## Abstract

Many have investigated the sensitivity of face processing to both spatial frequencies and face orientation, but few have researched the sensitivity of face processing to the orientation of spatial frequencies. One recent exception has been Yu, Chai, & Chung (2011), which investigated facial expression recognition in regards to the orientation of spatial filters and showed that most information is contained in the horizontal orientation. Here, we model the Yu, Chai, & Chung (2011) study using the EMPATH model, a feed-forward neural network that has been used to model facial expression recognition (Dailey, Cottrell, Padgett, & Adolphs 2002). We used the NimStim set of facial expressions, which were the basis for the Yu, Chai, & Chung (2011) experiment, and followed their method of filtering images through different spatial orientations. Our results show that this simple, biologically plausible model produces very similar results to that of human subjects in their study.

**Keywords:** emotions; facial expressions; spatial frequency; neural network; face recognition.

## Introduction

Many studies have been conducted regarding the role of spatial frequencies in human face recognition (Näsänen, 1999; Costen, Parker, & Craw, 1996; Gold, Bennett, & Sekuler, 1999), although the uniqueness of sensitivity of faces to spatial frequency has been debated (Williams, Willenbockel, & Gauthier (2009). However, few have explored how different *orientations* of spatial frequencies impact recognition of facial images. One such experiment was done by Yu, Chai, & Chung (2011), who passed facial images through orientation filters from -60 to 90 degrees in increments of 30 degrees. They found that the spatial information near horizontal (between -30 and 30 degrees) were the most important for normally-sighted human respondents to recognize facial expressions.

## Background: Yu, Chai, & Chung's Experiment (2011)

The aim of the Yu, Chai, & Chung (2011) experiment was to determine which spatial orientations on the face contained the most information for identifying emotions. The four emotions they tested were the closed-mouth forms of anger, fear, happiness, and sadness. Images were

obtained from the NimStim set of facial expressions (Tottenham, Tanaka, Leon, McCarry, Nurse, Hare, Marcus, Westerlund, Casey, & Nelson 2009), and were distorted with an orientation filter of bandwidth  $23^\circ$  in the Fourier domain, where the center of the filter ranged from  $-60^\circ$  to  $90^\circ$  in increments of  $30^\circ$ . Unfiltered images were used for comparison.

Their experiment consisted of having 15 normally-sighted human subjects try to recognize the expression displayed by each image under a four-way forced choice. The results indicate that the human observers had the most success with images filtered at orientations near the horizontal ( $-30^\circ$ ,  $0^\circ$ , and  $30^\circ$ ), suggesting that horizontal spatial information is most important for recognizing facial expressions. One modest exception to this trend is the fearful face; the human subjects tended to be significantly biased towards labeling a face as fearful as the orientation filter approached  $90^\circ$ , which seems to indicate that much of the information for fear is represented vertically.

The purpose of this current experiment is to determine if a neural network model can produce similar results as the human subjects, especially in regards to the increased recognition performance for horizontal orientations and the preference towards fear for vertical orientations. Such evidence would provide greater support for Yu, Chai, & Chung's (2011) findings and further validate EMPATH's flexibility and accuracy in modeling human face recognition.

## Methods

### The Model

The neural network used for this experiment closely followed the EMPATH model developed by Dailey et al. (2002), consisting of a biologically plausible, three-layer, feed-forward perceptron. EMPATH has been shown to have remarkable face recognition performance on aligned, grayscale images from Ekman and Friesen's POFA (1976). Without being tuned specifically to those images, the network classified the emotions Anger, Disgust, Fear, Happiness, Sadness, and Surprise with 90% accuracy on average, compared to 91.6% for human subjects (Dailey et al., 2002). For this experiment, we kept much of the settings (outlined below) identical to those of the original EMPATH

model, so the network was not tailored for the spatially filtered images or the NimStim dataset.

The first layer consisted of a set of model neurons based on the magnitude of Gabor filters, which have become a standard way to model complex cells in the early visual cortex (Daugman, 1985). In all, 40 different Gabor filters were used, in combinations of 5 scales and 8 orientations; filtering was done by passing the face images through a 29 by 35 “grid” of filters, resulting in 40,600 responses per image. Note that the orientations of the Gabor filters were the same as in the original EMPATH model, and were not changed to fit with the spatial filtering used in this study.

In order to reduce the dimensionality of the data set, we performed principal component analysis (PCA) on the Gabor filter outputs, producing 50 principal components (again based on the original EMPATH model). In this second layer, the principal components capture the distinguishing features of each facial expression but abstract away from details unique to each face; hence they allow the network to generalize to novel faces that are not part of the training set. As Dailey et al. stated, these components are similar to face cells in the inferior temporal cortex (2002).

Lastly, the principal components were fed into the third layer, consisting of a simple linear perceptron with six softmax outputs representing anger, fear, happiness, surprise, disgust, and sadness. This perceptron was trained using stochastic gradient descent with the cross-entropy error criterion. We used an “all-or-none” teaching signal that had “1” for each correct expression and “0” for the incorrect expressions. In order to replicate the four-way forced-choice employed by Yu, Chai, and Chang (2011), we only took the results of the four relevant emotions via a process described in “Training, Validating, and Testing.”

As stated in Dailey et al., we acknowledge that this perceptron is very simplistic (2002). However, since it was powerful enough to map the principal components to emotion categories, we did not feel that a non-linear classifier was needed.

## The Images

The images used in the testing set by Yu, Chai, & Chung (2011) consisted of morphs of images taken from the NimStim set (2009), which reduced variations among faces (such as race, gender, etc.). Without access to these exact morphs, however, we simply used some of the original NimStim images to create our training and testing sets. Given this difference, our results still closely matched those of Yu, Chai, & Chung (2011).

Our testing and training sets consisted of grayscale images of 30 different people (17 male, 13 female). Two of the images are shown in Figure 1. These images were judged to be the most frontally aligned, making them the most suitable for EMPATH. Each image was 240 x 292 pixels in size and was cropped closely about the face.

Both the testing and training sets contained images of six different emotions for each of the 30 people. These expressions were comprised of both open and closed-mouth

forms of anger, fear, happiness, and sadness; the open-mouth form of surprise; and the closed-mouth form of disgust.

Figure 1: Two of the cropped images, corresponding to Happiness and Sadness

The additional expressions were chosen for the training set so that the network would have a more comprehensive exposure to the range of different emotions, making it more similar to the experience of the human subjects in the experiment. Although the testing set also contained six expressions, our method for producing the network’s output was able to emulate a four-way forced choice among the four expressions used by Yu, Chai, & Chung (2011), which effectively limited the output to only those four choices (detailed in “Training, Validating, and Testing”).

**Processing the training set:** In order to better replicate the images used by Yu, Chai, & Chung (2011), the 30 sets of images were closely cropped about the face using an oval mask so that only an oval-shaped portion of the face was visible. The parts that were cropped out were filled in with a uniform gray color of RGB value 127, and the entire image was adjusted to have a root-mean-square contrast value of 0.096, as per specifications given in Yu & Chung (2011). Examples of images used in the training set are shown in Figure 2.

Figure 2: Two images from the training set

**Processing the testing set:** The process for creating the testing set was very similar to that of the training set. The 30 original sets of images were first cropped, aligned, and then processed using Yu, Chai, & Chung’s (2011) filters at six orientations from  $-60^\circ$  to  $90^\circ$  in increments of  $30^\circ$ , which selectively pass information at the specified orientations. Afterwards, the oval “mask” was applied to the images in the same way as that of the training set, and all of the images were again normalized to have the same root-mean-square contrast of 0.096. Examples of the test images are shown in Figure 3. These were then processed by the same Gabor filters as used in the training set, and the resulting filter responses were projected onto the 50 eigenvectors using the PCA that was computed on the training set.

Figure 3: All 6 filtering conditions shown horizontally from  $-60^\circ$  (top left) to  $90^\circ$  (bottom right).

### Training, validating, and testing

The last layer of the model was a 50-input, 6-output single layer perceptron with softmax outputs trained using cross entropy. This procedure leads to outputs that compute the conditional probability of the category given the inputs (Bishop, 1995). Hence the output of the network is a probability distribution over the facial expression categories.

Cross-validation and early stopping were used to prevent overfitting the network to the training set. Since there are thirty individuals in the training set, we performed thirty instances of cross validation, each time holding out a different individual in the training set to use for early stopping. This comprehensive cross-validation made the testing less prone to unevenness among the images. Overall, there were 30 independent test cycles; each time 1 set was chosen for testing, 1 chosen for validation, and the remaining 28 were used as the training set. The aggregate performance from these 30 sets of tests constituted the results for each filtering condition. The validation set was taken from the processed test set as a guide to know when to stop training (of course the validation and test images were never the same). Training was completed for each cycle once the cross-entropy error for the validation set was minimized using gradient descent, and the weights of the network were then used for the testing set.

The testing procedure involved computing the weighted sum of the 50-element test set using the weights from training, then again applying the softmax function. A simple max function was used to judge if the testing outputs matched the teaching signals, and to create the confusion matrix. However, since the weights were trained with six facial expressions, the max function was applied only among the four target emotions to create a four-way forced choice similar to what a human subject would have to perform. This is valid because the softmax function created outputs that were probabilities of each emotion being correct; thus, although the teaching signal was “all or nothing,” the outputs were not. We note that when humans undergo the task of selecting among four target emotions, it is entirely possible that the emotion they perceive is not among the four options, and thus they may have to answer with their second or third choice. This is essentially what we have emulated with our network.

### Results

Our model was able to fit the human data very well in several measures. Much of the data presented by Yu, Chai, & Chung (2011) is displayed in the form of confusion matrices, which pit the human responses against the actual targets. We used the same technique to display our data. Since Yu, Chai, & Chung (2011) presented their results on a poster, many of their figures lack numerical data. As such, much of our analysis will be dependent on comparing the visual presentations of data. The color spectrum of our confusion matrices were closely matched to that used by Yu, Chai, & Chung (2011) so that comparisons and conclusions can be made.

### Performance on Unfiltered Images

Figures 4a and 4b show the confusion matrix for the unfiltered images given by Yu, Chai, & Chung (2011) and by our model, respectively. In addition to the hits, the columns show false alarms and rows depict misses.

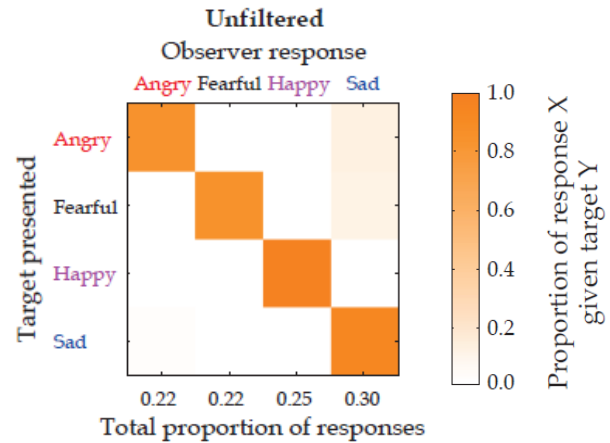

Figure 4a: Presented target vs. human responses (unfiltered) as presented in Yu, Chai, & Chung (2011).

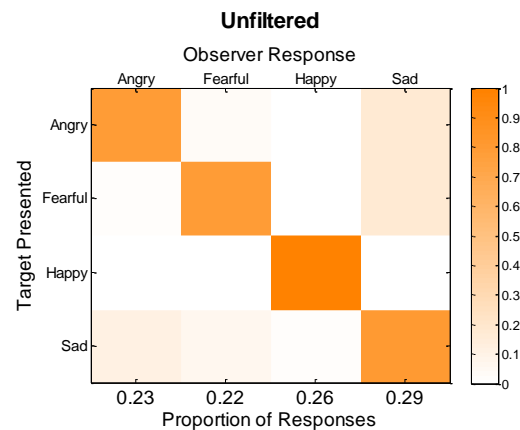

Figure 4b: Presented target vs. model responses, for unfiltered images.

Both the model and the human subjects demonstrated very good performance overall in recognizing the unfiltered images. The model also exhibited similar behavior as the human subjects in terms of having false alarms for sad faces when presented with Angry and Fearful faces. This is likely a characteristic of the closed-mouth sad faces in the NimStim set in general, since similar false alarms were present in Tottenham et al. (2009). The total proportion of responses was also similar between EMPATH and the human subjects, which suggests that the model was sensitive to many of the same facial features that the human subjects used for classification.

### Performance for individual filters

The results for the individual filters demonstrate that recognition performance decreased as the filter orientations approached 90°. Figures 5a and 5b illustrate the performances of humans and of our model, respectively.

Both sets of confusion matrices distinctly show greater occurrences of misses and false alarms at orientations near the vertical; i.e. 60°, -60°, and 90°. Some other general trends can be drawn from the data. For both humans and the model, sad faces tended to draw more false alarms and misses, regardless of the filter condition. Angry expressions tended to lose their uniqueness as the filters neared vertical, resulting in many misses, and few hits and false alarms.

One informative visualization of recognition performance is plotting the d prime calculations for each filter, which indicates how strong a signal is in relation to surrounding noise (Abdi, 2010). Hence, the d prime calculation for each filtering condition is proportional to how recognizable the expression is with that filter. Figures 6a and 6b depict graphs of d primes for each filtering condition normalized to the d prime of the unfiltered images (higher d primes still correlate to higher recognition performance).

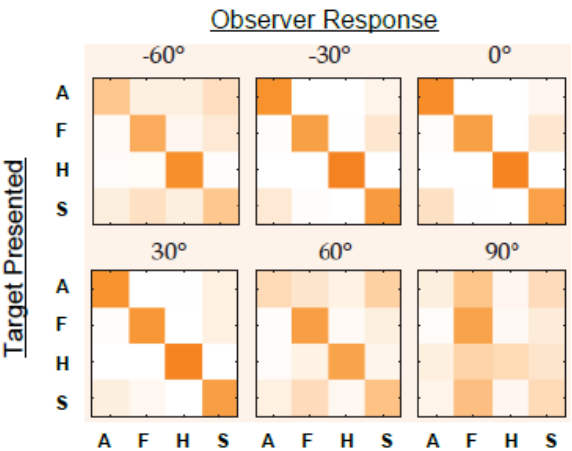

Figure 5a: Human performance for each filtering condition. From Yu, Chai, & Chung (2011).

Figure 5b: EMPATH performances for each filtering condition.

Figure 6a: Human data from Yu, Chai, & Chung (2011), showing d primes of each filtering condition, normalized to the unfiltered condition. Note that data for -90° was copied from data for 90°.

Figure 6b: Data from the EMPATH model showing d primes of each filter normalized to the unfiltered images.

Both d prime charts demonstrate lower recognition performance as the filters approached 90°. We note that

results from the EMPATH model are not as symmetrical as those from the human data (e.g. the discrepancy between the values for -30 and 30 degrees for happiness, and the M-shaped graph for fear). This is likely due to the fact that the original images are not vertically balanced; i.e. the positive and negative filters each obstruct slightly different features of the expressions. The resulting images were likely different enough to confuse the network. It would be worthwhile in the future to explore this phenomenon of asymmetry, especially since it was not apparent in the human data.

As noted earlier, fearful faces were less affected by the filter orientations as the other three emotions. Both d prime charts show that fear was the most easily recognized at the 90° orientation. The earlier confusion matrices (Figures 5a and 5b) likewise depict a relatively steady percentage of hits for fearful faces. Much of this is attributed to the fact that both human observers and EMPATH exhibited a significant bias towards fear at the vertical orientations, which increased the occurrences of both hits and false alarms. Figure 7 illustrates EMPATH’s high proportion of responses for fear at the vertical orientations. At the horizontal orientations, each emotion constituted close to 25% of the responses, but at the vertical orientation, responses in favor of fear approached 40%.

Figure 7: Total proportion of responses exhibited by EMPATH for each filter orientation.

### Aggregate Performance of 6 filters

EMPATH’s cumulative performance across all 6 filters is also similar to that of the human observers. Tables 1a and 1b show the overall performance of the human subjects and of EMPATH, respectively.

Firstly, the two tables show that with the exception of anger, EMPATH does significantly better in recognizing expressions than do the human subjects. Of course, the model can always be tailored to perform either better or worse, but we did not want to make adjustments just to suit these images. Secondly, the two tables depict many similar trends in the responses between the humans and the model. The overall proportion of responses shows that both the humans and the model were biased towards fear and

sadness, and that both were biased against anger. In both cases, anger was the most difficult expression to recognize and also the most difficult with which to be confused, based on the overall percentage of responses. The human subjects and EMPATH also had difficulty recognizing sad faces, but there was a high false-alarm rate as well. The Spearman rank correlation between the two matrices was very good, at  $r = 0.976$  ( $p < 0.001$ ) for the complete matrices. Since we were also interested in the misses and false alarms, we also calculated the rank just for the off-diagonals, which was very similar at  $r = 0.942$  ( $p < 0.001$ ).

Table 1a: Aggregate performance of human subjects for all 6 filter orientations.

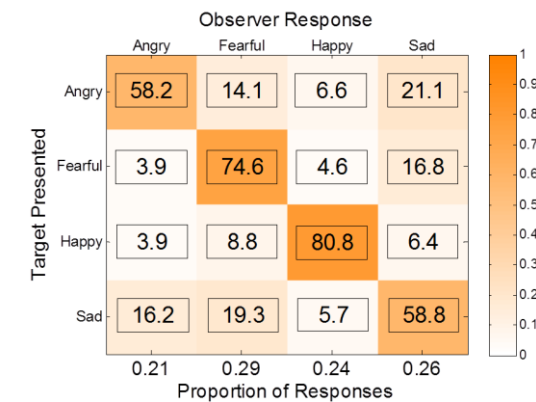

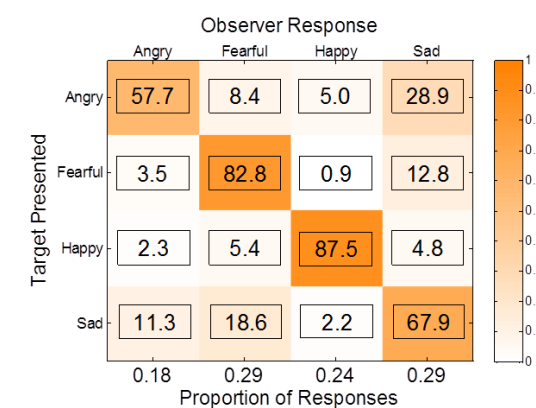

Table 1b: Aggregate performance of EMPATH for all 6 filter orientations

### Discussion

The aim of this present experiment was to model the experiment conducted by Yu, Chai, & Chung (2011) and determine if their results can be replicated using a neural network that was not specifically tuned to their images or their data. Our results demonstrate a strong similarity to the pattern of human responses, particularly in showing that information for facial expressions lies primarily on the horizontal orientation, with the modest exception of fearful faces, which solicited heavy bias from both human observers and EMPATH as the orientation approached

vertical. In particular, there was a very high proportion of hits and false alarms, suggesting that the vertical filter accentuated features in other expressions normally attributed to fear. Based on this data, it seems that much of the information for fear lies on the vertical, making it distinct from other expressions. It would be interesting to conduct further experiments with other image sets to determine if this phenomenon is a trait of the NimStim images or if it is more universal.

Some discussion regarding our use of  $d'$  prime is warranted. The procedure used by Yu, Chai, & Chung (2011) to calculate  $d'$  prime follows the standard guideline of  $d' = Z_H - Z_{FA}$ , where  $Z_H$  and  $Z_{FA}$  denote the inverse Gaussian distribution of hits and false alarms, respectively (Abdi, 2010). However, since this formula is typically used for two-way “Yes – No” tasks, the validity of using it for a four-way forced choice is debatable, since each emotion has one “Yes” response and three distinct “No” responses attached to it. Very little literature exist detailing  $d'$  prime calculations for multiple-way forced choice scenarios, but Alexander (2006) described an easily-computed approximation to the original version in Green & Swets (1966). Based on that, we have recalculated our graph of  $d'$  prime, which we depict in Figure 8. It should be noted that this approximation does not take false alarms into account. This resulted in a significantly higher  $d'$  prime for fearful expressions, which were actually greater for filtering conditions near vertical than for unfiltered images. Given that this is an approximation, the validity may of course also be debated, but we nonetheless present both calculations. This serves as a prediction of how the Yu, Chai, & Chung (2011) data will look if it were analyzed in the same way.

Given EMPATH’s demonstrated consistency in modeling human face recognition, another possible future experiment could be to determine which filtering orientations are ideal for recognition of each particular expression. It seems, based on this study, that the majority of expressions with the exception of fear would have an ideal filtering condition near the horizontal, but determining exact orientations would form testable hypotheses generated by the model.

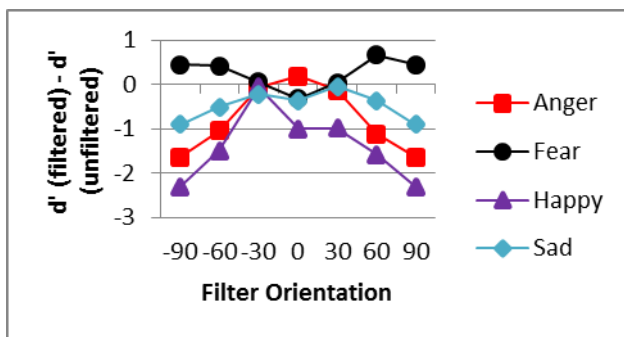

Figure 8: N-choice  $d'$  prime approximations, following procedure outlined by Alexander (2006) and normalized to the unfiltered images.

## Acknowledgements

We thank Dion Yu and Susana Chung for sharing their filtering code, and for providing us with ample clarification of their experiment. We thank Nim Tottenham for sharing the NimStim dataset with us. We also thank Gary’s Unbelievable Research Unit (GURU) for providing feedback on this project, and Matthew Tong in particular for overseeing part of the reconstruction of EMPATH. This work was supported in part by NSF grant #SBE-0542013.

## Abstract

Experts have remarkable capability of locating, identifying and categorizing objects in their domain-specific images. Eliciting experts' visual strategies will benefit image understanding by transferring human domain knowledge into image-based computational procedures. In this paper, an experiment conducted to collect both eye movement and verbal description data from three groups of subjects with different medical training levels (eleven board-certified dermatologists, four dermatologists in training and thirteen novices) while they were examining and describing 42 photographic dermatological images. We present a hierarchical probabilistic framework to discover the stereotypical and idiosyncratic viewing behaviors exhibited within each group when they are diagnosing medical images. Furthermore, experts' annotations of thought units on the transcribed verbal descriptions are time-aligned with discovered eye movement patterns to interpret their semantic meanings. By mapping eye movement patterns to thought units, we uncover the manner in which these subjects alternated their behaviors over the course of inspection and how these experts parse the images.

**Keywords:** Eye movements; eye tracking; verbal description; multimodal data analysis; graphical model; user study; diagnostic reasoning

## Introduction

Perceptual expertise is considered to be the crucial cognitive factor accounting for the advantage of highly trained experts (Hoffman & Fiore, 2007). Experts generate distinctively different perceptual representations when they view the same scene as novices (Palmeri, Wong, & Gauthier, 2004 ; Smuc, Mayr, & Windhager, 2010). Rather than passively "photocopying" the visual information directly from sensors into minds, visual perception actively interprets the information by altering perceptual representations of the images based on experience and goals. By analyzing the whole sequences of fixation and saccadic eye movements from groups with different expertise levels, significant differences in visual search strategies between groups show human expertise plays a great role in medical image examination. In (Manning, Ethell, Donovan, & Crawford, 2006), the nature of expert performance of four observer groups with different levels of expertise was investigated . They compared multiple eye movement measures and suggested these distinctive

variations among the observations of the better performance from higher expertise level are due to the consequences of experience and training. In (Krupinski et al., 2006), an eye movement study was conducted on diagnostic pathology of light microscopy to identify distinctive viewing stereotypes for each level of experience . Their results suggest eye movement monitoring could serve as a basis for the creation of innovative pathology training routines.

In knowledge-rich domains, perceptual expertise is particularly valuable. Medical image understanding via manually marking and annotating become not only labor intensive for experts but also ineffective because of the variability and noise of experts' performance (Gordon, Lotenberg, Jeronimo, & Greenspan, 2009). For training and designing decision support systems, the basic perceptual strategies and principles of diagnostic-reasoning are also desired (Dempere-Marco, Hu, & Yang, 2011). To address this problem, it requires the ability of extracting and representing experts' perceptual expertise in a form that is ready to be applied. In this work, our contributions are: first, we discover and represent expertise-related eye movement patterns exhibited among multiple experts in an objective and unbiased way; second, to validate these patterns, we identify their semantic meanings by time-aligning them with standardized thought units annotated by additional experts. Third, we also characterize the eye movement patterns of three different expertise levels respectively which can be used to categorize users' expertise levels based on their visual inspection on medical images.

Human viewing behaviors are valuable yet effortless resources worth of exploiting. In specific domains experts perceptual expertise is considered to be more consistent and informative than their manual markings. Human vision is an active dynamic process in which the viewer seeks out specific information to support ongoing cognitive and behavioral activity (Henderson & Malcolm, 2009). Since visual acuity is limited to the foveal region and resolution fades dramatically in the periphery, we move our eyes to bring a portion of the visual field into high resolution at the center of gaze. Studies have shown that visual attention is influ-

enced by two main sources of input: bottom-up visual attention driven by low-level saliency image features and top-down process in which cognitive processes, guided by the viewing task and scene context, influence visual attention (Torralba, Oliva, Castelano, & Henderson, 2006 ; Loboda, Brusilovsky, & Brunstein, 2011). Growing evidence suggests that top-down information dominates the active image viewing process and the influence of low-level saliency guidance is minimal (Castelano, Mack, & Henderson, 2009). These theoretical outcomes provide us with the possibility to capture experts' cognitive strategies, perceptual expertise and expectations by investigating their stereotypical and idiosyncratic viewing behaviors, and decode their semantic meanings.

In our work we focus on medical images where domain knowledge and perceptual expertise are in demand. We elicit and model physicians' perceptual and conceptual expertise from their diagnostic reasoning process while inspecting medical images. Physicians examine medical images and verbally describe their thinking process as if teaching a trainee, and both their eye movements and verbal descriptions are recorded. In order to capture the stereotypical and idiosyncratic eye movement patterns exhibited among these physicians, we develop a hierarchical dynamic model. This model allows us to build a library of all the patterns exhibited by physicians' time-evolving eye movement series (scanpaths) and each eye movement pattern essentially corresponds to a particular statistical regularity of the temporal-spatial properties inferred from multiple eye movement series. Thus each physician's eye movement time series can be characterized by a particular combination of a subset of these patterns from this library. To investigate the relationships between visual and verbal conceptual processing by analyzing the verbal descriptions, additional experts annotate the transcribed verbal descriptions using standardized semantic labels (thought units) that describe the process of creating a differential diagnosis from their domain knowledge (Habif, Jr., Chapman, Dinulos, & Zug, 2005). After time-aligning these thought units with the eye movements patterns, we discovered significant correlations between them. This results indicate that the patterns we extracted from eye movement data possess distinct and specific semantic meanings in terms of human capabilities of image understanding.

## Experiment

Subjects recruited for the eye tracking experiment belong to three groups based on their training level including 11 board-certified dermatologists (attending physicians), 4 dermatologists in training (residents) and 13 undergraduate lay people (novices). We also recruited physician assistant students who served as "trainees" in order to motivate dermatologists to verbalize their diagnosis reasoning using the Master-Apprentice scenario, which is known to be effective in eliciting detailed descriptions.

A SMI (Senso-Motoric Instruments) eye tracking apparatus was applied to display the stimuli at a resolution of

1680x1050 pixels for the collection of eye movement data and recording of verbal descriptions. The eye tracker was running at 50 Hz sampling rate and has accuracy of 0.5° visual angle. The subjects viewed the medical images binocularly at a distance of about 60 cm. The experiment was conducted in an eye tracking laboratory with ambient light.

A set of 42 dermatological images, each representing a different diagnosis, was selected for the study. These images were presented to subjects on the monitor. Medical professionals were instructed to examine and describe each image to the students while working towards a diagnosis, as if teaching. The experiment lasted approximately 1 hour. The medical professionals were instructed not only to view the medical images and make a diagnosis, but also to describe what they see as well as their thought processes leading them to the diagnosis. The novice observers were instructed to examine the images and offer a detailed description as if describing to their doctors over the phone. Both eye movements and verbal descriptions were recorded for the viewing durations controlled by each subject. The experiment started with a 13-point calibration and the calibration was validated after every 10 images. Calibration is accepted if its variance is less than 0.5°. The audio recordings of the verbal descriptions from the dermatologists were transcribed and annotated.

An annotation study was conducted on the transcripts to investigate the semantic interpretations of the estimated eye movement patterns. During annotation two highly trained dermatologists identified 9 thought units. A thought unit is a single word or group of words that receives a descriptive label based on its semantic role in the diagnostic process. The thought unit labels are patient demographics (DEM), body location (LOC), configuration (CON), distribution (DIS), primary morphology (PRI), secondary morphology (SEC), differential diagnosis (DIF), final diagnosis (Dx), and recommendations (REC). Words not belonging to a thought unit were designated as 'None'. These two physicians annotated transcribed verbal descriptions with these thought units. The annotation were then time-aligned with eye movement patterns. Using this method, each unit of eye movement data, which is composed of a fixation and its successive saccade, receives two labels: one is its pattern indicator inferred by the model and the other is its time-aligned thought unit annotated through the consensus of multiple experts. This result allows us to interpret the eye movement patterns by measuring the correspondence between them and the thought units.

## Hierarchical Dynamical Model

A hierarchically-structured dynamical model was developed to capture both the common eye movement patterns shared among multiple expertise-specific groups of subjects and unique eye movement patterns exhibited by individuals. The hierarchical beta processes proposed by Thibaux et al.(Thibaux & Jordan, 2007) as a prior distribution of our model provides the flexibility of discovering more patterns as new eye movement data are observed. Since fixation and

$\{(\theta_{jk}, p_{ijk})\}$  as subject  $i$ 's personal subset of eye movement patterns given group  $j$ , as shown in Figure 1.

The transition distribution  $\pi_{ij} = \{\pi_{z_q(ij)}\}$  of the hidden Markov model at the bottom level governs the transitions between the  $i^{th}$  subject's personal subset of eye movement patterns  $\theta_{jk}$  of group  $j$ . It is determined by the element-wise multiplication between the eye movement subset  $\{p_{ijk}\}$  of subject  $i$  in group  $j$  and the gamma-distributed random variables  $\{e_{ijk}\}$ :

$$e_{ijk}|\gamma_j \sim \text{Gamma}(\gamma_j, 1) \quad (5)$$

$$\pi_{ij} \propto E_{ij} \otimes P_{ij} \quad (6)$$

where  $E_{ij} = [e_{ij1}, \dots, e_{ijK_j}]$ . So the effective dimensionality of  $\pi_{ij}$  is determined by  $P_{ij}$ , which is inferred from observations.

We use Markov chain Monte Carlo sampler to do the posterior inference over this model. In one iteration of the sampler, each latent variable is visited and assigned a value by drawing from the distribution of that variable conditional on the assignments to all other latent variables as well as the observation. In particular, based on the sampling algorithm proposed in (Thibaux & Jordan, 2007), we developed a Gibbs sampling solution to the hierarchical beta processes part of the model.

## Results and Discussion

In Figure 2, we illustrate one set of observed data and estimating processes from the framework of the 11 dermatologists diagnosing a case of a skin manifestation of endocarditis. In the medical image, there are multiple skin lesions spreading over the thumb nail and tip, the two parts of index finger and the middle finger as marked in (b) of Figure 2. A primary abnormality is on the thumb tip. The scanpaths in Figure 3a (i) indicate that dermatologists fixated on the primary abnormality heavily and switch their visual attention actively between and within the primary and secondary findings. The estimated patterns are color-coded as panels shown in (d) of Figure 2. These panels describe the time-evolving manner in which each individual alters eye movement patterns at the individual level.

Pattern occurrence and thought unit alignment resulted in assignment of each fixation to a specific pattern and to a thought unit (or None). Initial integration of eye movement patterns with thought units was accomplished by calculating correspondence in Figure 4. Analysis shows, for example, that primary morphology (PRI) is closely related to the combination of two specific patterns: Pattern 2 is characterized by fixations switching between the primary and the different secondary abnormalities; and Pattern 7 by long fixations only on the primary abnormality. These patterns suggest dermatologists were seeking meaningful ways to integrate these two findings for some principled reasons, although these informative findings are separable in the sense that they are operationally defined and measured independently of one another. Pattern 7 has strong relationship to location (LOC) which ap-

(ii) shows the transition probability matrices of the nine eye movement patterns within the six scanpaths during diagnosis, which indicate the patterns are persistent. In (iii) the eye movement patterns are segmented from these corresponding scanpaths.

(b) Six inferred eye movement patterns from the 4 residents. In (i) the scanpaths of the 4 residents. (ii) shows the transition probability matrices of six eye movement patterns. In (iii) the eye movement patterns are segmented from these 4 scanpaths.

(c) Sixteen inferred eye movement patterns from the 13 novices. In (i) the transition probability matrices of the sixteen eye movement patterns, which suggest novices' visual behaviors are not persistent. In (ii) the patterns are segmented from these 7 scanpaths.

Figure 3: The inferred eye movement patterns of the three expertise-specific groups. Each observation unit of the eye movement sequences is composed of 4 components: fixation location (xy coordinate), fixation duration and saccade amplitude. We then apply our model on these sequential data to reveal the subtlety of the behavioral patterns varying over time. The inferred patterns were derived with 4 chains of 55000 sampling iterations. The color coding specifies the segments of each specific pattern.

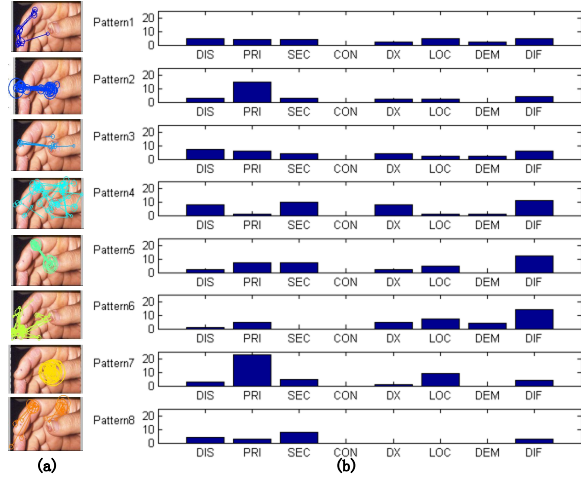

Figure 4: Correspondence between the 8 eye movement patterns of the 11 attendings (the rows) and their 8 thought units (the columns). (a) the representative patterns. (b) histograms show the corresponding relationship between discovered eye movement patterns and annotated thought units. For each pattern we plotted the counts of fixations which are labeled as the 9 thought units.

pears to correspond to the primary morphology location. Pattern 4 consists of scanpath segments which are characterized by shorter fixation durations and longer saccades. This scanning behavior strongly corresponds to thought units, including distribution (DIS), secondary morphology (SEC), diagnosis (DX) and differential diagnosis (DIF). Scanning pattern coupled with thought unit DX is possibly related to confirmation of secondary findings to support or rule out diagnostic hypotheses.

Some similar patterns also emerged in the resident group but is lacking in the novice group as shown in Figure 3b. This suggests that experts, equipped with domain knowledge organized in finer gradations of functional categories, can discriminate the significance of their findings in a particular context. In contrast, in Figure 3c the novices failed to do so, although they perceive the same abnormalities too. Compare Figure 3a (ii), Figure 3b (ii) and Figure 3c (i), the difference between the transition probability matrices of the three expertise-specific groups suggests professionals' eye movement patterns are more persistent than the novices'.

These results suggest that there exist structural regularities of experts' diagnostic-reasoning processes, and such perceptual and conceptual processing regularities can be captured and manifested through experts' eye movements. This is consistent with previous empirical studies (Patel, Arocha, & Kaufman, 2001). These discovered stereotypical eye movement patterns indicate that experts are able to rapidly invoke the appropriate specific knowledge and expertise, and initially detect a general pattern of disease. These capabilities lead them to a gross anatomic localization and narrow down the possible interpretations. On the other hand, novices have hard

Figure 5: Quantitative performance evaluations. (a) The likelihood-value plots of a Gaussian mixture model, a hidden Markov model and our model after 55000 sampling iterations on our data-set. (b) The histogram of the fixation duration distributions of the 15 professionals (attendings and residents) and our model's simulations over 42 images. (c) The histograms of the saccade amplitude distributions of the 15 professionals and our model's simulations over 42 images.

time to focus on the important structures and are more likely to maintain inappropriate interpretations.

To measure performance, we compared the log-likelihood values among our model, a hidden Markov model (HMM) and a Gaussian mixture model (GMM) as shown in Fig. 5 (a). To implement the HMM and GMM, we have to assume each eye movement sequence exhibits the same set of patterns. The log-likelihood values of our model and the GMM are 4000 vs. 300, which indicates our model fits the observation better. One possible cause is that the GMM makes a strong assumption that the eye movement data are independent which is hardly true. On the contrary, our model only assumes that the eye movement patterns are exchangeable in order. Additionally, our model and the HMM take sequential information of eye movements into account. We visualized the eye movement patterns from HMM and GMM in Fig. 6 (b)-(c) and make a comparison with our model's results in Fig. 6 (a). In Fig. 5 (b)-(c), our model generated 7356 fixation-saccade units to simulate the 15 professionals. It is worth noting that this result also validates the discovered eye movement patterns. Such simulation requires us to generate a set of realizations of eye movement patterns first from the hierarchical prior, simulate multiple possible sequences of these patterns, and then draw fixation-saccade samples from them.

## Conclusions

Our approach identified and semantically interpreted both stereotypical and idiosyncratic expertise-specific eye move-

ment patterns that only exist over time. In our future work, the discovered eye movement patterns will be related to image features by projecting the patterns from their temporal-spatial space into the image feature space. We will not only identify the most valuable image feature sets leading to a correct diagnosis but also uncover how a particular feature's importance changes over the course of the diagnostic reasoning process. These discoveries will provide training information to novices on how to look for relevant image features. Evaluation of a subject's expertise level is another future study. We can identify the expertise level given a subject's visual interaction with test images through calculating the model's posterior probability. Compared to simply calculating diagnosis error rates to evaluate expertise level, our approach can unveil which diagnostic reasoning steps lead to wrong diagnosis and the possible cognitive factors such as misconception, miscategorization and misperception, and form the basis of support systems.

## Abstract

Although musical training has been correlated with modulations of early perceptual and attentional processes, the majority of investigations neglect the possibility of cross modality enhancements. We investigated the effects of musical training by measuring spatial and temporal attention in a temporal order judgment task in auditory, visual, and crossmodal conditions with and without non-predictive cues. In Experiment 1, musicians had lower detection thresholds when compared to controls in all conditions (marginal in auditory). Experiment 2 showed mixed findings, with musicians demonstrating reduced capture from visual cues on the visual task compared to controls, and lower detection thresholds on the auditory task with visual cues. Adding spatial cues to the temporal order judgment tasks increased temporal thresholds for both groups, but only when they occurred within the same modality as the task, and not when presented in a different modality. The findings support both supramodal and segregated accounts of attentional resources.

**Keywords:** attention; perception; musicians; temporal order judgment; multisensory; visual; auditory; crossmodal

## Introduction

The human attentional system is impressively competent at processing information, considering how the efficiency and selectivity of attention facilitates perception and goal directed behavior amidst a constant plethora of stimuli. Interestingly, the neurological underpinnings of attention may change under certain conditions. This “plasticity” has been associated with compensations for losses in one sensory modality with enhancements in another modality (Röder et al., 1999). Furthermore, improved behavioral performance may also occur as a side effect of specific activities or hobbies such as video game playing (Granek, Gorbet, & Sergio, 2010; Green, Li, & Bavelier, 2010, but see Boot, Blakely, & Simons, 2011) and musical training (Hodges, Hairston, & Burdette, 2005; Lim & Sinnett, 2011).

Although the topic of non-musical cognitive benefits (e.g., mathematics, spatial-reasoning and linguistics) occurring as a result of musical training has been the focus of much research (for a summary, see Rauscher, 2003), there has been less emphasis on the effects of precise mechanisms of attention and perception. There is evidence from numerous studies conducted with musicians suggesting greater neuroplasticity when compared with non-musicians (see for example, Gaser & Schlaug, 2003; Münte, Altenmüller, & Jäncke, 2002). Although it should be noted

that these brain differences could equally be attributed to a predisposition that leads people to become musicians, rather than any specific training related enhancement. Even so, behavioral evidence from studies comparing musicians to non-musicians demonstrates improved perceptual abilities on various tasks in different modalities. These have included visual perceptual speed and discrimination (Helmbold, Rammsayer, & Altenmüller, 2005; Patston, Hogg, & Tippet, 2007) as well as auditory temporal discrimination (Hodges et al., 2005; Jones & Yee, 1997).

These studies also highlight an interesting possibility of training effects on attention: crossmodal enhancements (e.g., visual enhancements after auditory training). Some authors have suggested that the attentional system operates in a supramodal fashion, with all senses having access to a single reservoir of attentional resources (see Farah, Wong, Monheit, & Morrow, 1989; Pavani, Husain, Ládavas, & Driver, 2004; but see also Sinnett, Costa, & Soto-Faraco, 2006; C Spence & Driver, 1996; Wickens, 1984, for examples of a segregated attentional system). Thus, by testing musicians for enhanced attentional and perceptual capabilities in the visual modality, we can indirectly assess whether training in one sense (i.e., auditory musical training) leads to performance enhancements in another. This would provide support for a supramodal attentional system, and would closely align with recent investigations involving video game players, where auditory enhancements were observed despite the training being mostly visual based (Donohue, Woldorff, & Mitroff, 2010; Green, Pouget, & Bavelier, 2010).

The temporal order judgment (TOJ) task is an ideal tool to assess temporal processing differences between musicians and non-musicians. More importantly, the TOJ task can be presented under both unimodal and crossmodal conditions. The task requires participants to determine the correct order of subsequently presented stimuli, and allows for two measures of perceptual processing to be calculated: the just noticeable difference (JND), and the point of subjective simultaneity (PSS). The JND is a measure of the resolution or threshold of temporal discrimination, while the PSS is the time in which one stimulus can be presented before the other such that they are still perceived as occurring simultaneously (e.g., in a crossmodal task, it can indicate whether auditory or visual stimuli must be presented first for them to be perceived as simultaneous).

Humans are generally proficient at temporal discrimination. In studies examining within and cross-modal (visual, auditory, tactile) TOJs, Hirsh and Sherrick Jr. (1961) found that participants could discriminate temporal order between stimuli (JND) when presented as quickly as 20ms apart. Crucially, in crossmodal tasks (i.e., audiovisual presentations) the visual stimuli had to lead auditory stimuli by approximately 40-80ms for participants to perceive them as being presented simultaneously (PSS; see also Zampini, Shore, & Spence, 2003). Furthermore, research suggests that the resolution of temporal acuity is better in the auditory modality than in vision or touch (Chen & Yeh, 2009).

Given the efficacy at which humans can discriminate temporally, it is worth noting that significant gains or losses in TOJ performance can occur as a result of brain injury (Sinnett, Juncadella, Rafal, Azanon, & Soto-Faraco, 2007) or training (Donohue et al., 2010). This suggests that temporal perception is perhaps dependent on attentional mechanisms, and not purely a sensory-based process. Aside from studies showing *enhancements* on TOJs in video game players (e.g., Donohue et al., 2010), recent research has extended findings of better performance (lower JNDs) in the auditory modality to musical-conductors (Hodges et al., 2005) and in the visual modality to performing-musicians (Lim & Sinnett, 2011). Nevertheless, it is worth noting that research with musicians has not yet looked at crossmodal TOJs and the possibility that musical training, mostly auditory in nature, might have effects on visual TOJs.

Expert musicians were compared with non-musicians on a series of TOJ tasks that were presented under unimodal (visual or auditory), or crossmodal conditions. Given evidence from previous research, we expected to see lower JND scores for musicians when compared with controls in all conditions, but did not expect any differences in PSS scores.

## Experiment 1

### Participants

Twenty musicians (age =  $28 \pm 12$ ; 5 females) were recruited from the music department at the University of Hawaii at Manoa, local music studios, and through flyers. Musicians were required to have at least three years of formal training in music, and to have a regular practice schedule of at least six hours/week over the past six months. Control participants ( $n = 20$ ; age =  $22 \pm 5$ , 16 females. Note, pooled t-test comparisons showed no differences between males and females for any of the conditions, all  $p > .1$ ) were recruited from undergraduate courses, and had little or no training in music. All participants received either \$10 or course credit for their participation. Ethical approval was obtained from the University's Committee on Human Subjects.

### Stimuli and Apparatus

The basic TOJ task involves presenting participants with two stimuli separated by variable time intervals, referred to

as the stimulus onset asynchrony (SOA). The SOA length is manipulated to increasing or decreasing intervals that correspondingly makes the task easier or harder. A staircase approach was used in this experiment to adjust SOAs (see Stelmach & Herdman, 1991). The SOA started at 167ms and, for each successive trial, either decreased or increased (by 16.7ms) in a stepwise manner dependent on whether the participant answered the previous trial correctly. As the experiment progressed, each trial's SOA decreased making the order of occurrence difficult to determine. It can be inferred then, that as time progresses, changes in stepwise direction (up and down) will increase, reflecting increasing uncertainty in the participant. The task terminates once a total of twelve turning points have occurred.

Stimuli were presented on a 21" iMac using Bootcamp and DMDX software. Participants were seated at an eye to monitor distance of approximately 60cm. Prior to each trial a fixation-cross ( $0.5^\circ$ ) flanked by two square placeholders ( $1.4^\circ$ ) on the left and right was presented (see Figure 1). Stimuli for the visual task were horizontal and vertical lines ( $0.9^\circ$ ) and occurred centrally within the placeholders. For the auditory stimuli, processed samples of a dog and crow sound (350ms) were used (played at approximately 75db). In the crossmodal condition, the visual stimulus consisted of a black square ( $0.9^\circ$ ) within the placeholder, whereas the auditory stimulus was 50ms of white noise.

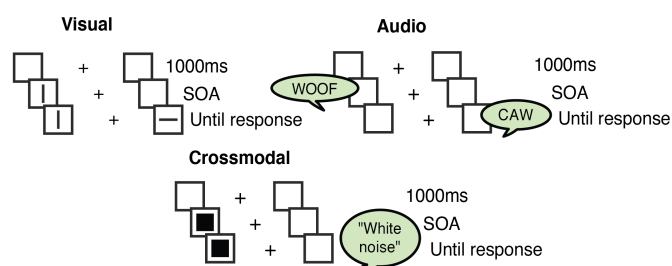

Figure 1. Stimuli for the three TOJ tasks in Experiment 1.

### Procedure

In all three conditions participants made unspeeded responses signaling which stimulus they believed had appeared first using one of two keyboard buttons. Onscreen instructions were presented first, followed by a short sequence of practice trials that included accuracy feedback. Presentation side (i.e., left or right) and stimuli order (e.g., horizontal or vertical line first) were randomized, as was the order of experimental conditions (e.g., audio, visual, crossmodal) for each participant.

### Results

Calculations of the JND and PSS were based on approaches used by previous studies (C. Spence, Baddeley, Zampini, James, & Shore, 2003; Stelmach & Herdman, 1991). Data from musicians and controls were pooled into separate groups. The average ratio of responses "horizontal line first" (e.g., for visual condition; for auditory condition ratio of crow sounds were used, etc.) was then plotted as a function

of the time in which the horizontal line preceded the vertical line. Data was then fit using a logistic function:

$$f(x, a, b) = \frac{1}{1 + \exp(-(x - a)/b)}$$

which was then used to obtain the JND and PSS estimates (similar to C. Spence et al., 2003). The PSS corresponds to parameter  $a$ , and is usually expected to fall at 0ms (or close) in unimodal conditions, as there is no reason to assume that a particular visual (or auditory) stimulus would be preferred over the other. It is more informative in the crossmodal condition as any shift would indicate whether auditory or visual events must precede the other for subjective simultaneity to be perceived. The JND relates to parameter  $b$ , which is adjusted to obtain the 75% JND as follow:

$$\text{JND}_{75} = \ln 3 \cdot b$$

Given that data was pooled within each group (musicians and controls), confidence intervals (95%) for each group's estimates and comparison p-values were calculated using a parametric bootstrap method with 999 replications (Efron & Tibshirani, 1993; for similar use of the bootstrap, see Azañón & Soto-Faraco, 2007).

**Auditory condition** Differences between musicians and controls were non-significant for PSS (2ms, CI = -8 to 12ms; vs. 9ms, CI = 1 to 16ms;  $p = 0.31$ ; respectively) and approaching significance for JND scores (43ms, CI = 34 to 53ms; and 56ms, CI = 45 to 68ms;  $p = 0.07$ ).

**Visual condition** The average PSS score for musicians' was significantly lower than controls by 10ms (-4ms, CI = -9 to 2ms; vs. -14ms, CI = -22 to 5ms;  $p = 0.037$ ; respectively), with negative PSS values indicating a possible bias in responses towards horizontal lines. The average JND score for musicians' was also significantly lower than controls by 18ms (29ms, CI = 23 to 35ms; vs. 47ms, CI = 37 to 56ms;  $p = 0.006$ ).

**Crossmodal condition** Differences between musicians and controls were non-significant for PSS (-43ms, CI = -60 to -25ms; and -63ms, CI = -93 to -30ms;  $p = 0.261$ ; respectively). It is worth noting that the negative PSS results indicate a bias in response towards the auditory modality (visual stimuli needed to be presented prior to auditory stimuli for simultaneity to be perceived). Musicians' average JND score was significantly lower than controls by 59ms (104ms, CI = 80 to 127ms; and 163ms, CI = 112 to 207ms;  $p = 0.021$ ).

## Discussion

There are two important findings that merit discussion. First, with the exception of the visual condition, no differences were observed for PSS between musicians and non-musicians. In the visual condition it is possible that there was a small bias towards horizontal lines for musicians, but note that performance hovered around zero as expected. The largest PSS differences were seen in the crossmodal condition. Specifically, visual stimuli had to precede auditory stimuli for both musicians and controls (by 43 and 63ms, see Figure 2) for them to be perceived as

occurring simultaneously (Hirsh & Sherrick Jr, 1961; Zampini et al., 2003).

Secondly, the temporal threshold for musicians was significantly lower in all conditions (visual, auditory, and crossmodal), although it should be noted that only marginal significance was observed in the auditory condition ( $p = 0.07$ ). Given that musical training is largely auditory in nature, a more robust difference in auditory JND scores was expected. It is possible that the "realistic" auditory stimuli used in our experiment may be more difficult than simpler tones, and therefore any effect might be somewhat masked. Furthermore, it might be possible that as the sounds were non-tonal, musicians may not have had a distinct advantage. Lastly, given that humans discriminate temporal events better in the auditory modality when compared to the visual modality, it is possible that performance was similar due to a ceiling effect.

Lastly, and also supported by Zampini et al. (2003), JND scores for the crossmodal condition increased nearly three-fold when compared to unimodal conditions, demonstrating that the task was more difficult.

Figure 2. PSS and JND scores for Experiment 1. For PSS scores, positive indicates stimuli crow/horizontal/audio, and negative indicates dog/vertical/visual stimuli appearing first. Error bars indicate 95% CIs.

## Experiment 2

Spatial cues can also be incorporated into the TOJ tasks, allowing for a measure of how attention is oriented and captured. The presentation of exogenous cues prior to stimuli onset in a TOJ task creates a 'prior entry' effect, where attention is directed towards the cued side and subsequently affects performance on the task, regardless of whether or not the cue is predictive of location (see Shore, Spence, & Klein, 2001)

Exogenous orienting can occur from any stimulus that causes a reflexive or automatic capture of attention (e.g., bright flashes, loud sounds, etc.). By presenting an

exogenous cue in the TOJ task prior to the onset of stimuli, the cued side will be perceived as having occurred first. The PSS score then indicates how much in advance the uncued side must be presented before the cued for simultaneity to be perceived (see Shore et al., 2001). Thus, Experiment 2 included all of the unimodal conditions of Experiment 1 with the addition of within and crossmodal cues to determine whether spatial attention would differ between musicians and non-musicians. If musical training can improve spatial and temporal processing, it would be expected that musicians should have a smaller orienting effect, which would be manifested in lower PSS and JND scores than controls across all conditions. This would be indicative of improved temporal processing (JND) and less influence from peripheral distraction (smaller PSS). Furthermore, to our awareness this would be the first time multimodal cued TOJ tasks were conducted on musicians.

### Participants, Apparatus, and Procedure

The same participants from Experiment 1 also took part in Exp. 2 (all conditions from both experiments were interleaved and fully randomized). The discussion of the experiments is separated here for ease of understanding.

Stimuli and procedure were identical to those in Exp. 1, except for the addition of exogenous non-predictive cues in all conditions. In the visual condition, the cue was created by thickening the placeholder box of the respective side to a thickness of 4 pixels for 45ms. In the auditory condition, the cue was a laterally presented 500Hz sine wave lasting 45ms. The crossmodal condition consisted of two tasks: the first was an auditory TOJ task with visual cues, while the second was a visual TOJ task with auditory cues. All cues were randomly determined and had an equal chance of validly or invalidly cuing the target stimuli.

### Results

The JND and PSS scores were calculated using similar methods as in Exp. 1, by pooling musicians and control participants into two separate groups. For each of the four conditions, data from the two groups were fit to a weighted logistic function according to which stimulus was cued (e.g., horizontal/vertical bar, dog/crow sound, etc). The overall PSS value for each condition was computed as half the distance between each of the PSS values for the two curves. The average of the two JND values for each curve was used as the overall JND score. This approach essentially calculates the PSS for each type of stimulus cued, and averages the effect (see Shore et al., 2001). In order to gauge the influence of the cue, the two fitted curves were compared against one another. Logically, if the two curves were to map out on top of one another then the average would be 0 (PSS), as would be expected if the cue did not have any effect (assuming no bias for one stimulus type or the other). Thus, the larger the difference between the logistic fits for each cue, the larger the PSS, and by extension the greater effect that the cues had in general. This can similarly be applied to the calculation of JND, although

as the slope, the JND scores are expected to be similar for each stimulus type.

**Unimodal Cues Auditory condition:** The magnitude of the PSS shifts was not significantly different between musicians and controls (23ms, CI = 12 to 37ms; vs. 29ms, CI = 17 to 42ms;  $p = 0.259$ ; respectively, see Figure 3). Similarly, there were no differences in JND scores between the two groups (92ms, CI = 77 to 110ms; vs. 109ms, CI = 93 to 125ms;  $p = 0.106$ ). **Visual condition:** The magnitude of PSS shifts was significantly lower for musicians than controls by 29ms (30ms, CI = 10 to 46ms; vs. 59ms, CI = 48 to 71ms;  $p = 0.023$ ). On the other hand, JND scores for both groups were not significantly different (80ms, CI = 63 to 93ms; vs. 84ms, CI = 75 to 96ms;  $p = 0.29$ ).

Figure 3. PSS and JND scores for Experiment 2. Asterisks indicate significant ( $p < .05$ ) between group differences. Error bars indicate 95% CIs.

**Crossmodal Cues Auditory TOJ with visual cues:** The magnitude of the PSS shifts did not significantly differ between musicians and controls (8ms, CI = 1 to 14ms; vs. 9ms, CI = 1 to 15ms;  $p = 0.39$ ; respectively). On the other hand, JND scores were significantly lower by 16ms for musicians compared to controls (47ms, CI = 42 to 56ms; vs. 63ms, CI = 53 to 73ms;  $p = 0.014$ ). **Visual TOJ with auditory cues:** The magnitude of the PSS shifts did not significantly differ between musicians and controls (10ms, CI = 6 to 14ms; vs. 13ms, CI = 8 to 18ms;  $p = 0.19$ ). Similarly, there were no differences in JND scores between the two groups (31ms, CI = 26 to 35ms; vs. 35ms, CI = 29 to 38ms;  $p = 0.088$ ).

**Cross experiment comparisons:** Further understanding of the cuing effects can be determined by comparing the results from the cued tasks in Experiment 2 to the no-cue unimodal tasks (auditory and visual) of Experiment 1. When doing so, JND differed for unimodal conditions but not for

crossmodal conditions. That is, the additional cues in Experiment 2 made the unimodal tasks harder for both musicians and non-musicians, as evidenced by longer temporal thresholds (JND) in both the auditory and visual modalities (all  $p < .01$ ). However, when the cues were presented in a separate modality (i.e., the crossmodal conditions of Exp. 2), JND scores were indistinguishable from the unimodal no cue conditions (Exp. 1) for both musicians and non-musicians (all  $p > .05$ ). Collectively, this may suggest that a difficult unimodal task can be made easier when presented as a crossmodal task (Sinnott et al., 2006; Sinnott et al., 2007; C Spence & Driver, 1996).

## Discussion

Robust findings from cross-experiment analyses broadly suggest that unimodal cues have detrimental effects on JND scores, whereas crossmodal cues do not. These results were similar for both musicians and controls. Excluding these cross experiment analyses, the only observed significant differences in Experiment 2 between musicians and controls were the lower PSS scores in the visual unimodal condition for musicians, and the lower JND score in the auditory-task/visual-cues condition for musicians. The lower PSS score indicates that musicians were captured less by the unimodal visual cues than non-musicians, while the lone JND difference seemingly suggests that crossmodal processing was easier for musicians, but only when judging temporal order for auditory targets that were cued visually.

## General Discussion

There are a number of important findings. To begin with, performance differences between musicians and controls were mixed in the auditory condition (musicians did have significantly lower JND scores in the auditory-task/visual-cues condition of Experiment 2, as well as marginally lower JNDs in the auditory condition in Experiment 1 [ $p = .07$ ], while the unimodal auditory condition of Experiment 2 was not significant). Thus, we do not see as strong a trend as Hodges et al. (2005), where auditory JND scores were significantly lower for musical conductors when compared to controls. This may be due to the use of different stimuli and experimental conditions. In the present experiment realistic sounds (dog and crow) were used, while auditory tones were used in Hodges et al.'s studies. Thus it is possible that pitch discrimination skills would not aid musicians in the auditory task used here. Furthermore, it is also possible that differences in auditory temporal processing may exist between conductors and performing musicians. It is worth noting however, that across all task types, JND scores for musicians were numerically lower than those for controls, although these differences were statistically significant in only four out of the seven conditions (Exp 1: auditory (marginal), visual, and crossmodal; Exp 2: Audio-task/visual cues).

Pertinent to the discussion is the tentative support for a supramodal account of attentional resources, supported by the fact that musicians outperformed controls on several

non-auditory related tasks, including smaller capture from visual cues, and lower JNDs for visual and crossmodal conditions (without cues). That is, it appears that musical training might have lead to improved visual processing. Having said that, as musical training involves much exposure to auditory stimuli, it was reasonable to expect enhancements in the auditory modality, although this was not consistently observed. Enhancements in the visual modality however, could be attributed to 1) better attentional resources, and/or 2) concomitant training in the visual modality from reading music while at the same time listening to and playing music, etc. Since we cannot rule out the second possibility however, these results can only be seen as tentative support for a supramodal account, pending further investigation with specific training conditions. Interestingly however, the robust findings of Experiment 2 where crossmodal PSS and JND scores were in fact lower than their unimodal counterparts (all  $p < .05$  and  $p < .001$ ; respectively), may provide stronger evidence for the exact opposite viewpoint: that is, a segregation of attentional systems (e.g., Sinnott et al., 2006; Wickens, 1984). Nevertheless, the current set of data makes it difficult to arrive at a decisive claim on either side of the debate, and may suggest a two-part attentional system that operates with both segregated and supramodal capacities. Indeed, it is likely that many previous findings supporting one theoretical account or the other may indeed be constrained by the varying methodologies used.

The segregated account is supported by the novel finding that was observed across both musician and control groups regarding the selective deficits in JND for only unimodal cues and not crossmodal cues. That is, when a within modality cue was added to the task, JND scores increased significantly for both musicians and control participants. However, when the cues were presented across modalities (i.e., a visual cue and an auditory TOJ task, or vice versa), performance was significantly better, and in fact did not differ from the no-cue conditions. This possibly suggests that the threshold of temporal detection may be robust to crossmodal distraction, while at the same time be vulnerable to distractions within the same modality.

As the between group differences in the auditory task in Experiment 1 were only marginally significant, this may suggest that auditory temporal acuity is less amenable to improvement through training (at least for the stimuli and task conditions used here), and that concomitant training effects are perhaps more robust in the visual domain. Importantly, the visual enhancements observed in JND in Experiment 1 lend support to the idea that attentional allocation, and therefore the improvement through training, may not be constrained within particular sensory modalities, but instead distributed to multiple modalities. Nevertheless, an important criticism of studies that used "trained" populations such as musicians and video game players, is the extent to which observed differences in experimental settings can actually be attributed to prior training. Boot et al. (2011), for instance, claimed that participants are often

aware of the purpose of the study as they are specifically recruited for their expertise, and that this awareness and potential motivational factor may very well influence performance. Unfortunately, our recruitment strategy for musicians did not allow us to keep them blind to the purpose of the study, and they may have been influenced by such knowledge. To this extent, our between group conclusions are largely speculative. Moreover, the nature of musical training in sighted individuals is in itself a multimodal experience, and further training studies would be better equipped to draw conclusions by controlling for the type of training each participant receives.

## Abstract

Although not currently a widely accepted notion, evidence suggests an anisotropy between horizontal and vertical orientations in visual processing. While there is evidence of an early neurological bias due to a greater number of cortical neurons tuned to the horizontal orientation, recent behavioral evidence suggests a “horizontal effect”, where performance for broadband horizontal stimuli is *worse* compared to vertical and oblique. Importantly however, this effect has only been observed for complex stimuli and is speculated to counterbalance for the greater occurrence of horizontal stimuli in the environment. In this experiment, we used a staircase temporal order judgment task in three spatial configurations (horizontal, vertical, and both) to test for 1) a bias towards either horizontal or vertical simple stimuli, and 2) whether performance would vary across different planes of stimuli presentation. A bias towards horizontal stimuli was observed, but only when presented in the horizontal plane. Theoretical implications are discussed.

**Keywords:** Horizontal bias; visual processing; anisotropy, stimulus orientation; temporal order judgment

## Introduction

Research has shown that in humans as well as many other species, visual (and tactile) stimuli are processed differently depending on their orientation. One of the more commonly observed biases in visual perception is a phenomenon termed the “oblique effect”, where stimuli presented in an oblique orientation are usually processed worse (i.e., in speeded detection, identification, resolution acuity and contrast sensitivity tests) than stimuli presented in the horizontal or vertical position (Appelle, 1972; Essock, 1980; for tactile, see Essock, Krebs, & Prather, 1997). Crucially, this phenomenon operates on at least two different levels. First, it has been linked causally to lower level vision, where it is attributed to differences in the number of cortical neurons in V1 tuned to stimulus orientation (Anzai, Bearse, Freeman, & Cai, 1995). Secondly, the effect also appears to be manifested in higher level cognitive processes such as memory, learning, and perception (for review, see Essock, 1980). The distinction between these two levels has in fact led to their classification as Class 1 and Class 2 oblique effects, respectively (Essock, 1980).

Apart from the well known oblique effect, studies that have attempted to compare anisotropies of horizontal and vertical orientations themselves against each other may not

have done so carefully (Hansen & Essock, 2004). It is worth noting that the current prevailing viewpoint is that horizontal and vertical stimuli are treated equally at the physiological level. Notwithstanding this dogma, there is considerable evidence suggesting that there is more neural circuitry in the visual cortex devoted to processing horizontal contours than vertical contours (Chapman & Bonhoeffer, 1998 (Figs. 1 and 2); Chapman, Stryker, & Bonhoeffer, 1996 (Figs. 1 and 2); Coppola, White, Fitzpatrick, & Purves, 1998; Mansfield, 1974; Mansfield & Ronner, 1978; Tiao & Blakemore, 1976). For instance, a study examining a large database of neurons in the cat’s striate cortex found that the largest population of cells are activated by orientations close to the horizontal position (Li, Peterson, & Freeman, 2003). Accordingly, it is curious that such a horizontal over vertical preference has not correspondingly been observed in behavioral tasks.

In fact, and despite the seeming neurological advantage for processing stimuli in the horizontal orientation, a study by Essock, DeFord, Hansen, and Sinai (2003) recently found diminished behavioral performance for horizontally presented stimuli (termed the “horizontal effect”). Furthermore, with complex “realistic” stimuli, they found that perceived orientation for broadband spatial content using horizontal, vertical, and oblique gratings was actually lowest for horizontal gratings, while oblique was instead seen best—a result seemingly contrary to the oblique effect, but solely at face value since the horizontal effect only appears to operate on complex stimuli. Interestingly, they explain these robust effects as being possibly due to a “whitening” mechanism that decreases the saliency of horizontal stimuli (which is argued to be most prevalent in natural scenes), thereby increasing the saliency of other broad-spectrum objects (such as predators, for instance).

Further research by Hansen and Essock (2004) replicated these findings in an experiment that used both simple and more complex “realistic” gratings. The classic “oblique effect” was seen with the simple gratings, whereas a “horizontal effect” (similar to Essock et al., 2003) was observed with the complex gratings. Additionally, the authors conducted an aggregate analysis of various natural scenes and found the prevalence of stimuli orientation in these scenes to be most prevalent in the horizontal orientation, then vertical, with the least prevalent being

oblique. They speculated that the horizontal effect may be a compensatory filter that at some level balances out for the greater abundance of such stimuli in the environment.

Hence, there appears to be evidence for both a bias towards, and a bias against horizontal oriented stimuli. That is, evidence at the physiological level suggests that the greater number of neurons tuned to horizontal orientations may lead to a bias in favor of horizontal detection. On the other hand, evidence also implicates the existence of a filter that may operate correctively against a bias towards greater occurrences of horizontal stimuli in the environment.

In light of these somewhat varying (but not mutually exclusive) viewpoints, several questions become relevant to the discussion. One is whether this “horizontal effect” is robust across all levels of perceptual processing. Recall that thus far the horizontal effect has only been observed with complex stimuli, therefore it is important to explore whether the same mechanism operates with simple stimuli, or if instead this mechanism only selectively operates in more complex “natural” scenes—as has been demonstrated in at least two studies (Essock et al., 2003; Hansen & Essock, 2004). Another issue is that, if this horizontal effect is somehow related to the prevalence of horizontal stimuli in natural scenes, might behavior change when presented with experimental layouts which contain more or less horizontal elements, and which are also holistically setup in a horizontal or vertical manner? Lastly, given that there appears to be a neurological bias towards detection of horizontally oriented stimuli as compared to vertically oriented (which to our awareness has never been demonstrated on behavioral measures), the question remains whether such a bias could in fact be detected at a behavioral level using simple stimuli? To better answer these questions, we designed an experiment consisting of a behavioral temporal detection task to test whether this bias exists with simple stimuli, using different experimental spatial layouts that contain varying elements of horizontal and vertical orientations.

