviors to explain the everyday ideal gas law phenomena, many of them focused only on the higher-level structure and function of the system, so the answers were coded on the important system behavior and function knowledge units (both higher-level and lower-level, highest score: 8, see Table 4) The agreement between the two raters was 85.2%. In this task, the participants were only asked to explain the phenomena without explicit questions asking about the molecular activity. The data also imply that in order to help the learners to integrate the invisible lower-level system behaviors into their explanation, another level of scaffolding for transfer might be needed.

Table 4. Transfer task mean scores

Group	Mean	N	Std. Deviation
HS&RMM	4.2500	8	2.81577
HS&N-RMM	4.2222	9	2.10819
N-HS&RMM	4.2222	9	1.30171
N-HS&N-RMM	4.1111	9	2.42097
Total	4.2000	35	2.11159

### Some Qualitative Analysis

For better understanding of the effect of hierarchical scaffolding, eight verbal protocols (4 from HS condition, 4 from N-HS condition) were transcribed and analyzed. It was hypothesized that more clear and efficient trajectories of mental model construction could be found in the HS condition. The qualitative data does indicate that the participants in the HS condition were more likely to progressively modify their mental models.

Below are parts of a participant's verbal transcript (HS condition) which demonstrate how he gradually construct scientific causal model of the system.

When the participant was learning the structure and fragmented behavior knowledge (step 1):

*"As the temperature goes down, the volume decreases, the volume goes down, the temperature decreases I guess... yeah...ha...I've no idea how that works...but that's what the simulation tells me. Why would that happen?"*

*'cause the Temperature goes up, the Pressure goes up, the volume goes down, the pressure goes up...when pressure is constant...when the temperature goes down, volume goes down...hum..."*

Here the participant was dealing with the higher-level system function (when pressure is constant, temperature changes cause volume to change), he was curious about how that happens, which prepared him to actively integrate and connect the lower-level molecular behaviors knowledge. This also supports the idea of function-centered scaffolding.

The second part of the transcript indicates the participant was now trying to connect the two levels of information. He was trying to clarify the causal relationship among all the lower level and higher level elements.

*"so the temperature and velocity are clearly related, because as I bring the Temperature down, the velocity of particles move. If we wanna keep the pressure the same...So I am guessing, if I move this back, the pressure is probably gonna go...oh the pressure stays the same, the temperature will have to go up...yeah...so as volume increases...the temperature has to go up because...how can I explain that...so we have a constant pressure here, so that means...all of these have to collide at the same rate, that means when there is less space, they have to move a lot slower to*

*maintain the same pressure...yeah...now they have to move a lot faster, the temperature has to go up"*

After successfully integrating the information, when the participant was asked to answer the question "why temperature increases, volume increases" in the retrospective mental modeling stage, the participant was able to provide a very sophisticated answer while visualizing the system processes.

*"so if the pressure is constant, then as volume decreases, the temperature also has to decrease because the particles have to move at a slower rate in order to maintain the pressure in a smaller volume."*

Below are parts of a participant's verbal transcript (N-HS condition):

*"so pressure is gonna be controlled...and...temperature and volume...temperature affects volume...so...when you increase the temperature, you increase the volume, you decrease the temperature, you decrease the volume...the velocity also corresponds...and now container-collision is gonna go up...(confused)"*

Here the participant was trying to learn the Temperature-Volume relationship when pressure is controlled. She was given the combined simulations interface at the very beginning (see Figure 2.) and had to construct a hierarchical mental model without the progressive scaffolding. It could be seen that she was trying to integrate all the functional and behavior knowledge, but she struggled in trying to give a coherent explanation.

When she was asked to answer the question "why temperature increases, volume increases" in the retrospective mental modeling task, she failed in integrating lower-level behavior knowledge in her explanation, as can be seen in the following transcript:

*"The temperature increased, the volume increased. When the temperature decreased, volume decreased...Why? I have no idea."*

The qualitative data implies that learners might need to interrogate with the system progressively and iteratively in order to form deep understanding. Experiencing the system function and integrate the system behavior knowledge based on the system function could be very effective. Another implication is that modeling causality after learners have observed all the system behaviors lead to more compact and sophisticated mental models.

### Discussion

This pilot study demonstrates that hierarchical scaffolding (HS) could help learners better integrate the lower-level system behavior knowledge and learn the causality. The interaction between hierarchical scaffolding and retrospective mental modeling is interesting. It seems retrospective mental modeling could enhance learning only when the learning process itself is well scaffolded. One explanation is that learners need to internalize the knowledge in a well structured way before they can mentally reorganize the information in a coherent manner.

Without such a structure, mentally reorganizing the information might counter learning.

### Limitations and Future Study

This pilot study only included three-step scaffolding because we assumed the adult learners should be already familiar with the everyday ideal gas law phenomena. The total learning time was very short since this system was not too challenging to the adult learners. Based on the implications from this pilot, we have designed an 8 session curriculum teaching ideal gas laws for 7<sup>th</sup> and 8<sup>th</sup> graders. The hierarchical scaffolding is now operationalized into 5 steps, which help the junior high students gradually construct better mental models of the systems. Everyday ideal gas law problems are also incorporated into the simulation environment (e.g., students are able to manipulate the fire icon to make a soda can explode, etc). In our future study, learners' learning trajectory will also be recorded and analyzed to better answer our research question. To reduce the cognitive load in integrating the system behaviors and modeling system causality, two techniques are used in designing the simulations: a. the everyday ideal gas law simulation and the gas molecules simulation are dynamically linked for students to compare and analyze the different levels of the system (example, see Figure 5). b. Concrete icons instead of bar diagrams are used in the flowchart simulation which helps learners to model system causality (see Figure 6).