The temporal order judgment task (TOJ) is an established psychophysical tool designed to assess the temporal processing of successively presented items. The task requires participants to determine the correct order of successively presented stimuli, and allows for two measures of perceptual processing to be calculated: the just noticeable difference (JND), and the point of subjective simultaneity (PSS). The former is a measure of the resolution or threshold of temporal discrimination, while the latter is the time in which one stimulus can be presented before the other such that they are still perceived as occurring simultaneously. Therefore, if a bias towards horizontal stimuli were to be observed, for instance, the PSS scores would indicate that the vertical stimuli must precede the horizontal (by a specific amount of time) for them to be perceived as occurring simultaneously.

It is worth noting that since humans are generally proficient at temporal discrimination (Hirsh & Sherrick Jr, 1961), the TOJ task is well suited for detecting small biases

in orientation processing. That is, using such a task would leave room for less error from extraneous variables such as task difficulty and interference from other cognitive processes that may come into play with other more complex stimuli and tasks.

For these reasons, the TOJ task appears to be particularly well suited for assessing threshold detection differences between horizontally and/or vertically presented stimuli. Subsequently, and to the best of our knowledge, this is the first time an adaptive step-function TOJ task has been used to investigate the anisotropy of stimulus orientation while also employing an adaptive staircase approach and the use of different experimental spatial configurations. The staircase approach will ensure that the majority of trials will occur at or close to threshold level.

In light of 1) existing neurological evidence for a horizontal bias, and 2) the lack of evidence for a countering “horizontal effect” for simple stimuli (the effect has only been observed for complex stimuli), we hypothesize that participants should be biased towards detecting horizontal stimuli better than vertical, although it is unclear whether the magnitude of this bias will be detectable here.

## Methods

### Participants

Participants ( $n = 33$ ; mean age =  $23 \pm 4$ ; 24 females) were recruited from undergraduate courses at the University of Hawaii at Manoa, and were offered course credit for their participation. All participants were naïve as to the purpose of the experiment and had normal or corrected to normal vision. Ethical approval was obtained from the University’s Committee on Human Subjects.

### Stimuli

Visual stimuli were presented on a 20”, Intel Core2Duo iMac using Bootcamp and DMDX software (Forster & Forster, 2003). Observers sat approximately 60 cm from the display. The targets in all tasks were vertical and horizontal lines that occurred within placeholder squares ( $2^\circ$  wide). These placeholders flanked a fixation cross in one of three different layouts (see Figure 1). These layouts corresponded to the three different tasks in this experiment.

### Procedure

Throughout each trial, the fixation cross and the two (in the horizontal and vertical layouts) or four (in the combined layouts) placeholders would remain on the display (see Figure 2). A target (either horizontal or vertical line, equiprobably) would appear in one of the place holders (also equiprobably) for a specified stimulus onset asynchrony (SOA) interval, followed by the other stimulus in the opposite place holder. The stimuli remained on the screen until participants then made an unspeeded forced choice response on the keyboard to indicate either “horizontal” or “vertical” first responses. An adaptation of Stelmach and Herdman’s (1991) step-function procedure was used to

determine the SOAs for each trial. Each trial began with an SOA of 167 ms. Depending on whether a correct or incorrect response was made, the SOA would respectively increase or decrease (by 16.7 ms) on the next trial. The experiment terminated after a total of 12 correct/incorrect reversals occurred.

In all three tasks, participants were first presented with onscreen instructions followed by a short sequence of practice trials, with accuracy feedback directly appearing after each trial. The experimenter monitored completion of the practice trials and ensured that participants understood the task requirements (repeating the practice session if necessary). Target presentation location (i.e., left, right, up or down) and stimuli order (e.g., horizontal or vertical line first) were randomized, as was the order of experimental tasks (i.e., horizontal, vertical, and combined) for each participant.

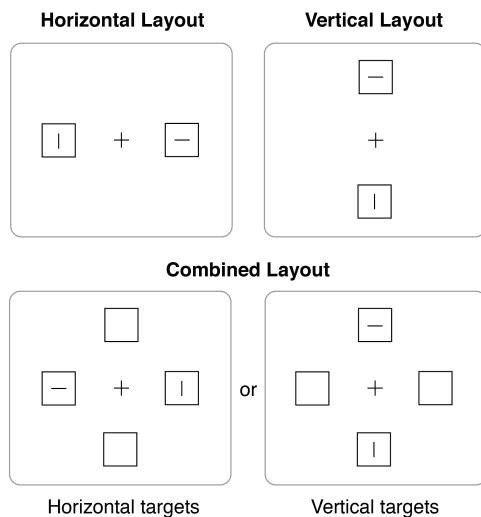

Figure 1. The three TOJ configurations. Each participant was tested on all three configurations. Note that on each trial in the combined layout, the task could occur on either the horizontal or vertical plane.

Figure 2. Example stimuli and time course for the TOJ task (horizontal layout displayed here; similar sequence occurred for the other layouts).

## Results

The results from the TOJ task can be analyzed to determine the point of subjective simultaneity (PSS). The PSS is the point in time in which one stimulus can be presented before the other such that they are still perceived as being

simultaneous. Note that this measure is usually expected to fall at 0 ms (or close to it, unless there is a bias in response). Additionally, the minimum amount of time that must separate two events such that they are still accurately perceived as occurring successively (and not simultaneously) can be measured. This is referred to as the just noticeable difference (JND) and is essentially a measure of the resolution or threshold of temporal discrimination. For this study we are more interested in the PSS than the JND, as the PSS can provide a measure of bias towards horizontal or vertical stimuli.

The calculation of both the PSS and JND was based on approaches used by previous research (for examples of other studies using similar methodologies and analyses, see Spence, Baddeley, Zampini, James, & Shore, 2003; Stelmach & Herdman, 1991). To begin with, the data from each of the three tasks were pooled together according to layout. The average ratio of responses "horizontal line first" was then plotted as a function of the time in which the horizontal line preceded the vertical line. For TOJ tasks, response rates typically follow a sigmoidal curve, from which data can be fit using the following logistic function:

$$f(x, a, b) = \frac{1}{1 + \exp(-(x - a)/b)}$$

where the response rate is mapped as a function of the SOA ( $x$ ), with two estimated parameters of central tendency ( $a$ ) and slope ( $b$ ; see C. Spence, et al., 2003).

Data was fit to this equation by minimizing the weighted sum of squares to obtain parameter estimates for  $a$  and  $b$ . The PSS, or SOA at which the participants considered the two stimuli to be simultaneous, corresponds to parameter  $a$ . The JND, or smallest interval between two stimuli giving a correct judgment probability 75% of the time, is directly related to parameter  $b$  (analogous to the slope of the central portion of logistic function). Here the relationship is that a steep slope will result in a smaller JND, and a shallow slope in a larger JND.

Figure 3. A typical TOJ response curve. Any bias in performance would be observed as a lateral shift of the curve, and correspondingly, the PSS score.

Confidence intervals (95%) for each group statistic were calculated using a parametric bootstrap method with 999 replications (for a similar bootstrap method employed in a TOJ study, see Azañón & Soto-Faraco, 2007; for an overview of the bootstrap, see Efron & Tibshirani, 1993). Given the unique nature of our dataset, we used a parametric bootstrap resampling approach for the statistical analyses due to particular benefits over more traditional means. That is, due to the varied number of trial observations and different response patterns resulting from the adaptive staircase paradigm, each individual's data points could vary significantly, and fitting the logistic function individually did not always converge or yield meaningful estimates. Thus, pooling data from all participants in each layout allowed for a better distribution of scores across all SOAs for the logistic fit from which we were able to extrapolate the overall PSS and JND values for each task using the above functions, and to subsequently estimate population parameters using bootstrapped confidence intervals<sup>1</sup>.

Furthermore, and in order to determine whether a PSS score, or bias towards a particular orientation was significant, we compared the results from each layout to a logistic function with identical parameters and characteristics, with the exception that the PSS was centered on 0 ms. This effectively allowed us evaluate the null hypothesis of whether the bias was significantly different from zero<sup>2</sup>.

### PSS scores

**Horizontal layout.** In the horizontal only configuration, there was a significant bias towards responding horizontal first ( $p < .05$ ). The magnitude of the PSS bias was 7ms, meaning that for horizontal and vertical lines to be perceived as occurring simultaneously, vertical lines had to precede horizontal lines by 7ms on average (CI = 1 to 12ms).

**Vertical layout.** In the vertical only configuration, the PSS was not significantly different than zero ( $p = 0.3$ ), with a 2ms bias towards horizontal first responses (CI = -3 to 8ms).

**Combined layout.** In the combined layout, when pooling the data across layouts, there was a significant PSS bias towards responding horizontal line first ( $p < .05$ ). The magnitude of this bias was 6ms (CI = 1 to 10 ms).

As the combined layout consisted of trials where the horizontal and vertical targets only occurred in either the horizontal or vertical plane (see Figure 1), we conducted a further analysis between these two sub-types to determine any differences in performance within the layout.

The PSS for the horizontal trials was significantly biased towards the horizontal stimulus ( $p < .05$ ). The magnitude of

Figure 4. Parametric bootstrap resamples for each configuration (red lines denote 95% confidence intervals).

Positive PSS scores reflect a bias towards horizontal stimuli, whereas negative scores reflect a bias towards vertical. A zero PSS score would indicate lack of bias for either type of stimuli.

<sup>1</sup> Note that there is a growing consensus that certain exploratory techniques such as confidence intervals may be as useful as confirmatory ones (for a review, see Loftus & Masson, 1994). For details on bootstrap CIs, see Efron & Gong (1983).

<sup>2</sup> Given the existence of prior evidence for a bias towards horizontal orientations over vertical (see Introduction), a bootstrap comparison analogous to a one tailed  $t$ -test was used throughout.

this bias was 10ms (CI = 4 to 17 ms). In contrast, the PSS for the vertical trials not significantly different than zero ( $p = 0.4$ ) with a 1ms bias towards horizontal stimulus (CI = -4 to 7ms).

Given that both trials occurred within the same task configuration, we also ran a direct parametric bootstrap comparison test between the horizontal and vertical trials, and found that horizontal biases between the two trial types, as reflected by the magnitude of the PSS shifts (10ms vs 1ms) was significantly different ( $p < .05$ ).

Figure 5. PSS (positive values indicate bias towards horizontal stimulus; negative towards vertical) and JND scores across the three tasks, with 95% confidence intervals.

### JND scores

Across all conditions, JND scores were 40ms on average, and as expected, scores did not significantly vary (all  $p > 0.1$ ). This confirms that the detection thresholds were similar in all configurations (see Figure 4), and that PSS differences across horizontal and vertical tasks were unlikely to be caused by extraneous variables such as the difficulty levels of the tasks.

### Discussion

Several novel findings were seen in this experiment. To our awareness, this is the first empirical investigation to examine performance among thousands of trials (the majority of them near threshold level SOAs) in a TOJ task to explore orientation bias between horizontal and vertical simple stimuli. We believe that this unique setup may have

allowed for the detection of orientation anisotropy between horizontal and vertical stimuli. Accordingly, an average bias of 9ms towards horizontal lines was observed during a horizontal task, suggesting that the vertical line must be presented on average 9ms before the horizontal line for simultaneity to be perceived. Thus, all things being equal, the horizontal orientation is preferred and appears to be processed more efficiently. Furthermore, this anisotropy was non-symmetrical in nature. That is, even in counterbalanced configurations with vertical placeholders, no similar bias towards vertical lines was observed (in fact, a very slight bias of 2ms on average towards horizontal lines was still observed in the vertical tasks, although this was not significant).

These findings are important for at least two reasons. First, in contrast to the prevailing view of equal treatment by the visual system for horizontal and vertical orientations, there is evidence that there may actually be an anisotropy between horizontal and vertical orientations. In fact, a bias towards the horizontal orientation has been observed at the neurological level in the visual cortex of several non-human animals (Chapman et al., 1996; Coppola et al., 1998; Li et al., 2003; Mansfield, 1974; Tiao & Blakemore, 1976) with visual systems expected to be ontogenetically analogous to humans. Thus our findings are the first to show a bias towards horizontally oriented simple stimulus, which speculatively may align with such findings of larger observed proportions of horizontally tuned cortical neurons. As stated by Essock et al. (2003), this result may not have been observed in the past due to the difficulty in obtaining large and unbiased samples. The use of the adaptive staircase design and parametric bootstrap analysis used here, however, offers a way of addressing this problem. Nevertheless, it is curious finding that we only observed this bias in the presence of a horizontal “plane”.

The fact that similar biases were only seen when performing the horizontal task (both in the horizontal and combined layouts) may suggest two possibilities: first, that the process of performing a horizontal task may facilitate the horizontal bias. The second possibility is that the process of performing a vertical task may inhibit the horizontal bias. Whether facilitation or inhibition (or both) is/are responsible for these results is beyond the scope of this paper. However, given the fact there we observed small (but non-significant) biases towards horizontal stimuli even for vertical tasks, we speculate that the inhibition argument may carry more weight.

Moreover, these results may dovetail with findings relating to the prevalence of horizons in natural scene layouts. Indeed, much of the world is sprawled out in a horizontal fashion due to the constraint of gravity, and it is thus conceivable for organisms to both have evolved visual systems that differentially process horizontal configurations for greater efficiency, and also to behaviorally adapt to such regularities in the natural world. Indeed, several examinations have been conducted on the statistical frequency of visual orientations in both naturalistic and

man-made environments, and have found greater occurrences of horizontally oriented stimuli (Baddeley & Hancock, 1991; Hansen & Essock, 2004; Keil & Cristóbal, 2000). To further add to this picture, learning may also play a vital role, as there is evidence of cross-cultural differences in visual anisotropies that can not be accounted for by mere exposure to a *carpentered* environment (Timney & Muir, 1976).

Interestingly, our findings can also be seen in a way to supplement the “horizontal effect”, which has been observed with complex broadband stimuli (Essock et al., 2003; Hansen & Essock, 2004). Specifically, in these studies the evidence for a “whitening” of (i.e., bias against) horizontally perceived orientations only occurred when complex broadband stimuli were used. From this study, we have confirmed that not only does the “horizontal effect” not apply to simple stimuli (lines), but also revealed the opposite: that in fact a bias towards simple horizontal stimuli can occur under conditions when a horizontal plane or task is present. Consequently, it is clear that comprehensive theoretical accounts of visual processing must ultimately reconcile and take into account these different phenomenological findings and the respective mechanisms responsible for such multi-level anisotropies.

## Abstract

Raven's Progressive Matrices (Raven, Raven, & Court, 1998) is one of the most prevalent assays of fluid intelligence; however, most theoretical accounts of Raven's focus on producing models which can generate the correct answer but do not fit human performance data. We provide a computational-level theory which interprets rule induction in Raven's as Bayesian inference. The model computes the posterior probability of each rule in the set of possible rule hypotheses based on whether those rules could have generated the features of the objects in the matrix and the prior probability of each rule. Based on fits to both correct and incorrect response options across both the Standard and Advanced Progressive Matrices, we propose several novel mechanisms that may drive responding to Raven's items.

**Keywords:** Rule induction, Bayesian inference, Raven's Progressive Matrices

## Introduction

Raven's Progressive Matrices (Raven et al., 1998; Raven's from here on) is one of the most widely used assays of fluid intelligence, and much attention has focused on the underlying elemental cognitive processes. Raven's has arguably gathered more attention in the cognitive literature than any other psychometric measure of fluid intelligence, largely because it is an induction task *par excellence* that can be modeled computationally (see e.g., Carpenter, Just, & Shell, 1990; Verguts, De Boeck, & Maris, 2000). For example, Carpenter et al. (1990) presented a production-system model of Raven's to support a two-factor theory of Raven's with working memory capacity (WMC) as the first factor and a second factor related to the ability to abstract relations. This latter ability has been associated with several attributes including rule generation speed (Verguts & De Boeck, 2002), inference speed (Rasmussen & Eliasmith, 2011), and analogical comparison (Lovett, Forbus, & Usher, 2010; McGreggor, Kunda, & Goel, 2010).

These extant models of Raven's have focused on cognitive processes and mechanisms that underlie the inference of rules from the objects in the matrix. Further insight can be gained by exploring a computational-level analysis (Marr, 1982). As performance in Raven's relies primarily on rule induction, the task is conducive to instantiation within a Bayesian framework. For instance, Bayesian models of rule induction have

been successfully applied to similar tasks, such as numerical sequence prediction (i.e., which number follows in the sequence: 1, 2, 3, 5, 7, 11?; Austerweil & Griffiths, 2011) and rule-based categorization (Goodman, Tenenbaum, Feldman, & Griffiths, 2008). Examining Raven's within the context of a Bayesian model allows exploration of questions about what people's priors (or in non-Bayesian terms, inductive biases) might be like for rules of the variety used in the Raven's test. Finally, the Bayesian formalism provides an extensible framework for using standard extensions to Bayesian models to capture other, more process-based interpretations of factors known to be relevant to performance on Raven's, such as memory and learning.

Here we present a Bayesian model of Raven's which interprets rule induction as Bayesian inference in which a set of rules with some prior probability are evaluated based on their ability to have plausibly generated the features of the items shown in the matrix. Rules are then sampled based on their posterior probability and Bayesian model averaging is used to predict which answers are most likely given the posterior distribution. Unlike extant models, which examine how successful the model is at predicting correct responses (e.g., Carpenter et al., 1990; Lovett et al., 2010; McGreggor et al., 2010), our model also makes predictions about the proportion of responses involving the various incorrect options.

## Bayesian Model of Raven's

Solving a Raven's problem can be conceptualized as a three-stage process involving feature extraction, rule-inference and prediction.<sup>1</sup> As illustrated in Figure 1, Raven's items have the following composition:

$$\begin{array}{ccc} O_{11} & O_{12} & O_{13} \\ O_{21} & O_{22} & O_{23} \\ O_{31} & O_{32} & ? \end{array} \quad (1)$$

where  $O_{ij}$  is the object in the  $i^{th}$  row and  $j^{th}$  column. Assuming the features of each object are extracted successfully,

<sup>1</sup>In the present model, we follow Carpenter et al. (1990) by hand-coding the features of the items. Several methods for extracting the features of Raven's items have been proposed (Lovett et al., 2010; McGreggor et al., 2010; Rasmussen & Eliasmith, 2011).

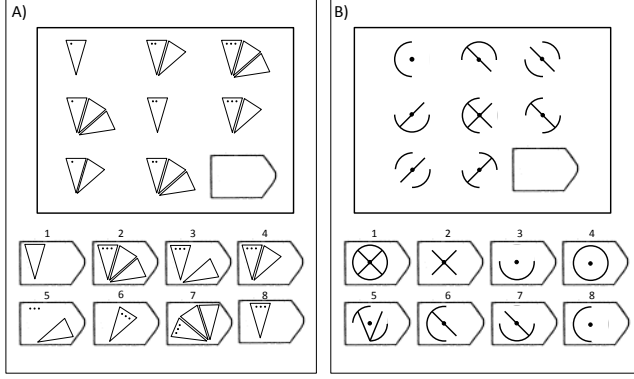

Figure 1: Two examples of matrices like those in the Raven's test. A: Example of an item containing a pairwise incremental rule, a constant rule and a permutation rule. B: Example of an item containing a constant rule and an XOR rule.

such that each object can be decomposed into  $N$  features,  $O_{ij} = \{f_1^{ij}, \dots, f_N^{ij}\}$ , then the goal is to infer the rule that generated the features of the last object in each row and column from the features of the first two objects in each row and column. By design, the rules that are applied to generate  $O_{13}$  from  $O_{11}$  and  $O_{12}$  are the same as the rules used to generate  $O_{23}$  from  $O_{21}$  and  $O_{22}$ . We refer to the set of rules that apply to each row  $G$ , where  $G = \{g_1, \dots, g_M\}$  is a collection of  $M$  rules for each feature. The third object in a row is assumed to have been generated by applying these rules to the features of the first two objects:  $O_{13} = G(O_{11}, O_{12})$  and  $O_{23} = G(O_{21}, O_{22})$ . We assume a separate set of rules,  $H$ , may apply to each of the features of the objects within a column,  $O_{31} = H(O_{11}, O_{21})$  and  $O_{32} = H(O_{12}, O_{22})$ . The column rules and the row rules may be different; however, because  $O_{33}$  can be predicted using either the rows or the columns, we restrict the following analysis to the row rules,  $G$ , but it also applies comparably to the column rules,  $H$ .

We assume that inferring a rule which generated a feature of the third object in a row or column can be conceptualized as finding the posterior probability of each possible rule applied to that feature:

$$p(g|f) = \frac{p(f|g)p(g)}{\sum_{i=1}^M p(f|g_i)p(g_i)} \quad (2)$$

where  $p(f|g)$  is the likelihood of generating feature,  $f$ , given the rule,  $g$ .

### Likelihood

In Raven's, all of the rules apply to individual features (which may be discrete or continuous valued; e.g., the three dots in Figure 1, panel A); hence, within a row, the likelihood will have a value of 0 or 1 depending on whether or not the rule successfully produces the features of the third object from the features of the first two objects in that row. To allow for miscalculations in the evaluation of a rule, we set the likelihood

equal to  $\epsilon$  whenever the rule could not have generated the features of  $O_{13}$  and  $(1 - \epsilon)$  whenever a rule could have generated the features of  $O_{13}$ , where  $\epsilon$  is a small number ( $\epsilon = .01$  in our simulations below). We make the further assumption that a rule may work within neither, only one, or both of the rows (or columns), in which case the probability of generating a feature given a rule across both rows is the product of the probabilities from each row separately:

$$p(f|g) = \begin{cases} (1 - \epsilon)^2 & \text{if the rule works for both rows} \\ \epsilon(1 - \epsilon) & \text{if the rule works for only one row} \\ \epsilon^2 & \text{if the rule works for neither row} \end{cases} \quad (3)$$

### Priors over rules

Carpenter et al.'s (1990) analysis of Raven's identified a taxonomy of rules used to create the Raven's problems. These rule types can be classified as involving transformations (e.g., a quantitative pairwise increment or decrement of a feature from one object in the matrix to the next, or a permutation of objects within a row or column), rules requiring logical operations (e.g., AND conjunctions, OR disjunctions and exclusive-or, XOR, relations between features; Matzen et al., 2010) and a constant rule in which features are maintained unchanged across items.<sup>2</sup> To provide a concrete example, Figure 1 presents two sample Raven's-like problems. The matrix in panel A contains a pairwise incremental rule (i.e., the dots increase across items from left to right) and a permutation rule (i.e., objects with 1, 2 and 3 triangles are permuted across rows and columns). The matrix in panel B contains a constant rule (i.e., the center dot appears in all items) and an XOR rule (i.e., features which appear in the first two objects do not appear in the third object and features which appear only in one of the first two objects also appear in the third object). Participants must infer these rules from the objects in the matrix and select the missing lower right object in each matrix from the set of possible response options below each matrix.

In total we used eight different rules derived from the taxonomy presented in Carpenter et al. (1990; see also, Matzen et al., 2010) and further analyses: 1) constant, 2) increment or 3) decrement, 4) permutation, 5) logical AND (i.e., maintain common features and delete unique features between objects), 6) logical OR (i.e., maintain unique features between objects), 7) logical XOR (see Figure 1, panel B), and 8) a Distribution of 2 rule.<sup>3</sup>

<sup>2</sup>Carpenter et al. (1990) refers to permutation rules as Distribution of 3 rules because the feature values appear once in the three objects within a row or column and to XOR rules as Distribution of 2 rules because the feature only appears in two of the three objects. Carpenter also refers to logical OR rules as addition and logical AND rules as subtraction.

<sup>3</sup>Six items that were generated using idiosyncratic rules were removed from the 72 Raven's Standard Progressive Matrices (RSPM) and Advanced Progressive Matrices (RAPM) items that we tested. We included the Distribution of 2 rule in our set because there are two items in the RAPM set which use a Distribution of 2 rule that is inconsistent with an XOR rule.

We tested three prior distributions on rules. First, we assumed that each rule had an equal prior probability (i.e., a *uniform* prior probability). Vodegel Matzen, van der Molen, and Dudink (1994) conducted a study using single rule matrices and found there was a clear order of rule difficulty, in which the easiest was constant in a row, followed by quantitative pairwise progression, permutation and logical rule operations, which were the most difficult. To capture this order of difficulty we developed a second prior which assumed that the probability of a rule was proportional to the ease with which that rule could be generated (e.g., the complexity of the rules, which is related to the mental effort necessary to infer and use a rule). For this prior (hereafter referred to as the *Carpenter* prior), we used the frequency with which each rule occurred in Carpenter et al.’s (1990) analysis as a proxy for the ease with which each rule could be generated and set the prior probabilities to be proportional to the presentation frequency. Finally, we assumed that the prior may be related to the accuracy with which items containing those rules could be solved. Again, the probabilities are also related to the ease or complexity with which a rule can be generated, but for this prior, we use the relationship between each rule and accuracy on items generated using that rule as a proxy for complexity. To compute this *accuracy-based* prior, we fit a logistic regression model using the rule profile of each item as the predictor variables (i.e., for each item,  $i$ , and for each rule,  $j$ , we set an indicator equal to 1 if item  $i$  was generated using rule  $j$  and to 0, otherwise) and the proportion correct for each item as the dependent variable. We then transformed the resulting exponentiated regression weights such that they ranged between 0 and 1 and summed to 1 across all of the rules. The actual probabilities for each of these priors are listed in Table 1.

Table 1: Prior probabilities for each rule.

Rule	Uniform	Carpenter	Accuracy-based
Constant	.125	.194	.150
Increment	.125	.223	.185
Decrement	.125	.223	.141
Permutation	.125	.058	.116
Logical AND	.125	.039	.167
Logical OR	.125	.058	.119
Logical XOR	.125	.165	.119
Distribution of 2	.125	.039	.081

### Predicting the response from the posterior

The perceptual complexity of the objects affects how easily rule inferences can be generated (Primi, 2001). For example, Meo, Roberts, and Marucci (2007) showed that performance was significantly worse when features within items were difficult to identify. We incorporate this finding into the current model by assuming that the response is based on the similarity between response options and objects predicted from the rules in the posterior, and for items which have features which are difficult to extract, the similarity does not need to be very high in order for the response options to match the object in the posterior.

Once the posterior probability of each rule is computed for each feature using Equation 2, we compute the missing objects as follows: For a given row rule,  $G_m$ , we predict the features of  $O_{33}$  by applying the rule to the features  $O_{31}$  and  $O_{32}$ . That is,  $\hat{O}_{33} = G_m(O_{31}, O_{32})$ . Response proportions are determined by computing the relative similarity of each response option,  $R_k$  to each object in the predictive posterior by  $s_{\{\hat{O}_{33}, R_k\}} = \exp(-c \times d_{\{\hat{O}_{33}, R_k\}})$ , where  $d_{\{\hat{O}_{33}, R_k\}}$  is the Euclidean distance between  $R_k$  and  $\hat{O}_{33}$  (i.e., the square root of the summed squared differences between the features of  $\hat{O}_{33}$  and  $R_k$ ) and  $c$  is a parameter which determines the steepness of the similarity gradient.

Similarities are weighted by their probability in the predictive posterior and normalized across response options to determine the probability that the model chooses each response option (see e.g., Rasmussen & Eliasmith, 2011). In our baseline model, we set  $c$  equal to 10 which results in strong responding to the response options which are represented most strongly in the posterior because the similarity gradient is quite steep when  $c \gg 1$ ; however, preliminary examination of the model fits to some items suggested that human responses were influenced by the similarity of some distractors to the correct response. For these items, we set  $c$  equal to 1, which implies a shallow similarity gradient and greater confusability between similar response options; we exhaustively tested each item to determine whether lowering  $c$  improved the fit for that item. We refer to this version of the model as the *Baseline + similarity model*. In this model, 20 of the 66 items had a lower  $c$  value than the other items (i.e., for these items,  $c = 1$ ).

Initial inspection of the model predictions additionally revealed a propensity for subjects not to choose response options which also appear as items in the matrix. To handle this, we introduced a heuristic into the model such that all objects that appeared in the matrix were removed from the posterior predictive distribution and from the response set before computing the response proportions. Through exhaustively testing each item, we determined that this heuristic improved the model’s predictions for 52 of the 66 items. We refer to this version of the model as the *Baseline + heuristic model*. We additionally tested a *full* model which incorporated both similarity-based responding and the response heuristic.

Table 2: Chi-square values for the fit to choice probabilities for Raven’s Standard Progressive Matrices and Advanced Progressive Matrices. The model that provides the best fit to the data for each prior is shown in bold.

Model	Uniform	Carpenter	Accuracy-based
Baseline Model	43603	37363	40699
Baseline + Heuristic	32642	32816	32871
Baseline + Similarity	23385	13884	19948
Full Model	<b>11761</b>	<b>12258</b>	<b>9010</b>

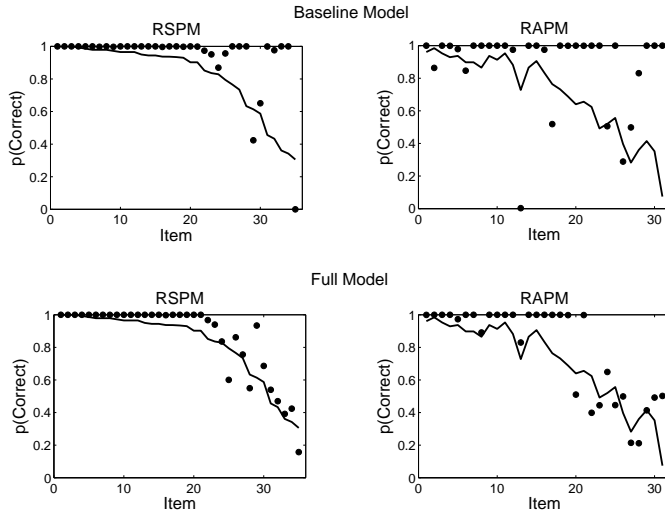

Figure 2: Baseline model and full model fits to proportion correct data from RSPM and RAPM (Little, Lewandowsky & Craig, 2012). Model predictions are shown by the black dots, the observed data are shown by the solid black line.

### Comparing the model to human performance

Descriptive statistics and accuracy data for the Raven's data were previously reported in Little, Lewandowsky, and Craig (2012); here, we are primarily concerned with how often each response option was chosen for each item. (Note that we have removed omissions from this data and look at the distribution of responses across the response options only for participants who actually gave a response). We fit the four versions of the model using the three different prior distributions to the response proportions from the RSPM and RAPM. Chi-square fit statistics are shown in Table 2. Based on these fit values, it is evident that adding similarity-based responding improves the fit over adding the response heuristic to the baseline model. Adding both modifications results in a substantial improvement when a uniform or an accuracy-based prior is used and a marginal improvement when the prior based on Carpenter's analysis is used. The overall best fit is found when the full model is used with an accuracy-based prior; consequently, we now focus on this model's predictions.

Figure 2 shows the accuracy predictions for the baseline and full models for the RSPM items (reordered according to accuracy rate observed in Little et al., 2012) and the RAPM items. The baseline model clearly predicts the correct answer for most of the Raven's items; however, this model overpredicts the propensity with which people choose the correct item for both RSPM and RAPM. By contrast, for the RSPM items, the full model accurately predicts the decrease in accuracy across the items. For the RAPM items, the full model predicts the decrease in accuracy for the hardest Raven's items, but still overpredicts the proportion correct for items in the middle difficulty range.

Figure 3 shows the (log transformed) predictions of the

Figure 3: Predicted (full model) and observed response proportions for all response options from RSPM and RAPM. The dotted line surrounds options for which the model predicts near zero response proportions.

full model (with an accuracy-based prior) across all of the response options against the observed response proportions.<sup>4</sup> For a large proportion of response options, the model predicts the observed proportions correctly; however, the model also erroneously predicts a large number of response options near 0 (predicted log proportion less than -6). These items are also the items for which the model overpredicts the correct response in Figure 2. Examination of the response profiles for individual items reveals that for many items this overprediction is not detrimental to the qualitative pattern of results (see Figure 4). One possible explanation for the discrepant results is that people are guessing the answer with some small probability which would reduce the accuracy for some of the items and increase the proportion of false alarms to some of the distractors.

### Discussion

This paper has defined a Bayesian model of Raven's Progressive Matrices that provides an account of Raven's based on the idea that people infer rules by computing the posterior probability of those rules and using the rules to generate plausible responses. We considered three priors and two ways in which the model could be modified to accommodate human performance. Ultimately, a model incorporating an accuracy-based prior and both modifications provided the best fit to the data.

The success of the accuracy-based prior suggests that rules vary in how they contribute to accurate performance in Raven's. This relationship may reflect sensitivity to differing levels of complexity between the rules, and one way to handle this prior in a more principled way is to instantiate the rules

<sup>4</sup>Proportions equal to 0 or 1 were corrected by setting these proportions equal to  $1/(4N)$  or  $[N - (1/(4N))]/N$ , respectively.

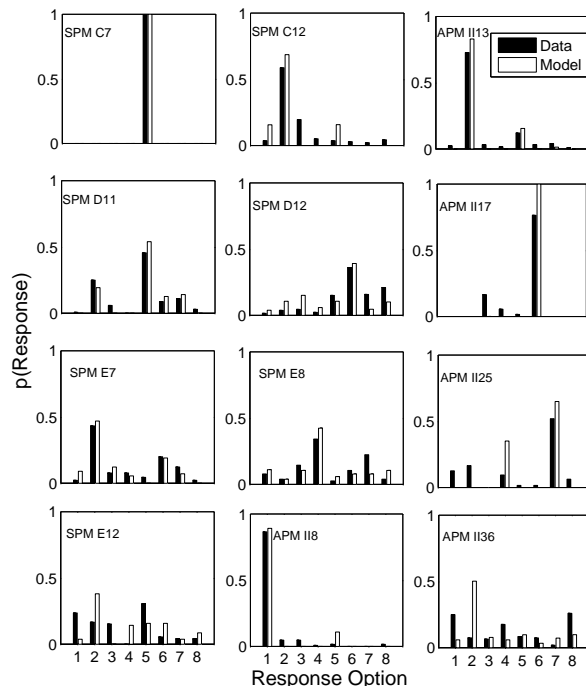

Figure 4: Model prediction profiles for a selection of items. Items SPM C12 (i.e. Standard Progressive Matrices item 12 from Set C) and APM II13 illustrate cases in which the model predicts response probabilities of 0 for responses that people occasionally select. Items SPM E12 and APM II25 illustrate two examples in which the model makes incorrect predictions. For item APM II36, the item with the highest error rate from either test, the model predicts that the correct response (option 2) should be selected most frequently, but humans prefer options 1 and 8.

using a common language with a formal definition of complexity, such as first-order logic (cf. Goodman et al., 2008).

The better fit produced by the similarity-based prediction modification suggests that people vary in how responses are generated to different Raven's items. For instance, for some items, responses are generated by comparing each response option to the possibilities in the predictive posterior; for these items, small differences in features of the response options do not result in a large difference in response prediction. For other items, the response must match the objects in the predictive posterior exactly. An aim for future research would be to identify what makes a feature hard to identify. This would allow appropriate *a priori* specification of the similarity-based prediction rather than the post-hoc approach adopted here. Finally, the heuristic mechanism suggests that people limit their responding to only the plausible response alternatives rejecting alternatives which are implausible because they duplicate items which appear as objects in the matrix.

One of the advantages of formulating a Bayesian model of this task is that we can make use of recent work that has explored how Bayesian models can be extended to cap-

ture different aspects of human cognition. One important aspect of performance on Raven's is that differences in WMC correlate highly with accuracy. Furthermore, the correlation with WMC increases as the items become more difficult (if the overall correlation between Raven's and WMC is large enough; Little et al., 2012). The model does not currently incorporate WMC; however, one possibility for extending the model is to represent the hypothesis space as a sampling distribution from the prior using importance sampling.

In an importance sampling scheme (Shi, Griffiths, Feldman, & Sanborn, 2010) samples from the prior are weighted by their likelihood to approximate the posterior distribution; more samples lead to a better approximation of the posterior. Differences in WMC could be modelled by varying the number of samples with high WMC participants having more samples from the prior. With more samples, the model is more likely to generate the correct answer. This idea is reminiscent of the difference between Carpenter et al.'s (1990) FAIRRAVEN and BETTERRAVEN models. The BETTERRAVEN model was given access to more rules than the FAIRRAVEN model and consequently was able to mimic the performance of participants with highly accurate Raven's performance and, by implication, higher WMC.

An alternative account of the relationship between WMC and Raven's is that higher WMC permits faster learning of what rules are likely to be necessary (Verguts & De Boeck, 2002). In support of this account, Carlstedt, Gustafsson, and Ullstadius (2000) found that WMC was correlated more strongly with homogenous intelligence test items (which all required the same rule to solve) than with heterogenous intelligence test items. Presumably, learning the relevant rule is easier for homogenous test items than for heterogenous items. In other related tasks, such as rule-based categorization, WMC is known to be correlated with learning rate (Lewandowsky, 2011; Sewell & Lewandowsky, in press). By this account, the rules at the end of the test are more diagnostic because they have had more time to be learned, thereby leading to greater divergence between low and high ability individuals. Learning in the Bayesian model of Raven's could be instantiated by using a special case of importance sampling known as particle filter sampling (Doucet, Freitas, & Gordon, 2001; Sanborn, Griffiths, & Navarro, 2010). In a particle filter model, a set of particles representing possible rules are drawn in proportion to their prior probabilities. As one progresses through the Raven's items, probabilities are updated in proportion to the success of each rule. Particles representing rules are maintained if they work, but are replaced with new samples from the prior if they do not. Again, higher WMC could be modelled using a larger number of samples. A particle filter model of Raven's would consider both Carpenter et al.'s (1990) and Verguts and De Boeck's (2002) accounts to be correct. That is, higher WMC allows for access to more rules by virtue of allowing more samples from the prior; higher WMC also allows for faster learning by allowing a larger number of particles to be updated from trial to trial.

Consequently, a particle filter model of WMC and Raven's provides a synthesis of these two approaches.

A limitation of Carpenter et al. (1990) and of our own work is that the inputs to the model are hand-coded (Lovett et al., 2010). Hand-coding ignores potentially important spatial representations between objects. Furthermore, Carpenter et al. (1990) did not model the process of rule discovery, but instead fixed the set of rules that were available to the model. The second criticism is less problematic because the rule set is comprehensive, covering the set of rules necessary to handle most of the items; rule discovery is couched in terms of updating the prior probability of each of the rules based on how well those rules work to explain the observed features.<sup>5</sup> Our Bayesian model is susceptible to the first criticism; however, in the present case, we argue that the model provides a good first step toward understanding how the features are used once they are extracted. It is possible that the feature extraction process might be modeled by introducing a prior over features (such as the Indian Buffet process prior, Austerweil & Griffiths, 2010; Griffiths & Ghahramani, 2011). We leave this as a prospect for future development.

## Abstract

Social facilitation and social support literature, diverging with regards to increasing versus decreasing of an individual's tension, apprehend different aspects of "the presence of others." To examine the neural correlates of social presence effects, whether "the presence of others" increases or decreases an individual's tension, we measured prefrontal activation while participants performed a driving video game task using near-infrared spectroscopy (NIRS). Participants were divided into single and paired groups, and then sub-divided according to their game proficiency (high and low). The participant's task was to drive from start to goal with a default route map without an observer (single group) or under observation by an acquainted partner (paired group). The paired participants alternated their player-observer roles in a turn-taking style (Driver first and Observer second: D1-O2; Observer first and Driver second: O1-D2). The behavioral data demonstrated that, regardless of game proficiency, D1 in the paired group yielded fewer errors and longer driving time than single players, while no differences were found between D1 and D2. The tension evaluation scores in single players and D2 were higher than D1. In turn, the NIRS data revealed that, in low-proficiency players, single players and D2 who first observed D1's performance showed higher activation than D1, but neither did so in high-proficiency players. These results suggest that the presence of an acquainted partner (O1) functions positively to reduce an individual's (D1) tension in low-proficiency players. However, prior observation of another's performance may negate the positive social presence effect leading to an increase of tension in the subsequent task.

**Keywords:** presence of others; social facilitation; social support; individual difference; prefrontal cortex (PFC); near-infrared spectroscopy (NIRS).

## Introduction

Social cognitive neuroscience is a burgeoning interdisciplinary field combining the tools of cognitive neuroscience with questions and theories from various social sciences such as social psychology. Classical literature in social psychology has been primarily subsumed under two heads: direct interpersonal influence via interaction between persons and indirect interpersonal influence induced by the presence of others (Allport, 1920).

The latter is a fundamental, as well as the oldest, experimental research in social psychology. As put by Gordon Allport (1954), "the first experimental problem ... was formulated as follows: What change in an individual's normal solitary performance occurs when other people are present?" (p. 46). The present study considers this type of question, and aims to examine the effects of social presence on the individual's neural state in a player-observer dyadic situation.

Two main existing areas of research deal with different aspects of the presence of others. One is social facilitation that investigates how social presence affects one's performance in a general way. Another is social support that focuses on the issue of how other person present relaxes an individual in the stressful environments.

Social facilitation literature has revealed inconsistent effects of social presence on performance; both performance improvement and impairment are possible. For instance, Floyd Allport (1924) demonstrated positive influence from social presence, coining the term *social facilitation* to describe the increase of response merely from the presence of others. However, not all research shows positive effects. Sometimes the presence of others impairs an individual's performance (e.g., Pessin, 1933). To explain the seemingly conflicting results, Zajonc (1965) offered a predominant interpretation based on the Hull-Spence drive theory. According to Zajonc's arousal theory, the presence of others increases an individual's general arousal level, which in turn enhances the emission of dominant responses. In a simple task, appropriate responses are typically dominant, and accordingly the presence of others will improve performance; whereas in a complex task, appropriate responses are more typically not dominant, thus performance will be impaired.

There has been general agreement with this arousal-based explanation in the following social facilitation literature, with considerable debate mostly centered on the source of arousal itself—evolving several conceptualizations such as evaluation-apprehension theory (Cottrell, 1972), monitoring theory (Guerin & Innes, 1982), and distraction-conflict theory (Baron, 1986; for review see Aiello & Douthitt, 2001; Guerin, 1993; Uziel, 2007). These theories clearly differ in their explanations for performance effects of social presence. However, attempts to pinpoint a single exclusively accurate theory have been proven unsuccessful (Guerin, 1993), due

mainly to two reasons: 1) the existing theories are not mutually exclusive—"the theories are unable to predict performance effects in such a way that eliminates other possible explanations" (Aiello & Douthitt, 2001); 2) these theories all attempt to explain why simple task performance is improved and complex task performance is impaired in presence of others without objective criteria for determining the task complexity (Uziel, 2007).

Extensive literature on social support, however, has consistently shown that social presence not only functions to increase an individual's tension level, it also decreases an individual's tension as an emotional coping recourse (e.g., Cohen & Wills, 1985; Lazarus & Folkman, 1984; Lazarus, 1999). In light of stress and coping theory, when the individual evaluates an observer as non-supportive, social presence would cause stressful circumstances, whereas when the individual appraises the others as supportive, social presence would produce relaxation.

Therefore, the incongruent results in previous social facilitation literature may be concomitant, if we accept that the effects of presence of others may be changed positively or negatively according to the cognitive setting that an observer regards others such as a dynamically changing state of the observer. For instance, proficiency in performance of a player would be one of the most critical factors that may change the meaning of others for the player him or herself.

To better understand the functional formation and mechanisms underlying the above social presence effect, there has been a growing effort to explore these outcomes in the presence of others via activity changes in the brain. Using electroencephalography (EEG), Kim, Iwaki, Uno and Fujita (2005) reported larger error-related negativity (ERN) at three brain locations (Fz, Cz, and Pz) in children when they performed a go/no-go task under observation by a friend than when performed individually. The results suggest that social presence may increase one's tension level and accordingly affect behavior as well as attitudes and feelings.

In contrast, in a functional magnetic resonance imaging (fMRI) study, Karremans, Heslenfeld, van Dillen and Van Lange (2011) demonstrated that the presence of a supportive partner reduced prefrontal activation due to easing of tension when participants endured stress during a ball-tossing game. It should be noted that, however, the partner in this fMRI study was not really present, but only virtually so via imagination. One of the reasons stems from technical limitation of brain imaging such as fMRI that is unable to assess cortical function in ambulant participants in social environments.

Near-infrared spectroscopy (NIRS) is also a non-invasive method for studying functional activation by measuring changes in the hemodynamic properties of the brain. Unlike fMRI, NIRS has few physical constraints on participants and is tolerant to motion artifact permitting serial assessments of tasks in relaxed and realistic settings (Cui, Bryant, & Reiss, 2012). In particular, Liu, Saito, and Oi

(2012) have used a 2-channel NIRS unit named as PocketNIRS due to its portability (length: 100 mm; width: 61 mm; thickness: 18.5 mm, and weight: 100 g including the batteries), and mobility (transmitting the hemodynamic signals wirelessly via Bluetooth) to investigate intrapersonal and interpersonal cognitive processes during a driving video game. They assigned participants into one control and two experimental groups. The participant's task in the control group was to drive to goal with a route-map illustrating default turning points, while the memory group was instructed to drive the memorized default route without map (intrapersonal process), and the emergency group was asked to drive with route-map but to change the default route immediately by an extrinsically given "verbal command" (interpersonal process). The results demonstrated an instantly increased activation in prefrontal cortex (PFC) during an urgent turning maneuver resulting from the "direct" interpersonal influence via verbal command, but not from the intrapersonal process.

With respect to social presence effects (i.e., "indirect" interpersonal influence), using NIRS, Ito et al. (2011) have measured prefrontal activation when participants performed a working memory task with or without evaluative observation by experimenters. The participant's task was to observe a sequence of stimuli, and to judge whether a currently presented stimulus was identical with the one presented *n* trials previously. They found that the participants under observation by the experimenters yielded more errors and showed higher activation in both left and right PFC than those who performed without observation. The results demonstrate that the presence of others, for instance strange experimenters in their experiment, increases an individual's tension and influences the prefrontal activation.

Early studies of social presence effects have mainly employed strangers or friends as observers. In the present study, to sustain homogeneity between single and paired groups, the participants were recruited from new students who took a general course of psychology, and the participants in the paired group were matched to soften the extreme polarization of familiarity, and to keep impartial appraisal of the pairs of acquainted participants.

We aimed to extend from the existing literature on social presence effect—demonstrating both the positive and the negative aspects of social presence in one experiment. To address these issues, we measured bilaterally the prefrontal activation in participants when they performed the goal-achievement driving task used in Liu, Saito and Oi (2012) either without an observer (single group) or under observation by a partner (paired group). Participants in both the single and the paired groups were divided into two sub-groups depending on their game proficiency (high and low). The paired participants were asked to alternate their player-observer roles in a turn-taking style (D1-O2: Driver first and Observer second; O1-D2: Observer first Driver second), exploring the possibility that in the first driving task the presence of a partner (O1) may act as a supporter of D1 in

unfamiliar experimental environments, whereas in the second driving after observation of D1's performance, O2's presence may change its role into a source of stress (i.e., non-supporter).

We tested the following three hypotheses: first, the participants in the paired group (D1) would show lower prefrontal activation than those in the single group due to easing of tension resulting from presence of an acquainted partner (positive presence effect); second, D2 would show higher prefrontal activation in the subsequent driving than D1 due to rising of tension based on observation of preceding D1's error performance (negative presence effect); third, low-proficiency players would be somewhat more sensitive to the social presence than the high-proficiency players (task proficiency effect).

## Method

### Participants

Sixty-two right-handed students (53 males, 9 females, age:  $21 \pm 2.2$  years) from Nagoya University participated in the present study for the course credit. Participants were assigned to either single or (same-gender) paired groups, and subdivided according to their game proficiency (high and low). The pairs partnered with each other voluntarily, and their friendships—defined as the duration of their acquaintance—were assessed by self-report in the post questionnaire (friendship:  $1.7 \pm 1.4$  years). All participants had normal or corrected-to-normal vision. They were informed about the purpose and safety of the experiment, and written informed consent was obtained prior to participation. This study was approved by the local ethics committee.

### Materials and design

The same driving video game used in Liu, Saito and Oi (2012) was employed in the present study. During the experiment, players took a seat in front of a 32-in. monitor either individually in the single group or with a partner sitting beside in the paired group. The driving game was displayed on the monitor without sound, and the players controlled the game using a Sony game pad. Distance from the players to the monitor was set to 120 cm.

The participants were asked to obey the traffic rules and drive from start to goal with a default route-map without an observer in the single group or under observation by an acquainted partner in the paired group. Further, two instructions were given to participants in the paired group: 1) the player's performance would be evaluated by their partner as an observer, who needed to report the player's driving performance after the experiment; and 2) they would be asked to alternate their player-observer roles in a turn-taking style during the experiment. With respect to performance, in the present study we defined driving errors as that which lead to collision or driving on the pavement, however, this criterion was not explained to the participants.

### Procedure

Players practiced operating the game pad for 180 s, and then they drove two training trials followed by four experimental trials with distinct routes. A single trial consisted of a driving phase and two rest phases (20 s each) before and after the driving phase.

### Apparatus

The PocketNIRS (DynaSense Inc., Japan), operated at 735, 810 and 850 nm wavelengths, was used to measure the concentration changes of oxygenated hemoglobin (CoxyHb), deoxygenated hemoglobin and total hemoglobin. Two probes were attached to the forehead using double-sided adhesive sheets and centered on Fp1 and Fp2 positions, according to the international 10–20 system. Each probe consisted of one emitter optode and one detector optode located 3 cm apart. During the experiment two sets of PocketNIRS triggered by one signal were employed to measure the activation changes in paired player and observer simultaneously. The sampling rate for each channel was 10 Hz.

### Data analysis

The NIRS data which contained more than 10% non-near-infrared light signals was defined as noise data. All noise data, as well as data obtained from participants who did not follow the instructions, was excluded from further analysis. Complete data was obtained from 15 single participants (6 high-proficiency, 9 low-proficiency), and 18 pairs of participants (D1: 10 high, 8 low; D2: 8 high, 10 low).

We focused on CoxyHb during the driving phase in each group, since the oxygenated hemoglobin is the most sensitive parameter of regional cerebral blood flow (Hoshi, Kobayashi, & Tamura, 2001). A linear baseline correction was conducted on the NIRS raw data to remove longitudinal signal drift using the mean value of CoxyHb during the 5 s before the driving phase. Then *z*-scores were calculated using the mean value and the standard deviation of CoxyHb during the baseline period in four experimental trials and in both the left and the right hemispheres, independently. To eliminate influence of the errors made by the players during driving on brain activation changes, the data during the error periods was excluded from the NIRS dataset. The *z*-scores were averaged finally for the driving phase over all trials, and group-averaged *z*-scores for each group were obtained.

## Results

### Behavioral data

In the present study, we calculated the driving time and counted the number of errors in the driving phase as the performance indices. Statistical analysis was conducted by means of Statistical Package for the Social Sciences (SPSS) and the significant level was set at  $p < 0.05$ .

**Single group vs. paired group (D1)** Figure 1 illustrates the driving performance including the driving time and the number of errors in the single and the paired (D1) groups. To examine the effects of the presence of a partner as an observer (O1) on the player's (D1) performance, we separately performed a two-way analysis of variance (ANOVA) on the driving time and error numbers with social presence (single and paired) and game proficiency (high and low) as the between-participants factors.

Fig.1 Mean driving time and number of errors in the single and the paired (D1) groups. D1 refers to the first driver in the paired group. Error bars represent standard deviation. \* indicates  $p < 0.05$ .

For both the driving time and the error numbers, analyses revealed significant main effects of social presence, respectively [ $F(1,29) = 4.49, p < 0.05, \eta_p^2 = 0.13$ ;  $F(1,29) = 4.36, p < 0.05, \eta_p^2 = 0.13$ ]. The participants in the paired group (D1) showed fewer errors and longer driving time than those in the single group. Neither the main effects of game proficiency nor the interactions were significant. These results indicate that participants performed better under observation by an acquainted partner than when alone, regardless of their individual game proficiency.

**Single vs. D2** To examine the social presence effects by O2 on D2's performance in the subsequent driving, we applied a two-way ANOVA [O2 presence (single vs. D2)  $\times$  game proficiency (high vs. low)]. For error numbers, no significant differences were found between single players and D2. For driving time, the analysis revealed a significant interaction [ $F(1,29) = 5.36, p < 0.05, \eta_p^2 = 0.16$ ]. In the simple main effect test, D2 showed a significantly longer driving time than the single high-proficiency players [ $F(1,12) = 7.35, p < 0.05, \eta_p^2 = 0.38$ ], but low-proficiency players did not. No significant differences were found between low- and high-proficiency players in either the single players or D2. These results suggest that after prior observation of D1's performance, the positive effect of social presence on performance disappeared in the subsequent driving of D2.

**D1 vs. D2 in the paired group** Figure 2 shows the driving performance in D1 and D2 within the paired group. To assess the effect of the prior observation of D1's performance on the subsequent driving of D2 under observation by O2, we performed a two-way ANOVA on the driving time and the error numbers independently with observation experience (D1 and D2) and game proficiency (high and low) as the between-participants factors. The result revealed no significant differences for both the driving time and the error numbers.

Fig.2 Mean driving time and number of errors in D1 and D2. D1 refers to the first driver in the paired group; D2 refers to the second driver in the paired group. Error bars represent standard deviation. \* indicates  $p < 0.05$ .

**Rating scores on participant's tension level** The tension scores were obtained through a questionnaire filled out by the participants after the experiment. The scores were on a 5-point scale (1 = not at all tense, 5 = extremely tense). The tension index shown represents the average and standard deviation of the participant's response in two domains (unsettled feeling and stress feeling). The tension index was  $1.5 (\pm 0.6)$  in the single players,  $1.1 (\pm 0.2)$  in D1, and  $1.4 (\pm 0.6)$  in D2, respectively. Paired t-test analysis revealed that the single players and D2 showed significantly higher tension than D1, respectively [ $t(17) = 2.06, p < 0.05, 1$ -tailed;  $t(21) = 1.90, p < 0.05, 1$ -tailed].

## NIRS data

**Single group vs. paired group (D1)** Figure 3 shows the average values of the z-score for CoxyHb in the driving phase in the single and the paired (D1) groups. To examine the social presence effect on prefrontal activation, we performed a two-way ANOVA [social presence (2)  $\times$  game proficiency (2)] in each hemisphere separately. In both the left and the right hemispheres, the analyses revealed significant main effects of game proficiency [ $F(1,29) = 8.75, p < 0.01, \eta_p^2 = 0.23$ ;  $F(1,29) = 7.29, p < 0.05, \eta_p^2 = 0.20$ , respectively], and interactions [ $F(1,29) = 11.10, p < 0.005, \eta_p^2 = 0.28$ ;  $F(1,29) = 6.24, p < 0.05, \eta_p^2 = 0.18$ , respectively].

In the simple main effect test, low-proficiency players showed significantly lower prefrontal activation in the paired group (D1) than those in the single group [ $F(1,15) = 11.83, p < 0.005, \eta_p^2 = 0.44$ ;  $F(1,15) = 7.44, p < 0.05, \eta_p^2 = 0.33$ , respectively], but high-proficiency players did not. In the single group no significant differences were found between high- and low-proficiency players. Whereas in the paired group, low-proficiency players showed significantly lower prefrontal activation than high-proficiency players [ $F(1,16) = 13.02, p < 0.005, \eta_p^2 = 0.45$ ;  $F(1,16) = 8.72, p < 0.01, \eta_p^2 = 0.35$ , respectively]. These results suggest that the presence of O1 decreased the tension level of D1 in low-proficiency players, but not in high-proficiency players.

Fig.3 Average concentration changes of oxygenated hemoglobin (CoxyHb) in the driving phase in the single and the paired (D1) groups. D1 refers to the first driver in the paired group. Error bars represent standard deviation. \* indicates  $p < 0.05$ .

**Single vs. D2** To examine the effects of O2's presence on D2's prefrontal activation, we conducted a two-way ANOVA [O2 presence (2)  $\times$  game proficiency (2)]. In both the left and the right hemispheres, no significant differences were found between single players and D2. The results suggest that the positive presence effect by O2 disappeared in the second driving of D2 within the same player-observer pairs.

**D1 vs. D2 in the paired group** Figure 4 shows the average values of the z-score for CoxyHb in the driving phase in D1 and D2. To examine the effect of the prior observation of D1's performance on D2's prefrontal activation in the subsequent driving task, we conducted a two-way ANOVA [observation experience (2)  $\times$  game proficiency (2)] in both the left and the right hemispheres, respectively.

In the left hemisphere, ANOVA revealed a significant interaction between observation experience and game proficiency [ $F(1,32) = 9.22, p < 0.005, \eta_p^2 = 0.22$ ]. No significant main effects were found. In the simple main effect test, low-proficiency players showed significantly higher prefrontal activation in D2 than in D1 [ $F(1,16) = 6.14, p < 0.05, \eta_p^2 = 0.28$ ], but high-proficiency players did not. In D1 low-proficiency players showed significantly

lower prefrontal activation than high-proficiency players, but did not in D2.

In the right hemisphere, the results demonstrated a significant main effect of game proficiency [ $F(1,32) = 4.33, p < 0.05, \eta_p^2 = 0.12$ ]. Neither the main effect of observation experience nor the interaction was significant. These results suggest that after prior observation of D1's performance, the presence of O2 increased the tension level of D2 in the subsequent task.

Fig.4 Average concentration changes of oxygenated hemoglobin (CoxyHb) in the driving phase in D1 and D2. D1 refers to the first driver in the paired group; D2 refers to the second driver in the paired group. Error bars represent standard deviation. \* indicates  $p < 0.05$ .

## Discussion

The present study was designed to examine the neural substrate of social presence effects in a natural player-observer environment. To achieve this goal, we measured prefrontal activation in participants without an observer (single group) and with an observer (paired group) during a driving video game using PocketNIRS. In this regard, we tested whether two paired groups (driver first D1 and driver second D2) manipulated in a player-observer turn-taking style consistently demonstrated lower prefrontal activation than the single players, regardless of prior experience of observation in D1 and D2.

Three main findings were obtained, and will be discussed in turn. First, the present data demonstrated lower prefrontal activation in the paired group (D1) than in the single group. The result is consistent with our hypothesis suggesting that the presence of others may serve as a supportive role relaxing an individual (positive presence effect).

Second, in the same social environment the present data revealed higher prefrontal activation in D2 than in D1. This result indicates that the supportive role of the observer may change to a non-supportive role, and increase an individual's tension (negative presence effect).

Third, as predicted, the above two effects were confirmed only in low-proficiency players, but not in high-proficiency players (task proficiency effect).

A unique aspect of the present study is that we demonstrated controversial aspects of social presence effects within one experiment: the presence of others may act positively to relax the individual as well as negatively to stress the individual, depending upon how the individual evaluates the role of the observer (supporter or non-supporter). Previous social facilitation studies have mostly emphasized the negative aspects of social presence leading to rising of tension. Social presence, however, is not just a major source of stress. Social support literature has also demonstrated the benefits of the presence of others to the individual's level of tension (e.g., Cohen & Wills, 1985; Lazarus & Folkman, 1984). Consistent with social support, the present study confirmed that the presence of others could reduce an individual's tension level. It is particularly interesting that after the prior observation of the partner's performance, the supportive effect of social presence disappeared; the supportive role of the observer may change to non-supportive role in the subsequent task.

The present study provides an important theoretical implication. The early social facilitation and social support literature has mainly focused on two distinct aspects of social presence effects, respectively (e.g., Cohen and Wills, 1985; Zajonc, 1965). The present study bridges a gap between them suggesting that research into social presence effects would benefit from combining the ideas of two theories and addressing the role of observer as an important moderating variable subject to subjective appraisal of the observer.

In conclusion, the present study suggests that research into social presence effect would be benefited by addressing individual differences, specifically how an individual evaluates the role of others, as well as the individual's task proficiency. Further study is needed to explore the neural correlates of the explicit role of the presence of others during cooperation and competition.

# Intentionality of Strong Anticipation in Motor Behaviors

Hsi-wen Daniel Liu (hwliu@pu.edu.tw)

Center for General Education, Providence University  
Shalu, Taichung 433, TAIWAN, R.O.C.

## Abstract

Pezzulo (2008) and Grush (1997, 2004, 2007) highlight, even insist, the role of representation and internal models in anticipatory systems, in contrast to the role of adaptivity in the so-called ‘mere adaptive systems’. The present paper argues against their claim, by alternatively arguing that the strong anticipation—anticipation without employing internal models—is primordial in the making of the anticipatory behavior, while internal models are supplementary in the light of efficiency. A novel notion of intentionality is raised for strong anticipatory behaviors, based on the history of on-line adjustments. The supplement of internal models on the top of a strong anticipatory system makes the resulting anticipatory system a Popperian machine, and consequently more flexible.

**Keywords:** Weak and strong anticipation; internal models; intentionality; motor behaviors.

## Introduction

The embodied and situated approach to cognition is a general revolt against the representationism, the thesis that cognition consists of representations. This thesis is challenged radically by the behavior-based robotics (e.g. Brooksian robotics, Gibsonian theory of vision) and dynamic systems approach to cognition. Wherein, the role of agent-environment interaction is highlighted in the making of cognition, and the notion of cognition without representation is radically raised. Within this approach, however, some contend that the role of representation should be preserved (Clark 1997, 2003; Keijzer 2001; Grush 1997), as is manifest in Clark’s notion of action-oriented representation. Later on, within the same approach does the need of representation scale up in the study of anticipatory systems. The role of representation (or, internal models) in such systems is highlighted, or even insisted, in contrast to the role of adaptivity in the so-called ‘mere adaptive systems’ (Pezzulo 2008; Grush, 1997, 2004, 2007). Model-based anticipation, thus, is seen as contrasted with adaptivity or reactivity, as is technically manifest in the contrast between weak and strong anticipation (Dubois 2003; Stepp and Turvey 2010).

According to Dubois (2003), anticipation is the determination of current states by taking account of future states. Weak anticipation predicts the future states with *models* of agents and the environment; whereas, strong anticipation predicts future states without such models. The strong anticipation employs the *system* itself (i.e. the agent and its immediate environment),<sup>1</sup> rather than an internal model (of agents and the environment). The role of models

<sup>1</sup> A slogan in favor of the strong anticipation is that the system itself is the best model (Stepp and Turvey 2010).

in anticipatory behaviors is well noticed (Pezzulo 2008)<sup>2</sup>, as anticipatory behaviors are maintained control with internal representations. By contrast, the role of strong anticipation seems to be underestimated. In fact, strong anticipation needs more study (Steep and Turvey 2010). That is, the role of adaptivity in the making of anticipation remains in need of research.

In what way do motor activities bear an intentional relation to the environment? This query is a bit hard to answer. The motor activities, on the one hand, are clearly not managed by thought. Nevertheless, such activities, on the other hand, do not seem to be completely meaningless, as manifested in a query of Wittgenstein’s: ‘When I raise my arm, my arm goes up. And the problem arises: what is left over if I subtract the fact that my arm goes up from the fact that I raise my arm?’ (Wittgenstein 1953, 1, paragraph 621). Motor activities, later, are considered in Merleau-Ponty’s (1962) notion of *motor intentionality* as activities that are between reflexes and deliberate actions (Kelly 2000). Such activities, as Merleau-Ponty describes, are controlled by “a motor power, a ‘motor project’ (*Bewegungsentwurf*), a ‘motor intentionality’ in the absence of which the order remains a dead letter (Merleau-Ponty 2006: 126-127)”. But, the question remains as to what this “motor power” is. If it is something that makes motor activities intelligent, then the question, further, would be twofold. The first is a ‘what is’ question: what is it that makes motor activities intelligent? The other question relates to the way in which the term ‘motor intentionality’ can make sense: can that motor power be understood with a certain sense of intentionality? Those two questions have been responded since the end of the last century.

Regarding the first question, the topic of motor control is well noticed both in psychology (Kawato 1999; Jeannerod 2006; Desmurget and Grafton 2000, to cite only three) and in philosophy (Christensen and Hooker 2002; Clark 2002; Clark and Grush 1999; Dreyfus 2007; Grush 1999, 2004, 2007). Motor activities are well conceived of in terms of anticipatory agents, emulators, feed forward models and feedback loops, etc. Regarding the second question, it has

<sup>2</sup> Pezzulo (2008: 179) understands anticipatory behaviors in terms of internal representation: “we argue that the ability that characterize and defines a true cognitive mind, as opposed to a merely adaptive system, is that of building representations of the non-existent, of what is not currently (yet) true or perceivable, of what is desired”, and ... “[a] real mental activity begins when the organism is able to endogenously (i.e. not as the consequence of current perceptual stimuli) produce an internal representation of the world in order to select and guide its conduct goal-directed: the mind serves to coordinate with the future.”

for long been conceived (as aforementioned in the notion of motor intentionality) that to account for motor activities would there be a sense of intentionality, which is very different from Brentano's notion of intentionality, a notion based on a standing-for relation that is typically adopted in the orthodox AI. However, two recent accounts attempt to re-affirm the importance of the standing-for-based intentionality in explaining anticipatory behaviors. The first, Grush (1999, 2004, 2007) maintains a difference between representational anticipation systems and adaptive systems. He highlights the role of internal representation in emulators—standing in for the actual motor activities—without discussing whether there is another sense of 'representation' (in other words, vehicle of intentionality) that can explain motor behaviors. The other, Pezzulo (2008) advocates the role of internal representation in explaining the guidance of goal-directedness in the anticipatory behaviors. Common in Grush and Pezzulo are two proposals: firstly, the contrast between truly cognitive minds and mere adaptive systems; and secondly, explaining cognitive mind/systems in terms of internal representations of the *non*-actual activities. A system with such internal representations, which can vanish before they are actually carried out, is called a Popperian machine, as Popper (1996) says that it can "let its hypothesis die in its stead" (cited from Pezzulo 2008: 195).<sup>3</sup> That system, in Pezzulo's (2008) term, is a system that can act on its representations instead of acting on its reference. Here, being a Popperian machine is taken as a requirement of a system's being cognitive.

The present paper argues for the three-fold primordial role of strong anticipation in the making of the anticipatory behavior. As we will see in the following sections, the strong anticipation is made possible by means of agent-environment coupling and system's (internal) states, while the weak anticipation by means of modeling. Firstly, the strong anticipation is primordial in the making of the anticipatory behavior, while internal models are supplementary in the light of efficiency. It is strong anticipation rather than the internal models of the system that makes possible anticipation. Secondly, a novel notion of intentionality, in contrast to that on the basis of the standing-for relation, is raised for understanding strong anticipatory behaviors: the relation in which the internal states of a body *brings about* a pre-registered end-state in the environment. On grounds of that novel sense of intentionality, strong anticipatory systems are intentional, apart from its being intelligent. Thirdly, the supplement of internal models on the top of a strong anticipatory system makes the resulting anticipatory system a Popperian machine, which is qualified to be a full-blown cognitive agent. The present paper puts discussions in the context of motor activities.

## Anticipatory Behaviors

### Internal Models

Reaching movement is a simple but paradigmatic example of the anticipatory behavior. The inverse internal models provide the feed forward motor commands that are necessary to bring about the desired trajectory in relation to a goal (Kawato 1999). Thus, prior to the onset of the reaching movement is a motor plan assembled. In the course of reaching movement, the motor plan is updated continuously by internal feedback loops. Internal feedback loops are employed because the biological mechanism of sensory feedback loops produces significant delays (Kawato 1999; Desmurget and Grafton, 2000). The internal feedback loops rely on forward models that integrate the sensory inflow and motor outflow to evaluate the consequence of the motor commands sent to a limb. The forward internal model predicts sensory consequences of issued motor commands (the probable position and velocity of an effector) with negligible delays, or even predicts them in advance. Thus, the forward models make the strategy of feedback loops efficient in the light of making a *real time* response for the reaching movement (Desmurget and Grafton, 2000). The representational status of anticipatory behavior is considered based on the importance of internal models, that make anticipatory behavior sufficiently efficient and accordingly make it possible in the ecological niche (Grush, 1997, 2004, 2007; Pezzulo, 2008).

### Strong Anticipation

An anticipatory system is a system that takes account of future states. A strong anticipatory system is an anticipatory system without employing an internal model; otherwise, it is a weak anticipatory system (Dubois 2003; Steep and Turvey 2010).

Steep and Turvey (2008) understands the notion of reaction in the sense that the determination of systems' states only takes account of current or past states, without considering future states. In this sense, homeostasis can be seen as reactive, as it is seen as involving no explicit goals at all. Examples of systems with no explicit goals are as follows: the single-cell *Euglena* approaching to the sunlight (Goodale and Milner 2004: 40), a reflex, the Watt Governor (WG, van Gelder 1997), and the wall-following machine (Martaric 1990). The reflex as the resulting response is not pre-specified in the reflex mechanism of the muscle system. The WG is a device for the speed control. The state with a constant speed is the end-state, without being explicitly specified in the device. The end-state is an end-point of a purely physical chain. This makes the WG to be merely adaptive, although it is indeed an intelligent design.

By contrast, a thermostat, which is a goal-pursuing machine, embraces an explicit goal that is regarded as a pre-fixed state. The explicit goal is to be compared with a current state, and an error to be reduced is consequently derived. In addition, the outfielder discussed in Steep and

<sup>3</sup> A similar point is put in terms of a Popperian creature (Dennett, 1995, p. 375)—a creature capable of breaking their cycle of direct interactions with the local environment (Clark and Grush, 1999).

Turvey (2008) has an explicit end-state—catching the flying ball.

The strong anticipation preserves a role contributing to flexibility of motor behaviors. Such a role is two-fold. On the one hand, a strong anticipatory system approaches to the goal in the complex environment. For example, by lining up with the flying ball that becomes a fixed point (Clark 2003), the outfielder is likely to catch the ball successfully. On the other, the motor controlling system, as a strong anticipatory system, can further connect to various inner models and consequently makes the system at stake a *weak* anticipatory system. The former one, that achieves the goal, is the primary concern of an anticipatory system. Whereas, the latter, that is supported with inner models, makes the anticipatory system a Popperian machine and consequently more effective and efficient. As to the effectiveness, avoiding some likely impediment and thus making the way to achieve the goal more likely to success. As to the efficiency, it makes the way of achieving the goal passing various real-time constraints.

### **Adaptivity in Strong Anticipation**

This section considers two remarkable ways of adaptivity appearing in strong anticipatory systems: coupling and sensory feedback loops.

#### **Coupling Ensures Completing a Task**

The agent-environment coupling, as considered previously in the example of an outfielder, ensures the completion of a task. When such coupling arises, a task would be accomplished effectively and efficiently. Consider the aforementioned outfielder problem. When the outfielder moves to a position where the trajectory of the ball is seen to be a point heading toward him, the coupling arises, and catching the ball is straightforwardly ensured. The accomplishment of the task is sometimes determined by that coupling condition.

In addition, coupling is inherent in the Gibsonian theory of vision and action. Visual affordances of an object, say, a cup, provide opportunities of actions, for example, grasping the cup. Consider the simple tasks consisting of single actions, such as the outfielder's catching the ball as aforementioned, and the task of grasping a cup. A coupling relation arises between the affordances of an object and the consequently provided action. As the visual affordances provide opportunities of an action, the coupling relation ensures the completion of a corresponding task.

#### **The Sensory Feedback Control for the System's Performance**

The sensory feedback control need *not* rely on an internal model,<sup>4</sup> if the efficiency of motor movement is not taken

into account. The former part, the role of the sensory feedback control, is based on the dual model theory of motor movements, according to which a motor movement begins with a motor plan that rapidly transports the hand near to the target, and then depends on sensory feedback loops that slowly direct the hand to the target. The latter part, the non-efficiency of the sensory feedback control, is evident in the remarkable delay resulting from the sensory feedback control (Desmurget and Grafton, 2000). By contrast, a feed forward model, as manifest in emulators (Grush 2004), is an internal model that provides a simulation of motor actions. Based on a simulated motor action, when compared with the target, an error is derived internally.

To be noted, the derivation of an error and the following behavior of getting closer to the target on the basis of the sensory feedback control, is managed by the *system* without recourse to internal models. By contrast, the *internal* feedback loops (as opposed to the sensory feedback loops) rely on a forward model that makes the feedback strategy efficient enough for the real-time reaching movement. The resulting efficiency can be understood as it is a Popperian machine. However, as will be argued in next section, the *intentional* relation of the reaching movement is basically manifest in the system with sensory feedback loops, if we can provisionally put the consideration of efficiency aside. Such sensory feedback loops unfold on account of the system's actual activities and the sensory feedback control. The sensory feedback control of the system (as opposed to a model), hence, is primordial in the making of the motor control. The agent's way of relating to the target turn up primordially in the system's feedback loops.

### **Intentionality of the Strong Anticipatory System**

Do strong anticipatory systems bear intentionality? If they do, in what sense are they intentional? Let us put discussions in the context of motor movement. Such questions relate to two considerations. For the first consideration, such a notion of intentionality, if there is, seems to have something beyond the standing-for relation, given that motor movements are not completely thought-like. The goal-state is brought about as an end-state of a *causal* chain.<sup>5</sup> The question, more specifically, concerns the sense of intentionality which is born by causal activities. Then, the second consideration is that the motor movements, if they indeed bear intentionality in any sense, should be distinct from physical reactions. This section discusses the above two questions, centered on the notion of the goal.

---

<sup>4</sup> An internal model is a model of the system, including the agent and its immediate environment (Dubois 2003). A remarkable example is emulators (Grush 2004). The term 'internal' is

---

contrasted with 'external', including the system as an embodied agent and the environment.

<sup>5</sup> An end-state of a motor system is a state specifying the way in which the target relates to its environment and the body.

## An Account of Pragmatic Intentionality

To respond to the first consideration, a novel notion of intentionality—pragmatic intentionality—is raised: an agent's motor activities bear intentionality in the sense that internal states of the agent's body *bring about* an end-state explicitly pre-registered in her perception or perceptual imagery. If we consider how it is possible that those internal states could bring about a specific end-state of a causal chain, then we need to understand the evaluative nature of the goal. The end-state is taken as the goal on grounds of evaluation. There should be discrepancies marked as negative values against states away from it, and there should be machinery of reducing such negative values. Thus, pragmatic intentionality can be further characterized: internal resources (such as sensory feedback loops, bones and muscles, energy, etc.) of an agent's motor system evaluate the discrepancies between the current state and an explicitly pre-registered end-state of the motor task, and reduce those discrepancies with the result of bringing about that end-state in the environment.

The involving motor activities are authentically intentional, as the agent with its body's internal resources cashes out an explicitly pre-registered end-state in perception or perceptual imagery by bringing it about in the environment. Those bodily internal resources transform the pre-registered end-state in perception or imagery into an end-state in the environment, an end-state consisting of inter-relations between the body, the target object and their environment. This is a pragmatic sense of intentionality because internal resources of the body are *used for* bringing about a pre-registered end-state. As a note, the above consideration has nothing to do with an internal model with a standing-for relation. As an example, a thermostat has pragmatic intentionality as it consists of a feedback model in relation to a pre-registered end-state.

To respond to the second consideration, the present paper highlights the role of the aforementioned pre-registered goal-state in the motor system. The end-state of the motor processing initially turns up in perception or perceptual imagery, and later is registered in the motor system before the motor processing unfolds. This pre-registered status makes the motor processing be neither physical nor reactive. It promotes the processing of the motor system from the physical level to an intentional level. To be noted, the goal has a two-fold role in the motor system. Despite the standing-for status of the goal, it does not stand on its own as an internal model (such as an emulator) of the motor system. The goal has a standing-for relation as it is initially marked in the perception or perceptual imagery. Yet, once it is pre-registered as the end-state of the motor processing, it stands in the *causal* relation to states of the motor system. A goal, hence, can be a part of a strong anticipatory system. This two-fold role based on the pre-registered goal-state in the motor system makes the motor system be neither purely physical nor completely reactive to environmental circumstances.

## A Primitive Shooting System and a Coaching System

A weak anticipatory behavior involves three elements: the system itself (or, agent), its environment, and internal models, while a strong anticipatory behavior involves only the former two elements. Consider the cognitive role of a strong anticipatory system, which is an agent in its environment. Let us discuss in the context of a premature shooting system supervised by a coaching system. Suppose that shooting system is capable of hitting the target with the probability of 10 % per shooting, that is, in average, hitting the target once in ten shoots. Let us further consider a shooting system with a supporting condition: the coaching system serves as a model that simulates the shooter's ten shoots, selects the best one, and accordingly the model draws the shooting system to the shooting conditions of that selected (best) one. Thus, the shooting system can shoot with 100 % accuracy in average. Such a shooting system is an anticipatory system, as the model suggests the shooting system on the basis of (simulated) future conditions.

Then, in theory, that shooting system would be capable of hitting the target accurately more efficiently. The aforementioned shooting system provides an analogy of an accurate motor system, in the sense that the internal model stands as a coaching system of the motor system.

One may contend that a motor system without the internal modeling is but a non-cognitive adaptive system like homeostasis. The coaching system is definitely cognitive, as it is a Popperian machine. Yet, a shooting system itself cannot be cognitive without the support of a coaching system. That the motor behavior is cognitive is because of the representing role of the internal models.<sup>6</sup> Such a representing role is that the internal models simulate and accordingly stand for the motor system together with its environment.

## Intentionality, Representation, and Decouplability

### The Intentionality of Anticipatory Systems

An anticipatory system can be seen as bearing intentionality, in the sense different from the Brentano's notion of aboutness—the traditional sense of intentionality. Note that intentionality is a relation between the internal states of a system and the world. Consider the reaching behavior as an example. The system directs the body of a robot or a biological body, such as limbs, to the target in the environment. The achievement of a goal, hence, cannot appear internally. Rather, it should take place with the real body of the anticipatory system in its immediate environment. The achievement of a goal should be controlled internally in the anticipatory system, with or without the support of an internal model. The internal states

<sup>6</sup> The theme of the present paper is intentionality, but not cognition *qua* cognition, hence the question of defining cognition is simplified.

of that system are dynamic, which may optionally be supported with internal models (as weak anticipatory systems). Let us discuss in terms of the control theory. In a strong anticipatory system, those internal states include the making of a motor plan (as an inverse model of the goal), sensory feedback loops (producing an error by comparing the current position of the hand and the goal), and the hand movement with a view to minimizing the errors. A weak anticipatory system, by contrast, is further supported with internal models. Both in the strong and the weak anticipatory systems, the internal states subserve the body in the light of reaching the target.

As a reminder, we previously made a pragmatic definition of intentionality for strong anticipatory systems. The goal-directed agent processes resources of an agent's internal states and uses them such that the agent's performance reaches an explicitly pre-registered end-state of processing. The goal-directed agent is qualified to be intentionality-bearing since the processing of internal states brings about performance in the environment. Note that the goal-directed action is made by the anticipatory *system's* internal control (not by internal *models*). The internal control is manifest in the agent(hand)-environment coupling when the feedback loops are running. The internal control shows a tendency to reach the goal state.

How do the internal states of an anticipatory system work apart from the functionality of its internal models? In weak anticipatory system, internal models (e.g. emulators) represent the way in which the system will unfold in the environment. They represent on grounds of the aboutness relation, that the internal states of the system stand for the system's mechanisms and the environmental conditions. By contrast, apart from the internal models, the internal states of the anticipatory system *encode* the way in which the system manages to bring about the bodily reaching. How could the strong anticipatory system bear intentionality?

### Rowlands' Account of Representation in Deeds

The notion of strong anticipatory behaviors is closely addressed by Rowlands (2006) in terms of *deeds*: deeds consist of "an array of on-line, feedback-modulated adjustments that take place below the level of intention, but, collectively, promote the satisfaction of the antecedent intention (p. 103)." Rowlands claims that deeds are truly representational, where representation is characterized with the five conditions: (i) informational condition, (ii) teleological condition, (iii) decouplability condition, (iv) misrepresentation condition, and (v) combinatorial condition. Among them, what seems hardest to justify is the decouplability condition: "[i]tem *r* qualifies as representing states of affairs *s* only if *r* is, in an appropriate sense, decouple from *s*. The problem is that it seems to conflict with their *on-line* nature of feedback-modulated adjustments. Even if this problem is solved, a further problem is that simple adaptive devices, such as the WG, the thermostat, and homeostasis, would consequently appear to be qualified as representing.

Those two problems seem likely to be solved in Rowlands' justification of decouplability: the learning history of a motor system provides it with a proper function, which can run "off-drive" in the absence of environmental stimuli (p. 166). Repetitive practice of a motor action, say, catching a flying ball, results in a proper function of ball-catching. The inner states of the motor action are decouplable from the real stimuli of a flying ball, as such states can run in absence of those stimuli. The activating instances of a catching-ball device may differ while some of them might fail in a catching action. Yet, the learnt motor system has obtained the proper function of ball-catching.<sup>7</sup> In addition, animals can learn, whereas the WG, the thermostat, and a homeostatic system cannot. As a consequence, such adaptive devices cannot have a bearing of representing.

Rowlands' justification of decouplability, however, assumes intentionality instead of explaining it, as it resorts to the history of learning (in his term, practice). The present paper would justify the aforementioned decouplability without recourse to either practice or learning, but, instead, relies on the history of the system's on-line adjustments. A successful catching system may operate on different objects, and may even fail in some instances; yet, it is truly a system that represents the states of affairs of catching-a-flying-ball. Such a behavior does not causally depend on a specific kind of objects or events in the environment; hence, that motor system represents the capability of catching-a-flying-ball.

By contrast, the WG, the thermostat, and a homeostatic system, are not representing in the previous sense. The WG and the thermostat are (artificial) devices that do not retain a history of adjustments. In addition, a homeostatic system does not respond to the common living world, world in the literal sense. Here we preserve the term of representation to systems that are capable of responding to the common living environment. Homeostatic systems may be perfectly anticipatory system; yet, it seems to stand at the nebulous boundary of representation that anticipatory systems have.

### Conclusions

The present paper explains motor intentionality, by arguing that strong anticipation is primordial in the making of the anticipatory behavior, while internal models are *supplementary* in the light of efficiency, like a coach supporting a baseball team. A baseball team can perform without a coach despite its lacking good strategies for winning.

The strong anticipatory system bears intentionality because it transforms itself from a body registering a perceptual or imaginary end-state into a body which realizes that end-state in the environment. Such an intentionality is pragmatic because internal resources of the body are used

<sup>7</sup> Rowlands deems that this way of justification is "all the decouplability we can reasonably require for the deed (167)."

for bringing about an end-state in the environment. The pragmatic nature of such an intentionality makes clear two components of the goal-directedness: an explicit end-state pre-registered in perception or imagery, on the one hand, and an evaluative sub-system and a machinery that reduces the negative values, on the other. The former component is put intuitively as a goal and the latter is machinery that brings about the goal in the environment. Thus, we can succinctly put the pragmatic intentionality of strong anticipation in terms of the relation of *bringing-about*, that is, internal states of the body bringing about the end-state in the environment. A novel sense of intentionality, in contrast to that based on Brentano's notion of aboutness, is characterized in terms of a system's history of adjustments.

A notable difficulty in considering a novel sense of intentionality for motor activities is the question of how to distinguish between motor intentionality and mere adaptivity. Both of them are put in causal chains; yet, the former is intentional, while the latter remains purely physical (or biological). To resolve this difficulty, the present paper resorts to the history of (on-line) adjustments in the systems' response to the real environment. This is a feature unseen in merely adaptive systems such as homeostasis, the Watt Governor, and single-cell *Euglena* approaching to the sunlight. They do not register their history of (on-line) adjustments, and accordingly are not anticipatory systems.

Motor behaviors are anticipatory. The present paper explains why and how they are representing, in response to the questions addressed by Wittgenstein and Merleau-Ponty, as mentioned in the introduction. The supplement of internal models on the top of a strong anticipatory system makes the resulting anticipatory system a Popperian machine, which makes the anticipatory systems more flexible. Because they are representing, the strong anticipatory systems discussed in the present paper are not 'mere adaptive systems' as conceived of by Pezzulo (2008) and Grush (1997, 2004, 2007). Internal models in the anticipatory systems are supplementary, although they are necessary in the light of efficiency that is manifest in efficient motor behaviors.

# Is Embodied Cognition Infallible or Falsifiable?

## Investigating the Thesis as a Sound Scientific Theory

### Abstract

Embodied cognition is a growing area of research within cognitive science—one that it is often presented as a framework that may help us account for cognition as a whole. It is, however, a theory and, as such, it must live up to the requirements that all scientific theories do. Of particular importance is the degree to which it is falsifiable. This paper investigates this issue.

**Keywords:** embodied cognition, embodiment, falsifiability

Embodied cognition has been a growing theoretical framework within the field of cognitive science for the past twenty years. It has influenced research on topics from low-level perception (e.g., Meteyard *et al.*, 2008) to high-level reasoning (e.g., Casasanto, 2009) and, as it continues to grow, it is often put forth as an organizing explanation of cognition in general (e.g., Schubert & Semin, 2009). That said, it is a *theory*—specifically, a scientific one. As a result it must be evaluated as any theory would be. To date, the field has done a reasonable job: confirmatory evidence has rolled in, and its methodologies have been refined (e.g., Spivey, 2007). However, despite the field's efforts to do good science through the lens of embodiment, one fundamental evaluation factor seems absent: “Is it *falsifiable*?” remains an open question. Given the importance of falsifiability to scientific enterprise, answering the question is necessary. Addressing this question of falsifiability is the goal of this paper.

### Part 1: What is falsifiability?

Falsifiability is a cornerstone of scientific theory. As Popper (1963) argued, the difference between theories such as Freudian psychoanalysis and Newtonian physics lies not in whether it is possible to verify each theory, nor in whether they possess explanatory power (e.g., a way of explaining experimental results), but in their capacity to be debunked.

For a theory to be *falsifiable*, it is insufficient to only provide ways of supporting it. Instead, it must be possible to specify the types of evidence necessary for showing that the theory would *not* hold. Because it is impossible to directly observe a theory (since a theory is only an organizing principle built to explain a body of information or phenomena), defining only what would support it may allow for confirmation biases and the exclusion of important data. Thus, a scientific theory must involve making specific predictions about what must or should be observed if it holds, *and* what

must or should not be observed if it does not.

Take, for example, the Bohr model of atomic structure. While it is unnecessary to go into detail, the model generally specified a structure of the atom and the way that its nucleus could be related to its electrons. Despite its seeming simplicity, the theory made predictions, including what the energy levels of certain atoms should have been if the theory was correct. Thus, boundaries of what the model could and could not account for were established. When these predictions were violated (e.g., multi-electron atoms displayed energy levels different from what the model predicted) the theory was falsified.

Having the ability to falsify a theory becomes crucial when competing theories exist. If each theory is not specific enough to make predictions, then it becomes impossible to decide which one (if any) is correct. Furthermore, theories that do not make such predictions are often over-generalized (e.g., Freudian psychoanalysis) such that they can account for almost any sort of data. As a result, they can be warped to account for any phenomenon, data, or unique case, creating a confirmation bias. In other words, they become explanatory catch-alls with little real explanatory power. Falsifiability protects against exactly these sorts of problems and, as a result, should play an important part in the development of any theory.

### Part 2: Embodiment and Falsifiability

“Embodied cognition” is something of an umbrella term for work that is interested in the ways in which the body is involved in cognitive processing. In fact, there are so many definitions under the umbrella its boundaries are somewhat contentious. Take, for example, the quantitative issue of how many types of embodiment there are: Shaprio (2011) outlines three types; Wilson (2002) presents six, and there are more accounts still (e.g., Anderson, 2003; Ziemkie, 2003).

This lack of agreement could be considered a complication with regard to evaluating the falsifiability of embodiment; after all, if there exists multiple theories, then each one may require separate analyses. However, the heart of the differences usually centers on what it means *philosophically* for the body to be involved in cognition. For example, the *Enactive Approach* seems premised on the idea that there is no core self that resides inside a body, but that the self dynamically makes itself through interactions with the world. Furthermore, the world is not taken as pre-given,

instead being shaped through the actions of the individual (Shapiro, 2011). As a result, all cognition is enacted through a symbiosis of body and world. *Situated cognition* is similar but it does not break down the concept of “self”, instead maintaining a philosophic distinction between self and not-self (Shapiro, 2011). Cognition ends up being equally dependent upon (and shaped by) pressures from the world, though the self remains a meaningful unit of discussion and study.

Despite the many definitions that exist within the philosophic literature, cognitive scientists and experimental researchers, generally define and operationalize embodiment as some version of the claim that the body affects cognition, or that the body plays a meaningful role in it (whether that be through changes in perception and attention, differences in behavior, or the activation of neural motor systems) (e.g., Markman & Brendl, 2005; de Koning & Tabber, 2011). Thus, while there do exist competing philosophic offshoots of this basic idea, this more basic theoretical claim underlies most of them; it is at the heart of how the theory is defined and used empirically. The goal of this paper is to look at embodiment within this type of empirical (read, practical or scientific, not philosophic) context; we are interested in the ways in which experiments are designed when inspired by it, and the ways in which results are interpreted in light of it. In other words, we are interested in embodiment as a true scientific theory. If it does not live up to this type of scientific standard, it is important to ask whether it should be used as the basis for empirical work, or alternatively, whether there is something that can be done to make it live up to scientific standards. To the point, we proceed with an analysis of existing work, with an eye specifically towards whether the current application of embodiment meets the requirement of falsifiability.

To start this analysis we begin by looking at some of the research that has been done thus far. The remainder of this section will analyze two papers that investigate the affects of the body on cognition, and which are often cited as quintessential exemplars of this type of research. Special attention will be paid to the interpretations of the findings and their potential for allowing embodied cognition to be falsified.

### Part 2.1

The paper “Action observation and acquired motor skills: An fMRI study with expert dancers”, by Calvo-Merino *et al.* presents the idea that motor history affects future cognitive processing. It has been cited approximately six hundred times<sup>1</sup>, often as evidence for a meaningful relationship between mind and body (e.g., Spivey, 2007; Barsalou, 2008).

The study addresses whether one’s motor history affects one’s ability to observe movements in others. For this project, a number of expert dancers (skilled in either ballet or capoeira), along with an untrained control group, were recruited. All participants were asked to watch videos of choreographed sequences from both dance styles. As participants watched the videos, neural activity was monitored with fMRI. Of interest were the premotor and parietal cortices, along with the superior parietal lobe and the superior temporal sulcus—areas previously associated with human action, and observation of action in others (Calvo-Merino *et al.*, 2004; Grafton *et al.*, 1996).

The hypothesis was that activity in these areas would be strongest when watching a dance sequence that one had enacted firsthand. This result was observed. Calvo-Merino *et al.* argued that it must be the case that watching physical activity in others activates some sort of sensory-motor representation (Calvo-Merino, 2004), furthering the idea that bodily experiences affect cognition (as embodied cognition theory posits).

In order to address the degree to which this design offers the chance for falsification of embodied cognition, let us consider other possible outcomes of the study, and how Calvo-Merino *et al.* could have interpreted them. First, the dancers (and/or the control group) could have shown more neural activation when watching dance sequences that they had not engaged in firsthand. Embodiment could be supported by such a result equally well by arguing that the finding was due to a need for learning: motor areas activated more for understanding movements that could not, immediately, be made sense of by referencing past experiences. In fact, this interpretation would be consistent with other data, since it has been shown that the same motor areas that Calvo-Merino *et al.* were interested in demonstrate increased activation during visuomotor learning (Ghilardi *et al.*, 2000). Consequently, whether or not the dancers showed more or less activation than controls, the embodied cognition thesis would still be supported given that bodily experiences would be shown to affect cognitive processing in either case.

Alternatively, the same activation could have been seen between the dancers and the control group, irrelevant of the observed sequences. However, this finding would not necessarily contradict embodiment either. Perhaps the *use* of representations does not require activation of the motor-systems, but encoding is entirely dependant upon them and, as a result, the body still affects cognition. Or, perhaps more radically, one might suggest that such an outcome implies that humans do not possess representations at all. In fact, this is a popular claim among some embodied cognition theorists (Varela, *et al.*, 1992; Smith, 2005) and it could be that no difference was found between groups because there are no static representations stored in the

---

<sup>1</sup> Per GoogleScholar.

brain to be activated in the first place, leaving only motor areas to encode the video information.

While the possible interpretations of the results of the present study certainly indicate that embodiment theory is confirmable, it does not bode well for its ability to be falsified. In fact, it would be equally possible to explain Calvo-Merino *et al.*'s findings by adopting a competing perspective. A disembodied framework could be supported by suggesting that the dancers had encoded static representations of the sequences, which included the muscle groups necessary for performing them. This would account for why the motor areas of their brains lit up in response to watching them, without a need for participants to "simulate" anything. This explanatory flexibility is not a new idea; Mahon and Caramazza (2008) explicated the ways in which many findings that are supposed to support embodied cognition (such as Calvo-Merino *et al.*'s) may also be used to support a disembodied theory of cognition. It is troubling, though, that the theory's explanatory flexibility would exist no matter how the experiment turned out.

One could argue that the problems with this study are a function of how easily neuroimaging can be misapplied, and not of embodied theory itself. However, neuroimaging is a tool and, as such, there will always be ways to use it well and ways to use it poorly. It is quite possible to use this tool well (e.g., Engel *et al.*, 1994), but doing so requires the production of specific predictions so that the meaning of the scans can be clearly interpreted. A failure to do indicates a problem with the theoretical framework underlying the scans. In the case of the current study, the problem lays with the fact that any scan result could have been used to support embodied cognition. This is a problem of the theory, not of the technology.

#### Part 2.2

As another example, consider Tucker and Ellis' "On the relations between seen objects and components of potential actions" (1998). With almost as many citations<sup>2</sup> as Calvo-Merino *et al.*'s work, this study looks at whether the presentation of objects also potentiates the affordances<sup>3</sup> that they allow from the human body. The primary concern of the study is how perception is affected by one's body, and the ways that one can interact with the world through it.

More specifically, the study looks at the relationship between the hand movements used when dealing with everyday objects and the ways that those objects are visually perceived. Tucker and Ellis argued that if an object's affordances are part of its representation, then

it should be easier or faster to respond to the object with a physical movement that is somehow aligned with the affordance. They addressed this question by conducting three experiments.

First, they investigated whether participants would be faster to identify an object if it were presented in congruency with the hand responding to the presentation. For example, if a picture of a knife were presented in the direction that it would be grasped with the right hand, then the interest would be in whether a participant would press a response button more quickly with that right hand since movement in the right hand would be primed. However, an obvious problem is that this design does not determine whether participants are simply sensitive to left/right orientation, or handedness specifically. Thus, the second study asked participants to respond with two fingers on the same hand; the idea being that if participants were sensitive to handedness, instead of left/right orientation, then greater efficiency should not be demonstrated on a single hand.

Results indicated that participants responded more quickly to objects when they were presented in congruency with the hand that was pressing the button (i.e., with the hand that would be used to interact with the object as it was presented). Furthermore, this effect was not confused with simple left/right orientation or response since one-handed responses showed no difference in response times between left and right finger responses.

At first glance, these findings support the idea that an object's affordances are a part of how it is perceived and responded to. Consequently, they seem to support the claim that worldly interactions are embodied; however, if the other possible ways that the study could have turned out are analyzed in the same way that Calvo-Merino *et al.*'s study was, it becomes improbable that such a claim could have been denied.

First, Tucker and Ellis could have found that participants responded more slowly when a stimulus was presented to match the side of the grasping hand (i.e., the experiments' results had come out the opposite way). An obvious explanation for such a finding is that participants were asked to push a button instead of actually grasping – given that these are two distinct movements, it could have been that pushing buttons did not represent the affordances properly, causing interference. In fact, Tucker and Ellis realized this, and offered a third experiment to address it.

In the third condition, participants were given a new response method: responding involved the same wrist rotation and hand positioning that would be required for interacting with the presentation objects. Interestingly, Tucker and Ellis did not find a strong effect between hand positioning and response times, however, they concluded that their findings suggest that more than hand selection (left versus right) is involved in seeing

<sup>2</sup> Per GoogleScholar.

<sup>3</sup> A concept developed by Gibson (e.g., 1950), affordances are the potential ways in which one can interact with a given object (i.e., what sorts of bodily movements that object affords the human body).

and responding to objects (Tucker & Ellis, 1998).

Even if Tucker and Ellis had found a strong effect in their third condition, it would be difficult to argue with (i.e., falsify) any embodied interpretation. First, it could have been that participants responded to a stimulus with convergent affordances much more slowly than they responded to a stimulus with divergent affordances. While the exact meaning of such a finding is not obvious, it would suggest that there is some systematic relationship between the ways that we think about an object and the ways we can interact with it. Perhaps it could be argued that when a stimulus is in congruence with the response action, we begin to activate the next step of movement necessary for interacting with the object and, as a result, move more slowly. For example, if we are presented with a teacup, perhaps we begin preparing our mouths for tea, or our throats for swallowing. Such an interpretation would be supported by other experimental data, which suggests that visually controlled grasping motions (especially in children) are preceded by a series of planning motions, sometimes causing longer response times if the plan is non-ideal (Hofsten & Rönqvist, 1988). Alternatively, embodied cognition often posits that representations (if they exist) are dynamically updated to include experiences (Smith, 2005). It could be argued that more processing time is required to recode a perceived thing based on new data.

Finally, it could have been the case that Tucker and Ellis found no relationship at all. Such a null result would likely be interpreted as puzzling and could be explained away by pointing out that this experiment (like any) required a commitment to a specific methodology and, therefore, specific types of movement and stimuli. One could argue that the movements chosen by Tucker and Ellis were simply non-ideal for demonstrating a relationship (perhaps a knife is more about chopping or sharpening than grasping, and perhaps tea cups are more about sipping, pouring, washing, dunking or even swallowing).

In short, the experiment, although motivated by a prediction of the embodied theory of cognition, provided no easy means for falsifying that theory without running conditions with every possible movement ever associated with a given object. However, even then, research into perceptual dominance could be mobilized to explain such null results. For example, it appears that some sensory modalities are more dominant than others. Vision is often considered the most dominant of human modalities (Sinnott *et al.*, 2007). As a result, any study that is interested in the embodied relationship between vision and bodily movement, and that involves visual stimuli while looking for manual or tactile responses, may be considered flawed in that it could be the case that simply showing a participant a visual stimulus activates more visual experiences or representations

(embodied or otherwise) than hand-oriented experiences or representations. If it is the case that visual responses dominate motor responses, then any null results from a methodology employing visual to manual responses could be criticized and dismissed.

Importantly, we are not suggesting that anyone would actually use some of these alternative outcomes to demonstrate that embodied cognition *is* the case (e.g., that some absence of proof is proof for the thesis). The point is that all of these outcomes *can* be dealt with within an embodied framework. Consequently, it does not appear that this experiment (like the last) offers much by way of an opportunity for falsification.

### Part 2.3

We are not lodging any sort of specific attack on the researchers whose work we have reviewed (these papers were selected for their popularity and clarity). Our concern is that given such experiments are used as support for embodied cognition *qua* a scientific theory (e.g., for Calvo-Merino's paper, Gallese, 2008; Barsalou, 2008; de Konin, 2011; and for Tucker and Ellis' paper, Wilson 2002; Semin & Smith, 2008). It is problematic that such experiments could accommodate, or even explicitly support, an embodied account, no matter how they turned out.

Likewise, we are not trying to discredit any of the subtheories or philosophic work that has been inspired by embodied cognition; certainly, their subtheories, and empirical work based on those theories, that do make and test predictions (e.g., Gray *et al.*, 2006; Hommel *et al.*, 2001). However, embodied cognition itself is not just an inspirational tool—it is posited as a theory in and of itself, and at this point, it is one that seems remarkably susceptible to methodologies that suffer from confirmation biases.

### Part 3: Can We Fix The Problem?

Just because something has not been done, does not mean it cannot be. Thus, it seems important to look at embodied cognition and to determine whether it is theoretically *possible* to falsify. We begin by making the requirements of falsification explicit.

For a theory to be useful scientifically, it cannot simply lend itself to supporting research, but must also be sensitive to the ways that it could be shown *not* to hold. This requires specificity: “theory *x* would be untrue if *y* (and *z* and [...]) were to happen”, where *y* and *z* are observable, measurable and definitive. Doing so ensures that everyone (both supporters and dissenters) can recognize when it is time to abandon the theory. Furthermore, we must accept the possibility (no matter how small) that the theory will be falsified. Falsification would not be such a bad thing though—after all, it would mean that we get an opportunity to build a new, more complete theory of cognition.

Currently, embodied cognition does not seem to have

these sorts of specific boundaries. To date, the closest attempt seems to be a set of claims explicated by Wilson (2002). Unfortunately, even they seem too vague (i.e., unobservable, unquantifiable, indefinite) to act as falsifying predictions. To see this vagueness in action, we consider the first three.

First, Wilson argues “cognition is situated”. That is, cognition takes place in an environment and, therefore, cannot take place without perception and action. It is studied by looking for the ongoing impact of perceptual input during cognitive tasks (Wilson, 2002). However, if this claim is a concrete prediction (open to falsification), then embodied cognition fails whenever such tasks are completed without perception or action. However, Wilson herself posits that this prediction may not hold for all types of cognition; she points out that some things do not always rely on the intake of new information (her examples include planning, reasoning, etc.). Thus, the claim does not involve a clear list of conditions under which it does or does not hold. As a result, it seems more like a “sometimes” prediction than a definitive one.

Second, embodied cognition is supposed to support the idea that cognition is “time pressured” (i.e., that, when pressured to work quickly, cognition can differ). This claim does not make any more forward momentum than the first. If it is a prediction, then falsification should occur any time that cognition does not change based on time-pressure. While, of course, many cognitive activities do, Wilson herself provides us with examples of “time-locked” cognition, such as skilled hand movements (Wilson, 2002). As a result, if this claim is a crucial prediction, the thesis is already in trouble. Alternatively, if it is a “sometimes” prediction like the last claim, then it is simply not specific enough.

Third, embodied cognition expects that we “off-load” cognitive work onto the environment. This claim is evidenced by the fact that people make use of items from the world to solve problems (thus lessening the work required of processes such as working memory). Obviously though, there are times that tasks are not off-loaded, even within the realm of a single task. For example, when determining where furniture should go in a room, it is possible to move it around or draw a diagram, or to visualize different patterns that may be used. It is also possible to mentally map the room instead. Embodied cognition is not definitive enough to predict the “why”, or enough of the “how”, to account for anything more specific than that it *can* happen. This seems incomplete and, again, not usefully predictive.

Because of space constraints, we cannot engage in a similar analysis of the other three claims. As they are, though, they offer no opportunity for falsifiability as they also reduce to variations of “the body is important for cognition under some conditions”. While it is true that such a claim can be turned into experimental work,

it is not enough to fill out the statement, “theory *x* would be untrue if *y* (and *z* and [...]) were to happen” with observable, measurable and/or definitive claims. Without the capacity to produce such claims, embodied theory remains unable to produce sufficiently specific predictions to be falsified.

Basing empirical work on a theory with an unclear foundation can be problematic. Any experiment (like those in Section Two) will have confusing results. No matter how such a study turns out, it can account for the data within the embodied framework, and any null result can be dismissed. This lack of definitiveness leaves researchers that are already invested in embodiment frozen in unsolvable debates without a real possibility of coming to a conclusion, let-alone unifying cognition. Similarly, researchers outside the debate may have trouble finding application for embodiment within their own domains.

Newell (1973) argued that Cognitive Science is often guilty of discovering a phenomenon, doing a plethora of experiments to explore it, and never moving on to think about what the research “means”. It seems that this “plethora” point is where embodied cognition is now—at the crux of exploration and synthesis, with a real opportunity to move forward. The collection of confirmatory data definitely suggests that the body is likely important for cognition *in some way*, however, we have yet to answer what this way is in a specific or systematic sense, and this is what needs to be changed.

We are not suggesting that there is a quick fix, however, we believe this issue of falsifiability can guide future research in a meaningful way: Researchers need to start asking a few questions every time they invoke embodiment. First, asking, “Under what specific conditions do we expect this cognitive process to be embodied?” in combination with, “What cognitive functions are most penetrable to bodily or action-based manipulations (and which are not penetrable at all)?” will allow for the boundaries of the theory to be reigned in. It is unlikely that the answer to every cognitive mystery is “embodiment”, so we need to commit to specific claims about when we think embodiment is meaningful and to what processes we think it makes an important difference. Second, asking “What would it mean for embodiment, as a theory, if my results came out differently?” will force attention to the issues raised in this paper. If this answer cannot possibly be “it would suggest that process *x* is not embodied”, then the methodology may need to be revised.

We are certainly not saying that embodiment should be dismissed (quite the opposite, actually). However, to the extent that embodied cognition is going to be used as a theory, limiting cases need to be defined. Any research that does this is a step in the right direction, and would be useful, not only for the embodiment community, but also for interested outside observers.

We cannot offer a definitive end point for such efforts—we wish we could provide a fast, or easy answer, however developing a comprehensive theory that is aimed at organizing cognition in a deep and meaningful way is not a simple task. Our goal is simply to point out what we see as an important problem. It is our hope that those dedicated to embodied cognition research will respond by becoming more sensitive to the issues raised here, and that, as a result, these researchers will start making their claims more explicit and, more importantly, begin establishing limiting cases of the theory.

## Abstract<sup>1</sup>

We question the need for recursion in human cognitive processing by arguing that a generally simpler and less resource demanding process – iteration – is sufficient to account for human natural language and arithmetic performance. We claim that the only motivation for recursion, the infinity in natural language and arithmetic competence, is equally approachable by iteration and recursion. Second, we submit that the infinity in natural language and arithmetic competence reduces to imagining infinite embedding or concatenation, which is completely independent from the ability to implement infinite computation, and thus, independent from both recursion and iteration. Furthermore, we show that natural language is a finite rather than infinite set.

**Keywords:** recursion; iteration; language; brain; infinity; embedding; arithmetic.

## Recursion and embedding

An influential line of thought claims that a hallmark of human cognitive processing is recursion (e.g. Fitch, Hauser, & Chomsky, 2005; Hauser, Chomsky, & Fitch, 2002; Premack, 2007). Hauser et al. (2002) drew a distinction between the whole language faculty, including the aspects shared with other species or faculties (the faculty of language in the broad sense) and the unique aspects of the language faculty (the faculty of language in the narrow sense). They hypothesized that the unique aspects of the language faculty comprise "only the core computational mechanisms of recursion as they appear in narrow syntax and the mappings to the Sensory-Motor and Conceptual-Intentional interfaces" (Hauser et al., 2002, p. 1573). Lately, this hypothesis has been vigorously challenged (e.g. (Jackendoff & Pinker, 2005; Pinker & Jackendoff, 2005). Interestingly, none of the challenges question the infinity in natural language, and recursion is contested only in Lieberman (2008) and Bickerton (2009) from a neuroscientific and linguistic perspective, respectively.

---

<sup>1</sup> An earlier version of this paper "The redundancy of recursion and infinity for natural language" appeared in *Cognitive Processing* (2011, 12 (1)). As compared to the earlier version, some inaccuracies have been corrected, loosely relevant parts omitted and new arguments added to the present paper.

## Recursion

**Defining recursion** Rogers Jr. (1987, pp. 5-6) gives the following description of a Gödelian recursive definition: "A recursive definition for a function is, roughly speaking, a definition wherein values of the function for given arguments are directly related to values of the same function for "simpler" arguments or to values of "simpler" functions." For example, in the recursive function for defining Fibonacci numbers (for integers  $n > 1$ ),  $Fib(n)$  is directly related to  $Fib(n-1)$  and  $Fib(n-2)$ :  $Fib(n) = Fib(n-1) + Fib(n-2)$ . For the present discussion, the most important aspect of recursion lies in its ability to describe an infinity of (input,output) pairs by a finitely definable set of operations in an effectively computable manner (see Odifreddi, 1992, pp. 34-36, for details).

Recursion differs from iteration (another form of repetition) in two essential respects. First, definitions employing iteration do not involve self-reference. Second, without self-reference, every (input,output) pair needs to be defined explicitly, rendering it impossible to define infinite sets by finite means other than by a control flow loop. Computationally, there is a clear difference between a procedure that invokes another instance of itself (recursion) and a procedure that repeats itself either mechanically or with a control flow loop (iteration). Recursion and iteration are the only computational solutions for handling repetition.

As a rule, implementations of recursive functions are slower than those of iterative because recursive functions must allocate memory for their multiple instances. In Abelson et al. (1996), the difference between recursive and iterative **processes** is captured as follows. Recursive processes are characterized by a chain of deferred operations and require that the interpreter keep track of the operations to be performed later on. An iterative process is one whose state can be summarized by a fixed number of state variables, together with a fixed rule that describes how the state variables should be updated as the process moves from state to state. All this being said, recursive **procedures** (or definitions) tend to be formally and notationally more elegant than iterative ones. The difference between process and procedure is explained below.

The influential paper by Hauser et al. (2002) was the first to explicitly formulate the view that recursion is a component of the language faculty (regrettably, no definition of recursion was given in the article). After

reviewing all statements about recursion in the paper the following definition emerges (numbers in brackets refer to the pages in Hauser et al. (2002)): recursion is a neurally implemented (p. 1574) computational mechanism (p. 1573) that yields a potentially infinite array of discrete expressions (pp. 1570, 1571, 1574) from a finite set of elements (p. 1571). Crucially, a computational mechanism with finite input and potentially infinite output, described here, does not imply recursion, as it is possible to generate a potentially infinite output from a finite set of elements without recursive operation by implementing  $n \rightarrow \infty$  operations iteratively. Hence, it is not clear whether the mechanism described by Hauser et al. (2002) is recursive or iterative. While it is plausible that the notion of recursion as applied by Hauser et al. (2002) refers to the 'recursion' in the Minimalist Program (Chomsky, 1995), the latter allows for a range of interpretations. Tomalin (2011, p. 308) has, usefully, distinguished between nine different interpretations of 'recursion' in formal sciences, with 'inductive definition' as the most broad one (and thus the safest for syntactic theory). Tomalin's (2011) theoretic variants and computational equivalents of recursion ( $\lambda$ -definability, Turing computability et al.) are more or less on the same level of abstraction but recursion can also be defined in five different levels (in the order of decreasing abstractness):

Table 1. 'Recursion' in five different levels.

1. Inductive (or recursive) definition: A definition with a base rule, specifying that certain "simple" objects are in the class, and an inductive (recursive) rule, stating that if certain objects are in the class, then so are certain other objects formed or derived from them (Minsky, 1972).
2. Recursive definition for a function: A definition wherein values of the function for given arguments are directly related to values of the same function for "simpler" arguments or to values of "simpler" functions (Rogers Jr., 1987).
3. Recursive function: A function that is defined recursively (see 2).
4. Recursive procedure: A procedure that, when executed, invokes another instance of itself (Abelson, Sussman, & Sussman, 1996).
5. Recursive process: An execution of a recursive procedure (see 4).

We suggest that, for cognitive and neural modelling, the procedural level (4) is of central importance. For the following discussion, it is crucial that the recursion we are looking for is implemented in the brain (Hauser et al., p. 1574), i.e. it is not something that is posited at the level of computational theory only (Marr's (1982) level 1 of his three levels of information processing). However, the situation is still very confusing, as it is possible to have neurally implemented recursion of level 1 that is

implemented non-recursively (i.e. by iteration) at levels 4-5! In the next section we will give an example of this. It is also important to note that level 1 in Tab. 1 corresponds to Marr's level 1 (computational theory) and levels 4 and 5 in Tab. 1 correspond to Marr's level 2 (algorithm and input/output representation) of information processing. The following section examines whether and how any of the levels in Tab. 1 can be connected to Marr's level 3 (hardware implementation) in the brain.

**Recursion, iteration, and inductive definition** All open-ended sets (e.g. language expressions,  $\mathbf{N}$ ) can be defined inductively, i.e. recursively in the broadest sense. For example, one can have the following inductive definition of 'bear': (a) *Ted is a bear*; (b) *All entities that share at least 98% of Ted's genome are bears*. Observe that, although the set of potential 'bears' is open-ended and inductively defined, no recursion is computationally necessary to determine its contents. An iterative process that compares Ted's genome to that of potential 'bears' would do the job. Importantly, the difference between iteration and recursion pertains to levels 4-5 only. Thus, even if recursion were used in levels 1-3, the involvement of a recursive process or procedure would not be implied, as it can be implemented with a purely iterative computational process (e.g. on a Turing machine).

Below is a strip of iterative pseudocode (1) that defines the infinite set of finite strings  $\dots[X[X[X[XY]]]]$  that is also defined by the recursive strip (2):

```
(1)  $Y \rightarrow XY$  (iteration) :
    s=Y           //assign Y to s
    while true:   //infinite loop:
        rw(Y,XY,s) //rewrite Y as XY in s

(2)  $Y \rightarrow XY$  (recursion) :
    s=Y           //assign Y to s
    rec(s)        //declare function rec(s)
    {             //start definition of rec(s)
        rw(Y,XY,s) //rewrite Y as XY in s
        rec(s)     //call function rec(s)
    }             //end definition of rec(s)
```

As one may observe, (1) and (2) are computationally equivalent – at the level of computational theory, both are described by the rewrite rule  $Y \rightarrow XY$ . Incidentally, this also means that rewrite rules can be "recursive" only in the sense of "recursive definition" (level 1 in Tab 1., which corresponds to Marr's level 1).

From the viewpoint of effective calculability, general recursion and Turing computability are equivalent (Kleene 1952, p. 300), and a universal Turing machine can enumerate any recursively enumerable formal language (an infinite set of finite strings) as can general recursion (Sipser, 1997). Turing machine is based on iteration, whereas general recursion is based only on recursion. Over finite

outputs, recursion and infinite iteration are computationally equivalent (Turing-equivalent).

Crucially, as there is no neural model of recursion (of whatever level), one is unable to identify it in the brain and, accordingly, unable to verify its existence. On the other hand, Lieberman (2008, p. 527) has recently suggested that "neural circuits linking local operations in the cortex and the basal ganglia confer reiterative capacities, expressed in seemingly unrelated human traits such as speech, syntax, adaptive actions to changing circumstances, dancing, and music", thus obviating the need for a neurally implemented recursion. Of course, the distinction between neurally implemented recursive and iterative processes is rather opaque for present-day methods, i.e. the possibility of a neurally implemented recursion cannot be ruled out. We argue for iteration only as a simpler and equipotent computational alternative to recursion.

In sum, there would be no sense in (and no obvious way of) implementing level 1 (in Tab. 1) in the brain separately from levels 4 and 5. As for levels 2 and 3, it would be outlandish to assume that the brain somehow (and apparently redundantly) implements **equations** of the processes it carries out. Thus, implementations of these levels can be ruled out as well. We have also argued that implementations of levels 4 and 5 would be impossible to identify in the brain with present-day knowledge and methods.

**Recursion, induction and self-embedding: a confusion** In computer science, on the procedural level, recursion denotes the syntactic property that a procedure definition refers to the procedure itself (Abelson et al., 1996). In Chomsky's (1956, 1971 [1957]) phrase structure grammar, recursion is a property of rewrite rules (all that is on the left side of the rewrite arrow repeats on the right side of the arrow, e.g.  $A \rightarrow AB$ ) (Chomsky, 1956, 1971 [1957]). Essentially, this notion of recursion reduces to inductive definition. For some other theorists, recursion is a structural property: a situation where an instance of an item is embedded in another instance of the same item (e.g. Heine & Kuteva, 2007; Jackendoff & Pinker, 2005). For clarity, let us call the three recursion, induction and self-embedding, respectively. Recursion and self-embedding are logically independent for the following reasons. First, a self-embedded structure (an NP within an NP, a box within a box etc.) does not have to be recursively generated. Jackendoff and Pinker (2005) submit a picture of a rectangular form within another rectangular form as an example of 'recursion in visual grouping'. Obviously, this has no bearing whatever on recursion. It would be outlandish to assume that recursion is necessary to put a box in a box, or for understanding that a box is in a box. Yet, for conspicuous (but nonetheless insufficient) reasons, this assumption is held with syntactic categories like sentence and NP. The reasons are, of course, the inductive rewrite rules of generative grammar (e.g.  $NP \rightarrow A NP$ ), and they are insufficient as the type of induction can be generated iteratively as well (cf. (1)). Furthermore,

iteration is defined as the repeated application of a transformation (Weissstein, 2003), which is something that Chomsky's (1956, p. 113) description of his early transformational version of generative grammar explicitly incorporates: "/---/ phrase structure is limited to a kernel of simple sentences from which all other sentences are constructed by repeated transformations". The confusion with recursion can be traced back to Chomsky (1971 [1957], p. 24; 1956, p. 115), who refers to loops as 'recursive devices'. The source that the formalism is taken from refers to the loops as 'circuits' ("a closed series of lines in the graph with all arrows on the lines pointing in the same orientation" – Shannon & Weaver, 1964 [1949], p. 47). The circuits pertain to a graphic representation of finite-state Markov chains, and to call them 'recursive' is jumping to the conclusion, as Markov chains do not prescribe an algorithmic realization for the circuits – Markov chains are confined to Marr's level 1 just like inductive definitions. In Chomsky (1959, p. 143), 'recursive function' is used as a synonym for 'Turing computable function'. Again, this is confusing, as computational equivalence does not imply algorithmic equivalence (which is absent in this case). In sum, the Chomskian notion of "recursion" is a case of confusing Marr's levels of information processing (1 and 2).

Fitch (2010) claims that iterative functions are inadequate for generating center- and/or self-embedding. As an example of the superiority of recursion over iteration, he presents a recursive center-embedding program generating  $A^n B^n$ . Below is an iterative pseudocode that does the same:

```
C = ""           //evaluate C to the empty string ""
for i = 0 to n do: //loop n times
  C = concatenate("A",C,"B") //concatenate "A", C and
                             //"B", and assign the result to C
```

The program embeds  $C$  between "A" and "B"  $n$  times, with  $i$  indicating the depth of embedding in each cycle of the loop. It is true that "recursive functions take their own past output as their next input" (Fitch 2010, p. 75) but this feature is not unique to recursion – in our above examples, concatenate() coupled with iteration does the same.

As for confusing recursion with self-embedding (characteristic to most linguists but not to Chomsky), the two are already in principle very different. Recursion pertains to a process or procedure, self-embedding pertains to a structure. A recursive process or procedure is something that, more often than not, cannot be directly observed. Self-embedding, on the other hand, is usually salient and a subcase of a cognitive phenomenon we term 'hierarchical interpretation'. A defining difference between hierarchical and non-hierarchical interpretation is that only the former allows the same unit to be interpreted simultaneously as a type (i.e. category) and as a token (i.e. instance), hence implying additional interpretative correlates not present in the input. The type/token distinction is a precondition for self-embedding, where tokens are embedded under the same type (e.g. NP or clause). An example of hierarchical

interpretation is natural language. Linguistic interpretation is compounding, merging smaller units that are per se meaningful in the code (Chomsky, 1995; Hauser et al., 2002). As far as we know, linguistic code is unique among natural communication systems in stipulating semantic compositionality, whereby meaningful units are combined into diversely meaningful higher-order units (e.g., words into phrases, sentences and compound words, phrases into sentences and higher-order phrases, etc.).

As an illustration that self-embedding is possible in hierarchical interpretation only, consider the following example: the inductive center-embedding rule  $AB \rightarrow AAB$  generates the strings  $AAB$ ,  $AAAB$  etc. It is impossible to tell by looking at these strings whether their generation procedure (or process) was recursion, iteration or neither (cf. Fitch, 2010, and the example above). Furthermore, it is impossible to tell whether the strings exhibit self-embedding. Without any a priori assumptions about the generative mechanism (e.g. stipulation of a certain phrase structure grammar), it is undecidable whether a string  $\dots AAB \dots$  is embedded, concatenated, or elementary (assuming that different generative mechanisms may allow for different elementary strings).

## Embedding

Embedding is a situation where an item is embedded in any item (with infinity not implied). Embedding is logically independent from recursion (i.e. there can be one without the other). First, embedding does not have to be generated by a recursive rule. It can be created iteratively or by any other function with relevant output. Second, a recursive process or procedure does not have to yield (relevant) output. Assuming that we cannot witness a recursive process or procedure in situ (e.g. in the brain), two conditions must be met for attesting it: (1) it must generate output, and (2) there must be a one-to-one correspondence between the values of the recursive procedure and its output. Logically, self-embedding is a situation where an instance of an item is embedded in another instance of the same item (with infinity not implied); thus, self-embedding is a proper subset of embedding. The fact that embedding is hierarchical has frequently raised speculations about a putative underlying recursive process or procedure (or more unfortunately, resulted in confusing embedding with recursion). As explained above, a hierarchical or embedded structure is insufficient to decide on its generative mechanism.

## Infinity in natural language and arithmetic competence

The central claim of Hauser et al. (2002) and Chomsky (2010) is that a neurally implemented recursive process introduces infinity to natural language and arithmetic. An example of (potential) infinity in natural language and arithmetic competence is the **knowledge** that one can add 1 to  $n$ , append a natural language expression to text or embed clauses indefinitely. Of course, we are incapable of

**performing** infinitely in any of these tasks (hence the famous competence/performance distinction – Chomsky, 1995).

Chomsky's derivation of neurally implemented recursion for operating on  $\mathbf{N}$  is as follows. A) Any formal definition of the set of natural numbers  $\mathbf{N}$  incorporates recursion by means of the successor function, where  $1 = S(0)$ ;  $2 = S(S(0))$  etc. B) We have knowledge of the properties of  $\mathbf{N}$  (i.e., given enough time and space, we can compute the sum of two numbers, and distinguish the right from the wrong answer). From premises A and B he conjectures that neurally implemented recursion is required for operating on  $\mathbf{N}$  (e.g. for adding 4555 to 7884). Thus, we have the following: (a) infinity in natural language and arithmetic competence (to motivate neurally implemented recursive process in the first place), (b) neurally implemented recursion is required to operate on  $\mathbf{N}$ , and (c)  $\mathbf{N}$  is an offshoot of the language faculty. From these premises, it follows that (d) neurally implemented recursion underlies both  $\mathbf{N}$  and natural language.

On the face of it, the above argument for neurally implemented recursion is consistent and logically sound. However, premises (a)-(b) are false, and in section "Arithmetic performance" we argue in more detail that neurally implemented recursion is not necessary to operate on  $\mathbf{N}$ . As explained below, infinity in natural language and arithmetic competence reduces to **imagining** infinite embedding or concatenation, and thus does not qualify as an output of a recursive process or procedure (as there is no reason to assume that conceptualizing infinity requires recursion). The concept of neurally implemented recursion is largely motivated by the 'discrete infinity' property of natural language (Chomsky, 1995; Hauser et al., 2002). In fact, the whole distinction between the broad and the narrow language faculties, as originally proposed by Hauser et al. (2002), can be derived from this property. Importantly, the infinity of natural language has been always taken as axiomatic and never proven. The last instance that Chomsky appeals to in this question is Wilhelm von Humboldt (1999 [1836]) who simply states the infinity of natural language as a fact.

One might start from the observation that the maximum possible natural language "corpus" – everything that has ever been and will be processed – is not infinite but a finite, just physically uncountable set. We propose that this is precisely the nature of language as it should be accounted for. In fact, the very spacetime that can support physical computational systems is finite (Krauss & Starkman, 2000). This substantial correction (physically uncountable finity instead of infinity) is suggested for the sake of unambiguity and exactitude. Physically uncountable sets can be finite or infinite. Set-theoretically, potential and actual infinity (Moore, 1990) are proper subsets of physical uncountability. The evidence that Hauser et al. (2002, p. 1571) submit for discrete infinity covers also physically uncountable finity: "There is no longest sentence (any candidate sentence can be trumped by /---/ embedding it in "Mary thinks that ..."). It

would be a contradiction to assume that the size of a finite, physically uncountable array can be compared to the size of all others, or that such array can be embedded (the mere fact that we can imagine embedding such an array does not account for its capacity of being embedded). "There is no non-arbitrary upper bound to sentence length." This is as true for an infinite as it is for a finite, physically uncountable array.

The finity of natural language can be also derived logically, without invoking physically instantiated computation:

1. Natural language has a limit which is either infinite or finite.
2. Natural language computation takes time.
3. From 1 and 2 it follows that, for any given moment in time, there is an infinite number of finite limits that are never reached.
4. Assuming that the cardinalities of natural language and  $\mathbf{N}$  are equal<sup>2</sup>, there is only one infinite limit that is never reached.
5. For any finite limit that is never reached, the probability of natural language having it is  $> 0$ .
6. From 3-5 it follows that the probability of natural language having the infinite limit is 0.

### Arithmetic performance

If recursion were involved in conceptualizing numbers, our brain would execute something like a successor function  $\dots S(S(S(0)))\dots$  for natural numbers and maybe also  $n*n*n*n\dots$  for base- $n$  integer exponents (since we normally use base-10 numeral system,  $n$  would normally equal 10). While  $n*n*n*n\dots$  can be coded and implemented recursively as well as iteratively, it is unlikely that anything approximating  $\dots S(S(S(0)))\dots$  or  $n*n*n*n\dots$  would be run in our brains for conceptualizing numbers and performing arithmetic on them. If it were, our arithmetic performance should be significantly better than it tends to be. If, on the other hand, our inferior arithmetic skills are down to general performance limitations and/or penalties for (other) arithmetic operations, there would be no apparent use for running these procedures for our mathematical capacity. The only remaining justification for  $\dots S(S(S(0)))\dots$  and  $n*n*n*n\dots$  would be recursion in the language faculty. However, for this concession to make sense, there would first have to be some evidence for recursion in the language faculty. As we have argued at length above, at present we have merely conjectures built on invalid premises (see section "Infinity...").

It is easy to demonstrate that conceptualizing a principle (recursion) for producing a pattern of output ( $\mathbf{N}$  or self-

embedding) does not entail (1) that the principle is necessary for producing the pattern (as  $\mathbf{N}$  or self-embedding can be also produced iteratively), and (2) that the principle itself must be neurally implemented for us to be able to conceptualize it. For example, we can conceive that all natural numbers are derived from the number 20098 by  $\pm 1$  operations, i.e. each time we conceptualize a natural number  $x$  that is less than 20098, we subtract 1 from 20098 until we get  $x$  and each time we conceptualize a natural number  $y$  that is greater than 20098, we add 1 from 20098 until we get  $y$ . We can conceive this principle. Does it follow that the "20098  $\pm 1$ " principle must be neurally implemented for us to be able to conceive it in the first place? Surely not. Observe that the situation with the "20098  $\pm 1$ " principle is similar to the recursive one: we can conceptualize the principles but both are at odds with human arithmetic performance. To circumvent the latter problem in the neurally implemented recursion hypothesis, the competence/performance distinction has been called into effect. However, a competence/performance distinction could be also invoked for explaining why our performance is at odds with the "20098  $\pm 1$ " principle. Besides, the distinction raises a non-parsimonious psychological duality as to the conceptualization of relevant syntactic and arithmetic properties – we can conceptualize that the properties are given to us by a recursive principle, but we do not seem to follow the principle neither in linguistic nor arithmetic processing/performance. Furthermore, it seems inconsistent to explain the apparent discontinuity between competence and performance in arithmetic and language by e.g. limitations in primary memory – what potential advantage could a neurally implemented recursive principle bestow if its effects are subject to so severe constraints?

### Conclusion

We conclude with the following points. First, both recursion and iteration allow for finite definitions of infinite sets. Moreover, iterative solutions are frequently less resource demanding than recursive ones (cf. section "Defining recursion"). Second, three logically independent notions of "recursion" are being conflated and confused in linguistics (e.g. Chomsky, 1956, 1971 [1957]; Heine & Kuteva, 2007; Jackendoff & Pinker, 2005): (A) recursive algorithm (Marr's level 2), (B) recursive (or better, inductive) definition (Marr's level 1), and (C) an instance of an item embedded in another instance of the same item. We suggest a terminological way out of the confusion, by reserving 'recursion' for (A) for which there are no alternative terms, and designating (B) and (C) 'induction' and 'self-embedding', respectively. Third, the technical preciseness of the notion of recursion makes it next to impossible to find evidence for it in the brain with the present-day methods, and there is no reason to assume neurally implemented recursion by default (see below). Fourth, contrary to Chomsky (Chomsky, 1995; Hauser et al., 2002) and many others, we argue that a property of natural language is not discrete infinity but physically uncountable finity. Fifth, we

<sup>2</sup> Since we are interested in an upper bound of computation/processing time,  $\aleph_0$  is sufficient. It is difficult to develop the argument here but the very fact that time intervals seem to exist suggests that time is not infinitely divisible ( $\aleph_1$  and beyond). Other indications of this are e.g. Achilles and the tortoise paradox and Planck time.

reject the received opinion, articulated by Chomsky et al. (Chomsky, 2010; Fitch et al., 2005; Hauser et al., 2002), that neurally implemented recursion is necessary to explain natural language and arithmetic competence and performance. The only motivation for neurally implemented recursion is infinity in natural language and arithmetic competence (e.g. the knowledge that one can add 1 to n, append a natural language expression to text or embed clauses indefinitely). We claim that infinity in natural language and arithmetic competence reduces to imagining infinite embedding or concatenation, which is completely independent from an algorithmic capacity for infinite computation, and hence, completely independent from neurally implemented recursion or iteration. In sum, there is no infinity in natural language and arithmetic processing, but even if there were, iteration would be sufficient for generating it.

### Acknowledgments

We thank Noam Chomsky and Margus Niitsoo for extremely helpful, thorough and critical discussions, and Märt Muts, Lameen Souag, Lutz Marten, Tania Kuteva, Michael Corballis, Panu Raatikainen, Tim Gentner, Geoffrey Pullum and the anonymous reviewers for their comments and suggestions. ## Abstract

People often have thoughts, attitudes and biases that are not themselves consciously aware of or that they would rather not share with others. To assess such attitudes, researchers use paradigms like the Implicit Association Test (IAT) that do not rely on explicit responding to determine the level of bias a person holds towards a particular target concept (e.g., race, gender, age). Responses in the IAT are assumed to reflect deeply held beliefs and attitudes, and not shallow, superficial associations. However, as linguistic distributional information has been shown to serve as a viable heuristic in many cognitive tasks, we investigated whether it could be used to predict the level of bias established by the IAT. We used a large corpus of language (Web 1T) and data from 16 IAT studies ( $N = 1825$ ) to examine whether the degree of linguistic co-occurrence for target concepts and attributes reflected the size of bias observed in human behavioural data. We found that the effect size of the linguistic biases corresponded strongly with the effect sizes from the behavioural data. We suggest that language reflects prevalent cultural attitudes which are captured by tasks such as the IAT, suggesting that the IAT may reflect shallow, linguistic associations rather than deeper conceptual processing.

**Keywords:** linguistic distributional information; implicit association test; IAT; attitudes; model.

## Introduction

If we openly asked people questions like "are you sexist" or "are you racist", we would probably expect people to be reluctant to respond, if we got any response at all. When asking for judgements on controversial topics and divisive issues, people have a strong desire to provide socially acceptable responses that may be contrary to their true beliefs (e.g., Furnham, 1986; Paulus, 1991). As such, there is often a disconnect between what people say and what they do. In order to avoid tasks that require explicitly thinking about a particular issue or that permit strategic responding by participants, researchers in social cognition have instead developed paradigms that try to tap into people's attitudes in a more implicit manner (Fazio, Jackson, Dunton & Williams, 1995; Greenwald, McGee & Schwartz, 1998). The most frequently used of these paradigms is the

Implicit Association Test, or IAT. The IAT is essentially a categorisation task, similar to many priming paradigms used across the cognitive sciences, designed to capture the degree of bias or prejudice that an individual has towards a particular concept. (e.g, race, age). We describe the task in more detail below.

A search using Google Scholar reveals that the IAT is referenced in over 4000 papers in the last 10 years alone. In spite of its widespread use, there is ongoing disagreement regarding what the IAT is actually measuring (Blanton et al., 2009; Fazio & Olsen, 2003; Greenwald, Poehlman, Uhlman & Banaji, 2009). Nonetheless, the creators and most proponents of the paradigm maintain that "the IAT assesses the strengths of associations between concepts" (p18., Greenwald, Poehlman, Uhlman & Banaji, 2009) and it is assumed to reflect deep, underlying, unconscious biases. However, when one situates the IAT within the broader context of cognitive research examining the structure of the conceptual system, such a claim is ambiguous.

Several researchers have described the conceptual system as comprising two distinct but interrelated components; a linguistic system and a simulation system (Barsalou, Santos, Simmons & Wilson, 2008; Connell & Lynott, 2011; 2012; Louwerse & Jeunieux, 2008). The linguistic system reflects language usage, and captures the distributional patterns (or statistical regularities) of words and phrases, making this system best suited for "quick and dirty" heuristic processing (Lynott & Connell, 2010). The simulation system, on the other hand, captures perceptual, affective and motor information from our environmental experience and is better suited to deep, slow, precise processing. Thus, performance in the IAT may reflect responses from one of these two systems, raising two alternative hypotheses. The first, is that the IAT indeed reflects personal attitudes emerging from deep-rooted, affective and conceptual processing in the simulation system. For example, an intelligence/obesity prejudice (O'Brien et al, 2007) would take the form of conceptual retrieval of a "fat person" automatically evoking associated concepts of "stupidity" and a negatively valenced affective association of "badness". This perspective is summarised by Nosek, Banaji and Greenwald (p112., 2002)

who argue that implicit attitudes "reveal the *deep* influence of the immediate environment and the broader culture on internalized preferences and beliefs".

The second option is that IAT scores reflect much shallower processing of the socio-cultural environment, specifically the token-to-token statistical patterns of the linguistic system. For example, people may often encounter the word "fat" in close proximity to the word "stupid" in conversations they hear or in texts they read, resulting in the automatic activation of the word "stupid" every time the word "fat" is encountered. Importantly, activating a word like "stupid" does not require full conceptual retrieval (Louwerse & Connell, 2011). Rather, linguistic associations like these operate at a shallow, superficial level that can produce a response to a given task without recourse to deeper conceptual or affective processing.

There is good reason to believe that the IAT may reflect the latter shallow linguistic associations rather than the former deeper, affective, conceptual attitudes. Several studies have shown that the linguistic system is used as a shortcut to provide a "good enough" response to conceptual tasks, whenever possible (e.g., Connell & Lynott, 2012; Louwerse & Connell, 2011). In particular, when processing demands are shallow and the participant is placed under time pressure the linguistic system provides a useful heuristic for responding without recourse to the greater computational expense of full, perceptual, affective and motor simulation of the concept. For example, conceptual tasks such as property-verification (e.g., making true/false judgments regarding object properties - *apple can be green*) can be successfully completed solely on the basis of the word-to-word associations of "apple" and "green"; these words frequently appear in close proximity and therefore it is a reasonable heuristic to assume that this property belongs to this concept. When participants respond quickly (Louwerse & Connell, 2011) or when the set of items is poorly constructed (Solomon & Barsalou, 2004) their responses are based on these linguistic associations and not on deeper conceptual representations. For example, using response time data from a property-verification task, Louwerse and Connell (2011) demonstrated that measures of distributional patterns from the linguistic system could be used to predict the faster responses of participants, but not their slower responses. Conversely, measures of the simulation system could predict slower responses, but not faster responses. Evidence that the IAT does not engage deeper processing is provided by a recent study by Foroni and Semin (2012). Foroni and Semin had two groups complete the IAT; one group completed the task as normal, while the other completed the task with facial feedback being inhibited by holding a pen between the lips during the task. Holding the pen in this position leads to sustained activation of the zygomaticus major muscle (used in frowning), which is normally activated following the presentation of a valenced stimulus. However, inhibition of this muscle during the IAT made no difference to the level of bias observed. This suggests that IAT does not engage

the affective system in a way that would be expected if the task required processing in the simulation system.

Given that the linguistic system is capable of providing quick and dirty responses in a variety of seemingly complex tasks and given that responses in the IAT may be of a superficial nature (i.e., not requiring the deeper processing of the simulation system), we considered whether IAT biases could be predicted by the statistical distributional associations in language. While the linguistic associations and simulation systems are closely related, they are not exact replications of each other because each system gains experience from a different source. Just because two words share a linguistic association in the socio-cultural environment, because they are sometimes juxtaposed, it does not mean that their referent concepts are tightly bound in a personal, affective/conceptual attitude. If IAT responses are predicted by linguistic associations then it suggests that the IAT itself is a shallow measure of the language structure to which an individual has been exposed and not necessarily a reflection of deeper biases. We describe below the IAT paradigm in more detail before outlining the current study.

Condition	Word belongs to...?	"stupid"	"smart"
Congruent	Bad OR Fat	fast	[incorrect]
	Good OR Thin	[incorrect]	fast
Incongruent	Bad OR Thin	slow	[incorrect]
	Good OR Fat	[incorrect]	slow

Table 1: Schematic of response patterns in an IAT on obesity prejudice. The first column describes category as congruent or incongruent pairings. The second column indicates the two judgements participants must consider for each target word. Third and fourth columns describe the predicted patterns for two target concepts "stupid" and "smart". "Incorrect" indicates a wrong answer (e.g., "stupid" should not be "good" or "thin")

### The Implicit Association Test

The IAT represents one of the most frequently used paradigms for examining implicit attitudes (e.g., Greenwald, McGee & Schwartz, 1998), with hundreds of studies already published using this approach (see e.g., Greenwald, Poehlman, Uhlman & Banaji, 2009). The IAT is used to give an insight into people's automatically activated biases and prejudices and is designed to overcome the issues of strategising and socially desirable responding by participants. The IAT achieves this by requiring extremely rapid and accurate responses from participants to tap into automatic associations between some target concept and an attribute. For example, O'Brien and colleagues (O'Brien, Hunter & Banks, 2007) examined people's anti-fat prejudices using the IAT to see whether people associated obesity with negative concepts like stupidity. The IAT contrasts performance for a *congruent* pairing of targets and attributes (e.g., obesity-bad; thinness-good) to an

*incongruent* pairing of targets and attributes (e.g., obesity-good; thinness-bad). The participant's task is to categorise target stimuli as they appear on screen using one of these two pairings. In a congruent block, if the word "stupid" appeared onscreen, the participant would press the key indicating they belonged to the "fat OR bad" category, while if the word "smart" appeared they would press the key to categorise it as belonging to the "thin OR good" category. In this way, each target attribute has an identifiably correct response. Table 1 presents a schematic of the responses in both congruent and incongruent conditions. Every participant completes both categorisation pairings in a counterbalanced fashion.

The key question is, which pairing do participants respond most quickly to. Once all responses have been made, a bias score can be calculated for each participant and then an overall bias can be calculated for the entire sample. If participants are generally faster in their responses for the congruent condition in the obesity IAT example above, this would indicate a negative bias towards obesity related concepts. In analysing response times, the IAT scoring algorithm calculates the difference in average response latency between the congruent and incongruent conditions and dividing by the standard deviation of all latencies for both conditions (Nosek, Greenwald & Banaji, 2007). For paper-based versions of the IAT the difference is calculated based on the number of correct responses in a 20 second period in the congruent/incongruent conditions (e.g., O'Brien et al, 2007). If there is a large difference between the categorisation conditions in terms of response times or number of correct responses, this will result in a larger bias score. The difference between congruent and incongruent response times or accuracy reflects the extent to which people believe that fat people are stupid and thin people are smart. The IAT is thus assumed to offer a window into deeply-rooted beliefs and prejudices that are otherwise difficult to impossible to access explicitly.

The IAT has been used to uncover and measure biases in a wide range of domains, such as attitudes towards race (Greenwald, McGee & Schwartz, 1998), gender stereotyping (Rudman & Kilianski, 2000), alcohol (Wiers et al, 2011) and doping among athletes (Brand et al, 2011) to name but a few examples. What's more, the IAT has been shown to be predictive of people's overt behaviors, underscoring its practical utility. In a meta-analysis of 156 studies, Greenwald and colleagues (Greenwald, Poehlman, Uhlmann, & Banaji, 2009) found that IAT measures correlated significantly with explicit measures of behaviour. In some cases, IAT scores are better predictors of behaviour than more explicit measures. For example, Asendorpf, Banse, and Mücke (2002) found that shyness in individuals was better predicted by a shyness-oriented IAT than by explicit self-ratings of shyness. In some ways the IAT seems to capture attitudes and beliefs that we hold, but that which find it difficult to consciously and explicitly access ourselves.

## The Current Study

We have described the IAT paradigm and suggested how it may draw on processing from either the shallow linguistic system or be reliant on deeper processing from the simulation system. To examine whether IAT performance is predicted by linguistic associations we used behavioural data from several published IAT studies and linguistic data extracted from the World Wide Web, using the Web 1T 5-gram corpus (Brants & Franz, 2006). The Web 1T is a snapshot of web pages indexed by Google in 2006 and contains over 1 trillion tokens, making it one of the most representative corpora of language available. Our aim was to examine whether co-occurrence patterns in the linguistic data could predict the effect sizes observed in the behavioural data. We expected that if implicit attitudes (as captured by the IAT) reflect the distributional patterns of language in the linguistic system, then we should see a significant fit between the two sets of data using regression analyses. On the other hand, if the IAT relies on deeper processing in the simulation system, we would not expect such a relationship to exist.

IAT Topic	Reference	N

Table 2: Sources of the 16 Implicit Association Tests used in the study, with number of studies from each source in brackets, and the total N participants for each source.

## Method

**Materials** We selected 16 IATs from journal articles that used lexical (as opposed to pictorial) stimuli and provided a full list of materials used. Table 2 lists the topics of investigation for each of the IATs, the source reference and the total sample sizes from the original studies; 15 of the studies come from published journal articles and one from a paper in preparation (O'Brien & Lynott, in prep). The IATs cover a broad range of topic areas, including studies of racial stereotypes, obesity and gender roles. Each IAT consists of a set of category concepts (e.g., male, female, good, bad) and a set of target attributes that are of positive or negative valence (e.g., reliable, pleasant, terrible, nasty). The number of attributes used by the IATs ranged from 3 to 25, with a total of 324 target stimuli.

Figure 1: Scatterplot, with line of best fit, for IAT scores from human behavioural data plotted against scores derived from log-transformed linguistic data.

**Human Behavioural Data** The 16 IATs represent data from 1825 participants. From each IAT we extracted the overall effect size of the bias found based on the human responses ( $D_H$ ). The IAT effect size is closely related to Cohen's  $d$ , a popular measure of statistical effect size.

**Linguistic Model** The aim of the model is to calculate the size of the linguistic bias ( $D_L$ ) for each IAT, based on the specific terms used in each task. In order to approximate the linguistic distributional information, we carried out a corpus analysis using the Web 1T 5-gram corpus. Using the corpus we are able to calculate the difference in the strength of associations for each categorisation condition in each IAT. For example, for an IAT examining preference for flowers versus insects, we calculate the level of association between one categorisation pairing (e.g., co-occurrences for "flower" and all positive attributes + co-occurrences for "insect" and all negative attributes) and the inverse, "incongruent" categorisation pairing (co-occurrences for "flower" and all negative attributes + co-occurrences for "insect" and all positive attributes).

The strength of association is calculated by summing the frequency of co-occurrences of category terms (e.g., flower, insect) with each of the attribute terms (e.g., nice, horrible, etc.). For each category-attribute pairing (e.g., flower-nice), we calculated the cumulative 5-gram frequency of forward and backward co-occurrences between the category word and attribute (i.e., the summed count of occurrences of

[flower ... nice] and [nice ... flower] in the corpus with zero, one, two and three intervening words: for a similar approach, see Louwerse & Connell, 2011). Because of the large number of calculations this required (>10,000), we developed a semi-automated tool to take each set of IAT terms and output the collocation frequencies from the Web 1T corpus. Using these summed frequencies we then calculated a linguistic effect size using two models; one model based on raw frequency counts and one model based on the log-transformed frequencies (using the natural log). Ji (2010) discusses the improvement in the distribution curves of datasets of seven sub-corpora after having undergone log transformation as the transformation mitigates the effects of extreme values (i.e., highly frequent terms). Thus, both linguistic models represent the ratio of the frequencies for the congruent categorisation condition compared to the frequencies of the incongruent categorisation condition. Finally, we conducted separate linear regression analyses for the two linguistic models using the linguistic bias ( $D_L$ ) as a predictor variable and the behavioural bias ( $D_H$ ) as the dependent variable.

## Results & Discussion

The effect sizes in the human data ranged from -.49 to 3.65 ( $M = 1.2$ ,  $SD = 1.07$ ), while the effect sizes in the linguistic data ranged from .2 to 7.3 ( $M = 2.02$ ,  $SD = 2.1$ ) for the raw frequency model and from .85 to 1.31 ( $M = 1.05$ ,  $SD = .14$ )

for the log-transformed model. Using linear regression analyses we found significant relationships between the effect sizes calculated from the human data,  $D_H$ , and the effect sizes calculated from the linguistic models,  $D_L$ . This positive relationship indicates that the larger the effect in the linguistic data, the larger the predicted effect in the human data. Figure 1 illustrates the relationship between the biases predicted from the log ratio linguistic model and those derived from the human data. The regression model for the raw frequency ratio model was significant ( $r^2 = .612, p < .001, n = 16$ ) resulting in a  $\beta$ -coefficient of .782 for the linguistic predictor ( $t = 4.696, p < .001$ ). The regression model for the log frequency ratio model was also significant ( $r^2 = .596, p < .001, n = 16$ ) resulting in a  $\beta$ -coefficient of .772 for the linguistic predictor ( $t = 4.544, p < .001$ ). This indicates that both models reflect approximately 60% of the variance in the human IAT scores.

## General Discussion

This study investigated whether linguistic distributional information can be used to predict levels of implicit attitudes as measured by the Implicit Association Test. We observed significant relationships between effect sizes from human behavioural data and effect sizes calculated from linguistic distributional data. This finding suggests that performance on the IAT may not reflect the deeply-rooted biases and beliefs held by individuals and groups, but instead reflects shallower linguistic associations they have encountered in their environment. While the present results are promising, there are of course some caveats we need to be aware of. We discuss some of these limitations and avenues for future research below.

An obvious question to ask is, if the IAT reflects only shallow linguistic processing, then how is IAT performance predicting overt behaviours? There are two issues here. The first is that the while IAT is successful in predicting outcomes in certain sub-domains (e.g., political preferences), it poorly reflects outcomes in others (e.g., sexual orientation; Greenwald et al., 2009). The second is that even where IAT performance is claimed to predict other behavioural outcomes, the claims may not stand up to closer scrutiny. It is important when comparing overt measures to IAT performance that one uses implicit tasks that have clear behavioural outcomes. Good examples of this are patient treatments and using realistic CVs/resumés for assessing job candidates. Green et al (2007) found that doctors' levels of implicit bias towards black patients did not always tally with their decision to offer treatment using thrombolysis to remove blood clots. Although doctors with higher anti-black bias were less likely to treat black patients than white patients using thrombolysis, those doctors with low anti-black bias (but not a *pro*-black bias) were actually more likely to treat black patients than white patients. In re-analysing data looking at racially discriminating behaviour in job candidate selection, Blanton and colleagues (2009) found that the IAT failed to predict any discriminatory behaviour when factors such as rater reliability and outlier removal were taken into account. In one case, previous

evidence of anti-black prejudice was actually reversed revealing a pattern of pro-black bias. However, the process of candidate evaluations can be broken down further. For example, selection and shortlisting of candidates can be viewed as more of a heuristic process, while providing specific grades to individual candidates can be seen as more deliberative. Blommaert, van Tubergen and Coenders (2011) distinguished between these two aspects of the candidate assessment process while examining the effects of implicit attitudes towards ethnicity and gender. They found that only explicit measures predicted people's grading of candidates, but that both implicit (IAT) and explicit measures predicted people's shortlisting of candidates. Thus, it is important to take into account both the task domain and the nature of the task (i.e., heuristic or deliberative) to have a clearer idea of whether the IAT and therefore linguistic distributional information may have a role to play in predicting behavioural outcomes.

A limitation of the current approach is that it does not discriminate between different groups and different task contexts and how this would affect performance on a given IAT. For example, we would not necessarily expect a group of American students and a group of Chinese students to show the same type of bias judging American and Chinese faces paired with positive or negative attributes. One possibility would be to extend the model to incorporate additional domain terms that would calculate co-occurrence frequencies but limited to specific contexts to attempt to approximate these contextual effects.

Although it may be argued that language reflects our cultural beliefs and social norms, it is difficult to establish a causal relationship between implicit attitudes and the linguistic data. It may be that the linguistic distributional information is a) driving the formation of these biases, b) is the behavioural outcome of these biases or c) part of a self-sustaining cycle of biases influencing language influencing biases and so on. However, it is clear that exposure to socio-cultural attitudes does impact our own attitudes and behaviours, as developmental changes are evident in IAT performance. For example, older subjects tend to show larger IAT effects than younger subjects (Hummert, Garstka, O'Brien, Greenwald, & Mellott, 2002). As language is one of the key methods for the transmission of socio-cultural information, this underscores the possible role for language exposure in the formation of implicit attitudes (Nosek, Greenwald & Banaji, 2007).

In conclusion, we present the first model of implicit attitudes based on linguistic data extracted from the world wide web. We found that linguistic models revealed a strong correspondence with human behavioural data. We see language as a primary means for transmission of attitudinal information and agree with Uhlman and colleagues (in press) that "implicit attitudes reveal the power of cultures to reproduce themselves in individual minds". However, our findings also suggests that such implicit attitudes may not represent deeply rooted beliefs as has previously been assumed. Ongoing work is exploring the predictive power of the model by using linguistic data to predict attitude

effect sizes in advance of behavioural studies, providing a strong test whether our hidden beliefs can be revealed in the patterns of our language use.

# External Working Memory and the Amount of Distributed Cognition

Naoki Maeda

Teachers College, Columbia University, 525 W. 120<sup>th</sup> Street  
New York, NY 10027 USA

## Abstract

While processing of a large number of (visuo-spatial) items are oftentimes necessary for ongoing cognitive activities, the biological working memory can process only about four items of information. Then it is a mystery how we cope with complex world situations. This is the paradox of working memory. This paradox is solved once we view the external features of the world as constituting part of working memory. Part of working memory is externally distributed if the external features of the world constitute part of material supervenience base of working memory. Tversky's Spractions (2010), or actions onto the world, are the key to offload of cognition, because they redirect the attention at the working memory level only to relevant aspects of the world. To see how people use spractions to offload working memory load, subjects were asked to build a Lego block in front of a camera. Using cognitive ethnography, it was observed that they all relied on spractions to cognize. From the fact that the biological working memory can process only about four items of information, the amount of working memory based distributed cognition can be calculated.

**Keywords:** paradox of working memory; external working memory; spractions

## Introduction

Working memory (hereafter WM) is a limited capacity system to temporarily maintain, access, and update information necessary for ongoing cognitive activities (Baddeley, 2000, 2003; Awh et al., 2006; Jonides et al., 2008). Traditionally it is conceived of as short-term memory (STM) buffer, characterized by the firing of neurons; it can hold information for a couple of seconds. Since STM does not involve structural change of neural networks, information stored in STM is transient. STM, and hence WM, is one of the core components of cognition. Hardly any cognitive task can be completed without the involvement of STM. For example, when you add some numbers, you have to create a temporal mental representation for those numbers. Biological WM is a limited capacity system; it can maintain, access, and update only limited amount of information simultaneously. In his seminal paper "*The magical number seven, plus or minus two*," George Miller (1956) argued that the capacity of WM is limited to about seven items of information. However, as later pointed out, Miller's magical number seven was inflated due to the confound effect of linguistic chunking, a strategy to group small items of information into an integrated representation (discussed more below). According to a more accurate estimate (Sperling, 1960; Landman et al., 2003; Cowan, 2001; Jonides et al., 2008; Hauser et al., 2000; Block, 2007), the capacity of biological

(visuo-spatial) WM of human adults is limited to about four items of information. That is, WM can selectively attend to only about four items of information simultaneously.

While the capacity of biological WM is limited to about four items of information, the world around us is full of complexity, rich in detail, and oftentimes cluttered (i.e. there are usually more than four items of information in the world, and they are oftentimes relevant to ongoing cognitive activities). Thus, there is an overflow of information at the WM level (Kessell and Tversky, 2010; c.f. Rowlands, 1999; Block, 2007, 2011). Although we have to cognize quickly in response to stimuli in the world to survive (c.f. Cruse, 2003; Kirsh and Maglio, 1994), given the complexity of the world and the limited WM capacity, it is not at all clear how we can do so. Nevertheless, we are almost entirely unaware of the limitation of biological WM in daily life except for some minor occasions such as remembering a telephone number for the first time, and cope with high cognitive tasks day by day. It is a mystery how a severely constrained WM can cope with the complexity of the world. I call this the *paradox of working memory*.

A traditional strategy to overcome this paradox is the aforementioned chunking. Chunking is a way to enlarge a representational unit of attention so that more items of information can be processed with the same WM capacity. For example, although a random sequence of alpha-numerical letters are difficult to remember and process due to the limited capacity of biological WM, once they are chunked into a meaningful sequence, they can be remembered easily. Thus, a seemingly meaningless sequence of "CIAUCLAKGB" can be remembered easily by means of chunking; they are chunked into "CIA," "UCLA," and "KGB". Chunking thus enlarges the conceptual unit of attention by means of LTM. Although linguistic chunking is well known, it is not the only chunking. Information can be *visually* chunked if visual information is stable over time (Magnuson et al., 1998). Such expanded STM capacity with the assistance of non-STM, such as LTM, is called *compound STM capacity* (Cowan, 2001). Visuo-spatial information can be chunked both verbally and visually. Chunking itself is a partial solution to the paradox of working memory.

The question is "is chunking sufficient to overcome the limitation of WM?" It does not seem so, first because the world contains a lot of visual complexity that cannot be verbally chunked and second because the world is not stable enough to enable visual chunks to be formed. This can be seen in change blindness (Simons et al., 2005). Change blindness refers to the surprising difficulty observers have in detecting a significant change to their visual field. In the

experimental setting, usually two different pictures flicker quickly. Although there is a significant difference between them, a large portion of subjects, to their surprise, does not detect the change. In the change blindness cases, the reason why participants cannot detect the change is precisely due to the instability of the scene. And they do not seem to linguistically chunk the visual stimuli. If they could chunk visual information perfectly in order to account for every visual stimulus into four items of information, they would detect every single change. Although whether this is a case of “blindness” characterized by lack of experience is a controversial issue (Block, 2007, 2011), it is relatively clear that there is no cognitive access to the change (because we are not “aware” of the change). Thus, it seems that chunking alone does not solve the paradox of working memory. We are then brought back to the paradox.

### External Working Memory and Spractions

How can we solve the paradox, then? I argue that the solution to the alleged paradox is to view the external world – space, gesture, body, action, and so on – as constitutive part of material supervenience base of WM. Once we view the human agent and its immediate surrounding environment as a coupled cognitive system (Clark and Chalmers, 1998), the external features of the world *in the coupled system* can be regarded as constituting part of material supervenience base of WM (Rowlands, 1999). The external features of the world can temporarily maintain, allow for access, and update information necessary for ongoing cognitive activities. As a consequence, the external features of the world can functionally augment the limited capacity of biological WM. Because of the external features of the world, I argue, we can cope with complex real world situations, even if our biological WM capacity is severely limited. To cognize efficiently, in other words, we are naturally exploiting the external features of the world as a material supervenience base of WM function. There is no problem with chunking per se; I am proposing that it is only a partial solution to the problem. Once theoretically conjoined with the external WM, they together solve the paradox of working memory.

Biological WM has been believed to be augmented by LTM, the external features of the world, and such; this functional whole has been called *compound WM* (Cowan, 2001). Under the concept of compound WM, however, components other than biological WM, such as LTM and the external features of the world, are considered mere *causal part* of WM. That is, while the external features of the world, in which we are embedded, are important aids to WM, according to this view, they are not themselves constituents of WM (c.f. Rupert, 2004). I argue that components other than biological WM, especially the external features of the world, are indeed *constitutive part* of WM. The coupled system of biological WM and the external features of the world together constitutes functional WM; WM is actually extended into the external world (c.f. Hutchins, 1995).

Although it might seem trivial, the difference between ‘causal’ and ‘constitutive’ is important. Roughly stated, constitutive part of something is part of what it is to be that something, while causal part of something is not. Block (2007) illustrates this point as follows; “cerebral blood flow is *causally necessary* for consciousness, but activation of the upper brainstem is much more plausibly a *constitutive condition*, part of what it is to be conscious” (p.482; emphasis mine). The distinction of causal/constitutive in cognitive science is captured by the debate between extended cognition and embedded cognition (Rupert, 2004; also discussed in Clark, 2008). The hypothesis of extended cognition (dubbed as HEC in the literature) asserts that the external features of the world constitute part of material supervenience base of cognition; the hypothesis of embedded cognition (dubbed as HEMC in the literature) holds that the external features of the world are causally relevant to cognition but do not themselves constitute part of cognition.

	External WM	Compound WM
External World is ...	Constitutive part of WM	Causal part of WM
Hypothesis of ...	Extended cognition (HEC)	Embedded cognition (HEMC)

Table 1. The conceptual difference between external WM and compound WM.

The original idea of external WM comes from Rowlands (1999). Using George Miller, Rowlands argues that biological WM is enormously limited, unstable, and unreliable so the main locus of WM should actually be external information-bearing structures. Challenging Rowlands, Rupert (2004) claims that external WM is not plausible, while compound WM is, based on the fact that the nature of the contributions of the biological WM and external features of the world are profoundly different. As Clark (2008; also Clark and Chalmers, 1998) argues, however, externalism does not demand fine-grained functional similarities of the inner and outer contributions. While precisely how WM is offloaded is debated (Gray et al., 2004; Gray et al., 2006), the general upshot, then, is that WM is externally distributed if the external features of the world constitute part of material supervenience base of WM, even if functional similarities are not fine-grained.

According to computational cognitive science, the basic function of cognition is largely accounted for by two main factors; computation and representation (c.f. Horst, 2011). The concept of computation and representation naturally applies to WM as well. By means of representation and computation, WM can store, update, and access information necessary for ongoing cognitive activities. Then, there are two ways how we externalize WM; by externalizing computation and by externalizing representation. Having said so, it is important to note that computational function and representational function do overlap (McClelland et al., 1986; Clark, 1989, 1993) so that the distinction is merely ideal-typical.

We seem to be naturally offloading complex computation onto the external world if it is an available option (Gray et al., 2004; Gray et al., 2006; Wilson, 1994). For example, although we can rotate objects mentally (Shepard et al., 1971), it is more efficient (faster and more accurate) to do so physically. The ubiquity of physical rotation as computational action is found by Kirsh and Maglio (1994). It seems that we use external computation when WM load is heavy (Kirsh et al., 1994). Also, we offload WM representational function by exploiting the stability of the world. That is, by leaving information in the external world, we reduce the WM load the biological WM has to process, as the external world is too complex to process in the biological WM. In a way, we use the world as its best model, as roboticist Rodney Brooks once put (1991). In a block-copying-task (Ballard et al., 1992), subjects are asked to replicate a model shown in the model box in the workspace, using blocks in the resource box. Eye-movement tracking reveals that subjects look at each box many times, the same pattern found in the eye-movement tracking of the change blindness experiment. A natural interpretation is that we do not construct detailed internal representations of the external world, because the world is reliably there and representing the external world accurately exceeds the WM capacity.

From the ‘load theory of attention’, it is known that appropriately directing attention requires the active maintenance of stimulus priority in WM (De Fockert et al., 2001). Under high WM load conditions, then, it is difficult to maintain stimulus priority. As a result, more distracters are processed in WM. In other words, as WM load increases, we get more confused. This is a dilemma, since at the perceptual level (i.e. early selection), heavier (visual) load, or more visual information processing, reduces distracters (Lavie, 1995). When the world is visually complex, however, there is likely a heavy WM load and overflow of information at the cognitive level (i.e. late selection). Tversky (2010) argues that gestures, use of tools, and reconfiguration of the space will help us cognize, because they abstract, schematize representations, and facilitate our attention. That is, by means of abstracting and schematizing, attention is directed only to important aspects of the world. Tversky calls such abstracting/schematizing actions *spractions* (space-abstraction-action). Actions onto the external world, such as gestures, use of tools, and manipulations of the world, facilitate directing WM level attention only to relevant aspects of the world to the task at hand. That is, via *spractions*, WM load is offloaded onto the world (c.f. epistemic actions of Kirsh and Maglio; 1995). The hypothesis entailed is that, as WM load increases (as the world gets visually complex), people offload it onto the world rather than process it internally, although it is in principle possible to process it internally. Consequently more *spractions* (or epistemic actions) are likely to be observed.

## Experiment

To test whether/how we are offloading WM onto the world, subjects were asked to build Lego blocks and the way they used the space – use of *spractions* – was analyzed. Lego was chosen because Lego block assembly consists of pattern matching, planning, decision-making, and problem solving, all of which rely on WM. As the model used in the experiment targets young children, WM load is assumed relatively light. If offload of WM load is observed in this experiment, it can be generalized to many of daily situations, which have higher WM load.

## Method

The basic methodology used here is generally called cognitive ethnography (c.f. Ball et al., 2000; Hollan et al., 2000; Kirsh, 1999; Kessell and Tverksy, 2010). It differs from the traditional ethnography in that it emphasizes specificity, purposiveness, and confirmation (Ball et al., 2000). Rather than observing a field without prior knowledge or theory, cognitive ethnography relies on small-scale data collection based on representative time slices of the domain of interests that is confirmable. Instead of thick description (Geertz, 1973), participants’ activities were videotaped to be analyzed. To guarantee the objectivity of analysis (and consequently confirmation), codes were devised, and Cohen’s Kappa ( $0 \leq K \leq 1$ ) was calculated. Codes were devised so as to pick up *spractions*. Cohen’s Kappa is an indicator of inter-coder agreement; as Kappa is higher, coders interpret the same data more similarly, and thus analysis is considered more objective. It turned out that Cohen’s Kappa was 1.

## Participants

Total 6 female students from the same graduate school participated in the experiment on a voluntary basis. All participants agreed on being videotaped. They were all in their twenties when the experiment was conducted. They were all naïve as to the purpose of the study. They all signed an informed consent approved by the University Institutional Review Board (IRB).

## Material

Lego Technic 8065 (target age 7-14) was used for the experiment. It was selected for a pragmatic reason. It can be easily completed within one hour. Subjects were asked to build Lego Technic 8065 based on the instruction manual while being videotaped. Two different models can be built out of Lego Technic 8065. All were given the instructions for one of the models. Although some instructions instruct to sort blocks in advance, this one does not.

## Results

Although it is possible to process information internally, it was observed that participants constantly engaged in one or more of *spractions* over the videotaped session. That is, they

constantly used the external space as external WM. Out of six participants, five did sorting regardless that the instructions did not say to do so (some Lego instructions instruct to sort blocks in advance). Two did sorting in advance only; one did sorting on demand only; two did both. One did not do sorting at all; she made a significant number of mistakes. Although the sample size is too small to make a generalization, sorting seemed to help participants to think. As sorting is time-consuming, if viewed purely from the pragmatic perspective, it is disadvantageous (c.f. Kirsh and Maglio, 1994). Also, in principle it can be done in the head. Regardless, the participants did sorting. All the participants separated assembled blocks from the resource pool. This pattern was consistent. When there was more than one assembled block, they were grouped together and placed separated from not-yet-assembled blocks.

All of them looked at the instruction and/or model after picking up a piece. Although it was difficult to follow participants' eye movements, it was a consistent pattern that all the participants looked at the instruction and the model many times after picking up a desired piece. In most cases, they first looked at the instruction to pick a piece. Once they picked up a desired piece, they again looked at the instruction to see where it fit. Although it is possible to process both types of information simultaneously (i.e. which piece and where it goes), looking at the instruction once, it does not seem cost-effective given the stable world is out there and given that making detailed mental representation seems time consuming. It seems that use of external representation was commonplace. This finding is consistent with the theory of the limited WM capacity and previous experiments, such as block-copying task.

All of them did physical rotation and alignment following the instruction. When the model in the instruction was flipped, participants flipped their model as well. Although the instruction instructs to rotate, it does not instruct to align the model to the instruction. All the participants consistently aligned the instruction and the model under assembly. Such actions (alignment and rotation) are disadvantageous if they are taken purely as physical actions (c.f. Kirsh, 1995), but clearly have epistemic advantage. Although the Lego Technic 8065 is relatively simple (target age is 7-14), it still is too complex to mentally manipulate accurately. Physical rotation and alignment are clear cases of spraction.

One participant counted the number of holes by using another piece as a counting tool. She had to connect two parts by putting two bars into holes; there were thirteen holes, and bars had to be connected to the fourth and sixth holes respectively. She counted the number of holes on the instruction booklet with the piece. All the participants compared a piece with the booklet by placing the piece on the instruction, at least once during the assembly. Length is oftentimes overestimated or underestimated (Jones et al., 2006). It is thus difficult to accurately represent length mentally (WM load is heavy). The accurate length is printed on the instruction (obviously for measuring purpose).

Consequently, all the participants compared the length of a piece with the instruction by placing it on the instruction.

## Discussion

The world is full of complexity and we have to survive in such a complex world. The complexity of the world easily overwhelms the capacity of biological WM (Kessell and Tversky, 2010). Biological WM alone, then, does not seem to suffice for us to live a normal, smooth daily life. People exploit the external world as the material supervenience base of WM by means of spractions. People gesture, arrange the world, and make symbols and artifacts. Spractions and their consequences, such as reconfigured space, augment the limited biological WM capacity. WM then is not an equivalent concept to biological WM but it consists of biological WM and the external features of the world (and perhaps more, such as LTM). Both the brain and the world can serve as the material supervenience base of WM (c.f. Rowlands 1999). There is no qualitative difference between the external features of the world and the biological WM.

To observe how external WM plays out in reality, participants of the experiment were asked to assemble Lego blocks in front of a video camera. The analysis of the videotaped session revealed how they used the external world as external WM. They externally did what they in principle could do mentally. For example, they looked at the instruction after they picked up a desired piece to see where it is assembled. In principle, one gaze suffices to construct a mental representation of the external world. However, they referred back and forth between the piece and the instruction diagram. Similarly, they sorted blocks before assembly. In principle, sorting of pieces can be done purely mentally (if you have a photographic memory, you can in principle memorize all the patterns and locations of pieces on the table and classify them according to some manner). However, as the capacity of biological WM is limited to about four items of information, and Lego block assembly requires processing of more than four items of information, it seems participants externalized (offloaded) their cognition onto the world. Overall, spractions were observed constantly over the videotaped session. As the model used in the experiment target children between 7 and 14 years old, WM load is assumed relatively light. As many of daily situations are assumed to have higher WM load, it is inferred that offload of WM functions is ubiquitous in daily life.

The idea of externalization of WM function might be challenged on the ground that some people can do tremendous amount of information processing in the head alone without externalizing WM function. For example, some expert abacus users can multiple large numbers within a minute. Rumelhart et al. (McClelland et al., 1986, chap. 14) speculate that the ability to do information processing that seems too difficult to do in the head derives from the ability to do so externally; they are merely visually imagining what we do externally. Frank et al. (2011) confirmed this. That is, mental calculation by abacus users involves visual manipulation of imagined abacus.

Furthermore, they demonstrated that the amount of visual information abacus users process in the head cannot exceed the capacity limit of the biological visuo-spatial WM (in their case, 3). Thus, the fact that some people can do tremendous amount of information processing in the head without relying on the external world does not seem to constitute a counterexample.

We can calculate the amount of distributed WM-based cognition. The amount of externalized WM-based cognition is equal to the relevant amount of information for a given cognition minus four chunked items, the items of information the biological WM can process, or

$$y = z - \sum_{i=1}^4 x_i,$$

where  $y$  is the amount of distributed cognition (measured in the number of items),  $z$  is the number of items (cognitive load) demanded for a task at hand, and  $x_i$  is chunked items of information processed in the biological WM.

## Abstract

In this study, we experimentally investigated the relationship between complacency, defined as missing automation malfunctions, anomalous conditions, or outright failures, and the human tendency to prefer either automation or manual operation. We experimented using two different tasks with human participants to evaluate their individual tendencies to lapse into complacency and to use automation. The result indicated that the participants who prefer manual operation also tend to lapse into complacency. We assume that participant vigilance against automation stability might link these two phenomena.

**Keywords:** Human-automation system interaction; Complacency; Automation usage; Vigilance

## Introduction

Progress in technology has provided many opportunities for people to use automation systems, including on airplanes, ships, and in automobiles (Parasuraman, Molloy, & Singh, 1993; MacFadden, Giesbrecht, & Gula, 1998; Rajaonah, Tricot, Anceaux, & Millot, 2008). Parasuraman and Riley (1997) defined automation as technology that performs actions for humans. Human workload can be reduced by automation; however, the automation performance is often degraded by sudden environmental changes and automation malfunctions. Therefore, using automation is not always efficient. In using such automation, complacency is one major problem encountered by people. Complacency is defined as missing automation malfunctions, anomalous conditions, or outright failures caused by inadequate monitoring (Parasuraman & Manzey, 2010). Complacency causes fatal accidents since users do not detect or are slow to detect automation failures (Parasuraman et al., 1993).

Parasuraman and Manzey (2010) described why complacency happens. They stated that in multi-task situations where users allocate one task to automation and perform the other tasks by themselves, they need to manually conduct their tasks while monitoring the allocated automated task performance. In such situations, the manual tasks compete with the automated task for the user attention, and users tend to concentrate on their manual tasks instead of the automated task. Therefore, the frequency of monitoring automation is lowered, and users often fail or become slow to detect automation failures. Moreover, Parasuraman and Manzey

(2010) showed that there are two types of complacency: fixation and attention failures. Fixation failure occurs when the automation failure is out of the users' sight. Attention failure occurs when the automation failure is within the users' sight, but out of their attention.

Many studies about complacency have experimentally investigated fixation failure with multi-task situations where the automated and manual tasks were displayed separately. The participants conducted their own manual tasks while simultaneously monitoring the automated task. Automation breakdown occurred during the experiments. When automation failure was detected, the participants had to push a particular button on their computer keyboards. Such task situations showed the following strong complacency effects: (1) when the automation capability is stable rather than variable (Parasuraman et al., 1993), (2) when the workload is high rather than low (Metzger & Parasuraman, 2005), and (3) when the arousal level is low rather than high (Singh, Molloy, & Parasuraman, 1993).

On the other hand, a few studies about complacency have experimentally investigated attention failure. Duley, Westerman, Molloy, and Parasuraman (1997) set up the same multi-task situation as in the previous studies about fixation failure, but they superimposed the automated task on the manual task on a single display. Automation breakdown also occurred during the task. In their experiment, complacency occurred on the superimposed display. They showed that even when the automated task is in the users' sight, complacency occurs because they do not focus on the automated task.

The previous studies of human-automation system interaction, which experimentally investigated the human preference to use automation or to conduct manual operation, indicated individual differences in the selection. Lee and Moray (1992, 1994) showed that users who have a tendency to use automation, i.e., automation-oriented users, tend to trust automation. Rajaonah et al. (2008) showed that manual-oriented users tend to perceive higher workload and greatly decrease their vigilance while monitoring automation more than automation-oriented users. Additionally, Maehigashi, Miwa, Terai, Kojima, and Morita (2011) showed that automation-

oriented users tend to select whether to use automation or manual operation by reacting more sensitively to the changes of automation capabilities than manual-oriented users.

As indicated above, many studies have experimentally investigated the nature of human complacency in automation usage and its orientation. However, no experimental investigations have focused on the relationship between these two phenomena. In this study, we experimentally investigated the relationship between complacency and a preference of automation usage. We drew the following hypotheses:

- Hypothesis 1: A relationship exists between complacency and a preference for automation usage.

If Hypothesis 1 is supported, two detailed hypotheses are raised. Lee and Moray (1992, 1994) showed that users who tend to use automation also tend to trust it. Parasuraman and Manzey (2010) argued that overtrust in automation may lower the frequency of monitoring it, causing complacency. Therefore, it is predicted that automation-oriented users will detect automation failures more slowly than manual-oriented users. Therefore, Hypothesis 2a is as follows:

- Hypothesis 2a: Users who prefer to use automation tend to lapse into complacency.

On the other hand, Rajaonah et al. (2008) showed that users who tend to conduct manual operation tend to greatly decrease vigilance while monitoring automation more than automation-oriented users. Vigilance is the ability to sustain attention, and a lack causes complacency (Molloy & Parasuraman, 1996). Therefore, it is predicted that users who tend to conduct manual operation will tend to detect automation failures slower than automation-oriented users. Therefore, Hypothesis 2b is as follows:

- Hypothesis 2b: Users who prefer manual operation tend to become complacent.

## Experimental task

We used two different experimental tasks. The first was the auto-manual selection task used by Maehigashi et al. (2011). We evaluated participant preferences to use automation based on their performances in this task, where they tracked a line that scrolls downward past a circle vehicle. When the circle vehicle veers off the line, the performance score is reduced as operational error. The participants were allowed to switch to either auto mode (operation completely performed by the program) or manual mode (operation performed by participants using left and right arrow keys) by pressing a selector on the keyboard. We manipulated the auto and manual capabilities with five levels, and the auto and manual capabilities changed independently. The participants had to compare the auto and manual capabilities to select the mode that shows higher task performance (see Maehigashi et al. (2011) for details). It is preferable to select the auto mode when the auto capability is higher and the manual mode when the manual capability

is higher. However, deviation from the normative behavior is caused by the participant tendencies to use automation. We evaluated their preferences to use automation based on the percentage of using the auto mode in the auto-manual selection task.

The second was a supervisory control task (Figure 1). We evaluated participant tendencies to lapse into complacency based on their performances on a dual task shown on a single display. One was a search task in which the participants looked for target stimuli (L) among distracter stimuli (T) that scroll downward. When the target was found on the screen, the participants pressed a selector on the keyboard while the target is inside the double line (detection area) at the display's bottom. If the target is successfully detected, the color of the target letter changes to red. When the participants missed the target or gave a false alarm, the performance score was reduced as operational error. We manipulated the number of target and distracter stimuli for high and low workload conditions in the experiment.

The other supervisory control task was a monitoring one. The participants monitored an auto that operates a circle vehicle to track a line. The line scrolls downward past the circle vehicle. When the circle vehicle veers off the line, the performance score is reduced as operational error. Basically, the auto perfectly performs the line tracking. However, in specific timing, auto failures occur and the circle vehicle stops tracking the line during the task. When the participants detect the auto failures, they need to manually operate the circle vehicle by pressing the left and right arrow keys. In the supervisory control task, the participants simultaneously conducted these two search and monitoring tasks. We evaluated their tendency to become complacent based on their reactions to the auto failures.

Figure 1: Supervisory control task: high (left) and low (right) workload conditions.

## Experiment

### Method

**Participants** Thirty-five university students participated in our experiment.

**Factorial design** In the supervisory control task, the experiment had a two-factor within participants design: (1) workload (high and low) and (2) type of failure (sudden and gradual). For the workload factor, 100 target and 400 distracter stimuli in the high workload condition and 25 target and 100 distracter stimuli in the low workload condition emerged during the task. For the type of failure factor, in the sudden

failure condition, the auto that has perfectly operated the circle vehicle suddenly stops because its capability suddenly becomes 0. The breakdown continues for 10 seconds. The circle vehicle that tracks the line suddenly stops moving and immediately veers off the line. In the gradual failure condition, the auto gradually stops operating because its capability gradually decreases to 0 for 40 seconds. The breakdown continues for 10 seconds. The circle vehicle that tracks the line gradually slows down and finally veers off the line.

**Procedure** Prior to the supervisory control task, we conducted an auto-manual selection task whose procedure was basically the same as in Maehigashi et al. (2011). First, the participants practiced conducting the task in two training trials. Next we conducted an experimental task that consisted of 25, 40-second trials. The auto and manual capabilities randomly changed among five levels during the task. When one trial ended and another began, the display showed “capabilities changed” at the center of the screen. Throughout the experiment, the values of the auto and manual capabilities were not displayed on the screen. The participants were required to achieve as high a score as possible. They were given a five-minute break after the auto-manual selection task was completed.

After the break, we conducted the supervisory control task. In the training trials, the participants first separately practiced conducting the search and monitoring tasks and then experienced both simultaneously. Each training trial lasted one minute. After the training trials, we conducted the experimental task that consisted of two blocks of nine trials each. One block was conducted in the high workload condition and the other in the low workload condition. The order of the workload conditions was counterbalanced among the participants. The auto failures occurred three times in each block. Sudden failure occurred 40 seconds after the second trial began. Gradual failures occurred from the beginning of the fifth (or sixth) and the ninth trials. The participants were required to operate the circle vehicle manually when auto failure occurred. However, participants were not informed about either types, the frequency, or the timing of the auto failure. When the auto capability recovered after the auto failures, the display showed “capability recovered” at the center of the screen. The participants were instructed to delegate the operation back to the auto after the recovery. Throughout the experiment, the manual capability was stable and sufficient to manually track the line.

## Result

**Manipulation check** In the auto-manual selection task, for all participants, the mean percentage of using the auto mode was 44.20%, and the mean task performance (the percentage the circle vehicle was on the line) was 75.02%. In the search task of the supervisory control task, the mean number of missed targets was 0.28 in the high workload condition and 0 in the low workload condition. The mean number of false alarms was 0.67 in the high workload condition and 0.31 in the low workload condition. Since the numbers of missed targets and false alarms were quite low, the participants conducted the search task almost perfectly. We conducted t-tests on the numbers of missed targets and false alarms in the high and low workload conditions. The number of missed targets was significantly higher in the high workload condition ( $t(34) = 2.53, p < .05$ ), and the number of false alarms was marginally higher in the high workload condition ( $t(34) = 1.77, p = .09$ ). These results confirmed that the workload was higher in the high workload condition than in the low workload condition.

**Evaluation index** We evaluated the participant preferences to use automation based on the percentage of using the auto mode in the auto-manual selection task. We evaluated the participant tendencies to lapse into complacency in the supervisory control task based on three evaluation indices: reaction time, distance, and accumulated distance. The reaction time was the time (msecs) from when the auto failure began to when the manual operation was first conducted. We utilized the time from when the auto breakdown occurred for the sudden failure and the time from when the auto capability started to decrease for the gradual failure. The distance (pixels) was measured between the circle vehicle and the line when the manual operation was first conducted during the auto failure. A distance over 30 pixels means that the circle vehicle is out of the line. The accumulated distance (pixels) is the distance accumulated from when the auto failure began through when the manual operation was first conducted. Table 1 shows the mean reaction time, the distance, and the accumulated distance for all participants in each condition of the supervisory control task.

**Consistency of tendency to lapse into complacency** Prior to verification of the hypotheses, we investigated the consistency of the participant tendencies to lapse into complacency. We conducted correlation analyses on the individual

Table 1: Mean reaction time, distance, and accumulated distance for all participants in each condition of supervisory control task. Values in parentheses show standard deviations.

	High workload		Low workload	
	Sudden failure	Gradual failure	Sudden failure	Gradual failure
Reaction time (msecs)	1051.74(425.16)	23350.63(9795.37)	1137.46(450.49)	24674.71(10222.56)
Distance (pixels)	19.83(7.44)	9.09(9.27)	20.96(7.75)	9.94(8.75)
Accumulated distance (pixels)	655.77(517.82)	1926.23(2165.69)	738.93(549.87)	1910.13(2025.02)

reaction times, distances, and accumulated distances across the four conditions in the supervisory control task (Table 2). The results showed similar correlations in each index. First, there were correlations between the high and low workload situations both in the sudden and gradual failure conditions. The results suggest that the participants who reacted faster to the auto failure in the high workload condition also reacted faster in the low workload condition. This consistency was observed only within the same type of auto failure. Moreover, there was a correlation between the sudden and gradual failure situations in the high workload condition, suggesting that the participants who reacted faster to the sudden failure also reacted faster to the gradual failure but only in the high workload condition.

The results of the correlation analyses in the supervisory control task showed the consistency of the participant tendencies to lapse into complacency. However, we only found consistency in the participant reactions to the different types of auto failures in the high workload condition. In the low workload condition, the number of search stimuli was low. The participants may have allocated enough attention to monitoring the auto operation to easily detect the auto failure. On the other hand, in the high workload condition, the participants probably had difficulty concentrating on the monitoring activities. Therefore, individual differences in complacency became salient only in the high workload condition.

### Relationship between complacency and tendency to use auto mode

To verify the hypotheses, we conducted a correlation analysis on the relationship between the individual reaction times, the distances, and the accumulated distances in the supervisory control task and the individual percentage of using the auto mode in the auto-manual selection task (Table 3). The results showed a correlation between each index in the sudden failure situation of the supervisory control task and the percentage of using the auto mode in the auto-manual selection but only in the high workload condition (Figure 2). The participants who had a tendency to conduct manual operation in the auto-manual selection task also tended to react slowly to the auto failure in the supervisory control task. The result supports Hypotheses 1 and 2b, but only in the sudden failure situations when the workload was high.

## Discussion

As a result of our experiments, we found a relationship between complacency and the tendency to prefer automation or manual operation. The participants who tended to conduct manual operation in the auto-manual selection task also tended to react to the automation failure slowly: they tended to lapse into complacency. This result supported Hypotheses 1 and 2b, but only in the high workload and sudden failure condition.

For the tendency to use automation, Rajaonah et al. (2008)

Table 2: Correlation matrices that show correlations on individual reaction times, distances, and accumulated distances among four conditions. Values are correlation coefficients ( $r$ ).

Reaction time		High workload		Low workload	
		Sudden failure	Gradual failure	Sudden failure	Gradual failure
High workload	Sudden failure	1			
	Gradual failure	.54**	1		
Low workload	Sudden failure	.54**	.27	1	
	Gradual failure	-.16	.40*	.09	1

Distance		High workload		Low workload	
		Sudden failure	Gradual failure	Sudden failure	Gradual failure
High workload	Sudden failure	1			
	Gradual failure	.48**	1		
Low workload	Sudden failure	.56**	.19	1	
	Gradual failure	-.02	.36*	.23	1

Accumulated distance		High workload		Low workload	
		Sudden failure	Gradual failure	Sudden failure	Gradual failure
High workload	Sudden failure	1			
	Gradual failure	.50***	1		
Low workload	Sudden failure	.59**	.26	1	
	Gradual failure	.15	.55*	.29	1

\* $p < .05$ , \*\* $p < .005$ , \*\*\* $p < .001$

Table 3: Correlation matrices that show correlations among individual reaction times, distances, and accumulated distances in four conditions of supervisory control task and individual percentage of using auto mode in auto-manual selection task. Values are correlation coefficients ( $r$ ).

		Supervisory control task					
		High workload					
		Sudden failure			Gradual failure		
		Reaction time	Distance	Accumulated distance	Reaction time	Distance	Accumulated distance

		Supervisory control task					
		Low workload					
		Sudden failure			Gradual failure		
		Reaction time	Distance	Accumulated distance	Reaction time	Distance	Accumulated distance
Auto-manual selection task	Percentage of using auto mode	-.28	-.26	-.30	.32	.26	.20

\*\*  $p < .005$

Figure 2: Correlation between individual reaction times, distances, and accumulated distances in high workload and sudden failure condition of supervisory control task (x-axis) and individual percentage of using auto mode in auto-manual selection task (y-axis).

showed that users who prefer manual operation tend to perceive higher workload and greatly decrease their vigilance while monitoring automation more than users who prefer to use automation. They discussed the possibility that manual-oriented users might try to avoid high workload and vigilance decrement without using automation. As a result, the manual-oriented participants in our study might tend not to use automation even when using it was efficient.

Next, for the effect of workload on complacency, the relation of the tendency to use automation in the auto-manual selection task and the reaction to the automation failure was detected only in the high workload condition of the supervisory control task. Molloy and Parasuraman (1996) showed that vigilance decrement is greater in the high workload condition than in the low workload condition. In our experiment's low workload condition, the number of search stimuli was relatively low so the participants could allocate enough attention to the auto operation. Therefore, the manual-oriented participants might be able to successfully manage vigilance

and quickly detect automation failure. On the other hand, in the high workload condition, the vigilance decrement became greater for the manual-oriented participants, resulting in slower detection of automation failure. That is the reason that we could only detect a significant correlation in the high workload condition.

Moreover, for the effect of automation failure types on complacency, the consistency of the tendency to use automation in the auto-manual selection task and the reaction to automation failure was detected only in the sudden failure situation of the supervisory control task. Endsley (1995) stated that individual differences in situation awareness influence individual decision making and the performances of actions. Endsley (1996) also indicated a relationship between vigilance and situation awareness decrements. In our experiment, in the gradual failure situation, the circle vehicle gradually slowed down and finally veered off the line. Some participants quickly shifted to manual operation after they noticed the irregular movement of the circle vehicle. Others might

continue to monitor the auto operation until just before the auto breakdown, anticipating that the circle vehicle would veer off the line after a certain amount of time. In such a situation, we assume that the participant reactions were influenced not only by individual differences in the awareness of the auto failure but also such factors as decision making strategy and action selections followed by awareness. By contrast, in the sudden failure situation, the circle vehicle suddenly stopped tracking the line and immediately veered off the line. In such a situation, the individual differences in the awareness of the auto failure directly influenced the participant reactions. As a result, there is only a relationship between the tendency to use automation and the reaction to the automation failure in the sudden failure condition.

Finally, Lee and Moray (1992, 1994) showed that users who tend to use automation tend to trust it. An overtrust in automation might lower the frequency of monitoring it and cause complacency (Parasuraman & Manzey, 2010). Therefore, we predicted that automation-oriented users would slowly detect automation failures. Contrary to our prediction, however, we found that manual-oriented users tended to slowly detect the automation failures, rejecting Hypothesis 2a. In our experiment, to evaluate the participant tendencies to lapse into complacency, we set up a situation where attention failure—not fixation failure—was induced using a superimposed display. Perhaps in such a situation, individual differences in vigilance rather than trust in automation link complacency and the tendency to use automation.

In this study, we investigated the relationship between complacency and the tendency to select whether to use automation or conduct manual operation. We evaluated complacency with a supervisory control task in which attention failure was induced. We evaluated the preference to use automation with an auto-manual selection task. Our experiment indicated that users who tend to conduct manual operation tend to lapse into complacency. However, such a relationship was found only in the high workload situation where sudden automation failure occurs. We assume that individual differences in vigilance link complacency and the tendency to use automation.

## Abstract

Most legal systems require jurors to consider all the evidence presented at trial. Hence when there is uncertainty over aspects of evidence this should be factored into juror judgments. Two experiments examined how mock jurors used uncertain information in their ratings of defendant guilt and final verdicts. Participants read scenarios where an eyewitness expressed uncertainty about the identity of a critical piece of evidence (e.g. the object a defendant was holding could have been a knife or a mobile phone). The respective probability of these alternatives was varied, as was their association with the alleged crime. When the probability of the alternatives was varied between subjects (Experiment 1) there was only weak evidence that jurors considered both alternatives. When probability was varied within-subjects (Experiment 2), jurors did consider both alternatives in their guilt judgments. The implications for theories of reasoning with uncertain information and forensic practice are discussed.

**Keywords:** Inductive reasoning; Probabilistic reasoning; Category-based induction, Forensic judgment

## Introduction

The process of deciding on the guilt or innocence of a defendant in a criminal trial could be seen as form of complex inductive inference (Lagnado, 2011). Induction involves drawing probabilistic inferences from given information. When the category membership of an object is known with certainty (e.g., a man at a robbery crime scene was carrying a *knife*) the process of inductive inference is relatively straightforward (e.g., the knife was likely being used as a weapon in the robbery).

However, the evidence presented in criminal cases is typically complex and fraught with uncertainty (e.g., an eyewitness may not be certain about the identity of the object that the defendant was holding). In such cases induction involves the consideration of multiple possible object categories that may have different implications for judgments about the defendant's guilt. For example, if a defendant was thought to be carrying a knife then a juror may judge the defendant as likely to be guilty of committing a crime. But if there is some chance that the object in the defendant's hand was something less incriminating (e.g., a metallic-colored mobile phone) then this may reduce belief in the defendant's guilt.

So just how do jurors respond to such uncertain alternatives when making inferences about guilt or

innocence? The legal answer to this question is straightforward and prescriptive. Most criminal jurisdictions specify that jurors should consider *all* evidence presented at trial when determining defendant culpability (e.g., Attorney General's Department of New South Wales, 2007). Laboratory studies of inductive reasoning with uncertain categories however, suggest a more complex answer (see Hayes, Heit & Swendsen, 2010 for a review).

Bayesian approaches to inductive reasoning, such as Anderson's (1991) Rational model, generally agree with the legal ideal, suggesting that reasoners incorporate information about all category alternatives when making inferences (hereafter referred to as *multiple-category reasoning*). To illustrate, let us assume that an eyewitness believes that the probability that the object the defendant was holding was a knife is 0.7 (which we will refer to as the *primary category*), with a 0.3 probability that the object was instead a metallic mobile phone (*the secondary category*). Further assume that these alternatives are associated with different conditional probabilities of guilt. If the person was holding a knife then the probability of them being guilty is high (e.g.,  $p(\text{guilt} | \text{knife}) = 0.9$ ), but if they were holding a mobile phone the probability of guilt will be much lower (e.g.,  $p(\text{guilt} | \text{phone}) = 0.2$ ). Applying Bayes' theorem, the Rational model combines the probabilities from the primary and secondary categories to give an estimate of the probability that the defendant was guilty, given they were seen with a metallic object in their hand ( $p(\text{guilt} | \text{metallic object}) = (0.7 \cdot 0.9) + (0.3 \cdot 0.2) = 0.69$ ). Note that this probability estimate is considerably lower than would be the case if the uncertainty over object identity was ignored. If the juror assumed that the object in the defendant's hand was a knife then the guilt estimate would be 0.9.

Unfortunately (from a legal point of view), empirical studies have so far found little evidence of multiple-category reasoning. Malt, Ross and Murphy (1995) for example, presented vignettes in which the category membership of a target character was uncertain, and asked participants to make various inferences about the targets. For each scenario two possible category identities were suggested, a more likely primary category and a less likely but plausible secondary category. The primary category was held constant across conditions (e.g., the vignette always made it clear that the target character was most likely a realtor). The secondary category however was varied; in one condition the target was most likely a *cable repairman*, in

another it was most likely a *burglar*. These alternatives have different implications for inferences such as “how likely is it that the man will pay attention to the sturdiness of the doors on the house?” Such behavior seems more likely if the target was a burglar than if they were a realtor or cable repairman. If people do consider multiple categories in induction, then their inferences should differ across the conditions with different secondary categories. Malt et al. (1995) however, found that participants tended to ignore the secondary category when making inductive inferences. Predictions were predominantly based on consideration of the primary category alone (also see Ross & Murphy, 1996).

Such “single-category reasoning” seems pervasive in non-forensic domains, having been demonstrated with a wide variety of artificial and natural categories (see Murphy & Ross, 2007, 2010 for reviews). Murphy and Ross (2007) suggest that single-category reasoning can be viewed as a cognitive heuristic that reduces the complexity of deriving inductive predictions from multiple uncertain alternatives.

The pervasive nature of single-category reasoning in previous studies leads to a negative prognosis for forensic reasoning, suggesting that jurors are also likely to use the single-category heuristic. Such a prediction is consistent with reports of juror “satisficing” where the juror focuses on aspects of trial evidence that are consistent with a single coherent story, ignoring contradictory evidence (Kuhn, Weinstock, & Flaton, 1994; Pennington & Hastie, 1992).

On the other hand, multiple-category reasoning may be more common in forensic situations because of their particular motivational demands. Motivational factors play an important role in determining the depth and complexity of reasoning (Gilovich & Griffin, 2010; Kunda, 1990). Forensic judgments like guilt or innocence are widely recognised as having profound consequences for a defendant and for the wider community (Bornstein & Greene, 2011). Hence jurors may be more likely to consider uncertain alternatives when making highly consequential judgments. Some support for this prediction comes from Hayes and Newell (2009) who found that multiple-category reasoning was more likely when neglect of the secondary category could lead to a highly negative outcome (e.g. when the primary category was a common but easily treatable disease and the secondary category was a rare but potentially terminal disease).

The main aim of the current studies therefore was to examine whether mock jurors would show multiple-category reasoning in cases where there was uncertainty about the identity of forensically relevant evidence in a criminal trial.

## Experiment 1

Experiments 1 and 2 were patterned after those of Malt et al. (1995) and Ross and Murphy (1996), using a design where probability estimates of guilt were compared across conditions in which the primary category was held constant and the secondary category varied (see Table 1). Participants in all conditions were shown written vignettes

which described criminal cases where there was uncertainty about the identity of a critical piece of evidence. An eyewitness testified that they observed the defendant carrying an object, which they believed to be a particular item (the primary category). However, they acknowledged that there was a lower probability the object may have been something else (the secondary category). In two Primary Related conditions (Comparison 1 in Table 1), the primary category consistently implicated the defendant in the crime (e.g., in a robbery the primary category was “knife”). However, the less likely secondary category varied such that it indicated that the defendant was guilty in one condition only (e.g., a stolen watch in one condition and a mobile phone in the other).

After reading the vignettes participants judged which object they thought the defendant was actually carrying (object categorization) and made inferences about the defendant’s guilt. Whether participants used single- or multiple-category reasoning to arrive at these inferences could be determined by comparing guilt estimates in the conditions where the secondary categories were varied (see Comparisons 1 & 2 in Table 1).

Table 1: Summary of the experimental design (with examples of critical object alternatives from the Robbery vignette)

	Secondary Category	
	Related (e.g., stolen watch)	Unrelated (e.g., mobile phone)
<b>Comparison 1</b>		
<b>Primary Category</b>	Primary = <i>knife</i>	Primary = <i>knife</i>
<b>Related</b>	Secondary = <i>stolen watch</i>	Secondary = <i>mobile phone</i>
(e.g., knife)		
<b>Comparison 2</b>		
<b>Primary Category</b>	Primary = <i>keys</i>	Primary = <i>keys</i>
<b>Unrelated</b>	Secondary = <i>stolen watch</i>	Secondary = <i>mobile phone</i>
(e.g., keys)		

A subsidiary aim of Experiment 1 was to re-examine the Ross and Murphy (1996) finding that multiple-category reasoning is more likely when the secondary category is closely linked to the prediction being made and the primary category is not. In a variant on the realtor/cable guy/burglar task, Ross and Murphy (1996) asked participants to make predictions that were more strongly associated with the secondary category of burglar but not with the primary category of realtor (e.g., the prediction “how likely is it that the man will try to find out if the householder keeps her windows locked?”). Participants were more likely to consider both categories when making such predictions.

Hence in the current study, we also ran a Primary unrelated condition where the primary category was not strongly associated with culpability and the association of the secondary category with culpability was varied. In the Primary unrelated, Secondary related condition the

secondary category was associated with guilt (e.g., a stolen watch), whereas in the Primary unrelated, Secondary unrelated condition, neither category was associated with the crime. Consideration of the secondary category should lead to higher guilt estimates in the Primary unrelated, Secondary related condition than in the Primary unrelated, Secondary unrelated group.

## Method

**Participants** Ninety-eight undergraduate students participated for course credit. The majority were female ( $n = 72$ ), and the mean age was 19.95 years ( $SD = 1.84$ ). All were Australian citizens aged 18 years or older, in accordance with Australian juror selection criteria.

**Design and Materials** The experiment followed a  $2 \times 2$  factorial design with the first factor being whether the *primary* category related to the crime and the second factor being whether the *secondary* category related to the crime (see Table 1). In Experiment 1 both factors were manipulated between subjects, with approximately equal numbers allocated to each experimental condition.

These factors were operationalized using written vignettes presented as brief criminal trial summaries. Each vignette was approximately 290 words in length and described a case in which an eyewitness reported seeing the defendant at the crime scene carrying an object whose identity was critical for evaluating defendant guilt (see Appendix for an example). Two category possibilities were provided for this object: a primary category, which was described as the most likely identity of the critical object (with an explicit likelihood of 70%), and a secondary category, which was described as having “a small chance” of being the identity of the object. Two vignettes with this structure were developed. One described a criminal trial for assault and robbery, and the other described a trial for arson.

Our assumptions about the relatedness of the various critical objects with the crime were confirmed in a pilot study. Fifty nine participants who did not take part in the main experiments read versions of the vignettes in which the eyewitness provided only one category for the critical object. Participants were then asked to rate the likelihood that the defendant was guilty on a 100-point scale (1= not at all likely, 100 = very likely). Defendants seen carrying “related objects” (*knife, stolen watch*) were rated as more likely to be guilty ( $M = 62.85$ ) than those carrying “unrelated objects” (*mobile phone, keys*), ( $M = 35.37$ ),  $F(1, 55) = 27.24$ ,  $p < .001$ .

**Procedure** Participants were told that they were to play the role of a juror in determining the guilt of a defendant in a criminal trial. Each vignette was then presented on a computer screen with the eyewitness evidence about the critical object alternatives written in bold type. After reading the vignette participants clicked an on-screen button which started a series of questions (with the vignette no longer visible). The first was a categorization question that asked

participants to rate the percentage likelihood that the item the defendant was carrying was (a) the primary category, (b) the secondary category, or (c) some other item, with the restriction that the three estimates must sum to 100 percent (see Murphy & Ross, 2010 for a similar procedure). This was followed by a filler question asking participants to recall the general location of the crime as described in the vignette. The final two questions required participants to infer defendant culpability based on the trial evidence. Participants first estimated the likelihood that the defendant was guilty on a 100-point scale (1=not at all likely, 100=very likely). They then rendered a binary verdict (‘guilty’ or ‘not guilty’) by clicking on one of two forced choice buttons.

Previous research (e.g., Harris & Hahn, 2009) indicates that mock jurors often give less weight to evidence that they perceive to be inconsistent. In our experimental vignettes all eyewitnesses expressed some inconsistency about the identity of the critical object. However, it is possible that the effects of this inconsistency on juror confidence in eyewitness evidence may have differed across experimental conditions (e.g., jurors may give more weight to evidence when both objects are positively related to the crime, than when one is related and the other is not). To check on this possibility all participants were also asked to rate their confidence in the reliability of the eyewitness on a seven-point scale (1= ‘very low confidence’, 7= ‘very high confidence’).

Within each condition participants completed both robbery and arson vignettes with order of vignette administration counterbalanced.

## Results and Discussion

**Preliminary Analyses.** The experimental predictions are based on the assumption that participants believe that the critical object was more likely to belong to the primary than the secondary category. The object categorization data identified 12 participants who did not rate the primary category as more likely. Consequently they were excluded from further analyses.

Preliminary analyses confirmed that the percentage likelihood ratings for membership of the critical object in the primary ( $M = 69\%$ ) and secondary categories ( $M = 26\%$ ) were close to those stated or implied in the vignettes. Notably participants in all conditions rated the likelihood of secondary category membership as well above zero (group means ranged from 21% to 30%). Hence participants in all conditions grasped the uncertainty about the category membership of the critical object.

Preliminary analyses confirmed that there were no significant differences between the robbery and arson vignettes in overall guilt estimates or ratings of reliability of eyewitness evidence. Consequently, in both experiments analyses of guilt judgments were collapsed across vignettes.

A two-way analysis of variance revealed a significant main effect of secondary category association on ratings of eyewitness reliability,  $F(1,82) = 6.36$ ,  $p = .01$ . Witnesses in

the secondary related conditions were rated as more reliable ( $M = 4.1$ ) than those in the secondary unrelated conditions ( $M = 3.52$ ). Hence, eyewitness reliability ratings were included as a covariate in analyses of guilt judgments.

**Guilt Likelihood Ratings and Guilt Verdicts.** Both variates were analyzed in  $2(\text{Primary category status}) \times 2(\text{Secondary category status})$  analyses of covariance with eyewitness reliability entered as a covariate. Figure 1 shows the adjusted guilt likelihood ratings for each condition. Not surprisingly the defendant was rated as more likely to be guilty when the primary category for the critical object was closely linked to the crime than when it was unrelated,  $F(1,81) = 32.97, p < .001$ . The more critical question was whether the status of the secondary category affected guilt estimates. There was no main effect of secondary category status on guilt likelihood ratings,  $F(1,81) = 0.02, p = .89$ , but there was a significant interaction between the status of the primary and secondary categories,  $F(1,81) = 5.05, p = .027$ . However, when Tukey's HSD tests were applied, there was no significant effect of secondary category association in the critical comparison between the two Primary Related conditions ( $q = 2.45, p > .05$ ) nor between the two Primary Unrelated conditions ( $q = -2.16, p > .05$ ).

Figure 1. Mean likelihood ratings of defendant guilt (with standard error bars).

The proportion of guilty verdicts was higher when the primary category was related to the crime ( $M = 0.6$ ) than when it was unrelated ( $M = 0.21$ ),  $F(1,81) = 28.80, p < .001$ . However, there was no main effect or interaction involving the status of the secondary category ( $p$ 's  $> .15$ ). In other words there was no evidence that participants considered the secondary category when deciding on guilt verdicts.

In sum, this study found minimal evidence for multiple-category reasoning in a forensic context. Note however, that there was considerable variance in guilt judgments *within* conditions. For binary judgments for example, the mean standard error across experimental conditions was 0.073 (in a scale ranging from 0.0-1.0). This high level of variability is consistent with previous findings that individual jurors presented with the same evidence often give very different absolute estimates of guilt (e.g., Solana, García, & Tamayo,

1998). Such levels of variability are likely to have reduced the sensitivity of our tests of multiple-category reasoning. Experiment 2 addressed this issue by manipulating the status of the secondary category *within* subjects.

## Experiment 2

Experiment 2 aimed to provide a more sensitive test of whether mock jurors use multiple-category reasoning when faced with uncertain alternatives. The design was similar to the first study except that all participants completed two versions of each trial vignette; one where the secondary category was related to the crime, and one where it was unrelated. Multiple-category reasoning would be indicated if different judgments about guilt are given in these conditions.

## Method

**Participants** Forty-two undergraduate students participated for course credit. The majority were female ( $n = 29$ ) and the mean age was 20.69 years ( $SD = 4.98$ ).

**Design and Procedure** The design of Experiment 2 followed the description given in Table 1. Unlike the previous study however, the status of the secondary category (related or unrelated to the crime) was manipulated within subjects. All participants completed two versions of each of the robbery and arson vignettes; one with a crime-related secondary category, and one with an unrelated secondary category. The order of presentation of these alternate versions was counterbalanced across participants. To reduce sequencing effects alternate versions of the same vignette were never presented consecutively. Before completing the study participants were warned that they would sometimes be reading summaries with similar details and were instructed to "do your best to evaluate the trial summaries independently".

As in the previous study the status of the primary category was manipulated between subjects. Equal numbers were randomly allocated to conditions in which the primary categories were related to the crime or were unrelated. In all other respects the procedure was identical to Experiment 1.

## Results

**Preliminary Analyses** Eleven participants failed to assign the highest categorization rating to the primary category in at least one scenario, and were excluded from further analyses. Preliminary analyses again found that for the remaining participants, ratings of the likelihood that the critical object belonged to the primary and secondary categories closely matched the probabilities stated or implied in the vignettes. Notably, there was no evidence of sequencing effects on guilt judgments for the secondary related and secondary unrelated versions of each vignette. The guilt estimates for these alternate versions were unaffected by which version was presented first ( $F < 2.0$ ). As in the previous study however, eyewitness reliability was rated higher in secondary related than the secondary

unrelated conditions,  $F(1,29) = 4.23, p < .05$ . Consequently, eyewitness reliability scores were again included as covariates in guilt analyses.

**Guilt Likelihood Ratings and Guilt Verdicts** Both variates were collapsed across scenarios and the binary verdicts were coded as per Experiment 1. Both data sets were entered into separate 2 (primary category status)  $\times$  2 (secondary category status) multivariate analyses of variance, with repeated measures on the second factor and eyewitness reliability scores entered as covariates. Figure 2 shows adjusted mean guilt likelihood ratings. Once again there was a significant main effect of primary category status,  $F(1,28) = 27.22, p < .001$ , with higher guilt estimates when the primary category was incriminating than when it was not. More importantly, in this case there was also a robust effect of secondary category status,  $F(1,28) = 36.46, p < .001$ , but no primary  $\times$  secondary category interaction, ( $F < 1$ ). When the secondary category was unrelated to the crime, ratings of guilt likelihood were lower than when that category incriminated the defendant. This shows that participants were factoring both primary and secondary categories into their guilt estimates.

Figure 2. Mean likelihood ratings of defendant guilt (with standard error bars).

A similar pattern was observed for binary guilt verdicts. The proportion of guilty verdicts was higher when the primary category was related to the crime ( $M = 0.63$ ) than when it was unrelated ( $M = 0.13$ ),  $F(1,28) = 22.83, p < .001$ . Critically there was also a robust effect of secondary category status,  $F(1,28) = 8.33, p = .01$ . The proportion of guilty verdicts was significantly lower when the secondary category was unrelated to the crime ( $M = 0.30$ ) than when it was crime related ( $M = 0.46$ ). There was no primary  $\times$  secondary category interaction, ( $F < 1.0$ ).

These data indicate that mock jurors were considering both category alternatives when inferring guilt.

## General Discussion

The goal of these experiments was to examine whether mock jurors consider more than one alternative scenario when inferring defendant guilt on the basis of uncertain evidence. In our trial vignettes there was always some

uncertainty about the category membership of a critical piece of evidence, with a more likely (primary) and a less likely (secondary) category alternative. Mock jurors in both studies acknowledged this uncertainty, recognizing that the object *could* have belonged to the secondary category.

In Experiment 1 we found minimal evidence that jurors factored these uncertain alternatives into their guilt judgments but analyses of the critical comparisons did not find these differences to be reliable. Notably though when within-condition variance was reduced by manipulating secondary category status within-subjects (Experiment 2), robust evidence of multiple-category reasoning was found. When there was a possibility that the defendant was holding an innocuous rather than an incriminating object, participants reduced their ratings of guilt likelihood and were less like to return a verdict of guilty.

This is an important result because most previous work (e.g., Malt et al., 1995; Murphy & Ross, 2007, 2010; Ross & Murphy, 1996) has failed to find evidence that people consider more than one category when making predictions about objects whose category membership is uncertain. Ross and Murphy (1996) reported some evidence of multiple-category reasoning but only when the secondary category was more highly associated with the prediction than the primary category (equivalent to our primary unrelated condition). In Experiment 2 however, we found multiple-category reasoning in both primary related and primary unrelated conditions. This result is particularly interesting because it shows that consideration of the secondary category can lead to either decreases in the probability of a given prediction (in the Primary related conditions) or increases in prediction probability (in the Primary unrelated conditions).

One concern is that our strongest evidence of multiple-category reasoning was found when participants completed both the secondary related and secondary unrelated versions of the vignettes. Under these conditions participants could conceivably compare the structure of the two scenarios and this may have increased their sensitivity to the role of the secondary category in determining guilt. In other words, the strong evidence of multiple-category reasoning may have been an artifact of the repeated measures design. To examine this possibility we looked at participant guilt judgments the first time the vignettes were presented and then the second time the vignettes were presented as two separate sets of data. This order-artifact account predicts that we should only see evidence of multiple-category reasoning the second time that a participant sees the vignettes as it is the exposure to the first version that directs attention to the secondary category. Contrary to this account however, the effect of the secondary category on guilt ratings was robust on the first presentation on both the guilt likelihood ratings,  $F(1,26) = 7.70, p < 0.05$ , and the proportion of guilty verdicts,  $F(1,26) = 16.02, p < 0.01$ . In other words, the first time participants read the vignettes

they factored category uncertainty into their guilt ratings.<sup>1</sup>

So just why did we succeed in finding robust evidence in multiple-category reasoning in Experiment 2 when a majority of previous studies have failed to do so? Further research will be required to give a complete answer to this question. As noted earlier however, the highly consequential nature of forensic decisions may lead participants to be more reflective in their consideration of uncertain alternatives. An analogous finding is that expert clinicians have been shown to consider multiple uncertain categories but only when making clinically relevant predictions (Hayes & Chen, 2008). When required to make predictions about nonclinical materials they ignored category uncertainty.

Overall these studies provide qualified support for the conclusion that jurors can use multiple-category reasoning when making inferences about guilt. Clearly much further work is needed to be able to generalize these results to more realistic trial contexts where, for example, the explicit probabilities of different alternative scenarios are unlikely to be given. Nevertheless our findings suggest that, at least in some contexts, jurors can satisfy the legal imperative to consider multiple uncertain aspects of evidence.

<sup>1</sup> It should be noted that although this first presentation is similar in design to Experiment 1, different results were obtained. There is no clear explanation for this discrepancy. One possibility is that this was due to the new instructions used in Experiment 2, which strongly encouraged participants to attend the details of the vignettes.

### Appendix

#### Excerpt from the Robbery Vignette used in Experiments 1-2 showing the primary categories (in bold) and secondary categories (in italics).

Ms. Kelly advised that the defendant Mr Bell was carrying a metallic looking object in his hands. She believed that the object was most likely a **KNIFE/ KEYS**. When asked to estimate her certainty Ms. Kelly advised that she was "reasonably certain, at least 70%". She advised that there was "a small chance" that the object was the *STOLEN WATCH/ a MOBILE PHONE*. In summary, Ms. Kelly testified that there was a small chance that the defendant was carrying the **STOLEN WATCH/ a MOBILE PHONE** but she believed the defendant was most likely carrying a *KNIFE/ KEYS*. Note that Ms. Kelly was sure that the defendant was only carrying one object.

## Abstract

The following paper presents the enhancement of indoor route instructions with descriptive generation strategies. We consider the latter to be highly important for the quality and helpfulness of automatically generated indoor route instructions. We conducted an experiment showing that participants receiving route instructions enriched with elaborate descriptive information instead of step-by-step procedural information for crucial route segments performed better in objective and subjective measures than those receiving only basic prescriptive route instructions. Based on the gained knowledge, we conclude that descriptive strategies are an important part of indoor route instructions and should be actively considered in system development.

**Keywords:** indoor route instructions; descriptive information; wayfinding; spatial cognition; navigation

## Introduction

Both navigation in indoor and outdoor environments profit from the use of landmarks since they are distinctive, easily recognizable and highly memorable (Sorrows & Hirtle, 1999). Humans select landmarks for their distinguishing characteristics (Presson & Montello, 1988). Although the importance of landmarks in route instructions is well established (Allen, 1997; Denis, 1997; Richter, 2007; Raubal & Winter, 2002), most research in automatic generation of route instructions focuses on one aspect of landmarks, namely to indicate the location at which a reorientation should take place in a network of paths. The main assumption of this approach is that good route instructions contain tightly coupled descriptive and prescriptive information. Therefore, current systems rely almost entirely on what Denis (1997) classified as Type 2 utterances – utterances coupling an action with a landmark. This leads to highly concise route instructions, but also limits the amount of descriptive information for each reorientation point to the mentioning of one landmark, possibly locating it with respect to the user.

While this approach is particularly useful for car navigation (Brenner & Elias, 2003) which occurs in network space, i.e. along a street network where clearly identifiable nodes (intersections) are connected by edges (streets), in pedestrian navigation the case is different. Pedestrian navigation includes many areas that belong to scene space: open areas which are characterized by the absence of clearly identifiable nodes and edges (Rüetschi, 2007; Schuldes et al., 2011). In network space, wayfinding consists mainly of selecting a path at each decision point, whereas in scene space, wayfinding is characterized by activities such as searching, exploring, and

matching. There are no clear paths to choose from, but large spaces, where piloting between landmarks is necessary. Oriented search might be used if the expected landmark cannot be seen (Allen, 1999). In such areas, route graph representations, and the resulting procedural information do not correspond very well to the needs of the wayfinder, as the function of landmarks changes from identifying a turning point to more vague orientational aid. Indoor navigation has elements of both network and scene spaces. In addition, indoor spaces are characterized by a very limited amount of different landmark types and a lack of highly salient landmarks. Usually landmarks consist mainly of doors, corridors and staircases, only very few of which are highly distinctive in comparison to outdoor landmarks which can be very diverse (a church, a petrol station, multiple intersections of different types, etc.). For this reason, the central roles of landmarks, i.e. signaling where actions should take place, as well as confirmation, are difficult to obtain in indoor scenarios. Additionally, this increases the difficulty of memorization, as it leads to instructions which contain a series of highly similar utterances.

A possible solution for these problems is the integration of more elaborate descriptive information into indoor route instructions. This can be realised by basing instructions on a scene space representation of space, and using a descriptive strategy for generating route instructions for those areas that can be characterized as scene space: Instead of superimposing abstract network representations onto open space areas, thereby producing a number of turning points and paths for an area which is viewed by a wayfinder as a coherent whole, this scene is described as one entity, and the location of the scene exit is described with respect to the scene. We assume that by introducing more elaborate descriptive information into indoor route instructions we can gain configurations of landmarks that can serve as highly salient landmarks, where simple landmarks will yield no sufficient differentiation. Moreover, we expect that the scene descriptions will enable more efficient localization of scene exits in the descriptions, minimizing the number of prescriptive statements. In contrast, the imposition of abstract networks onto open spaces will yield extra turns. We expect route instructions which integrate the descriptive approach to make it easier for participants to build up a mental image of the route in advance, leading to better memorization and increased confidence. In addition, mixing scene descriptions with prescriptive statements should yield more diverse route instructions, thereby additionally support-

ing memorization.

While our route instruction system has already been successfully evaluated (Cuayáhuatl, Dethlefs, Richter, Tenbrink, & Bateman, 2010), the goal of the present study is to explore the boundaries and potential for further development of the system by using a particularly difficult route which contains areas for which we consider the current (standard) approach lacking. For this purpose we first conduct and present an experiment which compares the wayfinding performance of participants receiving instructions, based either on solely procedural strategies as used by the system, or on a systematic mixture of procedural and descriptive strategies which the system currently does not provide. The results are presented and discussed with respect to the insights that can be gained for the development of route direction systems using natural language generation. In conclusion we propose directions that future research in the area could take.

### Experimental Setup

The experiment was conducted in GW2, a building at the University of Bremen which is notorious for its complexity. Each of the four floors has a different layout consisting of one or two main areas. The route (figure 1) was specifically chosen to be long and difficult, contain many turns and lead through a large portion of the 3rd level of the building. Secondly, it should contain two areas (A and B in figure 1) characterized by scene space rather than by network space. In both cases a diagonal crossing of the open area was necessary.

In our experiment the participants made use of an indoor route direction system called Infokiosk, developed as part of the I5-DiaSpace<sup>1</sup> project. Infokiosk (Cuayáhuatl et al., 2010) is a multimodal interactive spoken dialogue system for indoor wayfinding in complex buildings. It was developed based on a general computational dialogue system architecture and framework named DAISIE (Ross & Bateman, 2009), and can be described with the following three key components: 1) Dialogue management with a formal unified dialogue modeling approach combining information state update theories with generalized dialogue models (Shi, Jian, & Rachuy, 2011). 2) Route instruction generation with a combined computational model for generating unambiguous high-level context-specific route instructions (Richter, 2007). 3) Natural language generation with the probabilistic context-free representational underspecification framework (Belz, 2008) and the KPML natural language generation system (Bateman, 1997).

In the basic condition, the participants received route instructions generated automatically by Infokiosk. The instructions contained only procedural sentences in imperative mood, directly linking body turn actions to landmarks. An artificial route graph based on network space was superimposed onto the two open areas (figure 1, dotted grey lines), and they were described accordingly. Example (1) shows an instance of the instructions generated by the system in the basic condition for area A in figure 1:

<sup>1</sup><http://www.diaspace.org/>

Figure 1: The selected route for the experiment. Grey dotted lines show the superimposed route graph for the basic condition.

- (1) "... go straight on until the third turning point on the left. Turn left, and go straight until the first glass door on the right. Turn to the right,..."

At the current stage, representations appropriate to the descriptive strategy, and the generation of the corresponding utterances are not supported by the Infokiosk. The integration of that capability in the system is not straightforward and should only be approached if such elements do show to improve wayfinding in indoor environments. Thus, in the descriptive condition, the participants received hand-crafted instructions by interaction with the dialogue system. In these instructions, imperative and declarative clauses were used, and the two scene space areas were described with full scene descriptions containing an introduction to the general structure of the area, one or more intermediary landmarks, or configurations of landmarks, and a localization of the goal exit with respect to the intermediary landmarks. Example (2) shows the instructions received for area A in figure 1 in the DC.

- (2) "... straight on until you reach a big hall area. In the middle of the hallway there is a staircase. Behind the

*staircase there are two glass doors which are partly hidden by concrete pillars. Go through the left door."*

It must be emphasized that the difference between the two conditions is not merely quantitative in nature, i.e. including a higher amount of descriptive information in the instructions. There is a qualitative difference, as the basic condition relies on superimposing an artificial route graph on areas characterized as scene space, giving a high amount of procedural information which precisely specifies the path for crossing an open area while reducing descriptive information to the minimum. In the descriptive condition, however, scene space areas are considered as holistic scenes with an entry point and an exit point. The scenes are described as seen from the entry point, and the position of the exit point is identified with respect to the described scene without any procedural information mentioning the path to take to get there. The descriptive instruction is only slightly more verbose (98 words, as compared to approx. 85 in the basic condition), but a different kind of information is chosen for verbalization.

## Participants

32 participants were tested. Two participants had to be excluded from the overall evaluation, because they found the goal by accident due to its location close to their position in the route. These participants explicitly stated that they expected the goal to be at a different position and were not using a search strategy, but saw the final goal by mere coincidence. The remaining 30 participants were used for evaluation, 15 in each of the two conditions (basic vs. descriptive). The participants were mostly first semester students at the University of Bremen. All had native or near-native competence of German and were between 19 and 31 years old (mean: 22). There were 21 female and 9 male participants.

The participants had little or no prior knowledge of the building. On a 7-point Likert scale, scores for the basic condition ranged from 1 to 4 (median 2; mean 2.3; standard deviation (sd) 0.88) while in the descriptive condition the range was from 1 to 3 (median 2; mean 1.6; sd 0.63). Scores for the basic condition were significantly higher than for the descriptive condition. (Wilcoxon rank sum test (one-sided):  $W = 161, p = 0.02$ )<sup>2</sup>.

The experiment was conducted with respect to a route on the 3rd level of the building. Most participants had been to the 3rd level either never, or less than five times before the experiment with no difference between the two groups (Wilcoxon rank sum test (two-sided):  $W = 123.5, p\text{-value} = 0.64$ ). Five participants (3 in the basic condition, 2 in the descriptive condition) reported having been to that particular floor more than five times.

There was no significant difference for spatial abilities between both conditions, as measured by the Questionnaire on Spatial Strategies (Münzer & Hölscher, 2011) ("Global self-

confidence, related to egocentric strategies", Wilcoxon rank sum test (two-sided):  $W = 88, p = 0.32$ ); "Survey strategy" (Wilcoxon rank sum test (two-sided):  $W = 99.5, p = 0.60$ ); "Knowledge of cardinal directions" (Wilcoxon rank sum test (two-sided):  $W = 74.5, p = 0.10$ ).

## Procedure

The overall procedure consisted of several steps that we describe in the current section.

First, participants were brought to the starting point via a route that did not cross the target route – they reached the starting point by entering the floor directly from the elevator.

Then, all participants were asked to fill in a short pre-questionnaire concerning age and prior knowledge of GW2.

After the pre-questionnaire the experimenter instructed the participants. Their goal was to find the room of a given person and for that they were only allowed to use the help of the Infokiosk. The participants were strongly encouraged to acquire the information solely using natural language. Handling of the microphone was explained in a short briefing. At this stage, participants were told that they should follow the route given to them by the system from their own memory, as far as this was possible. They were not informed that they would be able to recheck the instructions en-route. In this way, we enforced that they attempt full comprehension and memory of the route instructions in advance.

Right after the dialogue with the system, the participants were asked to answer 3 questions regarding perceived helpfulness of the system, confidence that they would find their goal, and how well they could visually imagine the route.

In the next step of the procedure they were instructed that they should follow the given route as closely as possible from memory, but that they could recheck a printout of the instructions as often as they wanted. The experimenter informed them that in case of doubt it was preferable to recheck the instructions than take a wrong turn.

The participants followed the route accompanied by the instructor. The experimenter did not answer any clarification questions (except for the initial perspective from which the instructions were given, i.e. "the system has explained the route as from the position in which you were seated when you received the instructions"), but whenever participants were indicating they were unsure about the route to follow, asked clarification questions, or explicitly stated that they were lost or had forgotten the instructions, the experimenter informed the participants that it was no problem at all to recheck the instructions as often as they wanted. Whenever participants explicitly stated doubts that they were going to be able to find the goal, the experimenter informed them that it was possible for them to give up if they wanted to.

At last, after finding the goal (or giving up), the participants were asked to give a retrospective report of their wayfinding and any doubts or problems that had occurred at the decision points. They were brought back to the starting point to fill in a final questionnaire about their performance and the perceived

<sup>2</sup>As the data was not normally distributed, a non-parametric test was chosen. The same applies for all the following statistical tests where non-parametric methods were chosen.

Table 1: Participants' task success in both conditions.

succeeded	8	15

helpfulness of the system, and the Questionnaire on Spatial Strategies by Münzer and Hölscher (2011).

## Hypotheses

With respect to objective performance measures we expected the descriptive condition to improve task performance, yielding a higher task success rate, a lower number of wrong route segments travelled and a lower number of total route segments travelled. We also expected the descriptive condition to improve memorization, leading to less frequent consultation of instruction printouts.

With respect to subjective performance measures, the descriptive condition was expected to lead to higher self-ratings for confidence of being able to find the goal, subjective helpfulness of the instructions, and mental imagery.

## Annotation

In order to evaluate task success, the experimenter followed the participants in the wayfinding task and made a protocol of the path travelled and any instruction consultations. With respect to the used annotation scheme, the path was divided into segments, where each segment consists of the path between two decision points. At the end, every wrong segment that the participant travelled was counted. Only those segments were counted where the participant either travelled a segment that was not part of the intended route, or walked in the wrong direction along a segment that was part of the intended route. Wrong segments that were travelled several times in a task were counted several times accordingly. In order to be able to count the number of instruction consultations, participants were only given the instructions if they explicitly requested this and were not allowed to move while holding the instruction sheet. If participants had not moved at all between two consultations, this was counted as one consultation.

## Results

### Task Success

Task success is an objective performance measure indicating the number of participants that managed to find the target. As indicated in table 1, in the basic condition 7 out of 15 participants for that setting did not find the goal at all. Yet, in the descriptive condition all 15 participants managed to find the goal. The resulting difference is significant (Pearson's Chi-squared test with Yates' continuity correction:  $X^2 = 6.7081$ ,  $df = 1$ ,  $p = 0.01$ ). This result strongly supports our hypothesis that enriching route instructions with descriptive information significantly improves wayfinding success.

### Wrong Segments Traveled

Another objective performance measure that we considered is the number of wrong segments traveled during the wayfinding process. In the descriptive condition there were overall 82 wrongly traveled segments, with single participants travelling from 0 to 31 wrong segments (mean: 5.47, sd: 8.51), while in the basic condition there were 169 wrongly travelled segments altogether, single participants' error scores ranging from 0 to 27 (mean: 11.27, sd: 7.34).

In the descriptive condition, one participant contributed over 35% of overall wrong segments (31 out of 82) due to an exceptional misunderstanding that was not reproduced by any of the other participants. But even including this exceptional case, there remains a significant difference, indicating that participants receiving the basic instructions travelled more wrong segments than those receiving the descriptive instructions (Wilcoxon rank sum test one-sided, with continuity correction:  $W = 166.5$ ,  $p = 0.01$ ).

### Number of Instruction Consultations

The number of instruction consultations during wayfinding is as well an objective performance measure. It indicates how easy the given system instructions were to understand and memorize. The participants in the basic condition consulted the instructions en-route 74 times overall, ranging from 1 to 10 consultations (mean: 4.93, sd: 2.76) while the participants in the descriptive condition rechecked the instructions only 31 times, individual scores ranging from 0 to 6 (mean: 2.07, sd: 1.53). Participants in the basic condition consulted the instructions significantly more often than those in the descriptive condition (Wilcoxon rank sum test one-sided, with continuity correction:  $W = 180.5$ ,  $p = 0.002$ ).

### Confidence

As subjective performance measure we considered the participants' confidence. Immediately after they had finished the dialogue with the system, participants were asked how confident they felt that they would find their goal. This was before they were informed that they would be able to consult a printout of the instructions en-route. For this reason, confidence levels were generally fairly low, reflecting the difficulty of the task. In the basic condition, they ranged from 1 to 5 on a 7-point Likert scale (median: 3, mean: 3.13, sd: 1.30), while ranges in the descriptive condition were from 1 to 6 (median: 4, mean: 4.13, sd: 1.41). Confidence in the basic condition was significantly lower than in the descriptive condition (Wilcoxon rank sum test with continuity correction, one-sided:  $W = 70$ ,  $p = 0.04$ ).

### Mental Imagery

The level of mental imagery across all participants in both conditions shows the effect of the descriptions in both conditions on the participants' capability to envision the environment. Asked directly after the dialogue with the system, how well they could visually imagine the described route, participants in the basic condition gave scores from 1 to 5 on a

7-point Likert scale, (median: 3, mean: 2.93, sd: 1.39). Participants in the descriptive condition gave scores from 1 to 7 (median: 5, mean: 4.6, sd: 1.59). The difference is highly significant, indicating that participants in the descriptive condition could visually imagine the route better than those in the basic condition (Wilcoxon rank sum test, one-sided:  $W = 49.5$ ,  $p\text{-value} = 0.004$ ).

### Perceived helpfulness of the instructions

The scores participants gave for the helpfulness of the instructions given by the system show an interesting effect. Both conditions were perceived as equally helpful directly after receiving the instructions - in both conditions, scores ranged from 2 to 7 on a 7-point Likert scale with a median of 5 (basic condition: mean: 4.6, sd: 1.55; descriptive condition: mean: 4.73, sd: 1.58; Wilcoxon rank sum test with continuity correction, two-sided:  $W = 110$ ,  $p\text{-value} = 0.47$ ). After navigating the route, however, this changed. In the final questionnaire, scores for helpfulness in the basic condition ranged from 1 to 7 with a median of 3 (mean: 3.54, sd: 1.81), constituting a significant drop in comparison with pre-navigation scores (Wilcoxon rank sum test with continuity correction, one-sided:  $W = 155.5$ ,  $p\text{-value} = 0.036$ ).

For the descriptive condition, on the other hand, they stayed at the same high level, ranging from 3 to 7 with a median of 5 (mean: 5.27, sd: 1.49). Thus, the perceived helpfulness after navigation is significantly higher in the descriptive condition than in the basic condition (Wilcoxon rank sum test with continuity correction, one-sided:  $W = 51$ ,  $p = 0.005$ ).

## Discussion

The results clearly show that descriptive strategies can improve wayfinding in indoor environments. Participants in the descriptive condition had a higher success rate and walked the route with less wrong segments traveled than those in the basic condition. They also needed to consult the instructions less often. This is most likely due to the fact that the different structure of the environment, as compared to street networks, leads to differences in wayfinding strategies, and therefore different needs with respect to route instructions.

An important finding of this experiment is, that descriptive elements not only improve objective performance measures, but also subjective ones. The improvement of participants' confidence and mental imagery in the descriptive condition is a factor that is important for cognitively ergonomic route instructions. Humans should not only find their goal with automatically generated instructions, they should also feel comfortable and secure while doing so. The scores for perceived helpfulness of the system show an interesting effect: before wayfinding participants rate the instructions as equally helpful in both conditions, which is in contrast to the other subjective measures. After wayfinding the values change, resulting in a significantly higher value for the descriptive condition, matching objective performance and the other subjective measures. This might be due to the fact that before performance participants were not as secure about their quality

judgement as after, and possibly answers were influenced by their wish to be polite.

There are several reasons that might account for the better performance of subjects that were given the descriptive instructions. Firstly, the significantly higher values for mental imagery before setting off suggest that better mental imagery might be one of the factors that helped participants find their way more easily. Visuo-spatial imagery is an important factor in understanding and memorizing route directions (Denis & Fernandez, submitted). In addition, successful mental imagery involves deep semantic processing and the formation of a coherent situation model which have been shown to improve memory performance (Craig & Tulving, 1975; Kintsch, 1994). The greater difficulty of participants in the basic condition to visually imagine the route in advance indicates that these participants were not able to construct as good a situation model as those in the descriptive condition.

Another central aspect that was verified by statements of several participants in the retrospective reports is that configurations of landmarks can improve error-recovery and confidence en-route, acting as substitutes for highly-salient landmarks which rarely exist in indoor environments.

Finally, it is probable that the highly repetitive style which results from generating only prescriptive utterances yields a Ranschburg effect: The occurrence of several tokens of the same type in the input within a short time is known to have a negative effect on memorization (Jahnke & Bower, 1986; Kanwisher, 1987, compare). The Ranschburg effect has mainly been studied in series of unrelated numbers or words, but it is highly probable that the underlying mechanisms have an effect on the memorization of a series of highly similar sentences containing repeated instances of certain words, as seen in the basic condition of this experiment. The more varied linguistic structure and semantic content of the descriptive instructions neutralize this effect, thereby improving memorization.

## Conclusion and Future Work

Our work shows that the use of elaborate descriptive information into indoor route instructions can significantly improve the quality of automatically generated instructions. The reported results indicate that both objective and subjective performance measures rank the use of descriptive strategies higher than the condition in which only the prescriptive strategy was used. It needs to be shown, however, that the improvement remains significantly large when using computer-generated instructions based on the descriptive approach.

Also, buildings differ with respect to their structure. While this approach may be very useful for buildings that contain a high proportion of open spaces, it may not be necessary for buildings that consist entirely of long and narrow corridors with clearly identifiable intersections and can therefore be represented sufficiently by network space. It would be insightful to compare the two different approaches over a wider variety of routes in order to investigate how the two strategies

can best be combined, and how they interrelate with issues of conciseness: How much descriptive information is necessary, and at which points in a route should this type of information be provided? How do route length and dominance of scene space characteristics interact to favor one or the other type of instructions? It should also be examined whether the findings hold for pedestrian navigation in general.

Although we have hinted at some mechanisms that might underlie the performance improvements, a more detailed analysis of these mechanisms should be undertaken, in order to be able to clearly distinguish which aspects of the descriptions improve comprehension and memorization in which ways.

Natural language route direction systems for indoor (and pedestrian) navigation should take these results into account and find ways of modeling spatial information that allow for a more flexible combination of prescriptive and descriptive information.

# Connectionist Model Accounting for Retardation of Cognitive-Dissonance Reduction Caused by Attention-Focus Switching

Takao Matsumoto (matsumoto@c.dendai.ac.jp)

Tokyo Denki University  
5 Senju-Asahi-cho, Adachi-ku, Tokyo 120-8551, Japan

## Abstract

A novel connectionist model accounting for cognitive dissonance is described, in which the concepts of self and attention are considered. The model makes it possible to use mathematical formulas to represent the cognitive-dissonance process. Analysis reveals that the model fits experimental data of major paradigms in cognitive dissonance theory and that attention-focus switching causes building-up of cognitive dissonance and retardation of its reduction.

**Keywords:** cognitive dissonance; connectionist model; attention; self-concept; mathematical analysis

## Introduction

Cognitive dissonance theory insists that dissonance is a psychological state of tension that people are motivated to reduce (Festinger, 1957). Dissonance causes feelings of discomfort, unhappiness, or distress. Any two cognitions are dissonant when one of them follows from the obverse of the other. To reduce dissonance, people add consonant cognitions or change evaluations for one or both cognitions to make them more consistent.

Cognitive dissonance theory makes a clear prediction when a firm expectancy is involved as one of the cognitions in question (Aronson, 1969). A well-known example of this is the famous Aesop's fable "The fox and the grapes." In the story, a fox wanted to get some grapes hanging high on vines and leaped with effort, but couldn't get them. Walking away, the fox said, "The grapes are surely sour, and I do not need them." Since the expectation and experience were inconsistent, the fox had cognitive dissonance, which he reduced by convincing himself that the expectation was not appropriate.

Shultz and Lepper (1996) proposed a connectionist model accounting specifically for the mechanism of cognitive dissonance. A constraint satisfaction neural network model was used to simulate data from the several major cognitive dissonance paradigms (Shultz, Leveille, & Lepper, 1999). In it weights between nodes are fixed and activations of units are changed. Dissonance is defined by a formula that is a function of activations of units and weights applied to links in the network. Networks tend to settle into a less dissonant state as activations of units are changed according to update rules. Another connectionist model was proposed by Van Overwalle and colleagues (2002, 2005). They represented attitudes in a feed-forward neural network with the delta-learning rule in which weights are allowed to change. Input nodes represent the features of the environment and two

output ports represent behavior and affect. Dissonance is defined as the discrepancy between expected and actual outcomes. They also simulated the experimental results of major cognitive dissonance paradigms. Several other computational models have been reported that deal with attitude phenomena through simulation using constraint-satisfaction or non-constraint-satisfaction networks (Mosler et al., 2001; Petty & Cacioppo, 1986; Read & Miller, 1994; Spellman, Ullman, & Holyoak, 1993).

People are motivated to prioritize to protect their self-system. Self-consistency theory (Aronson, 1969; Thibodeau and Aronson, 1992) emphasizes that self is involved in dissonance arousal and that not only cognitions but also self-concept need to be considered in discussing dissonance. Judgment and assessment for cognitions performed by self possibly become motives for arousal of cognitive dissonance.

On the other hand, attention is an important phenomenon of information processing in cognitive systems (Pisapia, Repovs, & Braver, 2008). It is a function for selecting and enhancing a limited area of information, while suppressing other areas. Cognitions are included in these areas of information.

To the author's knowledge, connectionist models for cognitive dissonance taking the concepts of self and attention into account have not been presented. In this paper, a novel model considering these concepts is described and reduction of cognitive dissonance based on the model is discussed.

## Connectionist Model

Figure 1 shows our connectionist model accounting for cognitive dissonance. In accordance with the cognitive dissonance theory (Festinger, 1957), two cognitions are adopted in the model, which are depicted as units R and I. We assume that unit R is a reality-based cognition such as the cognition of behavior, experience, or actual situation, while unit I is an imagination-based cognition such as the cognition of expectancy, hope, or belief. In the case of the previously mentioned fable, the imagination-based cognition held by the fox is "The grapes can stave off my hunger" and the reality-based cognition is "The grapes do not stave off my hunger."

Attention plays an important role in cognitive systems. It selects and enhances limited cognitions and suppresses others. If we consider two cognitions alone, when one of them is selected and enhanced, the other is rejected and

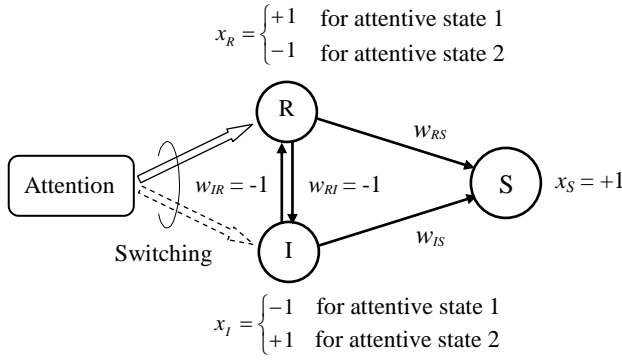

Figure 1: Connectionist model adopting the concepts of attention and self.

suppressed. Thus, the units of these cognitions perform a bistable operation. In order to achieve this operation, the units must be bidirectionally connected through links having negative weights as shown in Figure 1 (Rojas, 1996). In our model, to simplify the discussion, it is assumed that the activation level of units R and I is “+1” or “-1”, which correspond respectively to excited and inhibited state, and the weights between the units, i.e.,  $w_{RI}$  and  $w_{IR}$ , are -1. The bistable operation is determined by inputs to the unit pair applied through some additional links connected to the unit pair. The inputs’ condition depends on the attentive state. Since attention is usually focused on the cognition of unit R, the bistable operation is not perfectly symmetrical. There might be some bias difference between the inputs to the unit pair. In order to pick up the elements closely related to cognitive dissonance, such additional links are excluded from Figure 1.

Aronson (1969) emphasized that dissonance theory can make the clearest prediction of cognitive dissonance when we deal with the self-concept and cognitions about some behavior. Self is regarded as the key for arousing cognitive dissonance. In accordance with this view, we introduce a unit corresponding to self in our connectionist model, which is depicted as unit S in Figure 1.

Self is a complex system in which cognitive and affective elements are integrated. It is extremely difficult to rigorously represent the self in a simple connectionist model. Here, we assume that self is characterized by static equilibrium, in which there is resistance to incoming information that would change the status of elements (Nowak et al., 2000), and that, as pointed out in many studies of cognitive dissonance, people have a high or positive self-concept. Thus, we boldly introduce a single unit for self whose activation level is constant and takes a value of +1.

Cognition is composed of several elements having different attributes, each of which is related to the self with some evaluation given by the person. Cumulative evaluation

of all elements for a cognition is assumed to be the evaluation of the cognition. In our connectionist model, such an evaluation of cognition is represented by the weight of the link between the unit of the cognition and that of self. If the cognition is attractive for self, the evaluation or weight is positive, and if not, negative. The links are assumed to be unidirectional with directions from units R and I to unit S. The weight of the link between units R and S is  $w_{RS}$  and that between units I and S is  $w_{IS}$ . These weights take values between -1 and +1.

When we respectively represent the activation levels of units R, I, and S by  $x_R$ ,  $x_I$ , and  $x_S$ , the model’s cognitive dissonance can be described according to the definition given by Shultz and Lepper (1996) as follows:

$$CD = (2x_R x_I - w_{RS} x_R x_S - w_{IS} x_I x_S) / 4. \quad (1)$$

Focus of attention determines the state of the bistable operation of the unit pair composed of units R and I. We define attentive state 1 as the state in which attention is focused on the cognition of unit R and  $(x_R, x_I) = (+1, -1)$ , while attentive state 2 is defined as the state in which attention is focused on the cognition of unit I and  $(x_R, x_I) = (-1, +1)$ . Using Equation (1) and the previously-mentioned assumption that  $x_S = +1$ , cognitive dissonances for the two states are described as

$$CD = \begin{cases} (w_{IS} - w_{RS} - 2) / 4, & \text{for attentive state 1,} \\ (w_{RS} - w_{IS} - 2) / 4, & \text{for attentive state 2.} \end{cases} \quad (2)$$

## Analysis of Evaluation Change

In neural networks, the weight of a connection between two neurons changes according to the activation condition of the neurons. When the two neurons are excited simultaneously, the weight of the link between them increases and when they are not decreases. We assume that the weights in our connectionist model perform similarly to those of neural networks. The modified Hebbian learning rule presented by Oja (1982) incorporates the saturation characteristics of neurons into the original Hebbian rule. It represents the changes in weight as a function of the activation levels of input and output units, the weight between them, and a constant representing the learning rate during a time interval (O’Reilly & Munakata, 2000).

When we assume that the time interval is infinitesimal, the rule can be represented by the following differential equation:

$$\frac{dw}{dt} = \varepsilon' (xy - y^2 w), \quad (3)$$

where  $\varepsilon'$  is a constant representing the learning rate during a unit time interval.

In order to consider the behavior of  $w_{RS}$  we substitute  $w_{RS}$  for  $w$  in Equation (3). Since  $x = x_R = +1$  and  $y = x_S = +1$  for

attentive state 1 and  $x = x_R = -1$  and  $y = x_S = +1$  for attentive state 2, we obtain general solutions of Equation(3) as follows:

$$w_{RS} = \begin{cases} K_1 e^{-\varepsilon t} + 1 & , \text{ for attentive state 1,} \\ K_2 e^{-\varepsilon t} - 1 & , \text{ for attentive state 2.} \end{cases} \quad (4)$$

For  $w_{IS}$ , similar to the above, we can derive following solutions:

$$w_{IS} = \begin{cases} K_3 e^{-\varepsilon t} - 1 & , \text{ for attentive state 1,} \\ K_4 e^{-\varepsilon t} + 1 & , \text{ for attentive state 2.} \end{cases} \quad (5)$$

$K_1, K_2, K_3$ , and  $K_4$  are constants determined by initial conditions. Since the weights represent evaluations as previously mentioned, Equations (4) and (5) represent the time dependence of evaluations for cognitions R and I.

### Comparison with Experimental Results

To confirm the validity of our connectionist model and analysis, here we take up the free-choice paradigm as the first example, and compare theoretical results of our analysis and experimental results reported in the literature. In an experiment carried out by Brehm(1956), subjects were asked to rate each of a variety of items on desirability. They were next required to make a difficult choice, i.e., a choice between two items that they had rated high, or an easy choice, i.e., a choice between one item they had rated high and one they had rated low. The chosen items were given to the subjects who then rated them again. The experimenter measured the differences between the first and second ratings.

Applying our model to the experiment, we regard units R and I as the chosen and rejected items, respectively. This is because after a choice is made, its result is the reality for the subject and the chosen item becomes the element of the reality-based cognition, while the rejected item becomes that of the imagination-based cognition. Weights  $w_{RS}$  and  $w_{IS}$  are evaluations of the two items. We assume that the choice is carried out at  $\varepsilon t = 0$ . Weights' initial values at  $\varepsilon t = 0$  used in our theoretical examination are presented in Figure 2. The theoretical values are determined by making their maximum and minimum possible values, i.e., +1.0 and -1.0, correspond to the experimental maximum and minimum evaluations used in rating, i.e., 8 and 1, respectively. The values in the experiment and those in the theory are linearly related, and their correspondence is schematically shown in Figure 2. Since we consider the situation on the basis of reality, transitions of the weights or evaluations are calculated for attentive state 1.

Figure 3 shows our theoretical results at  $\varepsilon t = 0.7$  as well as the experimental data reported by Brehm(1956). Our theoretical results show that for both the difficult and easy

Figure 2 : Correspondence of the initial values of evaluation.

(a) Experiment (Brehm, 1956)

(b) Theory based on our model at  $\varepsilon t = 0.7$

Figure 3: Evaluation change in free-choice paradigm.

choices,  $w_{RS}$  increases and  $w_{IS}$  decreases, i.e., the separation between them increases, with the increase of time after the choice. The degree of separation increase is substantial for the difficult choice. Our results in Figure 3(b) are similar to the experimental data depicted in Figure 3(a).

We take up the insufficient-justification paradigm as the second example. In an experiment carried out by Freedman (1965), school children were forbidden to play with a desirable toy under either a mild or severe threat and the experimenter either stayed in or left the room while the children played. Actual play with the previously forbidden toy later indicated that derogation was greater under the mild than under the severe threat conditions only when there was no surveillance.

Applying our model to this experiment, we assume that units R and I are respectively the cognitions “I do not play with the toy” and “I play with the toy”. This is because, since the children are forbidden to play with the toy and are ordered to obey the directions, their reality-based cognition is “I do not play with the toy.” Weights  $w_{RS}$  and  $w_{IS}$  are respectively evaluations for not playing with and playing with the toy.

Here, we assume that weight  $w_{IS}$  is a compound of three subweights  $w_0(t)$ ,  $w_t$ , and  $w_s$  as shown in Figure 4. The intrinsic evaluation given by the subject for the cognition of unit I is  $w_0(t)$  ( $-1 \leq w_0(t) \leq 1$ ). Since the evaluation may change, it is represented by a function of  $t$ . The subweights  $w_t$  and  $w_s$  are additional weights caused respectively by the effects of threat and surveillance. Since the effects are independent of time,  $w_t$  and  $w_s$  are constants.

As mentioned above, we assume that the weights are bounded and take values between -1 and +1. Thus, we represent  $w_{IS}$  as follows:

$$w_{IS} = \begin{cases} w_0(t) + w_t + w_s, & \text{for } -1 \leq w_0(t) + w_t + w_s \leq +1, \\ -1, & \text{for } w_0(t) + w_t + w_s < -1, \\ +1, & \text{for } w_0(t) + w_t + w_s > +1. \end{cases} \quad (6)$$

Considering the situation on the basis of reality, we assume the attentive state is 1. Since threat and surveillance are unpleasant for the subject and thus function as negative elements of the cognition represented by unit I, we assume

Figure 4: Weights in the connection between units I and S for insufficient-justification paradigm.

Table 1: Weights used in the theory for insufficient-justification paradigm.

	Non-surveillance	Surveillance
Mild threat	$w_0(0) = +1.0$	$w_0(0) = +1.0$
	$w_t = -0.2$	$w_t = -0.2$
	$w_s = 0$	$w_s = -2.0$
Severe threat	$w_0(0) = +1.0$	$w_0(0) = +1.0$
	$w_t = -1.8$	$w_t = -1.8$
	$w_s = 0$	$w_s = -2.0$

$w_t < 0$  and  $w_s < 0$ . Applying Equation (6) to the theory described in the previous section, we obtain

$$w_0(t) = \begin{cases} w_0(0), & \text{for } w_0(0) + w_t + w_s < -1, \\ (w_0(0) + w_t + w_s + 1)e^{-\varepsilon t} - w_t - w_s - 1, & \text{for } w_0(0) + w_t + w_s \geq -1. \end{cases} \quad (7)$$

Table 1 presents the values of the weights (evaluations) used in our theoretical examination. Since the toy might be very attractive for the subjects, we assume that  $w_0(0)$  takes the maximum value, i.e., +1.0. As surveillance seems to be effective for forbidding and induce highly negative feeling in the subject, the absolute value of  $w_s$  under surveillance is assumed to be large so that  $w_{IS}$  takes the minimum value, i.e., -1.0.

Transitions of the weights or evaluations are calculated for attentive state 1. Figure 5 shows our theoretical results for  $w_0(t)$  at  $\varepsilon t = 2$  as well as the experimental data reported by Freedman (1965). The theoretical result shown in Figure 5(b) indicates that derogation is greater under the mild than under the severe threat conditions only when there was no surveillance, which is similar to Freedman's experimental result.

## Attention-focus Switching

Here, following the Aesop's fable, we anticipate a case in which a person has a certain expectation concerning something, and he fails to realize it in spite of his effort. The object of expectation is the cognition of unit I in Figure 1, and the result of failure is the cognition of unit R. Since the expected object is attractive for the person and causes positive feeling, the cognition of unit I is positively evaluated and thus we assume  $w_{IS} > 0$ . In contrast, since the failure result is disagreeable and causes negative feeling, the cognition of unit R is negatively evaluated and thus we assume  $w_{RS} < 0$ . Since cognitive dissonance occurs when we experience the failure and thus attention is focused on the cognition of unit R, we consider here the situation in

(a) Experiment (Freedman, 1965)

(b) Theory based on our model at  $\varepsilon't = 2.0$

Figure 5: Evaluation change in insufficient-justification paradigm.

attentive state 1. Assuming that, as an example,  $w_{IS} = +0.6$  and  $w_{RS} = -0.4$  are the initial conditions at  $\varepsilon't = 0$ , we can obtain  $w_{IS}$ ,  $w_{RS}$ , and cognitive dissonance ( $CD$ ) at  $\varepsilon't \geq 0$  by using Equations (2), (4), and (5), which are shown by the dotted lines in Figure 6. The abscissa is  $\varepsilon't$ , which is a parameter proportional to the time passed after the person made the trial and failed.

The decrease of  $w_{IS}$  and increase of  $w_{RS}$  with the increase of time shown in Figure 6(a) indicate adaptation or rationalization of the person under cognitive dissonance. In accordance with these changes,  $CD$  is reduced with the increase of time as shown in Figure 6(b). Such changes appeared in  $w_{IS}$ ,  $w_{RS}$ , and  $CD$  corresponds to the phenomenon predicted by the cognitive dissonance theory (Festinger, 1957).

Conventional research on cognitive dissonance does not seem to have amply discussed the effect of attention. Since the occurrence of cognitive dissonance induces unpleasant feeling, the person mentioned above might strive to reduce it. He might recall the expectation and imagine the result that could be obtained in success of his trial. The fox in the

fable might say after a short time, "I have gotten hungrier. If I could get the grapes now, even if they were not ripe, I might eat them and be feeling full now". In this way, the focus of attention is switched from reality-based to imagination-based cognition. However, since one cannot live on imagination only and must act on the basis of reality, it is not long before the focus of attention is switched back to reality-based cognition. Thus, we assume here that the focus of attention is switched and the attentive state is changed such that  $1 \rightarrow 2 \rightarrow 1$ .

Transitions of evaluation and cognitive dissonance under such switching are calculated and depicted by the solid lines in Figure 6. In the first period of  $0 \leq \varepsilon't < 0.1$ , where the attentive state is 1, cognitive dissonance is monotonically reduced with the increase of  $\varepsilon't$ . At  $\varepsilon't = 0.1$ , the focus of attention is switched to the cognition of unit I and cognitive dissonance is reduced stepwise. During the period of  $0.1 \leq \varepsilon't < 0.15$ , where the attentive state is 2, reduction of cognitive dissonance continues with a small reduction rate. At  $\varepsilon't = 0.15$ , the focus of attention is switched back to the cognition of unit R. Cognitive dissonance is then built up stepwise and takes an amount greater than would be taken when switching is not performed at all. After that, attentive state 1 is retained and monotonical reduction of cognitive

(a) Change in evaluation with increase of time.

(b) Change in cognitive dissonance with increase of time.

Figure 6: Changes in evaluation and cognitive dissonance under attention-focus switching.

dissonance continues. Consequently, attention-focus switching causes retardation of cognitive-dissonance reduction as shown in Figure 6(b), which induces lingering of unpleasant feeling or discomfort. If the switching is frequently repeated, cognitive dissonance remains for a long time.

The well-known saying “What’s done is done” might imply that it is not worth worrying about an unfavorable situation caused by past behavior. It might also warn of the building-up of cognitive dissonance caused by attention-focus switching and suggest that attention not be focused on imagination-based cognition. Another well-known saying, stated by Dante Alighieri, is that “There is no greater grief than to recall a time of happiness when in misery.” This implies that to obtain peace of mind, it is important to focus one’s attention on the reality and discard the imagination even if one finds the reality unpleasant. The insistence common to these sayings might support the results shown in Figure 6(b).

## Conclusion

This paper described a novel connectionist model accounting for cognitive dissonance, in which the concepts of self as well as attention-focus switching are adopted. The model was investigated not with the computer simulation widely used in conventional research, but with a mathematical analysis based on a differential equation. Predictions based on the model were confirmed to coincide with experimental data reported in the literature. It was shown that attention-focus switching between reality-based and imagination-based cognition causes building-up of cognitive dissonance and retardation of its reduction. This coincides with the implication of well-known sayings suggesting ways to keep the mind away from feelings of suffering or discomfort.

# Investigation of effects of working memory capacity on rule discovery process using eye movement data

Miki Matsumuro (muro@cog.human.nagoya-u.ac.jp)

Kazuhisa Miwa (miwa@is.nagoya-u.ac.jp)

Graduate School of Information Science, Nagoya University, Fro-cho, Chikusa-ku, Nagoya, Japan

## Abstract

Many studies have investigated the process of rule discovery. However, the data utilized in these studies, such as performance and verbal protocol data, were course-grained. In this study, we designed a new experimental method using eye movement data to observe the detailed process of rule discovery. In the proposed method, we corresponded the task display and a rule space in the participants' minds to understand how they consider the rules and observe instances by eye tracking. Then, we compared the process of rule discovery by people with high and low working memory capacities. The results of the experiment revealed that those with high working memory capacity tried to consider one or similar rules from multiple instances. On the other hand, those with low working memory capacity tended to consider various rules from one instance.

**Keywords:** Rule discovery; eye tracking; working memory capacity; search strategy

## Introduction

It is one of the most important activities to find regularities not only in science but also in many aspects of daily life. In this study, we tackle two goals in order to understand the process of rule discovery. Our first goal is to propose a new experimental method so as to observe the detailed process of rule discovery. The second goal is to investigate the relation between working memory capacity (WMC) and strategies of rule discovery.

The origin of this study is traced back to the dual space search theory proposed by Simon and Lea (1974). They suggested that the process of rule discovery develops through the interaction between two types of searches in two spaces, a rule space and an instance space. Problem solvers state rules by searching in a rule space while generating and observing instances in an instance space, and modify the rules or propose new rules based on their observations.

Although their theory can successfully explain the process of rule discovery, when conducting experiments based on this theory, there are limitations. One is that it is difficult to observe the detailed process of search in a rule space because the thought process to state rules cannot be monitored directly. To investigate this process, the researchers have utilized the protocol analysis method (e.g., Haverty, Koedinger, Klahr, & Alibali, 2000). The participants' think-aloud protocol data were used for this analysis. However, the data were coarse-grained on the time scale, and the participants mentioned only their conscious thoughts. Therefore, the analysis of the detailed patterns of search in the two spaces from protocol data often faced essential limitations. For these reasons, our first purpose is to propose a new experimental method to observe the detailed process of rule discovery.

The second goal is to investigate the relation between WMC and strategies of rule discovery. Dougherty and Hunter (2003) showed that people with high WMC maintained more alternative hypotheses in their mind when they engaged in hypothesis generation. However, their task was a probability judgment task and their analysis was based on participants' performance of the thought-listing task that was even more coarse-grained than the protocol data. Other studies also analyzed the effects of WMC based on the score of the reasoning tasks (e.g., Süß, Oberauer, Wittmann, Wilhelm, & Schulze, 2002). In the current study, we focus not on outputs as results but on the process of rule discovery by using eye movement data.

In summary, the first purpose of our study is to propose a new experimental method by which we obtain detailed data about the process of rule discovery. The second purpose is to investigate how participants' WMC affects such a process. Our method using eye tracking was established based on the SDDS (Scientific Discovery as Dual Search) model of Klahr and Dunbar (1988). The reason we use eye tracking is that eye movement data are more fine-grained than verbal reports and obtained directly without participants' conscious effort (cf. Rehder & Hoffman, 2005). With this method, we examine differences in search strategies affected by WMC, selecting those who have high or low WMC based on screening test scores.

## Experimental Method

### Search in Each Space

We designed an experimental method by means of eye tracking. We utilize the idea of the structure of a hypothesis space in the SDDS model. It extends the dual space search theory for investigating scientific discovery. The hypothesis space in the SDDS model corresponds to a rule space in dual space search. The hypothesis space includes all available hypotheses, each of which is connected with others through search paths. The search path does not connect hypotheses that have different schema. Therefore, similar hypotheses with an identical schema construct a subspace of the hypothesis space. Based on this idea, in our method, we manipulate the structure of a rule space by giving a different function to each rule. Since a different function evokes a different schema, only rules that have the same function are connected, and they construct a subspace in a rule space.

We obtain search patterns in the rule and instance spaces by means of eye tracking. First, we define search in each space as follows. The search in a rule space is the process where

Figure 1: Four search statuses of the rule and instance spaces and transition patterns among the statuses.

participants consider rules from instances. On the other hand, the search in an instance space is defined as the activities where participants generate or observe instances to consider rules. In actual processes of rule discovery, timing to switch between searches in the rule and instance spaces is not clear. Therefore, in this method, we collect eye movement data as the search in a rule space and observations of instances as the search in an instance space.

There are two modes in the search process (Figure 1): the *single-* and *multiple-subspace search* in a rule space and the *single-* and *multiple-instance search* in an instance space. First, we define two modes of search in the rule space. The single-subspace search is the search mode in which participants search only in one subspace. In other words, they consider rules in the same subspace that are characterized by an identical function. On the other hand, in the multiple-subspace search mode, they try to decide which subspace they should search. Whereas the single-subspace search is a “search in a subspace,” the multiple-subspace search is a “search for a subspace” to be focused on.

For search in the instance space, we also define two modes of search. Participants in the single-instance search mode focus on observing one instance. They consider multiple rules from a single instance. In contrast, they observe various instances for stating rules in the multiple-instance search mode. They compare multiple instances to obtain cues for rule discovery.

Each participant’s search status is categorized into one of the four search statuses in Figure 1. The single/single status is one in which participants observe one instance and consider rules with an identical function. When participants consider a complex process, they do so in this status because they may concentrate their attention on a single event. Participants in the single/multiple status also consider rules in an identical subspace, but they observe and compare multiple instances to obtain the cues for rule discovery. On the other hand, in the multiple/single status, participants consider rules with various functions across multiple subspaces while focusing on examining one instance. Last, the participants in the multiple/multiple status also consider various rules across multiple

Figure 2: Example screenshot of task display in this study. The upper panel is the number panel, the lower-left panel is the arrow panel, and the lower-right panel is the compass panel. The directions were presented in Chinese characters. The target alphabet is presented in the center of the display.

subspaces while observing multiple instances in a short time. This status seems not to be suitable for rule searching because they simultaneously vary both factors, rules and instances, preventing efficient searches for rule discovery. To identify each search status (a circle in Figure 1) and each transition among the search statuses (an arrow in Figure 1), we systematically designed a rule discovery task as follows.

### Rule Discovery Task Using Eye Tracking

The task display consists of three panels (arrow, compass, and number panels) and eight letters (a to h) in the center of the display as shown in Figure 2. The eight letters are placed in circle. The presented letter (we call this the “target”) is determined based on the objects displayed on one of the three panels. The participants are asked to find a rule determining which panel relates to the target and how the target is determined by the objects in the related panel. Only one of the three panels relates to the target and the other two panels have no relation to it. The participants are required to find a rule as quickly as possible.

The experimental procedures are as follows. Before the experiment, an experimenter prepares six instances as stimuli. In the example instance in Figure 2, the rule may be: “the target is the letter (h) in the opposite position (North-West) of the combination of two directions (South-East) on the compass panel.” In this case, the experimenter selects five other instances so as to be instances consistent with the same compass rule. The participants are instructed that only one panel is related to the target in advance. The participants observe all six instances one-by-one using right- and left-arrow keys on the keyboard. The panel that has the same function is always presented in the same position on the display. Additionally, the six instances are presented in a cyclic manner; the participants can observe instances as many times as they want. When the participants think of a rule, they press the space key and report their rule to the experimenter. When the

Table 1: Functions and example rules of each panel

panel	function	how to decide target	example rule (see example in Figure 2)
number	order	a letter corresponds to a number in alphabetical order (“a” is 1)	Target is the sum of numbers in alphabetical order (e.g., $1 + 3 = 4 \rightarrow d$ )
arrow	rotation	a letter corresponds to an angle of arrows	Target is a shifted letter from “a” by an angle of left object (e.g., 180 degrees $\rightarrow e$ )
compass	position	a letter corresponds to a direction (based on map)	Target is pointed at by right object (e.g., East $\rightarrow c$ )

correct rule is discovered, the experiment is terminated. Every five minutes, the calibration for recording eye movement is performed. Table 1 shows functions and example rules in each panel. Before starting the task, the participants learn these functions sufficiently.

### Data and Search in Each Space

Figure 3 shows example data obtained in the experiment. For example, from 520 to 530 seconds in Figure 3, this participant focused her attention on the arrow panel, meaning that she considered only rules that use arrows; that is, she searched in the subspace of “rotation” rules in a rule space. The shift of fixation from the arrow to the number panel at around 530 seconds means that her search subspace shifted to the “order” rule subspace. In the same manner, the behavior after 530 seconds is interpreted that she expanded her attention toward the three panels, meaning that she searched all subspaces in a rule space simultaneously. Soon after broadening the search, she fixed her attention on the compass panel. In the final part, she shifted her search subspace to the “order” rule without broadening the search. On the other hand, for the search in an instance space, the participant seemed to focus on a single instance before around 560 seconds. Then, she moved to observe multiple instances during a short time after around 570 seconds.

With reference to Figure 3, around 520 seconds, her search mode was in the single/single status. Then, she searched in multiple subspaces in a rule space with an identical instance at around 530 seconds, meaning that her search status shifted to the multiple/single. Soon, she came back to the single/single status, and this status continued for a while. After around 570 seconds, she observed multiple instances one-by-

Figure 3: Timeline graph of collected data.

Each red horizontal line indicates a panel that the participant focused on. Labels of the vertical axis indicate three panels. Arrows on the top of the graph mean timing at which the participant shifted an instance to the previous or next one.

one, meaning that she moved to the single/multiple status. As shown in this example, it is possible to obtain detailed search processes in the rule and instance spaces by our experimental method.

We conducted an experiment with this method to observe the process of searches in the rule and instance spaces to understand the effect of WMC on the rule discovery process.

## Experiment

First, we measured the participants’ spatial span capability as a screening test.

### Screening Test

Fifty-seven undergraduates engaged in the spatial span test by Shah and Miyake (1996). In the task, a capital letter was presented on a computer screen that was not in the upright orientation. The participants were asked to indicate whether the letter was normal or mirror-imaged and were required to store the orientation of each letter for a subsequent recall test. One participant whose judgment score was around the chance level was excluded from analysis. Fifty-six participants’ data were scored based on the partial-credit unit scoring by Conway et al. (2005). The mean score was 0.576 ( $SD = 0.200$ ), the highest score was 0.920, and the lowest score was 0.121.

### Rule Discovery Task

#### Method

**Participants** The twelve participants with the highest WMC scores participated as the high-WMC group. Their mean score was 0.825 ( $SD = 0.068$ ). The twelve participants with the lowest WMC scores participated as the low-WMC group. Their mean score was 0.290 ( $SD = 0.091$ ). The mean WMC score of the high group was significantly higher than that of the low group ( $t(22) = 16.318, p < .001$ ).

**Apparatus** We presented the task display on a 17-in. monitor with a resolution of  $1280 \times 1024$  pixels. The participants were seated approximately 60 cm away from the monitor. The size of panels was approximately  $5.25^\circ \times 7.82^\circ$  of visual angle. Each panel was placed as shown in Figure 2 on the upper-center, lower-left, and lower-right of the task display. The participants’ eye movements were recorded using the Tobii T60 eye tracker at 60 Hz. The participants were allowed to move their heads naturally.

Table 2: Rules used in this study

	panel	rule
task 1	compass	Target is the opposite position of combination of two directions on the panel
task 2	arrow	Target is a shifted letter by sum of an angle of two arrows on the panel and 135 degrees
task 3	number	Target is the sum of the difference between two numbers and the bigger one on the panel

**Procedures** Approximately one month after the screening test, the rule discovery task was conducted individually. First, the participants were instructed on the task and learned the function of each panel sufficiently through practice. Task 1 was preliminarily performed to let the participants establish their own strategies. In task 1, the participants needed to find a simple rule in ten minutes. Soon after task 1 ended, task 2 was conducted with the same procedure as that in task 1. The participants needed to find a relatively complex rule in twenty minutes in task 2. The data of task 2 were used for analysis. As an exception, the participants who found the rule before fifteen minutes passed were led to engage in another task (task 3) with the same procedure as that in task 2. In this case, the data of task 3 were used for analysis. Table 2 shows the rules used in the experiment.

## Results

One participant in the low group was excluded from analysis because we did not obtain the data for more than fifteen minutes. We analyzed only the participants from whom more than 60% of eye movement data were recorded correctly. Based on the criterion, six participants in the high group and two participants in the low group were excluded; therefore, the data of six participants in the high group (WMC score  $M = 0.858, SD = 0.058$ ) and nine participants in the low group (WMC score  $M = 0.289, SD = 0.100$ ) were used for analyses. The average WMC score of the high group was still significantly higher than that of the low group ( $t(13) = 12.551, p < .001$ ).

**Search Status** Fixations longer than 100 msec were analyzed, and fixations outside the panels were excluded from analysis. First, we traced each participant's data along a timeline to acquire on which panel the fixations were observed and when an instance was shifted, as shown in Figure 3. We defined that the fixation shift happened when the participant's fixation point was observed on a different panel from the preceding one. Similarly, we defined that the instance shift happened when the participants pressed the arrow keys to observe another instance. Based on the median of the fixation time in one panel (8.961 seconds) and the mean of observation time in one instance (7.531 seconds), we segmented the timeline

Figure 4: Ratio of segments in four search statuses in each WMC group (bars show standard errors).

every 7.5 seconds.

Then, we counted how many fixation and instance shifts happened in each segment. We also performed the same analysis with the segmentations at six, seven, and eight seconds, and similar results were confirmed. We defined that the participants were in the multiple-subspace search mode in a rule space when the fixation shifts were observed more than once in each segment. Similarly, for search in an instance space, in each segment when more than one instance shift were observed, the participants were defined to be in the multiple-instance search mode. Based on the definitions, we classified the participants' status in each segment into four categories shown in Figure 1.

Figure 4 presents the ratio of segments categorized into each search status in each WMC group. Mixed ANOVA with WMC (high and low) as between-subject factor and search status (four statuses) as within-subject factor was performed on the ratio of segments. The interaction between the WMC and the search status reached significance ( $F(3, 39) = 6.328, p = .001$ ). The ratio in the single/single status in the high-WMC group was significantly higher than that in the low-WMC group ( $F(1, 52) = 12.116, p = .001$ ). On the other hand, the ratio in the single/multiple status in the high-WMC group was significantly lower than that in the low-WMC group ( $F(1, 52) = 8.663, p = .005$ ). These results show that the participants in the high-WMC group compared multiple instances more frequently than those in the low-WMC group when they were in the single-subspace search mode in a rule space search. On the other hand, the participants in the low-WMC group searched in the single subspace in a rule space with fewer shifts of instances. When they searched in a rule space with the multiple-subspace search mode, there was no significant difference in search status between the two WMC groups.

**Transition Probability among Each Search Status** Next, we calculated the transition probability of shifting from one to another or being in the same search status. There are sixteen transition patterns shown in Figure 1. Figure 5 shows

Figure 5: Probability of each transition pattern in each WMC group (bars show standard errors). S/S = single/single, S/M = single/multiple, M/S = multiple/single, M/M = multiple/multiple.

the transition probability of each transition pattern in each WMC group. Mixed ANOVA with WMC (high and low) as between-subject factor and transition pattern (sixteen patterns) as within-subject factor was performed on the transition probability. The interaction between the WMC and the transition pattern reached significance ( $F(15, 195) = 5.323, p < .001$ ). Four comparisons reaching significance are shown in Figure 5: the transition probability of single/single to single/single in the low-WMC group was significantly higher than that in the high-WMC group ( $F(1, 208) = 43.283, p < .001$ ); the transition probability of single/single to multiple/single in the low-WMC group was significantly higher than that in the high-WMC group ( $F(1, 208) = 6.955, p = .009$ ); the transition probability of single/multiple to single/multiple in the high-WMC group was significantly higher than that in the low-WMC group ( $F(1, 208) = 14.012, p < .001$ ); and the transition probability of multiple/single to single/single in the low-WMC group was significantly higher than that in the high-WMC group ( $F(1, 208) = 9.819, p = .002$ ). Other comparisons did not reach significance.

These results indicate that when they searched in a single subspace of a rule space, the participants in the high-WMC group tended to continue the multiple-instance search in an instance space, and those in the low-WMC group tended to continue to the single-instance search. On the other hand, the participants in the low-WMC group tended to shift to the search in multiple subspaces of a rule space focusing on a single instance more frequently than those in the high-WMC group, even though their multiple-subspace search did not continue very long.

## Discussion

Our first purpose was to propose a new experimental method by which we could capture the detailed process of rule discovery. This purpose was achieved by manipulating a structure of a rule space and using eye tracking. We successfully

observed the search statuses in the rule and instance spaces and the transition patterns among those in detail. The second purpose of this study was to compare the process of rule discovery by people with high or low WMC. Our method detected the different processes of the two types of participants.

## Advantages of New Method

The protocol analysis has two main limitations; as a result, we could not capture the detailed process of search in a rule space. The first difficulty is the grain size of data. Reporting one's thoughts cannot happen at the speed of thought, making it impossible for participants to report all of their thoughts. Participants would omit reporting their short-term thoughts. The use of eye tracking has the potential to solve this problem. We can directly obtain which direction participants focus their attention in by eye tracking. Furthermore, the sampling rate is very fine, 60 Hz in this study.

The second limitation of verbal protocols appears when participants have difficulty putting their thoughts into words. Participants sometimes have "no idea" during an experiment. In this study, all except one participant reported in the post-task interview that there were periods when they came up with no idea. In such a situation, the participants were usually confused and had difficulties in putting their thoughts into words. Moreover, the verbalization of confused thoughts would further muddle their thoughts. Eye movement data are always recorded throughout the task, even if participants cannot verbalize their thoughts.

We designed our task based on the SDDS model by Klahr and Dunbar (1988) to maximize the advantages of eye movement analysis. The task display as the observable externalized space consistently corresponds to the subspaces in a rule space as the internal representation. Due to this design, we could analyze search in a rule space from eye movement data. These features in our experimental method enabled us to capture each search status and the transition among the statuses

in detail.

### Differences between Each WMC Group

As a result of the experiment, different strategies were observed according to participants' WMC.

The analysis of the occurrence ratio of each search status and each transition pattern suggested that the participants in the high-WMC group tended to search in a rule space focusing on one subspace compared to those in the low-WMC group. Additionally, when they considered the rules that have an identical function, they observed and compared multiple instances more continuously. These results suggest that the participants with high WMC considered complex rules with an identical function while comparing multiple instances, meaning that they preferred the depth-first search in a rule space. Note that they did not necessarily fix their search to one single subspace because they actually shifted the search from one to another subspace at their own pace.

On the other hand, quick shifts of fixation among multiple panels, i.e. being in the multiple-subspace search mode in a rule space, were more frequently observed in the low-WMC group. However, this mode did not continue, and they soon came back to the single-subspace search mode. These results indicate that the participants with low WMC searched in a rule space switching the single- and multiple-subspace search modes alternatively. For the search in an instance space, they did not observe multiple instances as the participants in the high-WMC group did. This implies that they tried to consider rules from one instance, whereas the participants in the high-WMC group tried to consider one rule from multiple instances. These results suggest that they valued the breadth-first search. These two strategies, depth-first and breadth-first searches, were also observed in our previous study (Matsumuro & Miwa, 2011).

We suggest a possible reason that the search strategy was different according to their WMC based on the studies of category learning. Two strategies have been shown (DeCaro, Thomas, & Beilock, 2008; Rehder & Hoffman, 2005): the rule-based strategy where participants conduct hypothesis testing explicitly, and the information-integration strategy where rules are learned implicitly by integrating stimuli across multiple dimensions. The participants in the high-WMC group in our study observed multiple instances while searching in a single subspace in a rule space. They would generate hypotheses by comparing instances and tested these hypotheses as with the rule-based strategy. The explicit strategy was suitable for the participants with high WMC because it relies heavily on working memory. By contrast, the participants in the low-WMC group searched in multiple subspaces with a single instance. They would have gathered information from multiple dimensions and tried to figure out the relation between the target and the objects on the three panels implicitly, as with the information-integration strategy. The implicit strategy is processed without conscious control. Therefore, this strategy is suitable for the participants with low WMC because it does not require working memory load.

Given these points, it may be possible that our participants in each group selected a strategy suitable for each WMC. Note that the search in multiple subspaces by the participants in the low-WMC group did not continue. They had to conduct explicit hypothesis testing because all participants were required to find a rule that could be reported in words.

To investigate this possibility, we should analyze verbal protocols along with the eye movement data recorded in this study. Additionally, in future work, we need to investigate the relation between the search strategies and the discovery rate, and interaction of such a relation and individual differences.

### Abstract

In a recent article, Bowers (2009) argues that local representations are more consistent with neuro-biological data than distributed representations, as typically generated in Parallel Distributed Processing (PDP) models. We present three reasons why *localised* neural representations are good candidates for supporting mental representations, as they provide a solution to the trade-off between combinatorial arguments that favour fully-distributed representations and metabolic arguments which favour localist representations.

**Keywords:** distributed representations, local representations, self-organising maps, synaptic pruning, brain metabolism

### Introduction

Over the last thirty years, hypotheses concerning the nature of mental representations have essentially been polarised to two interpretations: some researchers argue that brain representations are distributed (among them, proponents of the Parallel Distributed Processing (PDP) approach: e.g., Rumelhart, McClelland, & the PDP Research Group, 1986; Seidenberg & McClelland, 1989; McClelland & Rogers, 2003; Plaut & McClelland, 2010), while others suggest that local representations fit neuro-physiological data more accurately (e.g., Page, 2001; Bowers, 2009). Most of the arguments in favour of distributed representations fall into one of the following two categories: high combinatorial power and robustness with respect to lesions. In contrast, Bowers (2009) reviews neuro-biological evidence for relatively sharply tuned neurons reminiscent of localist representations and argues that distributed approaches fail to provide unambiguous representations under superposition.

We attempt to clarify the role of combinatorial power, in light of the superposition problem. We then introduce two metabolic arguments to the debate. We suggest that a potential solution to the debate relies on *localised* representations, capitalising on robust representations that span only a limited number of neurons, thereby minimising the energy expenditure associated with mental representations. Finally, we discuss the implications of this proposal and highlight examples already using localised representations.

### The combinatorial argument

The idea that distributed representations can code many more patterns than localist coding scheme is well established. Traditional binary coding, in which a neuron is either active or

silent, emphasises this difference. We will therefore reiterate this combinatorial argument using binary activation levels and comment on its validity in the context of decoding superposed patterns. The extension to continuous encoding will then be discussed.

### The case of binary encoding

**The coding advantage** Elementary calculus shows that  $2^n$  patterns can be encoded over  $n$  neurons, corresponding to the case of fully-distributed representations (see Fig. 1). With localised representations, the combinatorial power decreases rapidly. Suppose, for example, that each pattern can use at most  $n$  neurons out of a total system of  $N$  neurons. The number of patterns that can be stored in  $n$  neurons is then  $2^n$  in each of the subset of  $n$  neurons picked from the total pool of neurons. If  $n = N/2$ , for example, there are two subsets of  $n$  neurons, each coding  $2^n$  patterns. The total number of patterns  $p$  with a degree of localisation of  $n$  stored in  $N = 2n$  neurons would then be  $p = 2 \cdot 2^n$ . Fig. 1 depicts the number of patterns  $p$  that can be stored among  $N$  neurons (maximum 20 neurons in the simulation), for different levels of localisation  $n$ . A purely localist encoding ( $n=1$ ) can only store as many patterns as there are neurons. At the other end of the spectrum, fully-distributed representations can store  $2^n$  patterns. In between, the number of patterns one can store is directly related to the number of neurons that are involved in the coding of an individual pattern. As a consequence, localist representations have a limited capacity to store only as many separate representations as the number of neurons. Orders of magnitude can be gained by coding each patterns over a few neurons. With only 30 neurons, a fully-distributed approach would be able to store more than a billion different representations, a number that exceeds by orders of magnitude the likely capacity for human mental representations: “even if the distinguishable visual items are larger than the number of the different types of objects ( $< 100000$ ) that humans are able to discriminate, cortical visual neurons are certainly so numerous that there would be enough sets of them to represent each single object (or property)” (Pareti & De Palma, 2004, p.45). On the other hand, localised encoding ( $n > 1$ ) can rapidly reach the combinatorial power required to represent a very large number of different representations.

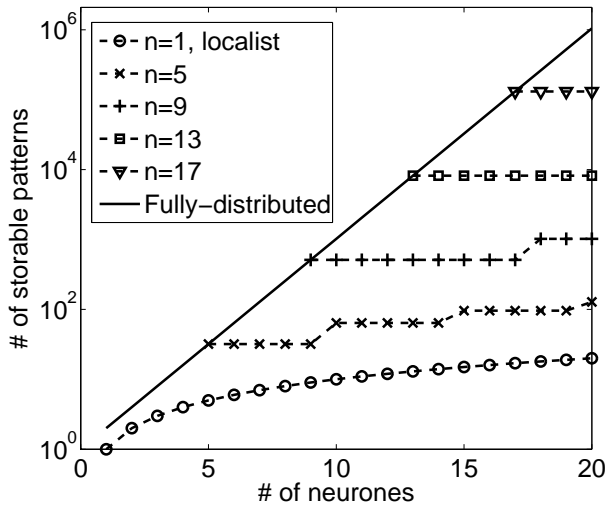

Figure 1: Number of patterns that can be stored as a function of the total number of neurones, using binary encoding. The different curves correspond respectively to a purely localist encoding, different levels of localisation and a fully-distributed encoding.

**The decoding problem** Encoding many representations is a necessary requirement for human cognitive performance. In many situations, multiple representations need to be encoded simultaneously. This leads to the potential ambiguity introduced by a superposition of representations. For example, visual scenes will contain a configuration of independent objects. A difficult task for the brain is therefore to be able to decode superposed representations unambiguously. Patterns of activation in the brain can be construed as multi-dimensional vectors. Elementary linear algebra constrains the number of linearly independent vectors to the number of dimensions represented in the system. Any additional vector can be expressed as a linear combination of other vectors. Consequently, there can be at most  $N$  independent patterns unambiguously coded across  $N$  neurones, on the assumption that each neurone encodes a separate dimension. Beyond that limit, additional representations can be misconstrued as a superposition of one or more other representations *even for fully-distributed representations*. If the network's task is to encode multiple patterns that can be superposed in the same neural substrate, the combinatorial advantage of distributed representations is compromised.

### The case of continuous encoding

Activation levels in neurones do not need to be restricted to a binary coding scheme. For example, simple rate coding models make use of a range of activation levels to encode different stimuli. More complex, and more realistic models of neurones make use of the rich dynamics of neuronal firing. A strict and complex mathematical analysis of the coding and decod-

ing capacities in both local and distributed representations for continuous coding schemes is beyond the scope of the present article. Nevertheless, it is worth commenting some implications of this approach.

A first observation is that coding is further enriched by the increased range of values any neurone can take. In fact, a single neurone could encode as many different patterns as needed, as long as the decoder has a resolution that is fine enough. The combinatorial advantage of distributed coding is still present for a decoder with a fixed resolution (e.g., the ability to detect subtle differences between relevant, and different, neural activation levels). However, as single neurones can encode many more patterns with continuous encoding schemes than with binary coding, fewer neurones are required to encode the same number of patterns. For example, 10 binary coding neurones are needed to represent 1000 patterns ( $2^{10} = 1024$ ), but if continuous activation levels can be detected with greater accuracy so that each neurone could take 10 distinct values each, only 3 neurones would then be required ( $10^3 = 1000$ ).

A second observation is that decoding subtle differences between different activation levels of neurones is a non-trivial problem. Presence of noise would limit the decoder's resolution and the more neurones needed to encode a representation, the more difficult it will be to decode that information and the more neurones required to act as decoders (e.g., see Földiák (2003) for a discussion of the advantage of representations that span fewer neurones (sparse representations) than fully-distributed representations for decoding).

The limited resolution of the decoder effectively reduces the case of continuous encoding to a simple extension of binary coding, where each neurone can have two distinct activation levels, to a case of  $N$ -coding, in which each neurone can take  $N$  distinct values. Small values for  $N$  magnify the problem of superposition of representations for distributed representations while reducing the problem of combinatorial limitations for localised representations. Large values for  $N$  would furthermore undermine the claim that localised (or even localist) representations cannot encode a sufficiently large number of different representations, while increasing the complexity and vulnerability of a decoder network that requires an increasingly large number of neurones.

### The metabolic argument

Let us turn now onto a consideration that can be made independently from the nature of the neural coding itself. It is often claimed that the resource needed to encode  $N$  patterns is less using fully-distributed representations than localist codes, thereby minimising metabolic expenses, because fewer neurones are required for distributed representations.

However, consider a brain structure with a given number of neurones required to represent a number of different patterns. The metabolic expense of the brain structure is, to a first approximation, proportional to the number of neurones that participate in the representation of the pattern(s) present

in a scene (or maintained/sustained in that brain structure). As a rule of thumb, if less neurons are required to participate in the representation of a pattern, the less the energy required for that task.

Fig. 2 depicts the energy consumption (as indexed by the number of neurons that participate in the representation) as a function of the number of patterns (or objects) that need being represented in a network of 20 neurons. Different curves

Figure 2: Energy as indexed by the number of neurons required to represent a number of objects simultaneously. The different curves correspond respectively to a purely localist encoding, different levels of localisation and a fully-distributed encoding. Localised representations use less energy than fully-distributed representations for a given architecture (in the present simulation, total number of neurons=20).

correspond to different localisation levels: in a purely localist coding, each pattern is represented by a single neuron. In this case, the energy consumption is proportional to the number of objects represented simultaneously. As the number of neurons involved in the representation of a given pattern increases, the energy expenditure increase for any number of patterns (or objects) being represented at a given time. Ultimately, fully-distributed representations require all neurons to participate in the representation of even a single pattern. Unless the system is working at full capacity at all times, energy consumption is minimised for localist representations but maximised for fully-distributed representations. Localised representations consume intermediate levels of energy.

### The synaptic pruning argument

Neural resources involve not only the cell bodies of neurons but also the connections between them. Associations between representations require appropriate connections or synapses.

Synaptic maintenance is also a contributor of energy consumption. For example, neural mappings between an object representation and its corresponding label require appropriate cross-modal synapses between visual and auditory areas. The number of cross-modal synapses required to form the mapping between the different brain structures depends on the degree of localisation of each representation in both structures. Figure 3 depicts the number of cross-modal synapses needed to maintain an appropriate mapping between representations in different neural structures, as a function of the degree of localisation of the representations in each structure (which have been chosen to be identical for the sake of simplicity). The number of synapses needed increases with the number of objects that are encoded in each modality. Note

Figure 3: Percentage of cross-modal synapses required to maintain the mappings between uni-modal representations without degradation, as a function of the degree of localisation. The different curves correspond to different network loads in terms of the number of objects that need to be represented in each modality. Note that pruning can only be achieved with reduced levels of localisation.

that fully-distributed representations (where the degree of localisation equals the number of neurons, 20) require the full set of cross-modal synapses ( $20^2 = 400$ ) even when each structure is only required to encode a single object. A lower number of synapses can only be achieved for reduced levels of localisation for the neural representations.

It is important to note that the number of synapses is not constant during brain development. After an early proliferation of synapses, their number remains approximately constant, before environmentally induced synaptic pruning reduces the total number of synapses (see Huttenlocher, 2002). The observed synaptic pruning mechanism is usually associated with either an improvement in cognitive skills (Miller, Keller, & Stryker, 1989; Chechik, 1998) and/or an optimi-

sation in metabolic resources (Roland, 1993; Feinberg, Thode Jr, Chugani, & March, 1990), potentially leading to an internally-driven reorganisation of neural representations. So that synaptic pruning can operate without being detrimental to the task, representations benefit from a reduced degree of localisation.

### Discussion: Solutions to the trade-offs

Mental representations can have different levels of localisation, as defined by the number of neurons that are required to take part in the representation of an individual pattern. Many constraints may impact this degree of localisation, such as the number of different patterns a neural structure can code, the capacity to decode a superposition of patterns, robustness arguments and metabolic constraints at the level of neurons and synapses. The exact solution to the trade-off between these constraints remains elusive. While there are many advantages in having more than one neuron involved in the representation of a given pattern (robustness, combinatorics), there are at least as many in restraining the number of neurons taking part in a representation; metabolic minimisation, synaptic pruning, simpler decoding. We suggest that computational approaches to neuroscience and psychology may need to adopt the perspective that patterns are represented in a localised fashion; not localist (only one neuron per pattern) nor fully-distributed. The degree of localisation can, of course, be modulated according to the structure under consideration or, if the function is highly abstract, according to the task.

Self-Organising Maps (SOMs) offer an approach in which degree of localisation is discovered from exposure to the input structure (Kohonen, 1984). SOMs form topographically organised maps of neurons, such that neighbouring neurons respond to similar input. The resources on the map dedicated to a particular pattern or category is determined by many factors such as the number of different patterns that a SOM has been exposed to, the number of neurons on the SOM, the frequency with which a given category of patterns is presented, and the magnitude of the pattern variations in each category. After exposure to a structured environment, SOMs display a partitioned map from a representational perspective: each pattern creates a unique pattern of *localised* neural activity and each category of patterns would tend to solicit the same group of neighbouring neurons in order to represent different patterns that belong to the same category.

The organisation of a SOM after learning mimics cortical maps observed throughout many different cortical areas. SOMs have been very successful at modelling the architecture of the primary visual cortex (Miikkulainen, Bednar, Choe, & Sirosh, 2005) where neighbouring neurons are responsive to similar orientations of the visual scene (Hubel & Wiesel, 1962). Topologically-organised maps have also been found in the human auditory cortex (Romani, Williamson, & Kaufman, 1975; Pantev et al., 1995), in the human frontal and prefrontal cortex (Hagler & Sereno, 2006) and in parietal cortex (Sereno & Huang, 2006).

Beyond mimicking the neuro-anatomical organisation of cortical maps, SOMs sustain representations that possess interesting properties from a psychological perspective. For example, categories are formed in an unsupervised way, similarly to infant's capacities to form categories in the absence of supervision (Younger, 1985) and discrepancies between a pattern and its representation provide an accurate index of looking behaviour of young infants during categorisation tasks (Gliozzi, Mayor, Hu, & Plunkett, 2009). When input patterns possess a family resemblance structure (e.g., basic level categories of objects, Rosch & Mervis, 1975), representations on the SOM are warped in a manner that mimic categorical perception (Mayor & Plunkett, 2010). Since a single pattern activates a localised pattern of neural activity on the map, only a limited number of neurons contribute to the pattern representation. However, when the number of patterns represented exceeds the number of neurons on the map, a single neuron must participate in the representation of multiple patterns from the same category. Consequently, some neurons are maximally active when an average of a few patterns is presented to the map. This provides a representation advantage for central tendencies, thereby implementing at a representational level the advantage of prototypes over atypical members of a category (Rosch, 1973; Mervis, 1984). Interestingly, the fact that multiple neurons contribute to the representation of different members of the same category of patterns maintains a sensitivity to within category variations, as observed in speech perception (McMurray, Tanenhaus, & Aslin, 2002).

Mayor and Plunkett (2010) have also evaluated the impact of synaptic pruning in a model of early word learning, consisting of two SOMs connected by cross-modal Hebbian synapses. Synaptic pruning was shown to enhance the quality of word-object mappings, once stable representations of objects and labels were achieved on the maps. The localised representations of individual objects and labels permitted high levels of pruning so as to associate objects categories and their corresponding labels in a one-to-one mapping. Synaptic pruning of any one-to-one mapping between cortical representations (or thalamo-cortical projections) would also benefit from such localised representations. In contrast, high levels of pruning would be detrimental to highly distributed representations. The presence of high levels of synaptic pruning from mid-childhood would seem to favour the formation of these relatively localised mental representations.

It is noteworthy that any representations requiring a relatively small number of neurons also satisfy the conditions for metabolic constraints and synaptic pruning. However, these constraints do not require that neurons supporting the representation of a given pattern need to be neighbours. Examples of sparse coding (Quiroga, Kreiman, Koch, & Fried, 2008; Quiroga & Kreiman, 2010), in which only a small subset of neurons is active for a pattern have been shown offer decoding advantages (Földiák, 2003) as well as minimising metabolic demand. SOMs offer sparse coding in which the few neurons

taking part in the representation of a pattern are proximate, thereby providing additional advantages in terms of mimicking cortical maps that are found across the human brain (Hubel & Wiesel, 1962; Romani et al., 1975; Pantev et al., 1995; Hagler & Sereno, 2006; Sereno & Huang, 2006) and constraining the need for long distance connections (Durbin & Mitchinson, 1990). SOMs may also provide a potential advantage in terms of decoding the information, as representations of different patterns that belong to the same category tend to be similar. As a consequence, SOMs, localised representations in general, should lead to enhanced robustness in the presence of noise.

## Conclusion

The resources needed for mental representation are constrained by many different, and often opposing, pressures. A solution to the trade-off between robustness and combinatorial power, which favour representations with many neurons, and metabolic and synaptic pruning constraints, which favour fewer neurons, is to limit the number of neurons needed to represent a pattern. Sparse, localised representations provide an elegant alternative to purely localist representations and fully-distributed ones. Self-Organising Maps provide a natural, and unsupervised, approach for forming localised representations which mimic cortical maps found throughout the human cortex. The topographical structure of these SOMs also permit efficient pruning mechanisms to operate, maximising metabolic efficiency and providing accurate models of human cognitive performance and development.

### Abstract

We consider an approach to blame attribution based on counterfactual reasoning in probabilistic generative models. In this view, people intervene on each variable within their model and assign blame in proportion to how much a change to a variable would have improved the outcome. This approach raises two questions: First, what structure do people use to represent a given situation? Second, how do they choose what alternatives to consider when intervening on an event? We use a series of coin-tossing scenarios to compare empirical data to different models within the proposed framework. The results suggest that people sample their intervention values from a prior rather than deterministically switching the value of a variable. The results further suggest that people represent scenarios differently when asked to reason about their own blame attributions, compared with the blame attributions they believe others will assign.

**Keywords:** counterfactuals; blame attribution; probabilistic models; causal reasoning

### Introduction

Alice and Bob play a coin-tossing game. If their coin tosses match, they win. Alice goes first and tosses heads, Bob goes second and tosses tails, and hence they lose. Who, if anyone, will be blamed? Counterfactually, what would have happened if Alice had tossed heads? One intuition is that how much someone will be blamed for an outcome is closely related to how strongly they affected the outcome (cf. Spellman, 1997). Through counterfactual thinking, people can reason how a change in the past would have affected the present and use such reasoning for cognitive tasks including social judgments, causal attribution, problem solving, and learning (see Roese, 1997; Byrne, 2002, for reviews). But how do people reason counterfactually? And what is the relationship between counterfactual thinking and blame attribution?

Psychological research on counterfactual reasoning has revealed factors that influence which events attract counterfactual thoughts, including unusual events (Kahneman & Miller, 1986), early events in a causal chain (Wells, Taylor, & Turtle, 1987), and late events in a temporal chain (Byrne, Segura, Culhane, Tasso, & Berrocal, 2000). There have also been formal accounts which aim to explain the empirical findings in terms of principled mental operations that do not depend on event features (Spellman, 1997; Byrne, 2002; Chockler & Halpern, 2004; Rips, 2010; Petrocelli, Percy, Sherman, & Tormala, 2011). Some of these formal models have been

separately tested against empirical data (Sloman & Lagnado, 2005; Gerstenberg & Lagnado, 2010).

Kahneman and Tversky (1982) suggest that people reason counterfactually by using a “simulation heuristic”, whereby they mentally alter events and run a simulation of how things would have gone otherwise given these changes. In this paper, we use a computational-level framework that formalizes the spirit of this suggestion: when attributing blame, people mentally alter each possible event in turn, consider the consequences for the outcome, and blame an event in proportion to how much the change would have improved the outcome.

We model this computation of counterfactual consequences using interventions on causal models (Pearl, 2000). We explore what causal models people use to represent the games in our experiments and how they choose alternatives when intervening on a particular event.

The plan for the paper is as follows. We first describe the formal framework this work is based on and the space of models we explore. We then report results of experiments in which we varied aspects of the coin-tossing game described above, and suggest a possible explanation for these results within our framework. We conclude by discussing implications and limitations of this account, and possibilities for future research.

### Formal framework

We assume that, when reasoning counterfactually, people represent the situation they are reasoning about using a probabilistic generative framework. Probabilistic models have been used to explain many aspects of high-level cognition, including perception, prediction, decision making and social reasoning (Tenenbaum, Kemp, Griffiths, & Goodman, 2011). In this paper, we use causal Bayes nets and the functional equations they are derived from as the underlying probabilistic generative framework (Pearl, 2000). Other representations are possible—see, for example, Gerstenberg and Goodman (in prep) for an approach to counterfactual reasoning based on probabilistic programs.

We model people’s reasoning about blame as follows. First, consider each event in the situation—represented by a variable in a causal Bayes net—and intervene on it, i.e., consider a counterfactual value for this event (‘do’ in Pearl, 2000). Each such intervention results in a distribution over

counterfactual worlds, where a counterfactual world is an assignment of values to variables. Next, compare these distributions to the actually observed world in order to assign blame. The variable being intervened on is assigned a degree of blame proportional to the difference in expected utility between the counterfactual world and the actual world. When interventions are chosen stochastically, we take the expectation over intervention values.

In our experiments, there are two possible outcomes, a win (1) and a loss (0), and the actual outcome is described as a loss. In this setting, our model of blame judgments is equivalent to assigning a degree of blame to a variable in proportion to the probability of reaching a counterfactual world in which the game is won after intervening on the variable. This combines the idea of using the ‘do’ operator as a psychologically plausible basis for counterfactual thinking (e.g., Sloman & Lagnado, 2005) with the idea of assigning causality by considering how each of the events in a given scenario affects the outcome (e.g., Spellman, 1997).

The framework as described presents at least two open questions about how people reason counterfactually to attribute blame.

**What generative structure do people use to represent a situation?** Even for simple scenarios, there exists a rich space of possible representations. Consider the coin-tossing game described in the introduction. Previous work suggests that people sometimes believe themselves or others capable of control over events such as coin tosses that are in fact random (Langer, 1975; Shafir & Tversky, 1992). Based on this work, we consider two simple generative models for the coin-tossing game, a *no-control* model that represents the coin tosses as independent, and a *control* model that represents the players as having some control over their tosses, assumes that they have knowledge of the previous player’s toss, and that they try to match this toss (see Figure 1). This ‘control’ is captured in the following way: If the coin tossed by the first player came up 1 (‘heads’), the bias for the second player’s coin getting 1 is now  $\alpha > 0.5$ . If the first player tossed 0 (‘tails’), then the bias for the second player’s coin getting 0 is now  $\alpha > 0.5$ . When we compute counterfactuals in the ‘control’ setting, we use the following functional equations that reflect this idea:  $u_1 = \text{Bernoulli}(\theta_1)$ ,  $u_{2a} = \text{Bernoulli}(\alpha)$ ,  $u_{2b} = \text{Bernoulli}(1 - \alpha)$ ,  $C_1 = u_1$ , and  $C_2 = u_{2a}$  if  $C_1 = 1$ , otherwise  $u_{2b}$ . We later discuss a perspective-dependent model, which combines the ‘control’ and ‘no-control’ models.

**What new value do people assign to the intervened-upon variable?** The ‘do’ operator produces counterfactual worlds when given a variable to intervene on and a value to set the variable to, but there is a question about what value people use. One possibility is that people set the intervened-upon variable to be different from what it was before the intervention. The idea of *only* considering alternatives to reality when reasoning counterfactually has intuitive appeal. This approach is taken by Gerstenberg, Goodman,

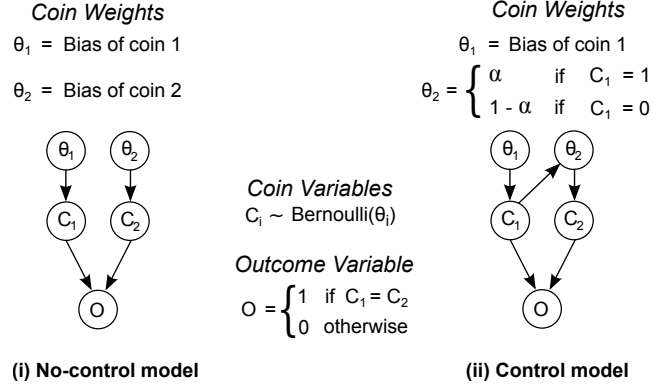

Figure 1: Different generative structures for the coin-tossing game. Coin tosses are drawn from a Bernoulli distribution with the coin bias as its parameter. ‘heads’ and ‘tails’, and ‘win’ and ‘lose’ are replaced by 1 and 0. (i) In the ‘no-control’ version the bias is simply the unchanged bias of the coin. (ii) In the ‘control’ version players are represented as having some influence over the coin, as is formalized in the text.

Lagnado, and Tenenbaum (2012) in reasoning counterfactually about physical events. In the case of binary variables, as in the current study, this involves simply switching the observed value, hence we refer to this way of choosing intervention values as *intervene-switch*. The generalization to non-binary variables is not immediate and is not considered here.

A second possibility is to draw the intervention value from the (conditional) prior over the variable being intervened upon. This allows an assessment of how unlikely the counterfactual event is, which has been stressed as an important factor by Petrocelli et al. (2011). We refer to this possibility for setting intervention values as *intervene-prior*. Figure 2 illustrates these two possibilities. A third possibility is that people choose an intervention value optimally, in such a way as to maximize the expected utility of counterfactual worlds. In our models for the coin-tossing domain, this possibility coincides with *intervene-switch*, hence we do not discuss it separately.

Each combination of these two factors—which causal structure to use, and how to choose an intervention value—results in a different model of blame attribution within our general framework. There are other factors which remain the subject of future research and which will almost certainly be necessary to predict subjects’ judgments in richer situations. However, even these two factors offer a space for exploring how people reason counterfactually and assign blame.

### A simple example of predicting blame judgments

Consider again the coin-tossing game with a fair coin, in which the player going first ( $C_1$ ) tosses heads and the player going second ( $C_2$ ) tosses tails, resulting in a loss. Who is to blame for the loss? We examine the predictions of four different models. In this scenario, some of the models make the same predictions; other scenarios used in our experiments provide additional discriminatory power.

1. *no-control/intervene-prior*: Coin tosses are independent

## 1. Actual world:

## 2. Intervention:

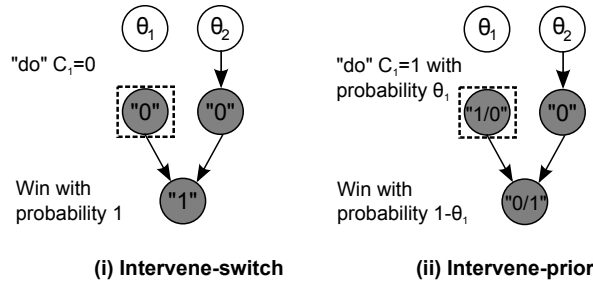

Figure 2: How to choose a new value for the intervened-upon variable, using the coin-tossing game as example. In the actual world the first player tossed heads (1) and the second player tails (0), and they thus lost. In intervening upon the first player's coin toss there are two possibilities: (i) *intervene-switch*: the first player's coin toss is changed to be the opposite of what it was (i.e. from 1 to 0), (ii) *intervene-prior*: intervention values are chosen from the prior and so there is a  $\theta_1$  chance of setting the first player's toss to heads and a  $1 - \theta_1$  chance of setting the first player's toss to tails.

and values for interventions are chosen by drawing them from the variable prior. We begin by considering an intervention to the variable  $C_1$ . Because the coin is fair, with probability 0.5 we choose the intervention 'tails', resulting in the outcome variable being assigned a 'win', as both players now tossed matching coins (counterfactually speaking). With probability 0.5 we choose the intervention 'heads', resulting in a 'loss'. So, by intervening on  $C_1$  we improve the odds of winning from 0 (actual observation) to 0.5, and the amount of blame assigned to  $C_1$  is 0.5. What about the second player's blame? For  $C_2$  the process is the same as  $C_1$ , thus the blame for  $C_2$  is also 0.5. Hence, this model predicts no difference in blame between  $C_1$  and  $C_2$ .

2. *control/intervene-prior*: Players are represented as having some control over their coin (Figure 1(ii)) and interventions are selected in the same way as before. The intervention on  $C_1$  works as described above, resulting in a 0.5 amount of blame. However, in intervening on  $C_2$ , we draw from a prior skewed towards 'heads' (the coin now has a bias  $\alpha > 0.5$  towards heads). With probability  $\alpha$  we choose the intervention 'heads' for  $C_2$ , and with probability  $1 - \alpha$  we choose 'tails'. This results in a 'win' with probability  $\alpha > 0.5$ , meaning  $C_2$  will be blamed more than  $C_1$ .
3. *no-control/intervene-switch*: Coin tosses are independent and the value used for an intervention is different from the observed value of the variable. Because  $C_1$  was observed to be 'heads', an intervention always sets it to 'tails', resulting in a 'win' with probability 1. This model also predicts no difference in blame between the players.
4. *control/intervene-switch*: Players are represented as having

some control over their coin (Figure 1(ii)) and the value used for an intervention is different from the observed value of the variable. Using this model, the control players have does not make a difference, as the intervention on  $C_1$  is always 'tails' (switching it from 'heads'), and the intervention for  $C_2$  is always 'heads'. In a way similar to the previous variant, the probability for a 'win' resulting from intervening on either  $C_1$  or  $C_2$  is 1, and thus both players receive the same blame.

## Experiment

### Procedures and methods

One hundred subjects per condition were recruited on Mechanical Turk. Approximately twenty subjects were dropped in each condition for failing comprehension questions. We presented descriptions of simple scenarios involving blame attribution in the aforementioned coin-tossing game. All scenarios share the following:

- (1) An introduction describing the game: Each person tosses a coin in turn. If all coins land the same, the players each receive \$1000, and otherwise receive \$0.
- (2) Subjects were told the order of play, and the result of each coin toss (e.g., "Bob tosses his coin first. It comes up heads. Then you toss a coin. It comes up tails.").
- (3) The end result was a loss.
- (4) Subjects were asked, depending on condition, how much blame they attributed to the players, or how much blame they believed the players would attribute.
- (5) Subjects responded using a discrete 1-7 scale, with 1 marked *minimal blame* and 7 marked *maximal blame*.

### Results and discussion

We use the space of models we have discussed to examine predicted differences in blame attribution, and test these predictions using one-sided Student *t*-tests.

**1. Same room, subject not involved** Subjects read descriptions of Player 1 and Player 2 playing the coin game. Player 1 tosses heads, then Player 2 tosses tails. Subjects were asked how much Player 1 would blame Player 2, and how much Player 2 would blame Player 1. The results of these and subsequent experiments, as well as the model predictions, are shown in Figure 3. This first experiment replicates the temporality effect (Miller & Gunasegaram, 1990) in the sense that subjects believe that Player 1 will blame Player 2 more than Player 2 will blame Player 1 ( $p < 0.0001$ , cf. Figure 3a). The only one of the four simple models under consideration which accords with these results (rows 3-6 in Figure 3) is the model which assumes causal control and draws intervention values from the prior. However, experimental results to be discussed shortly imply that the situation is more subtle. We first test the sensitivity of assumptions about causal control to knowledge about epistemic access (i.e. knowing the result of the the other player's coin toss).

Figure 3: **Empirical results and model predictions for the coin-tossing game.** Columns represent separate experiments, with the empirical data shown in the top row. The y-axis is the mean amount of blame subjects believe will be assigned to the player on the x-axis, by the other player in the game. For example, in Experiment 1 subjects believe that Player 1 is assigned a 2.42 blame rating by Player 2, while Player 2 is assigned a 3.56 blame rating by Player 1. In each sub-figure, the player on the left side of the x-axis is the one going first. For example, in Experiment 1 Player 1 tosses the coin first. Model predictions are colored blue if they qualitatively match the ordinal blame judgments in the empirical results, and are grey otherwise. The amount of blame predicted by the models is normalized. We set  $\alpha = 0.7$  in the above, but this makes no difference to the qualitative results.

**2. Different rooms, subject not involved** Subjects read descriptions of a game that only differed from the one in the previous experiment by players being in different rooms, such that Player 2 was unaware of the result of Player 1's coin toss. In this experiment, subjects predict that Player 1 will blame Player 2 significantly less than in the 'same room' scenario ( $p < 0.05$ , cf. Figure 3b vs. a). There is no significant difference in the amount of blame attributed by the first and second player.

One explanation of these findings is that causal control is only believed possible when the second player is aware of the first player's coin toss. That is, subjects have a sophisticated model of the situation that treats the other players as agents that have the capacity for control, but that requires epistemic access for the agents to make use of this capacity.

Lack of epistemic access is not the only way to explain the results of this experiment. The two models based on setting intervention values by switching the observation (*intervene-switch*) are also consistent with these results. We will shortly provide independent evidence for sampling from the prior over switching, but first we manipulate whether subjects report their own blame judgments or their predictions about the judgments of others.

The 'classic' temporality effect replicated in Experiment 1 may strike some readers as odd. Surely one person is not to blame more than another in a purely random game? To examine this intuition, which is supported by previous research (Mandel, 2003), we now compare first-person and third-person blame judgments.

**3. Same room, subject involved** The game was described as in Experiment 1, but the subject was described as playing the game with another player (denoted 'Other Player' in Figure 3). One group of subjects was told that they tossed first, while another group was told that they tossed second. In both cases the player going first tosses 'heads' and the player going second tosses 'tails'. Subjects were asked how much they themselves would blame the other player, and how much they believed the other player would blame them. When subjects are asked about how much they think the other player will blame them, the temporality effect is replicated. That is, subjects believe that the other player will blame them significantly more when subjects flip second rather than first ( $p < 0.001$  cf. blame to 'Subject' in Figure 3c and d).

Crucially, however, when comparing the amount of blame subjects attribute to the other player, we find no effect of position (cf. blame to 'Other' in Figure 3c and d). That is, the temporality effect does not exist when subjects are asked about the amount of blame they themselves attribute. As in Experiment 2, the *no-control/intervention-prior* model is consistent with the lack of a temporal effect, as are the two models in which intervention values are set by switching the observation. One hypothesis is thus that subjects do not themselves attribute causal control when assessing blame, but believe that other people do so (this possibility is represented by the 'perspective-dependent' model shown in the second row

of Figure 3). It is also possible, however, that people think about choosing the intervention values differently depending on whether they are taking a first or third person perspective. That is, when considering how other people model a situation, they draw interventions from a prior, but when reasoning about their own perspective, they draw interventions by switching variables. The latter suggestion appears overly complex, but is not ruled out by the evidence presented so far.

We thus consider an experiment aimed specifically at examining whether people do set intervention values by sampling from the prior.

**4. Biased coin, subject involved** Subjects were told that they participated in the game with one other player. In one case, they were told that the other player used a coin biased 70% towards heads, in another case biased 90% towards heads. In both cases, subjects were told that they went first and got heads, and the other player tails. Subjects were asked how much they blamed the other player. We find that the greater the bias of the coin, the more the other player is blamed. The other player is blamed significantly more when the bias is 0.7 than when the coin is fair ( $p < 0.05$ , data from Experiment 3 were used for this comparison), and significantly more when the bias is 0.9 ( $p < 0.05$ ; cf. blame to 'Other' in Figure 3e). Subjects' ratings about how they themselves will be blamed were not affected by the bias of Other's coin (cf. blame to 'Subject' in Figure 3e). For modeling this situation, we make the simplifying assumption that the second player's coin is entirely dependent on the specified bias, rather than on any causal control.

The models which are consistent with the effect of coin bias are those where values for the intervention are drawn from the prior. The results are analogous to experiments showing the tendency of people to focus on more unusual events when asked to reason counterfactually (Kahneman & Miller, 1986).

Given the small space of models we consider, one parsimonious account of the empirical data is that both when attributing blame themselves and when reasoning about how others attribute blame, people draw values for the intervention from the prior. Our results further suggest that people may assume that other people believe in causal control of random events, but that they themselves do not. This model of causal control seems to be sensitive to factors such as the other player's state of knowledge.

## General discussion

We have explored aspects of a psychological framework for counterfactual reasoning, focusing in particular on its use for blame attribution. We have assumed that people represent the situation using probabilistic generative models and that they assign blame to an event by determining the counterfactual consequences of intervening on this event.

Within this framework, we have investigated what causal structure people use to represent a given situation and how people assign values to intervened-upon variables in the do-

main of coin-tossing games. In this domain, psychological effects such as the temporality effect and the tendency to focus on unusual events seem to arise naturally from counterfactual reasoning using probabilistic models.

We have presented data that suggests that people sample the values of their interventions from a prior rather than deterministically switching the variable to an alternate, unobserved value. Experimental evidence suggests that people may represent situations involving random events differently when reasoning about their own judgements compared to their predictions about the judgements made by others. People may model others as believing that such situations involve causal control, but they themselves may not believe in such control. One possible explanation for this perspective-dependent representation is that people model others' views in less detail than their own. For example, people may have a default assumption of causal control, but in situations such as coin games, they may be able to suppress this assumption. This suppression may take additional resources which, in general, may not be available or used when predicting how others represent the same situation.

This perspective-dependent difference in representation or computation provides an intriguing avenue for future research. For example, does there exist a similar difference in games of skill where control is the correct assumption? Beyond perspective-dependent differences, it is almost certain that different people model identically described situations in different ways, which suggests a per-subject analysis in addition to the aggregate approach taken in this paper.

There are many other ways in which our modeling and experimental results can be extended, even in the simple coin-tossing game. First, we do not explicitly take into account the prior probability of winning a game. Second, we do not explore situations in which the value of multiple variables would need to change to result in a win, for example a situation in which six people were playing the game with two people tossing tails and four people tossing heads. Third, while our model predictions are quantitative, we have restricted ourselves here to a qualitative analysis. Fourth, while we have modeled agents in some situations as having causal control, we did not give a full account of agents as having — and reasoning about—intentionality, foresight, and complex epistemic states, which are known to affect blame attribution (Lagnado & Channon, 2008). To capture the subtlety of human blame attribution and counterfactual thinking, richer models which include a more sophisticated representation of agents and their beliefs will be necessary.

## Abstract

Lexical dependencies abound in natural language: words tend to follow particular words or word categories. However, artificial language learning experiments exploring word segmentation have so far lacked such structure. In the present study, we explore whether simple inter-word dependencies influence the word segmentation performance of adult learners. We use a continuous testing paradigm instead of an experiment-final test battery to reveal the trajectory of learning and to allow detailed comparison with three computational models of word segmentation. Adult performance on languages with dependencies is equal or lower to those without. Of the models tested, all perform worse on languages with dependencies, though a novel particle filter-based lexical segmentation model produces learning curves most similar to human subjects.

**Keywords:** Word segmentation; statistical learning; bigrams; computational modeling; dependency structures.

## Introduction

Human learners can use distributional information to segment an unbroken speech stream into individual words after a short, ambiguous exposure (Saffran, Aslin, & Newport, 1996; Saffran, Newport, & Aslin, 1996). Past artificial language learning experiments have typically generated words according to a uniform word frequency distribution and randomly concatenated word types to create the artificial languages. The process of learning to segment such synthesized languages may deviate significantly from learning to segment natural language, which contains asymmetric word frequency distributions, systematic dependency structure, and correlated variation in the lengths and frequencies of words.

In natural language, word-by-word transitions are governed by dependency relationships between word categories. For example, English prepositional phrases have the internal structure  $PP \rightarrow P + NP$ , and an NP typically consists of a determiner and a noun. Since prepositions and determiners are lexical classes containing a relatively small number of short words, many instances of PPs often result in collocations used frequently in discourse (e.g., *in the house* or *on a map*).

Does such collocation structure make segmentation easier or more difficult? Both possibilities have some support in the literature. Frequent phrases are known to be problematic for segmentation mechanisms, especially for algorithms that rely on transitional probabilities (TPs). Due to high internal TPs, these phrases are often segmented as one unit, rather than separated into the multiple words that they contain (Goldwater,

Griffiths, & Johnson, 2009). Thus, dependency structure has the potential to reduce segmentation performance.

In principle, however, there may also be the potential for increased performance in segmenting structured languages, especially if the learner is able to learn the dependency structure of the language along with the structure of individual words. For this reason, Goldwater et al. (2009)'s bigram model outperformed other segmentation models. Modeling dependency structure might also provide synergistic gains in learning: Johnson and Tyler (2010) found that an ideal learner that acquired words and word-object correspondences simultaneously was far more successful at both than each independently, but only when the learner assumed a rich collocation structure in the language.

Our current experiments test the relationship between dependency structure and segmentation performance for both human learners and computational models. We created languages with varied levels of category size asymmetry and test adult subjects' performance in word segmentation based on these languages. Two-alternative forced-choice tests administered after a discrete training phase, as used by past studies, do not produce an interpretable time course of learning. Thus, in Experiment 1 we use a new experimental paradigm that provides us with a time course of learning by testing subjects throughout the duration of exposure to stimuli (Kurumada, Meylan, & Frank, under review). In Experiment 2, we corroborate the results of the first experiment using a classic two-alternative forced choice paradigm. Both experiments, and a set of simulations with three computational models, show that asymmetric word-category sizes support adult segmentation learning considerably better than symmetric category sizes, but that performance on languages with dependencies is generally worse than performance on languages with randomly ordered words.

## Experiment 1

To test the effects of dependency structure on word segmentation, we created two classes of artificial lexicons, one consisting of 12 word types and another of 8, and concatenated them to make languages with different dependency structures. Figure 1 is a diagram of the grammars that we used to produce the 12 word languages. Each sentence had four words. Three of the language types (which we refer to as "1515," "2424,"

Figure 1: Schematic representations of the 4 types of languages used in Experiment 1. Circles represent individual words, arrows represent stochastic transitions.

and “3333”) were generated via a simple finite state grammar, while the fourth (unstructured) language type was generated by uniformly concatenating words with no notion of sentence position.

Each of the structured languages had a category structure such that sentences followed the form *ABCD*, where each category had a unique and non-overlapping set of words in it. The 1515 language, for example, had one word in the first category, five in the second, and so forth. We refer to such a language throughout as having “asymmetric” category sizes. In contrast, a 3333 language has “symmetric” category sizes. The 8 word languages were generated similarly, but only included three conditions (“1313,” “2222,” and unstructured).

We used a sentence-by-sentence segmentation paradigm (Kurumada et al., under review) to test adult learners’ segmentation performance and gather detailed information about learning trajectories in these languages. Learners listened to a set of sentences presented in a Flash web applet; after each sentence they were asked to click between syllables in an orthographic transcription to indicate where they thought word boundaries fell.

## Methods

**Participants** For the 12 word languages, we posted 128 separate assignments on Amazon’s Mechanical Turk (AMT) crowdsourcing platform and received 124 assignments from distinct individuals. For the 8 word languages, we posted 96 assignments and received 95. Subjects were paid \$1.00 for completing the task and were told that they would be paid an additional \$1.00 if they performed in the top quartile of participants. The mean task duration was 14 minutes and 17 seconds. Subjects needed to transcribe a common English word at the beginning of the task to access the task to confirm that they were English speakers.

**Stimuli** We created two classes of lexicons differing in the total number of word types (8 and 12). Words were made

by concatenating 2 – 4 syllables from a randomly selected inventory of consonant-vowel syllables. Stimuli were synthesized with the MBROLA synthesizer (Dutoit, Pagel, Pierret, Bataille, & Van Der Vrecken, 1996) at a constant pitch of 100Hz with 225ms vowels and 25ms consonants. Each syllable appeared in only one word type in each lexicon.

For the 12-type condition, 4 distinct languages were created by manipulating how many of 12 types (distinct word forms) appeared in each of four sentences positions (Figure 1): 1515, in which the words in the first and third sentence position were drawn from categories of a single type and the second and the fourth from categories with five types each, 2424, in which the words in the first and third sentence position were drawn from categories consisting of two types and the second and fourth from categories with four types, 3333 in which the word in each sentence position was selected from a category with three types, and unstructured, in which four words were selected uniformly at random from a single category of 12 types (without replacement, to avoid in-sentence repetition).

To reflect the relationship between frequency and word length seen in natural language (Zipf, 1965), the category assignment of lexical items ensured word length and frequency were inversely correlated (the shortest words appeared in the categories with the fewest types). Within each condition, 16 language variants were made using different phonemic inventories to control for unwanted phonological effects. The total number of word tokens per subject was 240 and the number of sentences was 60 in all languages. The total token frequencies of words were 60-12-60-12 in the 1515 condition, 30-15-30-15 in the 2424 condition, 20-20-20-20 in the 3333 condition. In the randomized condition each word appeared in each sentence position 5 times. Note that there was no discrete testing phase separate from the training phrase; rather, subjects were tested in the continuous paradigm on their knowledge of the language as they learned it.

Stimuli for the 8-type condition were similar to those in the 12-type condition except that we created only 3 languages: 1313, with the first and third word position drawn from categories with a single type and the second and fourth position drawn from categories with three types in each, 2222, in which each word position is selected from a category with two types, and randomized, where each sentence was composed from four words randomly selected from all 8 word types. 32 phonetic variants of each language were generated to control for phonological effects. The per-subject exposure was 240 tokens over 60 sentences, and the total token frequencies were 60-20-60-20 in the 1313 condition, and 30-30-30-30 in the 2222 condition; in the unstructured condition each word appeared 7 or 8 times in each position.

**Procedure** Before the experimental trials began, participants were instructed to listen to and transcribe a short, common English word to confirm that their computer’s audio system was working. Participants were then instructed that they would be presented with 60 consecutive sentences in a novel

Figure 2: Token F-scores (a measure of segmentation performance for individual words) plotted for Experiment 1. Symbols represent mean performance for each condition (see legend) on a single trial, across participants. Black lines show a smoothed estimate of performance (Lowess curves with a smoothing span of .5). Gray lines at bottom show permutation baselines based on mean token F-score from reshuffling participant responses 1000 times.

artificial language, and that from the beginning they would need to click the boundaries between syllables presented on screen to indicate what they thought the boundaries between words were in each trial. While they would not know the words at first, they were told that they would be able to discern patterns and recognize at least some of the words as the experiment progressed. Each trial contained both an audio presentation and an orthographic transcription with selectable boundaries between each syllable. After clicking segments in a sentence subjects clicked a button marked “next” to proceed to the next trial.

## Results and Discussion

To assess subjects’ segmentation performance, we calculated the precision, recall, and F-score (the harmonic mean of precision and recall, as described in Goldwater et al., 2009). This metric was computed by subject and trial, both for boundary decisions and tokens.<sup>1</sup> Figure 2 shows token F-score aggregated across subjects for each language and condition.

All conditions showed some learning. Unstructured languages were learned best, and learning was faster in the 8 word than the 12 word languages. Trajectories of the structured conditions maintained a relatively constant ordering:

<sup>1</sup>In our example sentence (“indiangorillaseatbananas”), we compute these measures for a participant who gave the segmentation “indian|gorillas|eatbana|nas.” Computing word boundaries, the participant would have 2 hits, 1 miss, and 1 false alarm, leading to precision of .66 (hits / (hits + false alarms)), and recall of .66 (hits / (hits + misses)), for an F-score of .66. On the other hand, for word tokens, the participant would have 2 hits (“indian” and “gorillas”), 2 misses (“eat” and “bananas”) and 2 false alarms (“eatbana” and “nas”), for precision of .5, recall of .5, and F-score of .5.

the more asymmetrical the categories in the language were, the better participants learned. In both the 8-type and the 12-type, the slope of the unstructured condition is steepest, demonstrating the greatest amount of learning of the latent structure.

We analyzed token-by-token segmentation performance separately for the 8 word and the 12 word languages using mixed-effects logistic models (Gelman & Hill, 2006; Jaeger, 2008). The dependent variable in these models was whether a particular token had been segmented correctly. In the 12 word languages, we found a strong positive main effect of the log input frequency of that token ( $\beta = .19, p < .001$ ) and a negative effect of word length ( $\beta = -.56, < .001$ ), as well as significant effects of the 3333 test condition ( $\beta = -.69, p < .05$ ) and the 2424 test condition ( $\beta = -.62, p < .05$ ) with respect to the unstructured condition. The 1515 condition also had a negative effect on token segmentation ( $\beta = -.29$ ), though this was not reliably different than the unstructured condition ( $p > .3$ ). As in the 12 word languages, in the 8 word languages there was a positive main effect of the log input frequency of that token ( $\beta = .26, < .001$ ) and negative effect of word length ( $\beta = -.68, < .001$ ). There were also significant effects of the 1313 condition ( $\beta = -.71, p < .05$ ) and the 2222 condition ( $\beta = -.95, p < .01$ ).

To summarize: in both the 12 word and the 8 word languages we observed the best performance in the unstructured condition and the worst performance in the condition where types are symmetrically distributed across categories/sentence positions.

Figure 3: Proportion of correct 2AFC trials for the languages in the 12-type conditions in Experiment 2. Each point represents a participant. The black bar shows the condition mean and the dotted line at-chance (50%) performance.

## Experiment 2

Experiment 2 was conducted to ensure that the effects of dependency structure could be captured in a classic two-alternative forced choice task, where subjects were asked to distinguish between a word from the language and a distractor.

### Methods

**Participants** For the 12 word languages, 144 assignments were posted on AMT, of which we received 133 completed by distinct individuals. For the 8-type condition, 96 assignments were posted, of which we received 89. The same payment method as in Experiment 1 was used.

**Stimuli** The process of generating stimuli was nearly identical to the procedures presented in Experiment 1. For the training phase, 150 input sentences (totaling 600 tokens) were generated. A discrete test phase consisted of 30 pairs of a target word from the language and a length-matched distractor word, composed of syllables randomly selected from that language’s syllabic inventory. Such test trials were intended to test if subjects had reliably learned which words belonged to the language.

**Procedure** Participants were instructed that they would listen to 150 sentences in a novel artificial language, then take a short test on what they had learned about the language. Training sentences were presented aurally; when the audio file finished playing subjects needed to press “next” to advance to the next trial. In the test phase they were asked to choose which of the two options “sounded like it came from the lan-

guage.” For the test trials, the two options were presented aurally and subjects could replay the audio if desired.

## Results and Discussion

In the 8 word languages, performance was at ceiling, with all condition means above 90% in the forced choice test. As such there was no meaningful variance across languages and we do not discuss these conditions further. In the 12 word languages, the pattern of mean performance across conditions corroborated our findings in Experiment 1 (Figure 3). Although there was considerable variation across participants, performance was higher in the unstructured and asymmetric conditions; performance was lowest in the symmetric condition. We analyzed trial-by-trial 2AFC performance for the 12 word languages using a mixed-effects logistic model. There was a weak negative effect of trial number ( $\beta = -.02$ ,  $p < .001$ ; recall all learning happened in this experiment after the trial phase) and word length, though unlike in the first experiment *longer* word length facilitated segmentation in the 2AFC ( $\beta = .40$ ,  $p < .001$ ). The 3333 condition had a significant negative effect on performance ( $\beta = -.38$ ,  $p < .05$ ). Thus, 2AFC results support the negative effect of symmetrical category sizes seen in Experiment 1.

## Online Segmentation Models

Our goal in modeling human performance in Experiment 1 was to understand whether proposed ideal observer models are affected by structural complexity in the input in the same way as human subjects. We thus selected a range of models that have been suggested by previous literature to fit human performance: an incremental version of a transitional probability (TP) learner (Frank, Goldwater, Griffiths, & Tenenbaum, 2010); PARSER, a heuristic, memory-based model (Perruchet & Vinter, 1998); and a new online implementation of a probabilistic segmentation model (Börschinger & Johnson, 2011) using a particle filter. All models took unsegmented strings of characters representing syllables as input and produced segmented output sentence-by-sentence.

### Models and Parameters

**TP-based model** The transitional probability model is a boundary-finding approach that segments on the basis of statistically less likely transitions from syllable to syllable under the premise that within-word syllable TPs are higher than those at word boundaries (Saffran, Aslin, & Newport, 1996). In the present study, we calculate syllable bigram counts at the end of each sentence and calculate TP as

$$p(a|b) = \frac{c(a,b)}{\sum_{y \in V} c(a,y)} \quad (1)$$

where  $a$  and  $b$  are syllables,  $c(a,b)$  is the count of the bigram  $ab$ , and  $V$  is all bigrams observed up to that point in the corpus. Sentence boundaries, which contain potentially useful information, were limited by a special symbol and treated as syllables. We systematically varied the threshold (0 – 1 in

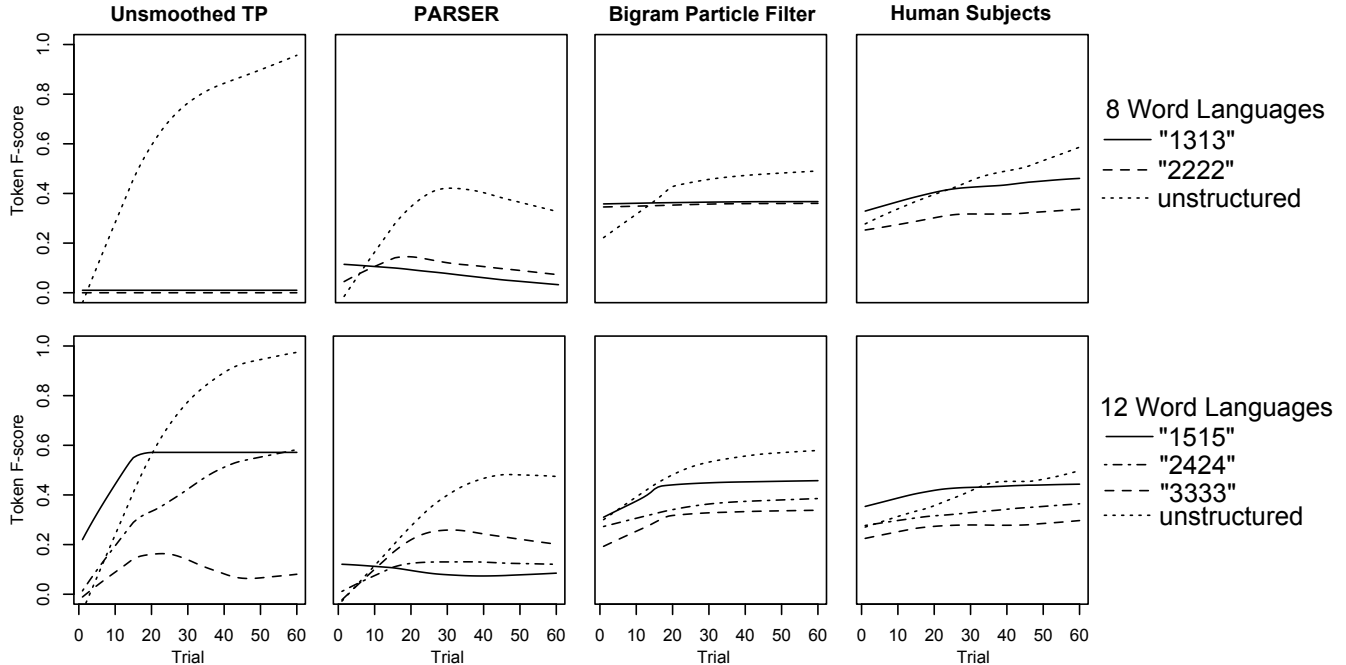

Figure 4: Lowess curves of mean token F-scores (smoothing span = .5) for the best fitting (using RMSE) parameter setting for each of the three models, plotted alongside human performance from Experiment 1.

.1 increments) at which a TP was low enough to constitute a word boundary, and placed boundaries between all syllables where TP was below the threshold.

**PARSER** PARSER (Perruchet & Vinter, 1998) is a lexicon-finding model that makes use of a persistent collection of segments whose weights increase when encountered in the input and decrease with exposure to new data lacking such segments. Found items similar to ones that are already in the collection also prompt a decrease in the weights of similar segments. The PARSER model has a high number of adjustable parameters, including initial weight, max segment length for consideration, the decay rate of material in the stored lexicon, the interference weight, a threshold to determine whether a parse should be considered a new word, and the reactivation gain. We adapted the model to output sentence-by-sentence segmentations, taking the initial parse of a new sentence (guided by the weights of the collection in memory) as the segmentation decisions for each sentence. For our simulations here, decay rate was most important, so we systematically manipulated this parameter. Among the other parameters, we used a max segment length for consideration of 3, an initial weight of 1, an interference rate of .005, a reactivation gain of .005, and a threshold of consideration as a new segment of 1.

**Bigram Model with Particle Filter Inference** The bigram model with particle filter inference is a new version of the Bayesian bigram model of Goldwater et al. (2009) that uses a particle filter rather than a Gibbs sampler to estimate the pos-

terior distribution over segmentations (Börschinger & Johnson, 2011). As in the original Bayesian bigram model, the lexicon for the particle filter is generated using a Dirichlet process, enforcing a probability distribution which gives higher probability to smaller lexicons with shorter words, and to a small number of high-probability collocations. Unlike the original version of the lexical model, however, the particle filter inference algorithm allows the model to be run incrementally through a corpus in a single pass, producing sequentially segmented sentences for our evaluation. In a particle filter, each particle constitutes a different set of segmentation hypotheses (see Börschinger & Johnson, 2011 for details). In our current study, we manipulated the number of different hypotheses that the model could track, with fixed concentration parameters of  $\alpha_0 = 12$  and  $\alpha_1 = 24$  in the 12 word languages and  $\alpha_0 = 8$  and  $\alpha_1 = 16$  in the 8 type languages.

## Model Results

For each model, we fit a single free parameter to human data, choosing one value that maximized Pearson's  $r$  and the one that minimized RMSE (threshold to treat as a boundary in the TP model, the decay rate of observed chunks in PARSER, and the number of particles for the particle filter bigram model). Figure 4 shows performance at the best-fitting parameter setting (according to RMSE) for each of the three models alongside the human data; Table 1 shows the RMSE and Pearson's  $r$  with the associated parameter setting in parentheses.

The bigram particle filter was the best-fitting model on both Pearson's  $r$  and RMSE. The particle filter also captured the

Model	Pearson's $r$	RMSE
Unsmoothed TP	.59 (.3)	.29 (.3)
PARSER	.70 (.05)	.23 (.008)
Particle Filter	<b>.71</b> (4)	<b>.07</b> (8)

Table 1: Two metrics of model fit for the three models

ordering of conditions observed in the human data, though the 8 type structured conditions were minimally distinguished from one another. PARSER performed well on  $r$ , but the forget rate (the fit parameter) with the highest correlation on  $r$  resulted in relatively low absolute performance (in the range of 0 - .2). Fitting PARSER to RMSE resulted in the selection of a much lower forget rate. The unsmoothed TP model performed poorly on both metrics. Though condition ordering for the TP model matched human results in the 12 type, both structured categories in the 8 type displayed no learning while the unstructured condition significantly outperformed human learners. Fit to RMSE, all three of the tested models demonstrated best performance on the unstructured input; fit to  $r$  there is a clear advantage for the unstructured condition, the only exception to this pattern being higher scores on PARSER for the 1515 condition.

### General Discussion

We began by noting a difference between natural languages and the artificial languages that have previously been used to study the phenomenon of ‘statistical word segmentation.’ Natural languages have complex inter-word dependencies, while previous experiments have purposefully created languages that lacked such dependencies. While this initial simplification was useful, it is uncertain whether dependency structure would be positive or negative for segmentation performance. Our experiments suggest that adults learn better from a language *without* dependencies than one with them. These results suggest that structural variability can be more helpful for the purpose of learning word segmentation than structural regularity, though whether this holds with larger languages remains to be examined.

Our method of using learning curves provided for a higher-resolution examination of the dynamics of both human word segmentation and of models instantiating hypotheses about the mechanisms of segmentation. The measurement of learning across time allows for a richer investigation of the performance for each model, revealing the baseline from which models initialize, their rate of learning, and their final attainment after having been exposed to the full set of stimuli.

In our estimation of whether the mechanisms of ‘statistical learning’ can scale to the task of learning the lexicon of a natural language, we must take into account the difficulties posed by dependency structure. Nevertheless, our studies—both experimental and computational—showed that there was an advantage for languages with an asymmetrical dependency structures. Languages with variability in the number of types assigned to categories facilitated segmentation, perhaps by

providing frequent tokens that served as anchors for segmentation (Kurumada et al., under review). Thus, as suggested by our previous work, it may be the case that high frequency material facilitates language learning by promoting segmentation of adjacent material.

## Abstract

Recent intelligent tutoring systems give participants various types of supports. We hypothesize that a high level of support activates participants' orientation to problem-solving goals but reduces the priority of attaining learning goals; as a result, higher problem-solving performance is attained, but the learning effect is reduced. We tested this hypothesis by using two relatively largely different experimental tasks: Tower of Hanoi puzzle as a simple problem solving task and Natural Deduction learning as a more complex learning task. Overall results supported our hypothesis and were discussed from the viewpoint of the assistance dilemma.

**Keywords:** Problem solving goal; Learning goal; Assistance dilemma.

## Introduction

Recently, highly interactive intelligent tutoring systems have been developed whose design principles come from cognitive science theories. A series of cognitive tutors has been constructed based on the ACT-R theory (Anderson, Corbett, Koedinger, & Pelletier, 1995). Intelligent tutoring systems give participants various feedback such as verification, correct response, try again encouragement, error flagging, and elaboration messages (Shute, 2008). In the interaction design between a tutoring system and learners, feedback to learners is a central issue.

In this context, the assistance dilemma has been recognized. Koedinger and Aleven pointed out a crucial question (Koedinger & Aleven, 2007): How should learning environments balance assistance giving and withholding to achieve optimal learning? High assistance sometimes provides successful scaffolding and improves learning, but at other times it elicits superficial responses without consideration from students. On the other hand, low assistance sometimes encourages students to make a large effort, but other times results in enormous errors and interferes with effective learning.

We reformulate the assistance dilemma as a tradeoff of selecting either the problem-solving goal or the learning goal. In a representative situation, participants learn while solving instance problems given by a tutoring system. Attaining the problem-solving goal means solving such instance problems as accurately and rapidly as possible. However, the learning goal requires another attainment that is usually more essential. A primary objective is not to solve instance problems but to learn by solving instances. Dweck classified two types of goals: learning and performance (Dweck, 1986; Ames, 1992). Highly motivated children tend to set learning goals to

increase their competence to understand or master something new rather than just solving problems. Comparing the learning and problem-solving goals in our current study corresponds to Dweck's learning and performance goals. Achieving a problem-solving goal is measured by the solution time and the error ratio for solving problems in the learning phase. The learning goal is usually measured by a posttest after the learning phase.

Another important difference between the two goals is that the problem-solving goal can be achieved with the support of a tutoring system, but the learning goal should be reached without supports of a tutoring system. Achieving the learning goal is usually measured in a setting without tutoring system support because learners should solve problems by themselves without external support from a tutoring system. The need for support means that participants do not complete the learning.

Participant goal setting may be influenced by the feedback information from a tutoring system. One perspective for characterizing the feedback is directive and facilitative (Black & William, 1998). Directive feedback tells participants what needs to be fixed in the next step. Such feedback tends to be more specific than facilitative feedback, which provides participants with comments and suggestions directly relating to the problem-solving. When participants are solving a problem, directive feedback may guide them to focus on the problem-solving goal.

Another perspective for characterizing feedback is its timing. Researchers have addressed whether feedback should be delivered immediately or delayed. Delayed means that it occurs minutes, hours, or even weeks later. Mathan and Koedinger reviewed various studies and concluded that timing effects emerge interactively with other factors such as task difficulty and individual student needs or characteristics (Mathan & Koedinger, 2002). Immediate feedback may facilitate problem-solving goals because participants are repeatedly given indications for determining what to do next when solving a problem.

In the context of the investigation of the assistance dilemma issue, we control the levels of support (LOS) in the following experiments. A high level of support means that more direct and immediate feedback is given. Our hypothesis is that a high level of support activates participants' orientation to problem-solving goals and reduces the priority of attaining

learning goals. This hypothesis predicts that in the high level support condition, the problem-solving performance is higher than in the low level support condition, but the learning effect was reduced; therefore in the posttest where no supports are given, participants who learned in the high level support condition score lower than those in the low level support condition.

We tested this hypothesis using two experimental tasks. In Experiment 1 we used the Tower of Hanoi (TOH) puzzle, which is one representative experimental task widely used in problems-solving studies. In Experiment 2, the participants engaged in a natural deduction (ND) task.

TOH is a simpler task. The problem space is systematically organized and is not so large. Problem solving is achieved by only one operator that corresponds to disk movement. The knowledge and strategies for the solution are represented by less than ten production rules. ND is a more complex task. Its problem space is much larger than that of TOH. To solve problems, since participants must acquire many kinds of inference rules and solution strategies, a complete model for solving ND problems consists of around a hundred production rules. In addition, TOH is basically a problem-solving task, but ND is a learning task. The participants in Experiment 1 joined the experiment in a laboratory setting; those in Experiment 2 engaged in it in a learning context. We confirmed our hypothesis using two relatively largely different experimental tasks.

## Experiment 1

### Task

The six disks TOH puzzle was used as an experimental task.

### Experimental system

The participants individually engaged in the task using an experimental environment established on a personal computer. Figure 1 shows an example screenshot of the experimental system. The participants selected one of the possible disk movements by clicking a button with a mouse. A production system model was mounted on the system to solve TOH by the perceptual strategy. The model infers the next step, the next five steps, and the next nine steps for reaching the goal state through the minimum steps and presents the participants the best next state, the best state after five, and nine steps as a hint.

The LOS was manipulated by the presented hints. In the highest LOS condition, the participants were presented the next step at every problem-solving trial. In other conditions where the best step after five or nine steps was presented, the participants were given such hints at every five or nine problem-solving trials. Higher supports mean direct and immediate feedback; therefore, the participants in these two conditions were given lower levels of support than those in the next step condition. Additionally, in the lowest LOS condition, the participants were given no hint information.

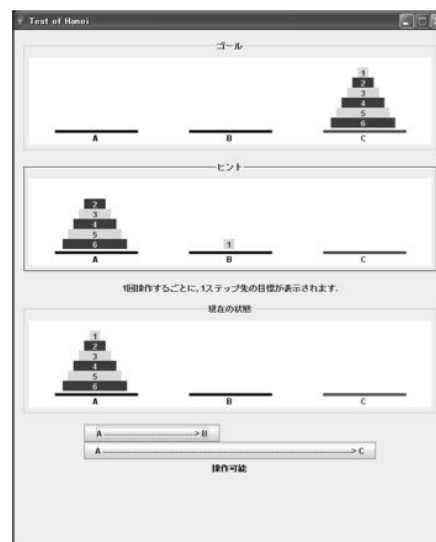

Figure 1: Example screen shot of experimental system for TOH. The upper and lower windows show the goal state and the current state. The middle window presents hint information; in this case the next one step is presented.

### Participants and Procedure

Seventy-one participants joined our experiment. 17, 19, 17, and 18 participants were assigned to the one step, five steps, nine steps, and no hints conditions, respectively. The experiment lasted 90 minutes. The participants were instructed to learn strategies for solving TOH and informed that after the learning session, a posttest would be performed to test their degree of skill acquisition.

In the initial stage of the experiment, the participants learned the constraints of the disk movements and how to use the experimental system. In the learning phase, they solved various types of six-disk-TOH problems in 40 minutes in one of the four experimental conditions. When one problem was completed, the next was given. After the learning phase, a posttest was performed in which the participants solved a test problem by themselves without hint information.

### Result

As a problem-solving performance measure, we used normalized steps for the solution in the learning phase. Figure 2<sup>1</sup> shows the average steps for the solution where the index indicated in the vertical axis was normalized by dividing the solution steps that the participants actually needed to follow by the minimum steps for reaching the goal state from the initial state in each problem. The value, 1.0, means the completed solution, and larger values indicate a poorer solution. The normalized steps needed for the solution were fewer in the one step, five, and nine step conditions where

<sup>1</sup>Note that in figures 2, 4, and 6, the value of the vertical axis is reversed to compare those with Figure 9 in conclusion.

Figure 2: Average steps for solving problems in learning phase (TOH). The value of the vertical axis is reversed to represent higher values as high problem-solving performances, i.e., value 1.0 means the optimal problem solving. An ANOVA indicates that the main effect of Conditions factor was significant ( $F(3, 67) = 12.5, p < 0.01$ ). Fisher's LSD analysis shows significant differences between one step and no hints ( $p < 0.01$ ), five steps and no hints ( $p < 0.01$ ), and nine steps and no hints ( $p < 0.01$ ).

hint information was presented than those in the no hint condition. Our prediction was confirmed because the result of the problem-solving performance was worst in the lowest LOS condition. However, we did not detect statistically significant differences among the three hint conditions. The normalized steps in the three conditions almost reached 1.0. This means that the hint information was sufficient for reducing the trial and error behavior of the participants, even in the nine step condition.

Next, to investigate to what degree each participant thoroughly considered rational actions in each problem-solving step, we calculated the average time to decide each disk movement. We assumed that the priority of the problem-solving goal over the learning goal reduces this consideration time. Figure 3 shows the time that passed between one disk movement and the next. The time in the one step condition was shorter than in the five and nine step conditions, confirming our prediction. However, in the no hit condition, the time was also shorter than the five and nine step conditions, contradicting our prediction.

Next, as a learning performance measure, we used the normalized steps for the solution in the posttest. Figure 4 shows the result. The average steps in the nine steps condition were fewer than those in the one step and no hint conditions. The graph shows that in the three conditions (one, five, and nine step conditions) where hint information was presented, as lower LOSs were given, the learning effect increased, confirming our prediction. However, in the no hint condition, the performance was poorer than that in the higher LOS (nine steps) condition, contradicting our prediction.

Contradictory to our prediction, in the no hint condition, the time for deciding the next disk movement was shorter, and the learning effect was poorer. Perhaps in the learning phase,

Figure 3: Average time for deciding disk movement (TOH). An ANOVA indicates that the main effect of Conditions factor was significant ( $F(3, 67) = 18.0, p < 0.01$ ). Fisher's LSD analysis shows significant differences between one and five steps ( $p < 0.01$ ), one and nine steps ( $p < 0.01$ ), five steps and no hints ( $p < 0.01$ ), and nine steps and no hints ( $p < 0.01$ ).

Figure 4: Average steps for solving problems in posttest (TOH). The value of the vertical axis is reversed to represent higher values as high problem-solving performances, i.e., value 1.0 means the optimal problem solving. An ANOVA indicates that the main effect of Conditions was significant ( $F(3, 67) = 3.25, p < 0.05$ ). Fisher's LSD analysis shows significant differences between one and nine steps ( $p < 0.01$ ) and nine steps and no hints ( $p < 0.05$ ).

it was difficult for the participants to learn strategies without hint presentation. This point will be mentioned below in the discussion and conclusion.

## Experiment 2

### Task

Natural deduction (ND) is a kind of proof calculus: e. g., inducing a proposition  $\neg Q \rightarrow \neg P$  from a premise  $P \rightarrow Q$ . Logical reasoning is expressed by inference rules closely related to a natural way of reasoning. They learned nine basic rules and five formal strategies, all of which are fundamental knowledge in ND. Most problems can be solved using this knowledge.

### Experimental system

The experimental system used in Experiment 2 was developed as a tutoring system for teaching ND to university un-

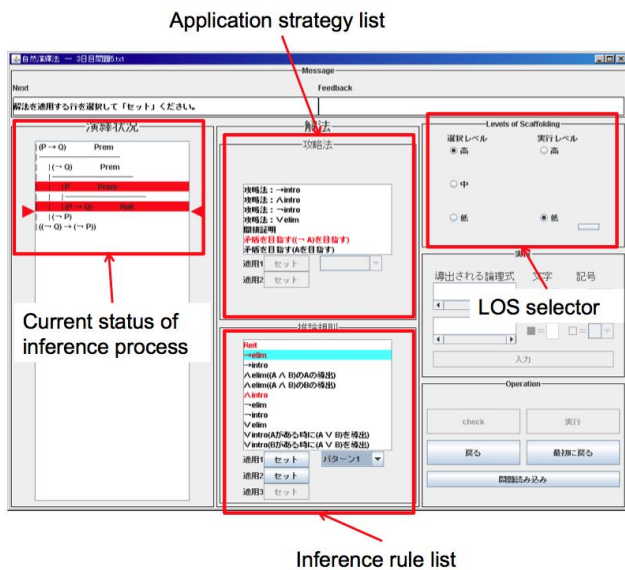

Figure 5: Example screen shot of ND tutoring system. The left side window shows a current status of inference processes where the red items are propositions to which the selected inference rule should be applied. The upper and lower center windows show a strategy list and an inference rule list where the red items are applicable candidates. The right upper window shows the LOS selector where the levels of support are controlled. In the current experiment, LOS was fixed based on the experimental manipulation.

dergraduates. Figure 5 shows an example screenshot of the tutoring system, which provides participants with lists of the inference rules and strategies. After users select one from the lists, the system automatically runs the rules and presents the inference result. The system scaffolds the participants by giving help information about the selection of the rules and strategies and presents the candidates of the rules that should be applied in a given situation.

The LOS was controlled by the presented hint information. In the high LOS condition, the system presented both applicable candidates (rules and strategies) and propositions to which the rules should be applied. In the low LOS condition, the system only presented a set of inference rules; no candidates were presented. The participants had to select an adequate rule from the list by themselves without system support. A high LOS means that the participants were given direct help that guides them to a determined behavior.

### Participants and Procedure

Twenty-nine participants joined our experiment. 13 and 16 were assigned to the high and low LOS conditions, respectively. The experiment was performed over three weeks in an introductory cognitive science class.

In the first week, the participants learned the basics of formal inference systems and ND as an example of the systems.

In the second week, the first half of the learning phase was performed where the participants learned the four basic inference rules. In this class session, all participants learned in the high LOS condition.

In the third week, the latter half of the learning phase followed where LOS was manipulated. The participants solved relatively complex problems for which a sub-derivation process with sub-goal setting was needed. The instructor demonstrated the solutions of two problems, and then the participants solved Problems 1 to 4 with the tutoring system. In the class, the participants were divided into two groups: high LOS and low LOS. After the learning phase, two posttests were performed. Posttest 1 was identical to Problem 2, which they solved in the learning phase, and Posttest 2 as a transfer problem was a new challenge for the participants.

### Result

The optimal steps for a solution are determined in TOH. However, in the solutions of some ND problems, various reasoning paths are rational; therefore we used the average time for solving each problem in the second half of the learning phase as a problem-solving performance measure. Figure 6 shows the result. The solution time was shorter in the high LOS group than in the low LOS group when solving Problems 3 and 4. This result is consistent with our prediction.

Figure 7 shows the time for deciding and implementing an inference rule to forward reasoning. The decision time was shorter in the high LOS group than in the low LOS group when solving Problems 3 and 4. This result is consistent with our prediction.

Next, we used the scores, i.e., the ratio of successfully solved tests, in the posttest as a learning performance measure. Figure 8 shows the result, indicating that when solving Posttest 2, more participants in the low LOS group reached the solution than in the high LOS group, confirming our prediction. This effect was only observed in solving the transfer problems, but not in the repeated problems. This result is consistent with earlier experimental studies, confirming that delayed and lowering supports make positive effects, especially in solving transfer problems (Schroth, 1992, 1997).

### Discussion and Conclusions

The assistance dilemma hypothesizes an optimum point of learning effects as a function of cognitive load. Koedinger et al. (2008) indicated two dimensions of assistance: the practice spacing dimension and the example-problem dimension (Koedinger, Pavlik, McLaren, & Aleven, 2008). They demonstrated a reverse U-shape learning curve on the two dimensions. We conceptualized such a learning effect curve with a problem-solving performance curve (Figure 9). As the support level increases, the problem-solving performance is gradually promoted; however the learning effect reaches maximum at a specific support level and decreases from the point.

When comparing this framework with the results of our two experiments, note that in Experiment 1, the results indi-

Figure 6: Average solution times for solving problems in learning phase (ND). The value of vertical axis is reversed to represent higher values as high problem-solving performances. T-tests show a marginal significant difference between high and low conditions in Problem 3 ( $t(22) = 1.92, p = 0.07$ ) and a significant difference in Problem 4 ( $t(15) = 2.70, p < 0.05$ ), but no differences in Problems 1 and 2 ( $t(25) < 1$ , n.s.;  $t(24) = 1.14$ , n.s.).

Figure 7: Average time for deciding inference rule (ND). T-tests show a marginal significant difference between high and low conditions in Problems 3 ( $t(22) = 2.55, p < 0.05$ ) and 4 ( $t(25) = 2.98, p < 0.01$ ), but no differences in Problems 1 and 2 ( $t(25) < 1$ , n.s.;  $t(24) < 1$ , n.s.).

Figure 8: Ratio of successful participants (ND). Chi square tests show a significant difference between high and low conditions in Posttest 2 ( $\chi^2(1) = 7.49, p < 0.01$ ), but no difference in Posttest 1 ( $\chi^2(1) < 1$ , n.s.).

cated in Figures 2 and 4 demonstrated this pattern, controlling the support level from the highest to the lowest on the diagram. But in Experiment 2, the results, as indicated in Figures 6 and 8, only demonstrated the left side of the pattern: control from the highest to the mid level. Our hypothesis was that a high level of support activates participant orientation to

the problem-solving goal and promotes the problem-solving performance, but reduces the priority of attaining the learning goal and decreases the learning effects. This hypothesis is consistent with the left part of Figure 9. On the right side, meaning no or a very low LOS, both the problem-solving performance and the learning effect decreased. This pattern suggests two interpretations. One is that in the right side situation, even if the participants set their goal to learning in the learning phase, they might not be able to decide what to do next and may make enormous errors, resulting in low learning effects. The other interpretation is that the participants give up the attainment of the learning goal because they face difficulties in learning without support. In the current study, we could not decide which explanation is better. Future work will address this issue.

We discussed a tradeoff between problem-solving and learning goals with the degree of support in the learning phase. This tradeoff issue appears in various research fields. For example, the effect of goal specificity has been investigated (Burns & Vollmeyer, 2002; Sweller, 1988). Participants often neglected to consider the theories or rules behind phenomena when they aimed for a specific goal. That is,

Figure 9: Conceptualized diagram of assistance dilemma and relation of problem-solving and learning goals.

they tended not to search in a hypothesis space, because they concentrated on a search in an instance space to achieve the goal. Consequently, they could not find any rules or underlying mechanisms of the task. Goal specificity studies have indicated that this tendency can be controlled by manipulating goal specificity. Specific goals are direct and immediate; therefore the degree of goal specificity is considered consistent with the levels of support in the current study. The results of our two experiments are consistent with the findings observed in many experiments conducted in the context of goal specificity studies.

Similar to our definition of the levels of support, in studies on automation usage, Sheridan & Verplank indicated ten grades of automation levels (Sheridan & Verplank, 1978). The highest level, Level 10, means that the computer acts entirely autonomously, and the lowest level, Level 1, means that a human does everything. Lin, et al. conducted a micro-world experiment where the participants controlled an atomic power plant under various levels of automation (Lin, Yenn, & Yang, 2010). Medium levels of automation maximized the participants' operations. The most important objective in the use of automation systems is stable manipulation while using the systems; therefore, the tradeoff issue of the two goals might not appear. However, researchers have pointed out the possibility that the continuous usage of automation systems may sometimes cause serious damage when the automation support is removed. For example, Parasuraman et al. argued that stable automation systems produce automation-induced complacency (Parasuraman, Molloy, & Singh, 1993; Molloy & Parasuraman, 1996). They demonstrated in a laboratory setting that operator detection of automation failures was substantially worse for constant-reliability than for variable-reliability (unstable) automation. As we mentioned, in the learning context, the problem-solving performance was measured with learning system support; on the other hand, the learning effect was usually tested without external support in posttests. In this sense, the complacency problem that

emerges when automation breaks down can be understood based on the tradeoff issue of the two goals.

## Abstract

People make logically inconsistent probability judgments. The “Linda” problem is a well-known example, which often elicits a conjunction/disjunction fallacy: probability of constituent event  $A$  ( $B$ ) judged more/less likely than their conjunction/disjunction. The Quantum Judgment model (QJM, Busemeyer et al 2011) explains such errors, which are not explainable within classical probability theory. We propose an alternative axiomatic approach in the framework of quantum probability theory that employs *positive* operators representing the set of general queries, in contrast to QJM which uses *projection* operators. Like QJM, our model accounts for conjunction/disjunction fallacies, averaging type errors, and unpacking effects, suggesting that it provides a viable model of judgement error. Further differences between our model and QJM are also discussed.

**Keywords:** Probability judgment; Quantum Probability theory; conjunction/disjunction fallacy; “Linda” problem.

## Introduction

People make probability judgments that are logically inconsistent with classical probability theory. The “Linda” problem is a well-known example: Participants are told that Linda was a philosophy student and an anti-nuclear supporter, and asked to judge her most likely current situation as either (a) feminist supporter, (b) bank teller, (c) feminist and bank teller—conjunction, (d) feminist, but not bank teller, or (e) feminist or bank teller—disjunction. Judging (b) as more likely than (c) is a *conjunction error* (fallacy), since by classical probability  $Prob(A \text{ and } B) \leq Prob(B)$ ; judging (a) as more likely than (e) is a *disjunction error*, since  $Prob(A) \leq Prob(A \text{ or } B)$ . These fallacies are well-known (Tversky & Kahneman, 1983; Bar-Hillel & Neter, 1993), but they are not explained by classical models (Busemeyer, Potheos, Franco, & Trueblood, 2011).

Busemeyer et al. (2011) proposed an alternative model based on *quantum probability theory* (QPT) (Peres, 1993). Their quantum judgment model (QJM) uses the properties of *quantum coherence* and *quantum interference* to explain conjunction and disjunction errors, respectively. An explanation of QJM follows (Appendix A summarizes QPT).

Using the Linda problem as an example, QJM assumes that beliefs about states of the world (e.g., *Linda is a feminist*) are represented as vectors  $\Psi$  in a *Hilbert space*  $\mathcal{H}$  where, e.g., the basis vectors represent feature combinations (e.g., non-/feminist, young/old, gay/straight). An event  $E$  (e.g., corresponding to the proposition *Linda is a bank-teller*) is

a *projection operator*, which projects the belief vector onto a subspace representing a possible outcome: e.g., *Yes* is a possible outcome (subspace) for *Linda is a bank-teller*. A *projection operator*  $E$  applied to  $\Psi$ , written  $E\Psi$  (i.e. vector/matrix multiplication), returns the probability of belief in that outcome, computed as  $Prob(E) = \langle \Psi | E \Psi \rangle$ , where  $\langle \cdot | \cdot \rangle$  is *Dirac notation* for the inner product. For events corresponding to conjunctions of propositions “ $E$  and  $F$ ” (e.g., *Linda is a feminist and Linda is a bank-teller*), the belief in an outcome is computed as: if  $Prob(E) > Prob(F)$ , then  $Prob(E \text{ and } F) = \langle \Psi | E F E \Psi \rangle$ , else if  $Prob(E) < Prob(F)$ , then  $\langle \Psi | F E F \Psi \rangle$ .<sup>1</sup>

In this paper, we provide an alternative formulation of human probability judgment within the framework of quantum probability theory. The most general class of queries is represented by the space of *positive operators*, which includes projection operators. Motivated by this observation, we propose a set of axioms to define a positive operator corresponding to the conjunction of a pair of general propositions. We provide an example that is consistent with this set of axioms. Moreover, we also show how this reformulation accounts for the conjunction and disjunction fallacies, averaging type errors, and unpacking effects.

## Quantum formulation using positive operators

A quantum system is described by a Hilbert space (see Appendix A). In quantum theory, a general query (or event) is represented by an operator  $A$  satisfying  $0 \leq A \leq 1$ . It should be noted that a projection operator also satisfies this condition. Thus an observable which takes a value in a set  $\Omega$  is represented by a positive-operator-valued measure (POVM)  $\{A_a\}_{a \in \Omega}$  on  $\Omega$ . Roughly, a POVM can be regarded as a “fuzzy” version of projection-valued measure (PVM). Thus a POVM is often called an unsharp observable.

**Assumption 1** A person’s belief state is described by a state of a quantum system.

We denote a Hilbert space by  $\mathcal{H}$ .

**Assumption 2** An event that has a family of possible outcomes  $\Omega$  is described by a family of positive operators  $E = \{E_i\}_{i \in \Omega}$  on  $\mathcal{H}$  that satisfies  $\sum_{i \in \Omega} E_i = 1$ . (Such a family of positive operators is called a positive-operator-valued measure (POVM).)

<sup>1</sup> $Prob(E \text{ and } F)$  is undefined when  $Prob(E) = Prob(F)$ .

In the above formulation, an operator corresponding to a proposition “A and B” is not specified. To give quantitative predictions, however, this operator needs to be specified. We take an axiomatic approach to identify a suitable operator. Let us denote the operator corresponding to “A and B” by  $\Lambda(A, B)$ . We assume that for a pair of POVMs  $\{A_a\}$  and  $\{B_b\}$ , an operator corresponding to “ $A_a$  and  $B_b$ ” does not depend on  $A_c$ ’s ( $c \neq a$ ) and  $B_d$ ’s ( $d \neq b$ ). That is,  $\Lambda$  is defined as a map  $\Lambda : E_+(\mathcal{H}) \times E_+(\mathcal{H}) \rightarrow E_+(\mathcal{H})$ , where  $E_+(\mathcal{H}) := \{A \mid \mathbf{0} \leq A \leq \mathbf{1}\}$ . It is natural to suppose that this  $\Lambda$  satisfies the following conditions:

- (o.b)  $\Lambda(A, B)$  satisfies  $\mathbf{0} \leq \Lambda(A, B) \leq \mathbf{1}$  for any  $A, B \in E_+(\mathcal{H})$ .
- (i.b) For any POVMs  $\{A_a\}$  and  $\{B_b\}$ , it holds that  $\sum_{a,b} \Lambda(A_a, B_b) = \mathbf{1}$ . (Thus,  $\{\Lambda(A_a, B_b)\}$  becomes a POVM.)
- (ii.b)  $\Lambda(A, A) = A$  for any projection  $A$ .
- (iii.b)  $\Lambda(A, \mathbf{1}) = A$  for any  $A \in E_+(\mathcal{H})$ .
- (iv.b)  $\Lambda(UAU^*, UBU^*) = U\Lambda(A, B)U^*$  for any  $A, B \in E_+(\mathcal{H})$  and any unitary operator  $U$ .

Some comments are helpful to understand each condition. Condition (o.b) is necessary to guarantee that the framework is closed under conjunction and well-defined. Condition (i.b) means that summation of the probabilities “ $A_a$  and  $B_b$ ” for running  $a$  and  $b$  is 1. Condition (ii.b) represents a trivial requirement. A proposition “Linda is a feminist and Linda is a feminist” is equivalent to “Linda is a feminist”. A restriction of  $A$  in condition (ii.b) may seem strange. However, even in a classical system, confirming that a fuzzy query is true does not guarantee that the same query is true. Therefore we impose a weaker condition than the one above.  $\mathbf{1}$  in condition (iii.b) represents a trivial proposition such as “Linda is Linda”. This condition implies that the proposition “Linda is a feminist and Linda is Linda” is equivalent to “Linda is a feminist”. Condition (iv.b) may need a detailed explanation. It means that an operator corresponding to “A and B” should be determined only by the interrelationship between  $A$  and  $B$ . In quantum theory, the relationship between  $A$  and  $B$  is exactly the same as that between  $UAU^*$  and  $UBU^*$  because unitary operation  $U$  can be interpreted as something like a “coordinate transformation”. Thus  $\Lambda(UAU^*, UBU^*)$  should be written as a function of  $\Lambda(A, B)$  and  $U$ . This function  $f(\Lambda(A, B), U) := \Lambda(UAU^*, UBU^*)$  must satisfy  $f(\Lambda(A, B), UV) = f(f(\Lambda(A, B), V), U)$ . Now we have  $f(\Lambda(U^*AU, \mathbf{1}), U) = \Lambda(UU^*AU^*U, \mathbf{1}) = \Lambda(A, \mathbf{1})$ . Using condition (iii.b), we obtain for any  $A$  and  $U$ ,  $f(U^*AU, U) = A$ . Setting  $U^*AU = B$  for an arbitrary  $B$ , we obtain

$$f(B, U) = UBU^*.$$

Thus it holds that  $\Lambda(UAU^*, UBU^*) = f(\Lambda(A, B), U) = U\Lambda(A, B)U^*$ . Note that these conditions are rather weak. For

instance, we do not require “A and B” to be equivalent with “B and A”.

Before showing the existence of a  $\Lambda$  satisfying these requirements, we show a proposition easily derived from them.

**Proposition 1** Suppose  $\Lambda$  satisfies the requirements (o.b) - (iv.b). It holds that for any projections  $P$  and  $Q$  satisfying  $P + Q \leq \mathbf{1}$ ,  $\Lambda(P, Q) = \mathbf{0}$ , and for any  $A$  with  $\mathbf{0} \leq A \leq \mathbf{1}$ ,  $\Lambda(A, \mathbf{0}) = \mathbf{0}$ .

**Proof:** Let us begin with  $\Lambda(P, Q) = \mathbf{0}$  for projections  $P$  and  $Q$  with  $P + Q \leq \mathbf{1}$ . We can define a PVM  $\{A_0, A_1, A_2\} := \{P, Q, \mathbf{1} - P - Q\}$ . Considering  $\sum_{a,b} \Lambda(A_a, A_b) = \mathbf{1}$ , we obtain

$$\begin{aligned} & P + Q + (\mathbf{1} - P - Q) + \Lambda(P, Q) + \Lambda(Q, P) \\ & + \Lambda(P, \mathbf{1} - P - Q) + \Lambda(\mathbf{1} - P - Q, P) \\ & + \Lambda(Q, \mathbf{1} - P - Q) + \Lambda(\mathbf{1} - P - Q, Q) = \mathbf{1}, \end{aligned}$$

where we used Conditions (i.b) and (ii.b). It concludes  $\Lambda(P, Q) = \mathbf{0}$ .

Consider a POVM  $\{A, \mathbf{1} - A\}$  and  $\{\mathbf{1}, \mathbf{0}\}$ . Condition (i.b) and (iii.b) are used to show

$$\begin{aligned} & \Lambda(A, \mathbf{1}) + \Lambda(A', \mathbf{1}) + \Lambda(A, \mathbf{0}) + \Lambda(A', \mathbf{0}) \\ & = A + A' + \Lambda(A, \mathbf{0}) + \Lambda(A', \mathbf{0}) = \mathbf{1}. \end{aligned}$$

It concludes  $\Lambda(A, \mathbf{0}) = \mathbf{0}$ . ■

To illustrate the existence of  $\Lambda$ , let us consider the following example.

**Example 1** Fix  $0 \leq p \leq 1$ . For any  $A, B$  satisfying  $\mathbf{0} \leq A \leq \mathbf{1}$  and  $\mathbf{0} \leq B \leq \mathbf{1}$ , we define  $\Lambda_p(A, B)$  by

$$\Lambda_p(A, B) = pA^{1/2}BA^{1/2} + (1-p)B^{1/2}AB^{1/2}.$$

Using  $\mathbf{0} \leq B \leq \mathbf{1}$ , one can show  $\mathbf{0} \leq A^{1/2}BA^{1/2} \leq \mathbf{1}$ . Thus  $\mathbf{0} \leq \Lambda_p(A, B) \leq \mathbf{1}$  holds and condition (o.b) is satisfied. Let us examine condition (i.b). Consider a pair of POVM  $\{A_a\}$  and  $\{B_b\}$ . We obtain

$$\begin{aligned} & \sum_{a,b} \Lambda_p(A_a, B_b) \\ & = \sum_{a,b} \left( pA_a^{1/2}B_bA_a^{1/2} + (1-p)B_b^{1/2}A_aB_b^{1/2} \right) \\ & = p \sum_a A_a^{1/2} \sum_b B_bA_a^{1/2} + (1-p) \sum_b B_b^{1/2} \sum_a A_aB_b^{1/2} \\ & = p \sum_a A_a + (1-p) \sum_b B_b = \mathbf{1}. \end{aligned}$$

Condition (ii.b) is satisfied because  $P^{1/2}PP^{1/2} = P$  holds for a projection  $P$ . Condition (iii.b) also follows immediately. In addition, it holds that

$$\begin{aligned} & \Lambda_p(UAU^*, UBU^*) \\ & = pUA^{1/2}U^*UBU^*UA^{1/2}U^* \\ & + (1-p)UB^{1/2}U^*UAU^*UB^{1/2}U^* \\ & = U\Lambda_p(A, B)U^*, \end{aligned}$$

where we used  $U^*U = \mathbf{1}$ . Thus condition (iv.b) is satisfied.

Thus we proved the following theorem.

**Theorem 1** *There exists  $\Lambda$  satisfying Conditions (o.b) - (iv.b). (This  $\Lambda$  is not uniquely determined.)*

### Conjunction and Disjunction Fallacies

The remaining task is to show that there exists a  $\Lambda$  that accounts for the conjunction and disjunction fallacies. We take  $\Lambda_{1/2}$  introduced in Example 1.

Let us consider a model described by a two-dimensional Hilbert space  $\mathcal{H} = \mathbb{C}^2$  which has an orthonormalized basis  $e_0$  and  $e_1$ . A pair of PVMs  $A = \{A_0, A_1\}$  and  $B = \{B_0, B_1\}$  are defined as  $A_n = |e_n\rangle\langle e_n|$  and  $B_n = |f_n\rangle\langle f_n|$  for  $n = 0, 1$ , where  $f_0$  and  $f_1$  are defined by

$$\begin{aligned} f_0 &:= \frac{1}{\sqrt{2}}(e_0 + e_1) \\ f_1 &:= \frac{1}{\sqrt{2}}(e_0 - e_1). \end{aligned}$$

Let us consider a pure state described by a vector

$$\Psi := \sqrt{\frac{9}{10}}e_1 - \sqrt{\frac{1}{10}}e_0.$$

The probability for each proposition is calculated as,  $Prob(A_1) = \frac{9}{10}$ ,  $Prob(A_1 \text{ or } B_0) = 1 - Prob(\Lambda_{1/2}(A_0, B_1)) = \frac{31}{40}$ ,  $Prob(A_1 \text{ and } B_0) = Prob(\Lambda_{1/2}(A_1, B_0)) = \frac{11}{40}$ , and  $Prob(B_0) = \frac{1}{5}$ . They satisfy

$$Prob(A_1) > Prob(A_1 \text{ or } B_0) > Prob(A_1 \text{ and } B_0) > Prob(B_0).$$

Thus this example shows both conjunction and disjunction fallacies. Note that conjunction and disjunction fallacies are supported by other choices of  $\Psi$ . It is an important future work to identify the relevant states.

In addition,  $\Lambda_p$  ( $0 < p < 1$ ) given by Example 1 is consistent with an observation of averaging type errors (Fantino, Kulik, & Stolarz-Fantino, 1997). Consider two general propositions  $A$  and  $B$ . Suppose that a state  $\Psi$  satisfies  $Prob(A) = \langle \Psi | A | \Psi \rangle > \langle \Psi | B | \Psi \rangle = Prob(B)$ . Then  $Prob(A) > Prob(A \text{ and } B)$  must follow. In fact, in our model it holds that

$$\begin{aligned} & Prob(A \text{ and } B) \\ &= \langle \Psi | \Lambda_p(A, B) | \Psi \rangle \\ &= p \langle \Psi | A^{1/2} B A^{1/2} | \Psi \rangle + (1-p) \langle \Psi | B^{1/2} A B^{1/2} | \Psi \rangle \\ &\leq p \langle \Psi | A | \Psi \rangle + (1-p) \langle \Psi | B | \Psi \rangle \\ &< \langle \Psi | A | \Psi \rangle = Prob(A). \end{aligned}$$

where we used  $B \leq \mathbf{1}$  and  $A \leq \mathbf{1}$ .

Unpacking effect, in its broad sense, is interpreted as a difference between  $Prob(A \text{ and } B) + Prob(A \text{ and } B')$  and  $Prob(A)$  (Rottenstreich & Tversky, 1997). That is, the law of classical (Kolmogorov) probability,

$$Prob(A \text{ and } B) + Prob(A \text{ and } B') = Prob(A)$$

is violated. We can show that this effect inevitably occurs between noncommutative sharp propositions no matter how we set  $\Lambda$ .

**Theorem 2** *Let  $P$  and  $Q$  be propositions represented by projection operators. If there is no state violating*

$$\begin{aligned} Prob(P \text{ and } Q) + Prob(P \text{ and } Q') &= Prob(P) \\ Prob(P \text{ and } Q) + Prob(P' \text{ and } Q) &= Prob(Q), \end{aligned}$$

*$P$  and  $Q$  commute with each other.*

**Proof:** If the above equations hold for arbitrary states,  $\Lambda$  satisfies

$$\begin{aligned} \Lambda(P, Q) + \Lambda(P, Q') &= \mathbf{1} \\ \Lambda(P, Q) + \Lambda(P', Q) &= \mathbf{1} \end{aligned}$$

and vice versa. These equations mean that PVMs  $\{P, \mathbf{1} - P\}$  and  $\{Q, \mathbf{1} - Q\}$  are jointly measurable. Hence,  $P$  and  $Q$  commute with each other (Miyadera, 2011). ■

Moreover, for general propositions, we have the following theorem.

**Theorem 3** *Let  $A$  and  $B$  be general propositions. If there is no state violating*

$$\begin{aligned} Prob(A \text{ and } B) + Prob(A \text{ and } B') &= Prob(A) \\ Prob(A \text{ and } B) + Prob(A' \text{ and } B) &= Prob(B), \end{aligned}$$

*their intrinsic ambiguities defined by  $V(A) = \|A - A^2\|$  satisfy*

$$V(A)^{1/2} V(B)^{1/2} \geq \frac{1}{2} \|[A, B]\|,$$

*where an operator norm  $\|\cdot\|$  is defined by  $\|A\| := \sup_{\Psi \neq 0} \frac{\|A\Psi\|}{\|\Psi\|}$ .*

This theorem was proved in Miyadera and Imai (2008).

### Discussion

In this paper, we provided an axiomatic formulation of human probability judgment within the general framework of quantum probability theory. A concrete instantiation was found that satisfies the axioms while accounting for the conjunctive/disjunctive fallacies, averaging type errors, and unpacking effects. We note, though, that QJM accounts for other effects that we have not yet addressed, e.g., *order effect*.

Here, we comment on some differences between our approach and QJM. In contrast to Busemeyer's model, our POVM formalism does not require computing  $Pr(A)$  (nor  $Pr(B)$ ) to obtain  $Pr(A \text{ and } B)$  because  $\Lambda(A, B)$  does not depend on a state. Also, in Busemeyer's formalism an exhaustive set of conjunctions may not sum to 1 (see Appendix B), whereas in our formalism the summation of probabilities is set to 1 (see Axiom (i.b)). Finally, our formulation can be naturally generalized to use mixed states. Further work is needed to explore the implications of these differences.

Proponents of QPT-based approaches divorce themselves from a commitment to the brain as a quantum device (Busemeyer et al., 2011). As a *descriptive* theory of human

judgment, one need not be committed to a quantum mechanical implementation. However, if a *causal* theory is sought—ultimately so for a science of cognition, then a theory based on QPT must be reconciled against the (lack of) evidence showing that the brain is indeed a quantum device (but, see Hameroff, 2002). An alternative to this predicament is to seek yet a further generalization of the quantum framework, which does not depend on quantum mechanics. *General operational probability* theory (Dvurecenskij & Pulmannova, 2000) and *category theory* (MacLane, 2000) are two possibilities for future investigation.

**Acknowledgments:** We would like to thank anonymous reviewers for valuable comments.

## Appendix

### Appendix A: Quantum Probability theory

A *quantum system* is described by a *Hilbert space*  $\mathcal{H}$ , which is a vector space (which we assume to be finite dimensional, i.e.,  $\dim \mathcal{H} < \infty$ ) over the complex field  $\mathbf{C}$  that is equipped with an *inner product*. The inner product  $\langle \cdot | \cdot \rangle$  defines a map  $\mathcal{H} \times \mathcal{H} \rightarrow \mathbf{C}$  satisfying: (i)  $\langle \phi | c_1 \psi_1 + c_2 \psi_2 \rangle = c_1 \langle \phi | \psi_1 \rangle + c_2 \langle \phi | \psi_2 \rangle$  for all  $c_1, c_2 \in \mathbf{C}$  and  $\phi, \psi_1, \psi_2 \in \mathcal{H}$ ; (ii)  $\langle \phi | \psi \rangle = \langle \psi | \phi \rangle^*$  for all  $\phi, \psi \in \mathcal{H}$ ; and (iii)  $\langle \phi | \phi \rangle \geq 0$ , and  $\langle \phi | \phi \rangle = 0 \Leftrightarrow \phi = 0$ . A family of vectors  $\{e_i\}_{i=1}^{\dim \mathcal{H}}$  is called an *orthonormalized basis* of  $\mathcal{H}$ , if it satisfies  $\langle e_i | e_j \rangle = 0$  for  $i \neq j$  and  $\langle e_i | e_i \rangle = 1$  for all  $i$ . A linear map  $A : \mathcal{H} \rightarrow \mathcal{H}$  is called an *operator*. Every operator  $A$  is associated with a unique operator  $A^*$  satisfying  $\langle A^* \psi | \phi \rangle = \langle \psi | A \phi \rangle$  (Riesz theorem);  $A^*$  is called a *conjugate operator* of  $A$ . An operator  $U$  satisfying  $UU^* = U^*U = \mathbf{1}$  is called a *unitary operator*. An operator  $A$  satisfying  $A = A^*$  is called a *self-adjoint operator*. A self-adjoint operator  $P$  satisfying  $P = P^* = P^2$  is called a *projection operator*. A self-adjoint operator  $A$  satisfying  $\langle \psi | A \psi \rangle \geq 0$  for all  $\psi \in \mathcal{H}$  is called a *positive operator*, written as  $A \geq \mathbf{0}$ , where  $\mathbf{0}$  denotes a null operator. Every projection operator is a positive operator. For a positive operator  $A$ ,  $A^{1/2}$  is defined as a unique positive operator satisfying  $A^{1/2} A^{1/2} = A$ .

State and observable are central notions in any physical theory. In quantum theory, a state is represented by a self-adjoint operator  $\rho$ , called a *density operator*, satisfying: (i)  $\rho \geq \mathbf{0}$ ; and (ii)  $\text{tr}(\rho) = \sum_i \langle e_i | \rho e_i \rangle = 1$  for any orthonormal basis— $\text{tr}$  is called *trace*. The set of all states is *convex*: i.e., any combination of two states  $p\rho + (1-p)\sigma$  (for  $0 \leq p \leq 1$  and states  $\rho, \sigma$ ) is also a state. A state  $\rho$  that does not have a nontrivial decomposition is called a *pure state*. A pure state is represented by a projection operator whose *rank* is 1, i.e., there exists a unit vector  $\psi$  ( $\|\psi\| = 1$ ) satisfying  $P\phi = \psi \langle \psi | \phi \rangle$ . ( $P$  is also written  $|\psi\rangle\langle\psi|$ .) This correspondence allows one to identify a unit vector with a pure state. A state that is not pure is called *mixed*.

An observable which takes a value in a set  $\Omega$  (assumed to be discrete set in this paper) is described by a family of positive operators  $\{A_a\}_{a \in \Omega}$  satisfying  $\sum_{a \in \Omega} A_a = \mathbf{1}$ . This is called a *positive-operator-valued measure* (POVM). The

probability of an outcome  $a \in \Omega$  in a state  $\rho$  is given by  $\text{Prob}(A_a) = \text{tr}(\rho A_a)$ . A POVM  $\{A_a\}$  is called a *projection-valued measure* (PVM) if  $A_a$  is a projection operator for each  $a$ . PVMs are often treated as more fundamental objects because each POVM can be represented as a PVM in an enlarged space (Naimark extension theorem). In fact, the space of projection operators can be regarded as a generalization of the Boolean algebra.

### Appendix B: Summation of the probabilities may not agree with one in Busemeyer et al. (2011).

Suppose that  $E$  and  $F$  (and their negations  $E' = \mathbf{1} - E$  and  $F' = \mathbf{1} - F$ ) satisfy for a state  $\psi$ ,  $\langle \psi | F \psi \rangle > \langle \psi | E \psi \rangle > \langle \psi | E' \psi \rangle > \langle \psi | F' \psi \rangle$ . Then we obtain  $\text{Prob}(E \text{ and } F) = \langle \psi | FEF \psi \rangle$ ,  $\text{Prob}(E' \text{ and } F) = \langle \psi | FE'F \psi \rangle$ ,  $\text{Prob}(E \text{ and } F') = \langle \psi | EF'E \psi \rangle$ ,  $\text{Prob}(E' \text{ and } F') = \langle \psi | E'F'E' \psi \rangle$ . Their summation may not agree with 1. In fact, let us consider  $\mathcal{H} = \mathbf{C}^2$  with an orthonormalized bases  $\{e_0, e_1\}$  and projection operators  $E$  and  $F$  defined by  $E = |e_1\rangle\langle e_1|$  and  $F = |f_0\rangle\langle f_0|$ , where  $f_0$  is defined by  $f_0 := \sqrt{\frac{1}{2}}e_1 + \sqrt{\frac{1}{2}}e_0$ . It can be shown that a state  $\psi = \sqrt{\frac{1}{4}}e_1 - \sqrt{\frac{3}{4}}e_0$  satisfies the above inequality, giving

$$\begin{aligned} & \langle \psi | FEF \psi \rangle + \langle \psi | FE'F \psi \rangle + \langle \psi | EF'E \psi \rangle + \langle \psi | E'F'E' \psi \rangle \\ &= 1 + \frac{\sqrt{3}}{4}. \end{aligned}$$

## Abstract

Task switching is a well-known cognitive paradigm to explore task-set reconfiguration processes such as rule shifting. In particular, endogenous task switching is thought to differ qualitatively from stimulus-triggered exogenous task switching. However, no previous study has examined the neural substrate of endogenous task switching. The purpose of the present study is to explore the differences between event-related potential responses to exogenous and endogenous rule switching at cue stimulus. We modified two patterns of cued switching tasks: exogenous (bottom-up) rule switching and endogenous (top-down) rule switching. In each task cue stimulus was configured in order to induce switching or maintaining rule. In Exogenous switching tasks, late positive deflection was larger in the switch rule condition than in the maintain rule condition. However, in endogenous switching tasks late positive deflection was unexpectedly larger in the maintain rule condition than in the switch rule condition. These results indicate that exogenous rule switching is explicit stimulus-driven processes whereas endogenous rule switching is implicitly parallel processes independent of external stimulus.

**Keywords:** Switching task; Event related potentials; rule shifting

## Introduction

Executive function is thought to be one of most important cognitive functions, and it is conceptualized as having four components: volition, planning, purposive action, and effective performance (Lezak, 1995). There are several neuropsychological tests that assess executive function, such as the Wisconsin Card Sorting Test (WCST), the Trail Making Test, and the Tower of London task. In WCST, the subject suppresses a no-longer-relevant task-set and replaces it with an appropriate new task-set; this process is called set shifting (Anderson, Damasio, Jones, & Tranel, 1991; Gold, Carpenter, Randolph, Goldberg, & Weinberger, 1997; Goldberg & Weinberger, 1994; Milner, 1963).

The task switching paradigm is a well-known and sophisticated paradigm that engages these cognitive processes and requires predictable or random alternation between two response selection tasks (Jersild, 1927; Rogers & Monsell, 1995). For example, participants have previously been instructed to switch between a letter classification task

(Task A) and a digit classification task (Task B) in a predictable sequence (e.g., AABB) or in a random sequence. Many studies using the task switching paradigm have observed that reaction time (RT) was reliably greater in switching trials than in maintain trials (no-switching trials) (Rogers & Monsell, 1995). Switch cost is estimated by subtracting the RTs in trials requiring no switch from those in trials requiring a switch; switch cost is thought to be an index of the extra difficulty associated with reconfiguring the active task-set.

Previous Event-related potential (ERP) and fMRI studies have identified the neural substrates of task switching processes. Some previous studies have implicated the lateral prefrontal cortex and the parietal cortex as being centrally involved in preparatory processing during task switching (Johnston, Levin, Koval, & Everling, 2007; Kamigaki, Fukushima, & Miyashita, 2009; Rowe J, 2008; Ruge, 2007). Savine and Braver (Adam C. Savine, 2010) reported that using incentives to modulate cognitive control specifically enhanced task-cue-related activation of the left dorsolateral prefrontal cortex. In an ERP study, Karayanidis et al. (Karayanidis, Coltheart, Michie, & Murphy, 2003) indicated that switch-related positivity and switch-related negativity were elicited by a target stimulus in switching trials. These ERP data reflected that switch-related positivity was unaffected by irrelevant task-cueing, whereas the amplitude and latency of switch-related negativity were modulated by the response-stimulus interval.

Many studies have used task switching, in which stimulus-triggered, bottom-up processes to shift between rules operate via external stimuli such as contextual stimuli, but few studies have focused directly on endogenous, voluntary rule shifting. Rogers and Monsell (Rogers & Monsell, 1995) used an endogenous task switching paradigm that required task-set alternation between trials; this paradigm places high demands on working memory. Participants were told to switch between “Task A” and “Task B” in a predictable sequence (AABB). Target stimuli were presented in one of four boxes continuously displayed on a computer screen, and stimulus position was rotated in a clockwise direction. Thus, on a given trial, the active task was cued by the position of the displayed stimulus. This paradigm seems to require a certain form of endogenous rule switching, because participants change tasks in a predictable sequence.

We believed that cognitive control of endogenous rule shifting is more difficult than control of exogenous rule shifting. For example, perseveration, which is a contextually inappropriate and unintentional repetition of response, is attributed to defective set shifting caused by frontal lobe lesion or cognitive dysfunction, and is often observed in patients with psychiatric disorders. Thus, people who display perseveration find it more difficult to move on from one idea to the next voluntarily than to follow instructions from others. It is likely that the neural substrates characterizing exogenous and endogenous rule shifting are different from one another.

No previous study has examined the neural substrate of endogenous rule shifting using tasks such as those reported by Rogers and Monsell. Their above-mentioned paradigm is simple, but the time point when participants switch rule voluntarily is unclear. Because contextual stimuli (four small squares occupying quadrants of the screen) are displayed continuously in their task and then there is no explicit cue which requires participants to switch rule endogenously. Therefore it seems to be difficult to measure neural responses to endogenous rule switching. It is worthwhile to examine differences in the neural activity elicited by exogenous and endogenous rule shifting in detail. We modified an existing cued switching task and configured the cue stimuli to induce two patterns of rule switching: exogenous (bottom-up) rule switching and endogenous (top-down) rule switching. Furthermore, we compared the neural responses elicited by exogenous rule shifting to those elicited by endogenous rule shifting using ERPs.

## Materials and methods

### Participants

Twelve right-handed student volunteers (12 male, aged 20–34 years, mean age 24.8 years) served as participants. All participants had normal or corrected-to-normal vision. None had a history of neurological or psychiatric disorders. All participants gave written informed consent, and the study was approved by the local research ethics committee.

### Procedure

We made novel cued switching tasks and configured cue stimuli in order to induce two patterns of rule switching: exogenous (bottom-up) rule shifting and endogenous (top-down) rule shifting. In practice trials, the participant learned to perform a two-choice response task accurately according to each of two response rules (see Figure 1). The first was an even vs. odd number classification rule, in which the participant was required to press a button with the left hand in response to an odd number or to press a button with the right hand in response to an even number. The second rule was a small vs. large number classification rule, in which the participant was required to press a button with the left hand in response to a number below five or to press a button with the right hand in response to a number above five. Figure 2 shows a schematic diagram of the cued switching task in

present study. In each trial, a cue stimulus was presented for 1000 ms and was followed by a target stimulus. The target stimulus remained on the screen until the participant pressed one of the two buttons. In the exogenous rule switching task, a white cue stimulus indicated that the subject should maintain the same rule as the previous trial; the white cue stimulus was presented in two or three consecutive trials, and then its color changed to red, indicating that the subject should switch to the other response rule. In the endogenous rule switching task, the cue stimulus was always white, and the participant was instructed to switch the response rule voluntarily every other trial, maintaining each response rule for two consecutive trials. Infrequently, an instruction stimulus showing another rule was presented instead of the cue stimulus; the instruction stimulus dictated that the participant had to switch the response rule immediately. This manipulation requires the participant to attend to the cue stimulus in every trial. If the participant sees the cue stimulus after two consecutive trials during which the same response rule was used, this means that the participant should switch to the other response rule endogenously. We thought that this procedure enables to measure neural response to endogenous rule switching effectively.

### EEG recording and analysis

An electroencephalogram (EEG) (bandpass 0.16–30 Hz, digitized at 500 Hz) was recorded from 55 electrodes according to the international 10–10 system. Ag/AgCl electrodes were used, and impedance was kept below 10 kΩ. All electrodes were referenced to linked earlobes. An electrooculogram (EOG) was recorded from electrodes lateral to and below the left eye. The signals were digitized for an epoch of 800 ms starting 200 ms prior to the presentation of the cue and target stimulus respectively. During the present study, we recorded large volumes of ERP data, but we conducted a conventional ERP analysis using only a small number of channels and achieved satisfactory findings. We measured the mean amplitude of the ERP’s late positive component (LPC) over 250–300 ms to cue stimulus and LPC over 400–700 ms to target stimulus. A three-way repeated measures ANOVA with Greenhouse-Geisser correction was performed to compare mean LPC amplitudes on the basis of cue modality factor (exogenous vs. endogenous), response rule switching factor (maintain vs. switch), and electrode site factor (Fz, Cz and Pz).

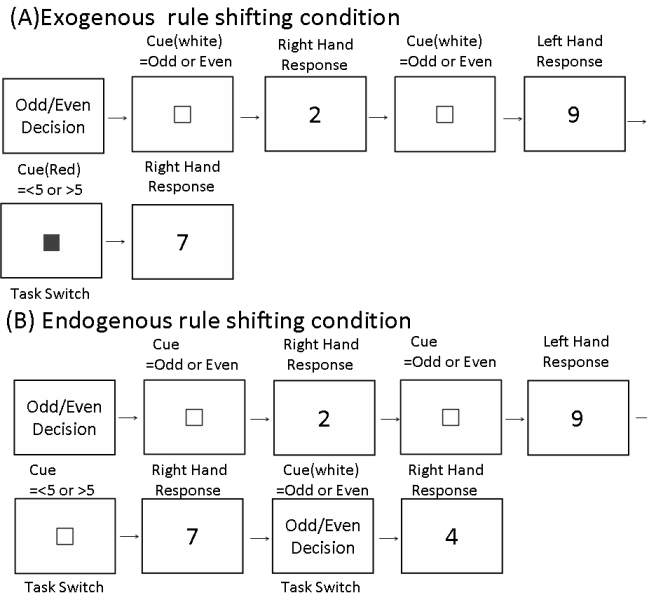

Fig. 2: Schematic diagram of cued switching task

## Result

### Behavioral data

We measured mean reaction times (RTs) and calculated switching costs (RT during trials in which the response rule switches minus RT during trials in which the response rule is maintained) for all conditions (see Figure 3). For RT data, the ANOVA revealed only one significant main effect, which was of switching,  $F(1, 11) = 35.25, p < .001$ . RTs in trials when the response rule was switched were significantly larger than RTs in trials when the response rule was maintained. A t-test on the switching cost results revealed no significant differences between the exogenous and endogenous switching conditions,  $T(11) = -0.76, p = .46$ .

Fig. 3: Behavioral data

### ERPs data

Figure 4 shows the grand-averaged ERP waveforms elicited by the cue stimuli in our study. Figure 5 shows mean LPC amplitude by the cue stimuli at Pz. For the late positive component (LPC) mean amplitude data, the ANOVA revealed only one significant main effect, which was of electrode site factor,  $F(2, 11) = 5.43, p < .05$ . In addition, there was a significant interaction between cue modality factor and switching factor,  $F(1, 11) = 20.31, p < .01$ . LPC deflection in the exogenous task was larger in the switch condition than in the maintain condition, but this pattern was inverted in endogenous task; LPC amplitude in the endogenous task was larger in the maintain condition than in the switch condition.

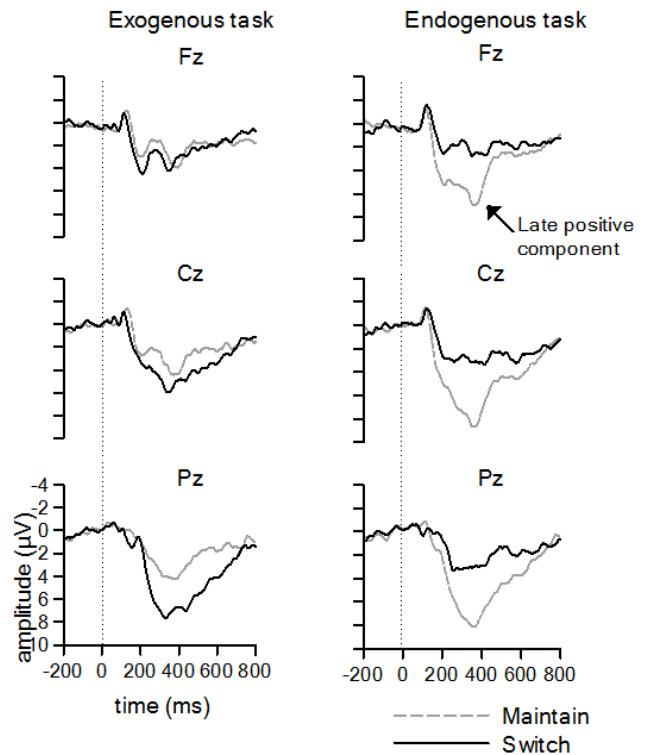

Fig. 4: Grand-averaged ERP waveforms in cue stimuli

Fig. 5: Mean LPC amplitude in the cue stimuli at Pz

Figure 6 shows the grand-averaged ERP waveforms elicited by the target stimuli in our study. Figure 7 shows mean LPC amplitude by the target stimuli at Pz. For the late positive component (LPC) mean amplitude data, the ANOVA revealed significant main effect in electrode site factor,  $F(2, 11) = 14.90, p < .001$  and response rule switching factor  $F(2, 11) = 11.43, p < .006$ . In addition, there was a significant interaction between cue modality factor and switching factor  $F(1, 11) = 25.82, p < .001$ . In the target stimuli, LPC deflection in the endogenous task was larger in the maintain condition than in the switch condition but there was no significant difference in the exogenous task.

## Discussion

The purpose of the present study is to explore the differences between ERP responses to exogenous and endogenous rule switching at cue stimulus onset. This study elucidated interesting ERP waveform changes elicited by the cue stimuli in various conditions. First we discuss the LPC amplitude at the cue stimuli. In the exogenous switching task, late positive component (LPC) amplitude was larger in the switching condition than in the maintaining condition, and thus, the ERP waveform pattern results ran parallel to the reaction time (RT) results. It is possible that changing the cue stimulus drives rule representation retrieval and working memory updates, and thus contributes to increases in positive deflection. Larger ERP deflection elicited by changing the cue stimulus is associated with the lengthening of RT upon presentation of the target stimulus. Surprisingly, the pattern of ERP deflection observed in endogenous task was reversed in the exogenous switching task. LPC amplitude was larger in the maintaining condition than in the switching condition when the switching criteria were endogenous, and this pattern contrasted with RT results.

This disparate pattern of ERP waveforms in the cue stimuli between the endogenous and exogenous tasks from the standpoints of reaction time (RT) measurements and task structure. We hypothesized that changing the cue stimulus in the endogenous switching task triggers voluntary top-down processing for response rule switching (such as memory retrieval and working memory updates) and therefore elicits a larger neural response, reflected by late positive component (LPC) amplitude. Contrary to our hypothesis, the results reflected a reduction of LPC amplitude in the response rule switching condition. Since the response rule was changed every two trials in the endogenous task, preparatory or anticipatory processes for rule switching might operate before the onset of the switching cue. In the present study's endogenous task, we occasionally presented instruction stimuli instead of cue stimuli, forcing participants to switch response rule at an unexpected time. Because of the inclusion of the instruction stimulus, participants could not switch the response rule thoughtlessly after two trials using the same response rule; participants still needed to identify the presentation of the switching cue stimulus carefully. We think that reduction of LPC amplitude in the switching condition indicates that the substance of the endogenous rule shifting process finishes before cue stimulus onset, and the cue stimulus is no more than a confirmation of the already-prepared new response rule. In addition, an increase in LPC amplitude during the ensuing maintaining trial might indicate the operation of proactive partial switching processes that anticipate the next trial. Since the maintaining condition is the last trial during which the participant uses an old response rule, the cue stimulus in maintain trials represents both the preservation of the current rule representation and its subsequent extinction. Because participants likely exercise considerable cognitive efficiency, processes of endogenous rule switching most likely take place at the earliest possible time. Therefore, the cue

stimulus in maintaining trials might cause the allocation of large attentional resources to subsequent rule switching and thus elicit large positive deflections in ERP. The switching cue stimulus presented during the following trial might only confirm an already-updated response rule and thus demand fewer resources, causing a smaller positive deflection. In the exogenous switching task, participants need to evaluate the content of the cue stimulus in every trial, and thus, preparatory or anticipatory rule shifting processes might not operate before the switch trials begin.

Secondly we discuss the LPC amplitude at the target stimuli. In the endogenous switching task, the late positive component (LPC) amplitude was larger in the maintain condition than in the switching condition, and this pattern contrasted with reaction time (RT). However in the exogenous switching task, there was no significant difference between the switching condition and maintaining condition (Fig.7). This result indicated discrepant pattern similar to ERPs of cue stimulus. It is likely that additional cognitive processes operates at target stimulus in maintain condition in endogenous task. In maintain condition, RT was smaller than in switch condition and thus additional process reflected by larger LPC might not be associated with reaction processes to target stimulus. We thought that this process is similar to results of cue triggered ERPs in endogenous task and associated with operation of proactive partial switching processes that anticipate the next trial.

Contrary to ERP results, switch cost, which is the difference in reaction time (RT) between switching and maintaining conditions, showed no significant differences between exogenous and endogenous switching tasks. A previous study conducted by Rogers and Monsell indicated that switch cost varies according to the response-stimulus interval (Rogers & Monsell, 1995), which corresponds to the cue-target interval in the present study. Although variation of switch cost is thought to be associated with processes of task-set reconfiguration (Karayanidis, et al., 2003), this is inconsistent with ERP results in present study. In endogenous task late positive component deflection elicited by switching cue stimulus was reduced but RT was larger than in maintain trial. Some previous studies indicate that switch cost reflects not only task-set reconfiguration before target response but also certain proactive interference (e.g., Karayanidis, et al., 2003). In present study the representation of the new response rule determined by the cue stimulus in both tasks might not be fixed perfectly in the participant's mind at the time of target stimulus onset. In addition participants' lack of experience in applying a new response rule just after applying an old response rule might contribute to this lengthening of RT.

## Conclusion

The ERP results suggest that participants' rule switching strategies vary implicitly according to task structure. To the best of our knowledge, no study has compared bottom-up and top-down task switching processes directly. We used a novel cued switching task to find differences between

neurophysiological responses during exogenous and endogenous rule shifting processes. We can say that exogenous rule switching is explicit stimulus-driven processes whereas endogenous rule switching is implicitly parallel processes independent of external stimulus.

## Acknowledgments

We obtain the knowledge of the difference of neural response between exogenous and endogenous rule shifting. We are grateful to our participants and would like to acknowledge the reviewers of this manuscript.

## Abstract

This study investigated correlations between understanding of hidden emotion and theory of mind. Five- and six-year-old children ( $N = 105$ , 48 boys and 57 girls) took hidden emotion tasks (TEC component 7), first- and second-order false belief tasks, and a vocabulary test. Teachers rated the children's social interactions in terms of peer relationships. Individual differences in children's understanding of first- and second-order false belief and understanding of hidden negative emotion were associated with differences in language ability. Individual differences in understanding of first-order false belief and understanding of hidden negative emotion were correlated, and this association remained after controlling age and language ability. The results also showed that children who were more advanced in understanding of first-order false belief are more likely to have fewer peer problems. These findings were discussed in terms of social and cognitive development.

**Keywords:** young children; hidden emotion; theory of mind; peer relationship.

## Introduction

Over the past 30 years, researchers have demonstrated that children's ability to understand mental states (desires, thoughts, belief, and emotions) develops throughout their childhood (Astington, Harris, & Olson, 1988; Pons, Harris, & de Rosnay, 2004). One such ability, theory of mind, which is narrowly defined as the understanding of other's mind, such as false belief, dramatically develops between the ages of 3 and 6 (see Wellman, Cross, & Watson, 2001), while there exist some cultural differences. For example, several studies have shown that Japanese children lag significantly behind American and British children on false belief tasks (Hughes, Ensor, Allen, Devine, De Rosnay, Koyasu, Mizokawa, & Lecce, 2011; Lewis, Koyasu, Oh, Ogawa, Short, & Huang, 2009; Naito & Koyama, 2006). Another important element of social competence, understanding of hidden emotion (Saarni, 1979, 1999), also emerges during the preschool period, between the ages of 4 and 6 (Gross & Harris, 1988; Harris, Donnelly, Guz, & Pitt-Watson, 1986). It has been found that there are no differences in age in regards to understanding of hidden emotion between American, British, and Japanese children (Gardner, Harris, Ohmoto & Hamazaki, 1988).

Children's theory of mind ability is traditionally measured by their performance in false belief tasks. The first-order false belief task measures children's ability to

attribute a first-order false belief to a story character (e.g., a mistaken belief about an object's identity or location). Most children pass the first-order false belief task by the ages 6 (Perner, 1991; Wimmer & Perner, 1983). They then pass the second-order false belief task between the ages of 6 and 9 (Perner & Wimmer, 1985). The second-order false belief task measures children's ability to attribute a second-order false belief (i.e. a mistaken belief about a belief) to a story character. Recently, a less demanding second-order false belief task has been created, making it easier to understand for young children (cf. Sullivan, Zaitchik, & Tager-Flusberg, 1994).

To measure children's understanding of emotion, including hidden emotion, Test of Emotion Comprehension (TEC; Pons & Harris, 2000) has been widely used for over the past 10 years. The TEC is an extensive measure of emotion comprehension, which evaluates nine components of emotion understanding. Component 7 assesses whether children understand that one can hide an underlying, or true, emotional state. Pons et al. (2004) found that 50% of 5-year-olds and 65% of 7-year-olds were able to distinguish expressed emotion from actual, felt (hidden) emotion, while only 5% of the 3-year-olds were able to understand the hidden emotion. The hidden emotion tasks include both hidden negative emotion tasks, where the protagonist is motivated to hide inner negative emotion, and hidden positive emotion tasks, where the protagonist is motivated to hide inner positive emotion. To distinguish between expressed apparent emotion and hidden inner emotion, it is necessary to identify the actual emotion and to keep it distinct from the apparent emotion. This ability is also required in false belief tasks. For example, in the unexpected displacement task, which is one of the most popular false belief tasks, participants have to retain the original placement of an object in their mind as well as its present location. In this light, the cognitive ability to understand incongruence between apparent and hidden emotion may relate to the understanding of others' false belief that is not based on reality.

Banerjee and Yuill (1999) addressed 4- to 6-year-old children's understanding of false emotion (hidden negative emotion: hiding inner negative emotion and expressing apparent happiness or neutral emotion) with self-presentational and prosocial motivation, and its association with second-order mental state understanding. They found that only an appreciation of self-presentational false

emotional expression was associated with children's performance on the second-order false belief task. Mizokawa and Koyasu (2007) revealed the association between 4- to 6-year-olds' understanding of pretend crying (hidden positive emotion: hiding inner positive emotion and expressing apparent sadness) and performance of both first- and second-order false belief tasks. These associations between understanding of hidden emotion and development of theory of mind stem from the nature of emotion hiding, which includes the potential that the person who looked at the false emotional expressions would be deceived and adopt a false belief.

As noted above, TEC component 7 assesses children's understanding of the fact that one can hide an inner emotional state. Although this component has been used as a unific index of understanding of hidden emotion, it seems that the tasks in component 7 include some different aspects of mental state understanding. One salient feature is that this component is made up of two hidden positive and two negative emotion stories. Note that there are some findings demonstrating that the expressers' motivation to hide emotion affects children's performance in understanding of hidden emotion (cf. Banerjee & Yuill, 1999; Mizokawa, 2007). However, the protagonist's motivation to hide inner emotion is not clearly specified in each task of TEC component 7.

Previous research suggests that understanding hidden positive emotion (i.e. revealing negative or neutral emotion when one actually has positive emotion) is more difficult for children than understanding hidden negative emotion (i.e. revealing positive or neutral emotion when one actually has negative emotion) (Mizokawa, 2007). That may be because, in some social situations such as receiving unwanted gifts (Saarni, 1979), parents want and instruct their children to mask their negative emotion and express positive emotion to protect another's (i.e. the sender's) feelings. Thus, hiding negative emotion would be internalized through such socialization processes in their early life. Meanwhile, children are rarely "taught" in society to hide their positive emotion as not to hurt others feelings (e.g., it is not appropriate to celebrate too much when one wins a game and another loses the game). Moreover, the expression of positive emotion is likely to be considered as generally "good" and "desirable" in the sense of strengthening social bonds. Children are rarely asked to inhibit or hide positive emotion except in special social situations, such as funerals. So, it may be relatively difficult for children to guess or infer the motivation for hiding positive emotion because they do not have much experience in hiding positive emotion by themselves or being taught to hide positive emotion. From this perspective, children understand hidden negative emotion (i.e. the discrepancy between hidden negative emotion and expressed positive or neutral emotion) somewhat automatically, that is, they can understand that people hide negative emotion without consciously thinking about the effect that others' emotional expressions have on recipients' mental states, what the recipient of the apparent

emotional expression feel, or whether the recipient has a false belief about expresser's actual emotion after witnessing the apparent emotion. They simply need to identify the inner emotion and to keep it distinct from the apparent expressed emotion. After witnessing hidden positive emotion, on the other hand, they might need to think more deeply and make guesses about what is going on in the expresser's and the recipient's mind. We expected that there would be different associations between understanding of hidden emotion and development of theory of mind according to positive-negative valence of emotion. To address these issues, we tested links between young children's understanding of false belief, and hidden positive and negative emotion individually.

In the present study, we also explored the relationship between mental state understanding (first- and second-order false belief and hidden emotion) and peer relations. It has been shown that the development of theory of mind is central to successful social interactions. Some studies have shown that the development of theory of mind is related to important aspects of children's social interactions (cf. Astington & Jenkins, 1995; Dunn & Cutting, 1999; Walker, 2005). As for emotion understanding, it has been revealed that children with greater emotion knowledge demonstrate more empathic and prosocial behaviors and popularity with peers (cf. Cassidy, Parke, Butkovsky, & Braungart, 1992; Denham, 1986; Garner, 1996; Walden & Field, 1990). However, there is little research addressing the link between understanding of hidden emotion and social interaction. We tested the association of individual measures of mental state understanding (first- and second-order false beliefs, hidden positive emotion, and hidden negative emotion) to peer problems. We hypothesized that children's theory of mind and their ability to understand hidden positive emotion would be negatively related to peer problems.

Overall, in the present study, we tested the difference between children's understanding of hidden positive emotion and understanding of hidden negative emotion, the association between hidden emotion and first- and second-order false belief understanding, and association between these mental state understandings and rated peer problems.

## Method

### Participants

One hundred and five Japanese children (48 boys and 57 girls, mean age = 6:1) and twelve teachers (11 women and one man) participated in this study. All were native Japanese speakers.

### Materials and Procedures

Tasks for children were administered individually by the experimenter (the first author) at their school in a quiet room. These children were also examined in a cross-cultural study by Hughes et al. (2011). The children's homeroom teachers rated each child's social interactions in terms of

peer relationships. The order of study tasks for children was counterbalanced across the participants.

**PVT-R** The children's language ability was assessed using PVT-R (Ueno et al., 2008), which requires them to select the picture named by the experimenter from an array of four pictures.

**False belief tasks** The children's understanding of first- and second-order false belief was assessed via four stories (cf. Hughes, Adlam, Happe, Jackson, Taylor, & Caspi, 2000). These included two first-order false belief tasks (Harris, Johnson, Hutton, Andrews, & Cooke, 1989), and two second-order false belief tasks (Sullivan et al., 1994).

In the first-order false belief tasks, participants were shown puppet-based stories that involved a nice surprise story and a nasty surprise story, and were required to answer the protagonist's first-order false belief question, a reality question, and control questions.

Following is an example of a story and questions used in the first-order false belief task (a nice surprise story): *I'm going to tell you a little story about Monty and his lunch box. Look, here's Monty. He wants Freddie to put an apple in his lunch box to take to school. But Freddie says there are no apples left, so he'll have to take a pear instead. Monty doesn't like pears at all. He really wanted an apple! He's so cross about the pear that he stamps all the way upstairs. [Q1 (control 1): How does Monty feel when he gets a pear? Does he feel happy or not happy?] [Q2 (control 2): How does Monty feel when he gets an apple? Does he feel happy or not happy?] But look, while Monty is out of the kitchen, Freddie finds one apple left in the cupboard. He decides to give Monty a nice surprise, and so takes out the pear, and puts an apple in Monty's lunchbox instead. Then he puts the lunchbox in Monty's bag. Monty comes back, picks up the bag and hurries off to school. So Monty doesn't see what's inside his lunchbox. Now it's lunchtime. Monty takes out his lunchbox. [Q3 (first-order false belief): What does Monty think is in the box, an apple or a pear?] [Q4 (reality): What is in the box really, an apple or a pear?]*

In the second-order false belief tasks, participants were shown picture-based stories and asked to answer first- and second-order false belief questions, a reality question, and memory control questions.

Following is an example of a story and questions used in the second-order false belief task: *This is Peter. Today is his birthday, and Peter's Mum is going to surprise him by giving him a puppy. She has hidden the puppy in the shed until it's time for Peter's birthday party. Peter says "I really hope you've got me a puppy for my birthday, Mum." But remember, Mum wants to surprise Peter. So instead of telling Peter she has got him a puppy, Mum says, "Sorry, I didn't get you a puppy, Peter. Actually, I've got you a really good toy for your birthday."* [Q1 (first-order false belief): *So, what did Peter think he was getting for his birthday?*] [Q2 (reality): *What was his Mum giving him really? (If child passes both Q1 and Q2, continue story. If child fails, stop story here.)* Now Peter decides to go outside to play.

*On his way out, he goes into the shed to get his bike, and he finds the birthday puppy! Peter says to himself, "Wow! Mum didn't get me a toy, she really got me a puppy for my birthday!" Mum didn't see Peter go to the shed, so she doesn't know he found the birthday puppy. Inside, the telephone rings. It's Peter's Granny, calling to find out what time the party is. Granny says to Mum, "What does Peter think you've got him for his birthday?" [Q3 (second-order false belief): What does Mum say to Granny?] [Q4 (memory control): Did Mum see Peter go into the shed?] [Q5 (memory control): What has Mum really got Peter for his birthday?]*

For the two first-order false belief tasks, the children's responses were judged as correct when they answered all the four questions correctly (a first-order false belief question, a reality question, and two control questions). Each of the two second-order false belief tasks included first- and second-order false belief questions, a reality question, and memory control questions. When children passed both a first-order false belief and a reality question, they got 1 point for first-order false belief understanding. When they passed a second-order false belief question and memory questions, they got 1 point for second-order false belief understanding. These tasks yielded two scores: the children's understanding of first-order false belief was indexed by summing the scores across the four tasks (scores ranged from 0 to 4), and their understanding of second-order false belief was indexed by summing the two tasks (scores ranged from 0 to 2).

**Hidden emotion tasks** The children's comprehension of hidden emotion was assessed by means of the TEC (Pons & Harris, 2000), component 7 (Hiding). The children were read four picture-based stories and asked to attribute an emotion to a character, who was motivated to hide his or her real emotion from another child and express a different emotion. These four stories were made up of two hidden positive emotion stories (hide inner positive emotion and express sad or neutral emotion) and two hidden negative emotion stories (hide inner negative emotion and express happy emotion). In the hidden positive emotion scenario, the story character gets a new bicycle, but he tries to hide how he feels inside in front of his friend, who does not have his own bicycle (positive 1), and the story character wins a game but she tries to hide how she feels inside in front of her friend who loses the game (positive 2). In the hidden negative emotion stories, the story character falls over in front of his friend, and he tries to hide how he feels inside (negative 1), and the story character is teased by her friend and tries to hide how she feels inside (negative 2). In TEC component 7, the children were asked to attribute an emotion to characters in each of the four stories. They were given 1 point if they attributed the appropriate emotion to each story character (ranging from 0-2).

**SDQ-Peer Problems subscale** Teachers completed a shortened version (in Japanese) of the Strengths and Difficulties Questionnaire (Goodman, 1997) that contained five items. For each item, they rated children's social

interactions using the 3-point Likert scale (not true, somewhat true, or certainly true). The five items were: (1) Rather solitary, tends to play alone; (2) Has at least one good friend; (3) Generally liked by other children; (4) Picked on or bullied by other children; (5) Gets on better with adults than with other children. 'Somewhat true' was scored as 1. 'Not true' was scored as 0 in item 1, 4, and 5, and scored as 2 in item 2 and 3. 'Certainly true' was scored as 2 in item 1, 4, and 5, and scored as 0 in item 2 and 3.

The total score is generated by summing the scores from the five items (scores ranged from 0 to 10). Note that a higher score indicates greater difficulties in the child's peer relationships.

## Results

There were no significant gender differences in any of the study measures. Table 1 shows the descriptive statistics for each study measure.

Table 1: Descriptive statistics for all measures

Measure	<i>M</i>	<i>SD</i>
Age (months)	73.29	3.96
PVT-R	28.87	3.63
HE positive	1.09	0.82
HE negative	1.18	0.83
FB (1st)	2.71	1.36
FB (2nd)	0.57	0.73
Peer problem	1.76	1.87

Note: HE= hidden emotion, FB = false belief.

### Hidden Positive Emotion vs. Hidden Negative Emotion

There was no significant difference between the mean scores of hidden positive emotion tasks and hidden negative emotion tasks (*n.s.*).

### Association between the Study Measures

Correlation and partial correlation coefficients between the different pairs of measures were calculated. Table 2 shows the correlation coefficients and partial correlation coefficients between language ability (PVT-R score), the hidden positive and negative emotion score, the first- and second-order false belief score, and the peer problem score.

Table 2: Correlation coefficients and partial correlation coefficients between study measures

	1	2	3	4	5	6
1 PVT-R	-	.09	.27**	.52**	.36**	-.15
2 HE positive	-	-	.25*	.08	.13	.11
3 HE negative	-	.23*	-	.32**	.11	-.10
4 FB (1st)	-	.05	.21*	-	.59**	-.24*
5 FB (2nd)	-	-.10	.01	.50**	-	-.11
6 Peer Problem	-	.11	-.08	-.19†	-.08	-

Note: The upper off-diagonal elements represent correlation coefficients, while the lower off-diagonal elements are partial correlation coefficients controlling age, and PVT-R score. \*\**p* < .01, \**p* < .05, † *p* < .10. HE = hidden emotion, FB = false belief.

**Language ability and mental state understanding (hidden emotion and false belief)** There were significant correlations between language ability (PVT-R score) and the understanding of hidden negative emotion (*r* = .27, *p* < .01). Children's language ability was clearly related to first- and second-order false belief understanding (first-order: *r* = .52, *p* < .01; second-order: *r* = .36, *p* < .01). There was no significant link between language ability and understanding of hidden positive emotion (*n.s.*).

**Hidden emotion and false belief** There was a significant correlation between understanding of hidden negative emotion and first-order false belief (*r* = .32, *p* < .01). Significant partial correlations were also found between the dyads when age, and PVT-R score were partialled out (*r* = .21, *p* < .05). There was no significant link between understanding of hidden positive emotion and understanding of first-order false belief, and between understanding of both positive and negative hidden emotion and understanding of second-order false belief (all: *n.s.*).

### Relation of Understanding of Hidden Emotion and False Belief to Peer Problems

Teachers rated 101 of 105 children's social interactions. Thus the data of 101 children-teacher pairs were used for the analysis. As shown in Table 2, there was significant negative correlation between the scores for peer problems and performance in first-order false belief tasks (*r* = -.24, *p* < .05). Significant partial correlations were also found between the dyads when age, and PVT-R score were partialled out (*r* = -.19, *p* = .05). That is, the children who were good at understanding other's first-order false beliefs have fewer difficulties in their peer relationships. There was no significant link between the scores for peer problems and any other mental understanding measures (second-order false belief, hidden positive emotion, and hidden negative emotion) (all: *n.s.*).

## Discussion

This study investigated differences between children's understandings of hidden positive and hidden negative emotions and examined associations between their understanding of hidden emotions and theory of mind. We also addressed the link between understandings of mental states and peer relationships. Individual differences in children's understandings of hidden negative emotions and first- and second-order false beliefs were clearly associated with differences in language ability. This result supported previous research demonstrating an important role for language in the development of theory of mind (Happé, 1995).

We found no significant differences between the mean scores for hidden positive emotion tasks and hidden negative emotion tasks, but did find a correlation between children's understandings of hidden positive and hidden negative emotions. The result was not consistent with that of a previous study, which reported that understanding hidden

negative emotions was more difficult than understanding hidden positive emotions (Mizokawa, 2007). This inconsistency may be attributable to differences between the tasks used in the previous study and those used in the current study, especially with respect to those used to address hidden positive emotions. In component 7 of the Test of Emotion Comprehension (TEC), each protagonist in the hidden positive emotion tasks had a motivation to “hide” happiness. On the other hand, because Mizokawa’s study focused on fake crying, each protagonist in the hidden positive emotion tasks had a motivation to “hide” happiness and “express” sadness. Given that the expression of negative emotions is generally construed to be undesirable, the TEC hidden positive emotion tasks used here may have been easier than those used in the previous study.

Although we found no significant difference between children’s scores on hidden positive and hidden negative emotion tasks, the two kinds of hidden emotions (positive and negative) differed in their relationships to aspects of theory of mind. However, the direction of this correlation was opposite to our expectation. We found an association between understanding of others’ minds and hidden negative emotions, whereas no significant link between children’s performances on hidden positive emotion tasks and false belief tasks was observed. One possible explanation of the association between these dyads may be that language ability facilitates children’s understanding of both first-order false beliefs and hidden negative emotions. However, this seems unlikely because these associations remained even after controlling for language ability and age. Although we had expected children to think deeply and make guesses about what was going on in the expresser’s and recipient’s minds when in the presence of someone else’s hidden positive emotion, the results revealed the opposite pattern. It is necessary to conduct further investigations into how children use their ability to understand what is going on in others’ minds in hidden emotion tasks to clarify the meaning of this finding.

In terms of children’s social interactions, the data indicated that children who were more advanced in their understanding of first-order false beliefs were more likely to have and be liked by peers. No association was found between understanding hidden emotions and peer problems. Children who understand first-order false beliefs may have more sophisticated communication skills based on their understanding of others’ minds. Interestingly, language ability *per se* was not associated with children’s peer relationships. These findings suggest that the development of theory of mind transforms and/or is transformed by children’s social interaction skills, as Hughes and Leekam argued (Hughes & Leekam, 2004). Moreover, these results also suggest the possibility that training related to understanding first-order false beliefs leads to fewer peer problems (cf. Ozonoff & Miller, 1995; Slaughter, Dennis, & Pritchard, 2002).

The findings of our study also suggest that understanding hidden emotions, as measured by component 7 of the TEC,

is not a unitary concept. That is, understanding hidden positive and hidden negative emotions should be viewed as related but distinct aspects of emotional understanding. In the hidden positive emotion tasks in component 7 of the TEC, children need to think more deeply and make guesses about another’s mind, which differs from the requirements of the hidden negative emotion tasks. We found no relationship between children’s performance on the hidden emotion tasks and their performance on the second-order false belief tasks or between peer problems and performance on the second-order false belief tasks. This may be due to a floor effect in the second-order false belief tasks.

Our study found a relationship between children’s understandings of first-order false beliefs and their understanding of hidden negative emotions. Although these measures are correlated with each other, only the understanding of first-order false beliefs was linked to peer relationships. When we observe children’s communication with peers, we can see that children who are good at understanding how people control emotional expression have complex relationships (e.g., those involving negotiation) with their peers. It may be expected that aspects of social interactions other than peer problems are linked with understanding hidden emotions. Future research is needed to reveal whether and how children’s understandings of mental states such as hidden emotions come to be reflected in their social interactions.

## Acknowledgments

This research was supported by a grant from MEXT to Masuo Koyasu (grant 70115658). We would like to express our thanks to the children who participated in this study and their parents and teachers.

# The Effect of Visually and Phonologically Misleading Nonwords on Lexical Decisions of Native Japanese Readers

Rika Mizuno (mizunor@isc.chubu.ac.jp)

Takao Matsui (mat@psy.chubu.ac.jp)

Department of Psychology, Chubu University  
1200 Matsumoto-Cho, Kasugai-shi, 487-8501 JAPAN

## Abstract

Native Japanese readers were found to rely heavily on visual codes and scarcely on phonological codes in letter/word processing (Mizuno, Matsui, & Bellezza, 2007). This study aimed to determine if this processing feature of native Japanese readers influenced their process of lexical access by lexical decision tasks using visually misleading transposed-letter (TL) nonwords, phonologically misleading pseudohomophones, and standard nonwords. Lupker and Pexman (2010) found that the performance on a lexical decision task of native English readers was impaired by both TL nonwords and pseudohomophones. However, the results of two experiments in this study showed that the performance of native Japanese readers was impaired not by pseudohomophones but by TL nonwords. The results suggested that the processing features of native readers of various languages should influence their process of lexical access.

**Keywords:** lexical decision; nonwords; transposed-letter; pseudohomophone; native Japanese readers; native English readers

## Introduction

A lexical decision task (Meyer & Schvaneveldt, 1971) is a task in which participants decide whether presented letter strings are words or not. The lexical decision time of a word is considered to reflect the access time to lexical representation of the word, and the task has been used in many studies to explore the structure of lexical representation or the process of lexical access.

Various features of words have been found to influence lexical decision time. Such features include word frequency (e.g., Glanzer & Ehrenreich, 1979), neighborhood size<sup>1</sup> (Coltheart, Develaar, Jonasson, & Besner, 1977), semantic relation to primes (Neely, 1977), spelling-to-sound regularity (Parkin, 1982), and so on.

However, some research has shown that the effects of the features of nonwords on lexical decision time are also not negligible. For example, Shulman and Davidson (1977) found that pronounceable nonwords delayed the lexical decision time of words more than unpronounceable nonwords. Perea and Lupker (2004) found that the transposed-letter (TL) nonwords, which were made by transposing the two letters of words, delayed the lexical decision time for both words and nonwords. Lupker and Pexman (2011) compared the size of frequency effect in the TL, pseudohomophone, and standard nonword conditions. Frequency effect means that the lexical decision time of

more frequent words is shorter. They found that lexical decision time was longer and that frequency effect was greater in the TL and the pseudohomophone nonword conditions than in the standard nonword condition.

These findings about the effects of nonwords on lexical decision time not only contributed to the improved understanding of the process of lexical access but suggested that the features of nonwords should also be considered in using lexical decision tasks.

As described above, visually misleading TL nonwords and phonologically misleading pseudohomophones were confirmed to influence lexical decision time of words and nonwords. However, they were confirmed only with native English readers. Mizuno, Matsui, and Bellezza (2007) and Mizuno, Matsui, Harman, and Bellezza (2008) conducted several letter-matching experiments with native English and native Japanese readers, and found that native Japanese readers rely heavily on visual codes and not as much on phonological codes as native English readers do. Mizuno and Matsui (2012) also showed that visual similarity, rather than phonological similarity, between targets and distracters increased attentional blink of native Japanese readers, while Chun and Potter (1995) suggested that phonological similarity had a significant effect on the attentional blink of native English readers.

Consequently, we hypothesized that performance on a lexical decision task by native Japanese readers would not be impaired by phonologically misleading pseudohomophones because they rely scarcely on phonological codes. If this is verified, we will be able to not only indicate that their processing features of letters influence performance on lexical decision tasks but also alert many researchers using lexical decision tasks to take the processing features of their participants into account in choosing nonwords.

## Experiment 1

Experiment 1 compared lexical decision time and error rates of native Japanese readers across the TL nonword condition, the pseudohomophone condition, and the standard nonword condition. We predicted that their lexical decision time would be delayed and error rates for nonwords would be high only in the TL condition, and not in the pseudohomophone condition and the standard condition.

## Method

**Participants and Design** Thirty-six undergraduate students (14 women and 22 men) who were native Japanese

<sup>1</sup> The number of words that can be created by changing one letter while maintaining letter positions.

readers participated in return for course credit. Participants were assigned to all three conditions: the TL nonword, the pseudohomophone, and the standard nonword conditions.

**Equipment** The experiment was conducted on a personal computer (Fujitsu, FMV Esprimo D5350) running an experimental software (Cedrus Co., SuperLab2.0) with a 17-in. liquid crystal monitor (EIZO, FlexScan S1731). Responses were collected by a response box (Cedrus Co., RB-730). A chin support (Takei, T.K.K. 123i with 123j) was placed on the edge of the desk. The distance between participants' eyes and the screen was about 45 cm, and the height of the chin support was adjusted for each participant.

**Stimuli** All the stimuli were two-character and four-mora *Kanji* words. In total, 120 words and 120 nonwords (40 TL nonwords, 40 pseudohomophones, and 40 standard nonwords) were selected/created in the following manner: 240 words of frequencies between 15,000 and 100,000 were selected from the database (Amano & Kondo, 2003); 40 TL nonwords were made by transposing two *Kanji* characters (e.g., "盟連", from "連盟"), confirming that they had no homophones; and the remaining 200 words were divided into five sets of 40 words each. Three sets were assigned to word sets, another set was used for making pseudohomophones, and another was used for making standard nonwords. Forty pseudohomophones were made by replacing each *Kanji* character with another *Kanji* character with the same phone (e.g., "案低", from "安定"). The 40 standard nonwords were created by exchanging one of the two *Kanji* characters with one of the other words (e.g., "開税"), confirming that they were nonwords and had no homophones. The three nonword sets were combined with the three word sets to form six counterbalancing groups.

Japanese letters are typically written from left to right or from top to bottom but sometimes from right to left. The two letters, therefore, were written vertically from top to bottom lest the TL nonwords should be regarded as words. A two-letter stimulus presented on the monitor subtended 3 degrees of visual angles vertically and 1.5 degrees horizontally.

**Procedure** Six participants were allocated to each of the six counterbalancing groups. In each group, the orders of three nonword conditions were counterbalanced among the six participants.

Participants were tested individually. Each participant completed eight practice trials with standard nonwords followed by three blocks of 80 experimental trials. The order of the 80 trials was randomized. Participants were instructed to decide as quickly and accurately as possible whether the letter strings were a word or a nonword by pressing the right-most key if they were a word and the left-most key if they were not. In each trial, after a 1,100 ms interval, two asterisks written vertically were presented on the middle of the screen for 550 ms followed by the stimuli, which remained on the screen for three seconds or until the

participant responded.

Results

Trials involving latencies greater than 1,500 ms (1.2% of the word trials and 3.2% of the nonword trials) were removed from the following analyses according to Lupker and Pexman (2010).

**Word Lexical Decision Time** Means of correct lexical decision time for words in the three nonword conditions are shown in Figure 1. One-way repeated measures analysis of variance (ANOVA) revealed that the effect of the nonword condition was significant,  $F(2, 70) = 27.29$ ,  $MSE = 5,528.08$ ,  $p < .001$ . Multiple comparisons showed that the mean lexical decision time in the TL condition was significantly longer than that in the pseudohomophone condition and the standard nonword condition,  $ps < .01$ ,  $HSD = 53.04$ .

**Word Error Rates** Means and standard deviations of error rates for words in the three nonword conditions are shown in Table 1. ANOVA of arcsine transformed error rates revealed that the effect of the nonword condition was not significant,  $F(2, 70) = 1.62$ ,  $MSE = 37.97$ ,  $p = .20$ .

**Nonword Lexical Decision Time** Means of correct lexical decision time for nonwords in the three nonword conditions

Figure 1: Mean and standard deviation of lexical decision time for words in each nonword condition in Experiment 1.

Table 1: Mean and standard deviation of error rates for words in each nonword condition in Experiment 1.

	Nonword Condition		
	Transposed -letter	Pseudo -homophone	Standard
Mean	0.061	0.048	0.060
SD	0.043	0.039	0.037

Figure 2: Mean and standard deviation of lexical decision time for nonwords in each nonword condition in Experiment 1.

Table 2: Mean and standard deviation of error rates for nonwords in each nonword condition in Experiment 1.

	Nonword Condition		
	Transposed -letter	Pseudo -homophones	Standard
Mean	0.097	0.042	0.060
SD	0.044	0.034	0.032

are shown in Figure 2. ANOVA revealed that the effect of the nonword condition was significant,  $F(2, 70) = 29.86$ ,  $MSE = 13,857.37$ ,  $p < .001$ . Multiple comparisons showed that the mean lexical decision time in the TL condition was significantly longer than that in the pseudohomophone condition and the standard nonword condition,  $ps < .01$ ,  $HSD = 83.97$ , and that the time in the pseudohomophone condition was shorter than that in the standard nonword condition,  $p < .05$ ,  $HSD = 66.71$ .

**Nonword Error Rates** Means and standard deviations of error rates for nonwords in the three nonword conditions are shown in Table 2. ANOVA of arcsine transformed error rates showed that the effect of the nonword condition was significant,  $F(2, 70) = 19.98$ ,  $MSE = 26.92$ ,  $p < .001$ . Multiple comparisons revealed that the error rate in the TL nonword condition was higher than that in the pseudohomophone condition and the standard nonword condition,  $ps < .01$ ,  $HSD = 3.70$ , and that in the pseudohomophone condition was lower than that in the standard nonword condition,  $p < .05$ ,  $HSD = 2.94$ .

## Discussion

The lexical decision time for words in the TL condition was longer than the lexical decision times for words in the pseudohomophone condition and in the standard condition.

This result was different from that of Lupker and Pexman (2010) with native English readers, which showed that lexical decision times for words in the TL condition and pseudohomophone condition were longer than the corresponding time in the standard nonword condition. This result suggests that lexical decision time for words of native Japanese readers, who do not rely so much on phonological codes, is not delayed by phonologically misleading nonwords. Error rates for words did not differ among nonword conditions, consistent with the result of Lupker and Pexman (2010).

As for nonwords, the results showed that lexical decision time in the TL condition was longer than in the other two conditions, and that error rates in the TL condition were higher than those in the other two conditions. However, Lupker and Pexman (2010) with native English readers showed that their lexical decision times and error rates in the TL and pseudohomophone conditions were greater than those in the standard nonword condition. These results indicated that the effect of phonologically misleading nonwords was scarce in the case of native Japanese readers.

Nonetheless, we did not expect that the lexical decision time in the pseudohomophone condition would be shorter than that in the standard nonword condition, or that the error rate in the pseudohomophone condition would be lower than that in the standard nonword condition. These results were inconsistent with the previously mentioned results indicating that phonological codes have a scarce effect on lexical decisions of native Japanese readers, and we considered it implausible to suppose that the phonological codes of pseudohomophones made lexical decision of nonwords easy.

Therefore, we reexamined the frequencies and stroke counts of all *Kanji* characters consisting of the nonwords in the three conditions. The stroke counts of *Kanji* characters (see Table 3) reflect their visual complexities. The means of frequencies and stroke counts (with standard deviations in parentheses) were, respectively, 456,281.6 (566,312.9) and 9.775 (4.40) for TL nonwords, 305,685.2 (392,268.0) and 8.91 (3.24) for pseudohomophones, and 497,443.0 (515,634.1) and 9.56 (3.73) for standard nonwords. The mean frequency and the mean stroke count of pseudohomophones were smaller than the others. A low frequency was likely to increase both lexical decision time and error rate. It could not unexpectedly decrease lexical decision time, or the error rate in the pseudohomophone condition. Therefore, we concluded that the low stroke counts were the real cause. Because native Japanese speakers tend to rely heavily on visual codes, it was

Table 3: Examples of stroke counts.

Stroke Count		
3	8	13
大	性	新

extremely plausible that the small mean of stroke counts of pseudohomophones made lexical decision time shorter and error rates lower than those of standard nonwords.

In Experiment 2, therefore, some of the *Kanji* characters consisting of pseudohomophones and standard nonwords were substituted so as to make the means of stroke counts and those of frequencies as even as possible in the three nonword conditions.

## Experiment 2

### Method

**Participants and Design** Thirty-six undergraduate students (13 women and 23 men) who were native Japanese readers participated in return for course credit. Participants were assigned to all three conditions: the TL nonword, the pseudohomophone, and the standard nonword conditions.

**Stimuli** The 120 words and 40 nonwords in the TL conditions were the same as those used in Experiment 1. Some of the *Kanji* characters in the pseudohomophone condition and the standard nonword condition used in Experiment 1 were substituted with other *Kanji* characters to make the means of stroke counts, along with the frequency of *Kanji* characters composing the nonwords, in the three conditions as equal as possible. The resultant means (with standard deviations in parentheses) of stroke counts and frequency of *Kanji* characters composing the nonwords in the TL condition were 9.78 (4.40) and 456,281.6 (566,312.9), respectively, those in the pseudohomophone condition were 9.76 (3.52) and 412,652.3 (369,488.1), and those in the standard nonword condition were 9.78 (3.72) and 422,790.2 (454,322.7).

**Equipment and Procedure** These were the same as in Experiment 1.

### Results

Trials involving latencies greater than 1,500 ms (2.9% of the word trials and 6.7% of the nonword trials) were removed from the following analyses as in Experiment 1.

**Word Lexical Decision Time** Means of correct lexical decision time for words in the three nonword conditions are shown in Figure 3. One-way repeated measures ANOVA revealed that the effect of nonword condition was significant,  $F(2, 70) = 12.47$ ,  $MSE = 5,572.14$ ,  $p < .001$ . Multiple comparisons showed that the mean lexical decision time in the TL condition was significantly longer than that in the pseudohomophone condition and the standard nonword condition,  $ps < .01$ ,  $HSD = 53.25$ .

**Word Error Rates** Means and standard deviations of error rates for words in the three nonword conditions are shown in Table 4. ANOVA of arcsine transformed error rates revealed that the effect of the nonword condition was not significant,  $F(2, 70) = 0.32$ ,  $MSE = 48.80$ ,  $p = .73$ .

Figure 3: Mean and standard deviation of lexical decision time for words in each nonword condition in Experiment 2.

Table 4: Mean and standard deviation of error rates for words in each nonword condition in Experiment 2.

	Nonword Condition		
	Transposed -letter	Pseudo -homophone	Standard
Mean	0.051	0.059	0.048
SD	0.044	0.049	0.038

**Nonword Lexical Decision Time** Means of correct lexical decision time for nonwords in the three nonword conditions are shown in Figure 4. ANOVA revealed that the effect of the nonword condition was significant,  $F(2, 70) = 16.55$ ,  $MSE = 9,425.45$ ,  $p < .001$ . Multiple comparisons showed that the mean lexical decision time in the TL condition was significantly longer than that in the pseudohomophone condition and the standard nonword condition,  $ps < .01$ ,  $HSD = 69.25$ .

**Nonword Error Rates** Means and standard deviations of error rates for nonwords in the three nonword conditions are shown in Table 5. ANOVA of arcsine transformed error rates showed that the effect of nonword condition was significant,  $F(2, 70) = 5.36$ ,  $MSE = 32.03$ ,  $p = .007$ . Multiple comparisons revealed that the error rate in the TL nonword condition was higher than that in the pseudohomophone condition and the standard nonword condition,  $ps < .05$ ,  $HSD = 3.21$ , and no difference was found between the latter two conditions.

### Discussion

As expected, the lexical decision time for words in the TL nonword condition was longer than that in the pseudohomophone condition and the standard condition, and there was no difference between the latter two conditions.

Figure 4: Mean and standard deviation of lexical decision time for nonwords in each nonword condition in Experiment 2.

Table 5: Mean and standard deviation of error rates for nonwords in each nonword condition in Experiment 2.

	Nonword Condition		
	Transposed -letter	Pseudo -homophones	Standard
Mean	0.101	0.064	0.068
SD	0.055	0.036	0.050

This result suggests that phonologically misleading nonwords have no effect on the lexical decisions of native Japanese readers. The error rates for words did not differ between the three nonword conditions, which is with the results of Lupker & Pexman (2010) with native English readers.

The lexical decision time for nonwords was the longest in the TL nonword condition, and there was no difference between that in the pseudohomophone condition and that in the standard nonword condition. This result was also expected and indicates that native Japanese readers rely scarcely on phonological codes. The error rate for words in the TL condition was higher than that in the standard nonword condition, and no other difference was found. Lupker and Pexman (2010) found that error rates in both the TL condition and the pseudohomophone condition were higher than the error rate in the standard nonword condition with native English readers. This result, therefore, suggests that native Japanese readers make fewer errors when deciding if phonologically misleading nonwords are nonwords because they scarcely rely on phonological codes.

## General Discussion

In Experiment 1, the lexical decision times for words and for nonwords were shorter and the error rate for nonwords was lower in the pseudohomophone condition than those in

the TL nonword condition. These results suggested that the processing feature of native Japanese readers relying heavily on visual codes and scarcely on phonological codes had influenced their performance on lexical decision tasks. However, it was inconsistent with their processing feature that the lexical decision time for nonwords was shorter and the error rate for nonwords was lower in the pseudohomophone condition than those in the standard nonword condition. This was considered due to the stroke counts reflecting the visual complexity of *Kanji* characters consisting of pseudohomophones more than those consisting of TL nonwords and standard nonwords used in Experiment 1.

In Experiment 2, the experiment was replicated after making the means of the stroke counts of *Kanji* characters consisting of nonwords in the three conditions as equal as possible. Consequently, lexical decision time was longer and error rate was higher in the TL conditions than those in the pseudohomophone condition and the standard nonword condition, and no difference was found between the latter two conditions. These results indicated that native Japanese readers rely scarcely on phonological codes but rely heavily on visual codes.

These results, in general terms, serve as evidence that processing characteristics of native readers of a certain language could influence performance on the lexical decision task. We hope that this will be a warning to all researchers who use this task.

We finally discuss the process of lexical decision of native Japanese readers in terms of some models of lexical access. According to Shimomura and Goryo (1998), the models of lexical access are roughly divided into two categories: single-route models and dual-route models. Single-route models suppose that phonological information processing always mediates lexical access (e.g., Van Orden, 1987). Dual-route models suppose that visual information processing and phonological information processing proceed in parallel (e.g., Coltheart, 1978), and some models also suppose that the two routes interact with each other (e.g., Ferrand & Grainger, 1994).

The results of this study indicated that phonologically misleading pseudohomophones had no effect on the performance of lexical decision tasks by native Japanese readers. They indicate that phonology does not necessarily mediate lexical access; this finding contradicts the single-route model, which supposes phonological mediation. At the same time, the results of this study contradict the dual-route model as well—the very reason Coltheart (1978) proposed a dual-route model was that pseudohomophones delayed the lexical decision time of native English readers.

However, a few recent studies support the validity of the dual-route model. Grainger, Muneaux, Farioli, and Ziegler (2005) examined the effect of visual and phonological neighborhood density on lexical decision time. They found that lexical decision time was short when both visual neighborhood and phonological neighborhood were dense or sparse because the target lexicon was likely to be the same, namely, because the cross-code consistency was high.

They also found that lexical decision time was prolonged when only one of the neighborhoods was dense because the target lexicon was likely to be different, namely, because cross-code consistency was low. They asserted that these results support the dual-route model, and these results were also found by Hino, Nakayama, Miyamura, and Kusunose (2011) with native Japanese participants.

We, therefore, felt that the results of this study should be explained by a dual-route model. We also considered that it is basically implausible to suppose that the processes of lexical access are disparate among native readers of different languages. How, then, could the results with native English readers and those with native Japanese readers be explained by the same dual-route model?

The Japanese language features an unparalleled number of homophones. This situation is similar to the situation when phonological neighborhood is dense and visual neighborhood is sparse—the cross-code consistency being very low. Native Japanese readers do know that the use of both visual and phonological codes, especially of phonological codes, delays their lexical access. Accordingly, they choose to rely heavily on visual codes and scarcely on phonological codes. On the other hand, the English language does not have as many homophones, and the cross-code consistency is high. Native English readers know the situation and do not reduce their reliance on phonological codes. Therefore, the use of pseudohomophones impaired their performance on lexical decision tasks. In brief, we believe that the results of this study are inconsistent with those of Coltheart et al. (1977) because the phonological processing features of native Japanese readers differ from those of native English readers, although their processes of lexical access are basically similar.

Human information processing must be highly efficient; it is unconceivable that people adhere to inefficient processing. We consider that it is most natural and reasonable to suppose that people change flexibly the weights of visual and phonological processing according to the features of their languages or situations, realizing the most efficient lexical access.

## Abstract

Previous research has provided evidence that mental imagery and embodied action can facilitate word learning in a novel language. However, it is unclear *how* these factors interact—as well as *why* they play a role—in word learning. Through a set of four experiments, this research demonstrated that neither mental imagery nor embodied action directly promotes the acquisition of second language (L2) words by adult learners. Notably, both passive viewing of images and gestures, as well as active engagement in mental imagery and gesture enactment, were insufficient to enhance L2 word learning. These results suggest that adults are effective L2 word learners, and that, because of this, embodied action does not play an essential role in supporting L2 lexical acquisition.

**Keywords:** Second language acquisition, word learning, gesture, mental imagery, embodied cognition

## Introduction

When setting out to learn a new language, it is common to start by learning the meanings of its conceptually simplest units: words. When learning a word, learners must associate the acoustic and/or orthographic form of the word with a representation of the word's meaning. These representations are based on real-world interactions between the learner and the object to which the word refers; thus, they are a composite of the object's properties, as perceived and acted upon by the learner. As a result, word learning likely depends heavily upon both mental imagery and embodied action, in conjunction with text/speech processing and memory. The present research sought to investigate—and dissociate—the contributions of mental imagery and embodied action to second language (L2) word learning. This research was based on two major goals: (1) elucidate the cognitive processes responsible for L2 word learning in adulthood; (2) determine how to engage these processes, thereby enhancing L2 word learning.

Several lines of research indicate that mental imagery plays a central role in L2 word learning. In the keyword method of L2 word learning (Atkinson, 1975), learners are instructed to choose a word from their native language that is phonologically similar to the target L2 word, and to formulate a mental image of the referents of these words

interacting. For example, for the Spanish word *chico* (boy), a learner might choose the similar-sounding English word *chick*, and then could imagine a boy holding a chick. This method has been shown to be a more effective strategy for L2 word learning than verbal association of target words and translations (Atkinson & Raugh, 1975; Levin, McCormick, Miller, Berry, & Pressley, 1982; Raugh & Atkinson, 1975; Van Hell & Mahn, 1997). There is also evidence that, particularly in the early stages of L2 learning, the meanings of target words are learned more effectively via physical images, which cue mental imagery through isomorphism, than via verbal translation (Carpenter & Olson, 2011; Chun & Plass, 1996). These findings indicating that mental imagery promotes L2 word learning can be explained by dual coding theory (Paivio, 1990), which posits that long-term memory encoding can be enhanced via the simultaneous processing of visual and verbal information.

Aside from mental imagery, embodied action—action that learners perform using their bodies—also plays an important role in L2 word learning. Because learners' representations of word referents entail actions that learners have performed on these objects, the use of embodied action during word learning allows learners to create deeper, more meaningful word-referent associations. One method that has taken advantage of embodied action is the Total Physical Response Method (Asher, 1969), which has been successfully used to teach L2 words to novice learners (Asher, Kusudo, & Torre, 1974; Asher & Price, 1967). In this approach, the instructor teaches the target word by saying it while demonstrating its meaning using the body, and learners re-enact the instructor's actions using their own bodies in order to demonstrate comprehension of the words' meanings. Other evidence supporting embodied action comes from research showing that the enactment of gestures representative of word meanings (e.g., placing the hands together and opening them for *book*) during learning facilitates recall of target words to a greater degree than passively viewing pictures or representative gestures (Tellier, 2008). Taken together, these findings indicate that embodied action allows L2 learners to tap into their representations of word referents, creating robust,

multimodal associations between target words and the objects that they represent.

Although extant research suggests that mental imagery and embodied action both contribute separately to L2 word learning, it is unclear from this work if—and how—they interact. One way by which their respective contributions could be clarified is by investigating whether gesture, which typically accompanies and complements speech (McNeill, 2005), facilitates L2 word learning. Iconic (i.e., representative) gestures are created via embodied action and evoke mental imagery via their iconicity, which conveys visuospatial properties of the referent. Several studies (Allen, 1995; Kelly, McDevitt, & Esch, 2009; Tellier, 2008) have shown that L2 words are recalled more accurately over longer intervals when they are learned via representative iconic gesture than when they are learned via speech. Additionally, when L2 words are accompanied by non-representative iconic gesture (e.g., placing the hands together and opening them as for *book* while the word *drink* is presented), they are learned less effectively (Kelly et al., 2009). All of these findings indicate that the combination of mental imagery and embodied action in iconic gesture is a powerful tool for enhancing L2 word learning when it is synchronous with the meanings of the target words.

The objective of the current research was to clarify the independent contributions of mental imagery and embodied action—as well as their interactions—to L2 word learning. To this end, target words were presented in four conditions in which words were accompanied by stimuli that crossed these factors in a 2-by-2 design (see Table 1). These stimuli were designed to elicit either active or passive processing of mental imagery and embodied action, depending on the task instructions. Based on the research discussed above, it was predicted that iconic gesture viewing and enactment would result in the highest number of L2 words recalled, followed

by mental imagery, followed by meaningless embodied action and text/speech only. Furthermore, it was predicted that active learning conditions would allow participants to recall more words than passive conditions due to greater engagement of the sensorimotor system.

## Experiment 1

### Methods

Twenty-six undergraduate students (age:  $M = 20.25$ ;  $SD = 1.5$ ; sex: 11 males; 15 females) at a medium-sized public university in the US participated in return for partial course credit. All participants were fluent English speakers and had no knowledge of Hungarian.

Twelve Hungarian words and their English glosses were used in this research (see Table 2). Prior to this research, 15 English speakers who did not participate in this study were asked to rate the concreteness, imageability, and meaningfulness of the English glosses of 80 candidate words, and to gesture in a way that represented the meaning of each gloss. The 12 words with the most consistent responses from each of the categories were selected for the study. Videos of iconic gestures were created by recording a fluent Hungarian-English bilingual saying these words in each language while enacting the gestures produced by the most participants. Images were line drawings representing the English glosses of Hungarian target words from the International Picture Naming Project (Szekely et al., 2004). In order to control for possible vocal iconicity, audio of the pronunciation of Hungarian and English words was extracted from the iconic gesture videos and was played during presentation of referent images and text of words. Beat gestures—simple, non-iconic hand movements in time to speech prosody—represented embodied action without cuing mental imagery. Videos of these gestures were created by recording the Hungarian-English speaker saying the target words in each language while enacting beat gestures. These videos were presented with their own sound track in order to preserve prosodic speech-gesture synchrony.

The learning phase of this study consisted of three blocks comprising 12 trials apiece. In each learning trial, the

Table 1: Experimental design for Experiments 1-4.

	Mode	+ Mental Imagery	- Mental Imagery
+ Embodied Action	Passive	Iconic gesture	Beat gesture
	Active	Gesture enactment	Meaningless hand motion
- Embodied Action	Passive	Physical images	Text/Speech only
	Active	Mental imagery formation	Verbal repetition only

Table 2: Hungarian and English words from Expts. 1-4.

Hungarian	English
Betegség	Illness
Kalapács	Hammer
Kulcs	Key

Mászni	To climb
Megütni	To hit
Orá	Watch
Öröm	Joy
Seprű	Broom
Tréfa	Joke
Unott	Bored
Varrni	To sew

following sequence of events was repeated twice: a randomly-selected Hungarian word was presented for 2000 ms., and after a 1000 ms. interstimulus interval, the corresponding English word was presented for 2000 ms. This study used a within-participants design; thus, for each experimental session, three Hungarian words and their English glosses were assigned at random to each of the following conditions: (1), iconic gesture, in which words were accompanied by video of a gesture representing their meaning; (2), beat gesture, in which words were accompanied by video of simple, non-iconic gestures made in time to speech; (3), image, in which words were accompanied by an image representing their meaning; (4), text, in which words were presented as text (see Materials section for a description of the stimuli used in each condition).

The test phase of this study consisted of a single block in which each Hungarian word that participants had learned was presented as text and speech. Participants responded by saying the corresponding English word or by saying “skip” if they could not remember it. In order to examine how learning conditions affected long-term L2 word recall, participants completed the test phase at three intervals following the learning phase: five minutes, one week, and one month.

## Results and Discussion

L2 word recall was quantified by scoring responses using a binary coding scheme (1 = correct, 0 = incorrect/skipped), and by converting scores into proportion correct for each participant and condition (in order to control for unscorable responses due to factors such as unintelligibility or technical errors in running the recall task). Proportional scores were submitted to repeated measures ANOVAs, in which participant and word were used as fixed factors.

This analysis revealed a main effect of recall interval,  $F_{pp}(2, 51) = 12.16, p < .001, \eta_p^2 = .36$ ;  $F_{word}(2, 18) = 6.42, p = .008, \eta_p^2 = .42$ . Bonferroni-corrected post hoc analyses showed that participants recalled more L2 words after five minutes than they recalled after one week ( $p_{pp} = .03$ ;  $p_{word} = .02$ ) and one month ( $p_{pp} = .001$ ;  $p_{word} = .06$ ). There was also a main effect of learning condition,  $F_{pp}(3, 77) = 7.70, p < .001, \eta_p^2 = .26$ ;  $F_{word}(3, 27) = 7.04, p = .001, \eta_p^2 = .44$ , see Figure 1. Post-hoc analyses showed that participants learned more words via text than they did via beat gesture ( $p_{pp} = .002$ ;  $p_{word} = .008$ ), iconic gesture (by participant;  $p_{pp} = .05$ ;  $p_{word} = .34$ ) and images ( $p_{pp} = .08$ ;  $p_{word} = .05$ ). However, the interval by condition interaction failed to reach significance. Together, these results suggest that orthographic representations of words may play a more integral role in L2 word learning than mental imagery or embodied action.

## Experiment 2

One possible explanation why L2 words learned via text were recalled better than words learned via iconic gesture, beat gesture, or images is because Hungarian words were

Figure 1: Percent of word meanings recalled by condition and recall interval for Expt. 1 (error bars represent *SEM*).

presented as text in test trials. This learning-test similarity may have resulted in transfer-appropriate processing, which occurs when similar cues are present at encoding and retrieval (Morris, Bransford, & Franks, 1977). In order to determine whether transfer-appropriate processing was responsible for the facilitatory effect of text observed in Experiment 1, recall trials were modified so that Hungarian words were presented as speech only, without any text. If, under these conditions, participants recalled similar numbers of L2 words presented as text, representational gesture, beat gesture, and speech, it could be concluded that the facilitatory effect of text observed in Study 1 was due to transfer-appropriate processing. Given a lack of conclusive reported evidence showing that L2 words learned as text are recalled better than words presented via other modalities (e.g., images), it was predicted that no significant advantage of text would be found in Study 2.

## Methods

Twenty-six undergraduate students (age:  $M = 20.64$ ;  $SD = 1.56$ ; sex: 12 males; 14 females) at a medium-sized public university in the US participated in return for partial course credit. All participants were fluent English speakers and had no knowledge of Hungarian. Additionally, participants had not participated in Experiment 1.

Learning conditions and trials were identical to those used in Experiment 1. Recall trials were also identical to those of Experiment 1, except that Hungarian words were presented as speech only, while the task instructions were displayed on the screen as text.

## Results and Discussion

As in Experiment 1, L2 word learning was quantified proportionally and was submitted to repeated measures ANOVAs with participant and word as fixed factors. This analysis revealed a main effect of recall interval,  $F_{pp}(2, 51) = 7.11, p = .003, \eta_p^2 = .31$ ;  $F_{word}(2, 10) = 47.14, p < .001, \eta_p^2 = .90$ , see Figure 2. Bonferroni-corrected post-hoc analyses showed that participants recalled more words after five

minutes than they recalled after one week ( $p_{pp} = .04$ ;  $p_{word} = .001$ ) and one month ( $p_{pp} = .05$ ;  $p_{word} = .004$ ). However, learning condition failed to reach significance, as did the interval by condition interaction. These results indicate that the superior recall for words learned via text observed in Experiment 1 was due to the presence of text in both learning and test trials.

Figure 2: Percent of word meanings recalled by condition and recall interval for Expt. 2 (error bars represent *SEM*).

### Experiment 3

Contrary to the predictions, Experiments 1 and 2 failed to show that iconic gesture, mental imagery, or beat gesture promote L2 word learning via mental imagery and embodied action. One possible reason why iconic gesture may not have produced the facilitatory effect observed in other similar studies of L2 word learning is that participants may have encountered difficulties mapping gestures onto the words that they were intended to represent. Despite the care that was taken in selecting gestures to represent target words based on gesture production data from the norming study, it is possible that the gestures chosen may logically map onto the meanings of more than one word (e.g., the gesture representing to *climb* may also map onto *ladder*). Unclear gesture-word mappings such as these may cause confusion, unnecessarily increasing cognitive load upon presentation of “correct” English glosses, which in turn may negatively impact L2 word learning and recall. Experiment 3 attempted to control for gesture-meaning mismatches by presenting English glosses prior to Hungarian words, in order to ensure that iconic gestures were immediately associated with their intended meanings.

In addition to the reversal of language presentation order, the text condition was replaced with a speech only condition. The rationale for this replacement was that speech with no visual representation may be a more appropriate baseline condition (- embodied action, - mental imagery) for this research than speech with text.

### Methods

Twenty-seven undergraduate students (age:  $M = 21.05$ ;  $SD = 1.83$ ; sex: 13 males; 14 females) at a medium-sized public university in the US participated in return for partial course

credit. All participants were fluent English speakers and had no knowledge of Hungarian. Additionally, participants had not participated in Experiments 1 or 2.

Learning trials were similar to those of Experiments 1 and 2, except that the order of language presentation was reversed (2000 ms. English gloss, 1000 ms. ISI, 2000 ms. Hungarian word). Learning conditions were also similar to those of Experiments 1 and 2, except that the text condition was replaced with a speech only condition, in which words were presented as speech concurrently with a blank screen. Recall trials were identical to those of Experiment 2.

### Results and Discussion

As in Experiments 1 and 2, L2 word learning was quantified proportionally and was submitted to repeated measures ANOVAs with participant and word as fixed factors. This analysis revealed a main effect of recall interval,  $F_{pp}(2, 53) = 24.81$ ,  $p < .001$ ,  $\eta_p^2 = .61$ ;  $F_{word}(2, 14) = 36.59$ ,  $p < .001$ ,  $\eta_p^2 = .84$ , see Figure 3. Bonferroni-corrected post-hoc analyses showed that participants recalled more words after five minutes than they recalled after one week ( $p_{pp} = .04$ ;  $p_{word} = .002$ ) and one month ( $p_{pp} = .04$ ;  $p_{word} < .001$ ). However, learning condition failed to reach significance, as did the interval by condition interaction. Taken together with the findings of Experiments 1 and 2, these results confirm that, in the passive form, mental imagery and embodied action do not significantly enhance the acquisition of L2 words.

Figure 3: Percent of word meanings recalled by condition and recall interval for Expt. 3 (error bars represent *SEM*).

### Experiment 4

The objectives of this experiment were to examine the effects of the active engagement in embodied motion and mental imagery on L2 word learning, and to compare them to the effects of their passive counterparts, as documented in Experiments 1-3. For young children, only enactment—not mere viewing—of iconic gestures enhances word learning (Tellier, 2008). Thus, it is possible that L2 word learning

may be enhanced via *enactment* of iconic gestures and *visualization* of mental imagery, even though word learning was not facilitated via passive *viewing* of iconic gestures and physical images. Experiment 4 tested this possibility by examining the effectiveness of L2 word learning via the active equivalents of the learning conditions of Studies 1-3.

## Methods

Twenty-eight undergraduates (Age:  $M = 20.67$ ;  $SD = 1.56$ ; Sex: 12 males; 16 females) at a medium-sized public university in the US participated in return for partial course credit. All participants were fluent English speakers and had no knowledge of Hungarian. Additionally, participants had not participated in Experiments 1, 2, or 3.

As in Experiments 1-3, the learning phase of Experiment 4 consisted of three blocks of trials that varied by condition within participants. In learning trials, participants viewed video of a speaker saying an English gloss while producing a gesture representative of its meaning for 2000 ms., and after a 1000 ms. interstimulus interval, viewed video of the speaker saying a Hungarian target word while making the same gesture for 2000 ms. After one additional repetition of this sequence of events, participants repeated the English and Hungarian words aloud while performing the action corresponding to the condition to which the word had been assigned for that session. For words assigned to condition (1), gesture enactment, participants enacted the gesture that they had viewed in the video; for words assigned to condition (2), mental imagery formation, participants closed their eyes and visualized the words' meaning;<sup>1</sup> for words in condition (3), meaningless hand motion, participants made an X-shaped hand motion three times; for words in condition (4), repetition, participants repeated the words aloud while keeping their hands still. Recall trials were identical to those of Experiments 2-3.

## Results and Discussion

As in Experiments 1-3, L2 word learning was quantified proportionally and was submitted to repeated measures ANOVAs with participant and word as fixed factors. This analysis revealed a main effect of recall interval,  $F_{pp}(2, 56) = 12.90$ ,  $p < .001$ ,  $\eta_p^2 = .52$ ;  $F_{word}(2, 20) = 10.37$ ,  $p = .001$ ,  $\eta_p^2 = .51$ , see Figure 4. Bonferroni-corrected post hoc analyses revealed that participants recalled more words after five minutes than they recalled after one week ( $p_{pp} = .05$ ;  $p_{word} = .02$ ) or one month ( $p_{pp} = .03$ ;  $p_{word} = .01$ ). However, learning condition failed to reach significance, as did the interval by condition interaction. These results suggest that, although enactment facilitates L2 word learning by children, it does not seem to enhance L2 word learning by adults.

<sup>1</sup>The results of two participants who indicated in response to a question on the post-experimental survey that they did not follow the instructions regarding mental imagery were excluded.

Figure 4: Percent of word meanings recalled by condition and recall interval for Expt. 4 (error bars represent *SEM*).

## General Discussion

The present research examined the independent roles and interactions that passive and active engagement in mental imagery and embodied action play in L2 word learning. The lack of differences in word learning as a function of condition suggest that neither of these factors plays an integral role in L2 word learning by adults. Given that adults are particularly effective word learners (Snow & Hoefnagel-Höhle, 1978), it is likely that the participants of this study were using alternative methods to associate target words with their meanings, such as phonological association or generation. One notable difference between this study and others (Kelly et al., 2009) is that, in the interest of ecological validity, the stimuli accompanying the target words in the current study were either congruent or neutral to the word meanings. As a result, the variation in word learning between conditions in the current study was more modest than that observed in previous studies. This greater similarity between conditions may explain the lack of significant differences between conditions, as well as why the results of the current study failed to replicate those of previous work (e.g., Kelly et al., 2009; Tellier, 2008).

Surprisingly, the results failed to show that meaningful embodied action, in the form of representative iconic gesture, facilitated L2 word learning and recall more effectively than mental imagery. This finding is inconsistent with several previous studies showing superior recall of L2 words learned via viewing or enactment of iconic gesture (Kelly et al., 2009; Tellier, 2008) or enactment of meaningful motion using the body (Asher, 1969; Asher et al., 1974). There are several possibilities why iconic gesture may have failed to facilitate L2 word learning in the current research. One possibility is that the gestures chosen to represent target words may not have been sufficiently iconic, and thus, may not have been as imagistic and meaningful as gestures used in other studies. Another possibility is that the learning phase may have been too brief to allow for associations between gestures and target words

to be formed. Future research should test these possibilities by examining the acquisition of L2 words via imagistically-rich gesture during an extended learning period, and by comparing the results to those of the current research.

Overall, the results of the current research suggest that neither mental imagery nor embodied action plays a key role in L2 word learning by adults. More specifically, the results indicate that the viewing of iconic gesture, images, and text during L2 word learning result in comparable recall of target words across both long and short learning-test intervals. Finally, the results demonstrate that L2 words are recalled more accurately over short (5 min.) learning-test intervals than longer intervals (1 week, 1 month). Taken together, these findings fail to replicate the results of work showing that representative iconic gesture viewing and enactment enhance L2 word learning (Kelly et al., 2009; Tellier, 2008), suggesting that the word learning techniques of adult L2 learners are already so effective that mental imagery and embodied action have a negligible impact on them.

# How the Hands Cue the Mind: The Effects of Iconicity and Enactment on Sign Language Acquisition

Laura M. Morett (morett@pitt.edu)

Department of Psychology, University of Pittsburgh  
210 S. Bouquet Street, Pittsburgh, PA 15260 USA

## Abstract

Iconicity is a powerful cue to symbolic meaning. However, it is unclear from previous research whether language learners benefit from iconicity. Prior research indicates that the motor system supports language acquisition, suggesting that iconicity expressed via this modality may be particularly salient. The present study investigates the effects of iconicity and enactment on the acquisition of American Sign Language by hearing adults. The results reveal that enactment enhances sign learning in general, but fail to show that iconic signs are learned more effectively than non-iconic signs. As such, they indicate that the motor system—but not iconicity—plays a key role in sign language acquisition.

**Keywords:** Second language acquisition, sign language, mental imagery, embodied cognition.

## Introduction

Sign language is the only type of natural language that is comprehended and produced exclusively in the visuospatial modality. Given that the visuospatial modality allows for greater isomorphism between symbols and their referents than the auditory modality, it follows that sign language should be more iconic than spoken language, and there is evidence that this is indeed the case (McNeill, 2005; O'Brien, 1999). Thus, although hearing speakers are accustomed to processing language in the auditory modality, they may be able to take advantage of this iconicity to expedite their learning of sign language. If iconicity plays a pivotal role in sign language acquisition, learners should be able to acquire sign languages more quickly and effectively than they learn spoken languages. Moreover, learners should be able to learn iconic signs and expressions more efficiently than lexical items that are not iconic.

Unlike spoken language, which is articulated primarily with the mouth and vocal tract, sign language is articulated with the hands and body. As such, another factor that may play an integral role in the acquisition of sign language is the engagement of the motor system. Theories of

embodied cognition posit that representations of language are inherently perceptual, and are encoded and retrieved via the body's sensorimotor system (Barsalou, 1999). Thus, these theories would predict that enacting signs—especially those that are iconic—allows sign language learners to tap directly into these perceptually-based representations, thereby facilitating their recall and comprehension. If the motor system does contribute significantly to sign language acquisition, learners should recall iconic signs better than non-iconic signs due to the isomorphism between the visuospatial properties of motor representations of signs and their referents.

## Iconicity and Language Acquisition

Meaningful hand movements, including gestures and signs, vary on the basis of several qualities, including conventionalization, semiosis, and relationship to speech. In order to show how different types of hand movements relate to one another on the basis of these characteristics, Adam Kendon and David McNeill (1992) developed a continuum, which is illustrated below in Figure 1. At one extreme of the continuum lies sign language, which is highly conventionalized, segmented and analytic, and occurs in lieu of speech. At the opposite extreme lies gesticulation, which is unconventionalized, global and synthetic, and occurs concurrently with speech. Although iconicity is not plotted on this continuum, it can be inferred that, due to its global and synthetic (i.e., holistic) nature, gesticulation is highly iconic, whereas sign is the least iconic of the hand motions.

It is important to note that iconicity varies within and between sign languages. Much of this variation can be explained by ontogenetic development. There is evidence that the home sign of individual deaf children as well as pidgin sign languages created by communities of deaf children are generally more iconic than conventionalized sign languages (Kendon, 1980; Senghas, Kita, & Özyürek, 2004). Moreover, even within highly-conventionalized sign

Figure 1: Kendon's continuum, as characterized by McNeill (2005).

languages, recently-coined signs are more iconic than signs that have been in the language longer (Frishberg, 1975). This is likely the case because signs are initially based on referents' affordances, which become obfuscated through inter-generational transmission of signs.

Obviously, it is quite plausible that iconicity may facilitate the acquisition of signs, due to its isomorphism with the visuospatial properties of the referent. Nevertheless, research has failed to provide conclusive evidence that children learn iconic signs more readily than they learn arbitrary signs. One study of the acquisition of American Sign Language (ASL) by congenitally deaf children showed that only 30% of these children's first 10 signs are iconic, and that this number increases to only 34% at 18 mos. (Orlansky & Bonvillian, 1984). Another study (Miller, 1987) showed that 3-year-old hearing children unfamiliar with ASL were unable to reliably select the correct referent of iconic signs on the Peabody Picture Vocabulary Test, a standardized, forced-choice measure of vocabulary development (L. M. Dunn & Dunn, 1997). Taken together, these findings suggest that both deaf and hearing children are unable to use signs' iconicity to associate them with their referents, thereby facilitating sign language acquisition.

Related work examining gesture comprehension has provided insight into the question of why young children are unable to associate iconic hand movements with their referents. One study showed that, by 26 months of age, children were able to associate iconic gestures with objects with similar affordances, even though they were unable to do so at 14 mos. of age (Namy, 2008). Another, more recent study demonstrated that 4-year-olds were better able than 2-year-olds to learn object labels associated with iconic gestures, but that both age groups learned object labels associated with arbitrary gestures at a comparable rate (Marentette & Nicoladis, 2011). Although this study also showed that 4-year-old children treated iconic gesture as an action associate rather than a label, 2-year-olds were not tested. The seeming inconsistency between the results of these two studies can be explained by the fact that the objects' affordances were demonstrated to children in the earlier study, but not the more recent study. Thus, this work demonstrates that children who were able to effectively associate iconic gestures with corresponding objects understand the relationship between them, allowing these children to use gesture as an embodied aid in word learning.

To date, no published research has examined whether the iconicity of sign language facilitates its acquisition by adult learners. However, there is evidence that adults unfamiliar with sign language can effectively guess the meanings of highly iconic signs, even when their referents are metaphorical (O'Brien, 1999). Work has also shown that adults are able to learn words from a novel spoken language accompanied by representative iconic gestures more effectively than words presented as speech only or words accompanied by non-representative iconic gestures (Allen,

1995; Kelly, McDevitt, & Esch, 2009). Given that adults understand the correspondences between object affordances and iconic hand movements—including signs—it follows that they should be better able to learn highly iconic signs than arbitrary signs.

## **Enactment and Language Acquisition**

Aside from being more iconic than spoken language, sign language is also more embodied than spoken language. Because the hands and parts of the body other than the vocal tract and face play a larger role in sign language than in spoken language, sign language engages the motor system to a greater degree than spoken language. This engagement of the motor system likely produces memory traces that are richer and more multimodal than those produced by spoken language, providing learners with additional recall cues.

Research examining recall of spoken language has provided evidence that engagement of the motor system during language processing enhances memory encoding and retrieval. For example, when presented with a series of instructions, adults recall more spoken instructions when they act them out than when they repeat them aloud (Svensson & Nilsson, 1989). Moreover, adults are more likely to recall spoken instructions for tasks that they have enacted for a longer time period (30 s.) than those that they have enacted for a brief time period (5 s.) (Cohen & Bryant, 1991), indicating that greater engagement of the motor system produces richer, more robust memories. A separate line of research has provided evidence that adults are more likely to produce sought-after words during speech disfluencies when they gesture than when they keep their hands still (Frick-Horbury, 2002; Frick-Horbury & Guttentag, 1998), indicating that gesture facilitates lexical access. Taken together, the results of all of this work suggests that the enactment of meaningful hand motions during language processing allows speakers to tap into their semantic representations more effectively, thereby promoting language encoding and recall.

There is also evidence that the motor system plays a key role in language acquisition. To this end, research has revealed a tight relationship between motor and language milestones in childhood, demonstrating that the onset of babbling is accompanied by repetitive motor movements (Iverson & Fagan, 2004), and that the transition to two-word speech is accompanied by gesture-word combinations (Capirci, Iverson, Pizzuto, & Volterra, 1996). Furthermore, several studies have shown that children are able to express symbolic meaning via hand motions before speech (Acredolo & Goodwyn, 1988; Bonvillian, Orlansky, & Novack, 1983; Iverson & Goldin-Meadow, 2005), and that children's iconic gesture production predicts their vocabulary development (Rowe & Goldin-Meadow, 2009a, 2009b; Rowe, Özçalışkan, & Goldin-Meadow, 2008). Finally, there is evidence that school-aged children are better able to learn the meanings of novel words from both

ASL Sign					
English	Adult	To answer	Box	Color	To count

Sign Type	Iconic	Iconic	Metaphorical	Metaphorical	Iconic

Figure 2: ASL signs and English words used in study, listed by sign type.

their native language and unfamiliar second languages when they enact iconic gestures representing the words' meanings (Tellier, 2005, 2008).

It is important to note that the facilitatory effects of enactment observed in most studies discussed above stem from a combination of embodied action and mental imagery. Furthermore, there is experimental evidence that learning techniques incorporating mental imagery enhance second language vocabulary acquisition (Atkinson, 1975; Atkinson & Raugh, 1975). Aside from investigating the effects of iconicity and enactment on sign language acquisition, a secondary goal of the current study was to disambiguate the roles that embodied action and mental imagery play in sign enactment. As such, the study included conditions that were designed to elicit mental imagery and embodied action in combination, only mental imagery, only embodied action, and neither mental imagery nor embodied action.

To date, no published research has investigated whether enactment facilitates the acquisition of signed second languages by adults. On the basis of previous research, it was predicted that the enactment condition would result in ASL sign acquisition superior to that observed under the other conditions. This prediction stems from enactment's incorporation of both mental imagery and embodied action, and its resulting engagement of both the visuospatial and motor systems.

## Method

### Participants

Undergraduate students were recruited from the participant pool at the University of Pittsburgh, and received partial course credit in return for participation. All recruited individuals were fluent English speakers<sup>1</sup> and confirmed that they had no knowledge of American Sign Language (ASL) prior to the experiment. Additionally, all recruited individuals had normal hearing and normal or corrected-to-normal vision. 6 individuals were eliminated due to technical difficulties or failure to return for all three sessions, resulting in a final sample of 29 participants (age:  $M = 20.79$ ,  $SD = 1.65$ ; sex: 11 males; 18 females).

### Stimuli

Twenty ASL signs and their English glosses were used as stimuli for this research (see Figure 2). Each sign was classifiable into one of the following three types: Iconic, metaphorical, or arbitrary. Iconic signs depicted their

<sup>1</sup> Participants were not required to be native English speakers in order to participate, given that the English glosses of the signs were common words, and should thus be comprehensible to non-native undergraduate students, whose proficiency must be sufficient to comprehend academic English.

referent holistically or metonymically (e.g., pantomiming hammering for *hammer*); metaphorical signs represented the source domain of the conceptual metaphor structuring their referent (e.g., cupped hands moving forward three times, as if conveying an entity of information from the signer to the listener, for *to teach*); and arbitrary signs bore no structural resemblance to their referent (e.g., two fingers from both hands tapping one another repeatedly for *name*). The distinctions between these sign types were supported by empirical data collected from a separate group of participants unfamiliar with ASL (O'Brien, 1999), ensuring that they were applicable to the target population of the current study.

A female native signer of ASL was video recorded demonstrating the twenty signs used in this study. The signer was unaware of the goals of the study. Video footage of each sign was segmented and trimmed, yielding stimuli averaging 2.5 s. in duration. Additionally, ambient audio captured during video recording was expunged from the footage, yielding silent stimuli.

## Procedure

This experiment consisted of three sessions, the first of which included both a learning and test phase, and the second and third of which included only a test phase. In learning trials, participants were presented with video of a randomly-selected sign (~2500 ms.), and after a 1000 ms. interstimulus interval, were presented simultaneously with the corresponding English gloss as text and audio (2500 ms.). After one additional repetition of this sequence of events, participants performed one of four actions. For words presented in the enactment condition, participants enacted the sign with their own hands; as such, this condition included both mental imagery and embodied action. For words presented in the imagery condition, participants closed their eyes and visualized the sign's referent in their mind's eye without moving their hands; as such, this condition included mental imagery, but not embodied action. For words presented in the motion condition, participants made an X-shaped motion with their dominant hand three times; as such, this condition included embodied action but not mental imagery. For words presented in the comprehension condition, the learning sequence was repeated one additional time, and participants were not explicitly told to do anything; as such, this condition did not include either mental imagery or embodied action. Within each experimental session, each sign was randomly assigned to one of these four conditions in a within-participants design, such that five signs were presented in each condition for each participant. The learning phase consisted of 3 blocks comprising 20 trials apiece (one for each sign), yielding a total of 60 learning trials altogether.

Following the learning phase in the first session, participants were given a 5-minute break, and then completed the test phase. In test trials, upon being presented with English glosses as text and audio, participants were

asked to produce the corresponding ASL sign. Participants were instructed to try to recall the sign as best they could, but were told that they could say "skip" to move on if they could not recall a sign. During test trials, participants' signing was recorded by a video camera set approximately 45° to the left of their central viewing point. The test phase consisted of one block of 20 trials (one for each sign). Overall, the first experimental session lasted about 30 minutes.

In order to examine how long-term recall of signs varied by condition, participants returned to the lab for two follow-up sessions held one week and four weeks after the first session. In each of these sessions, participants completed the test phase in the manner described above. Each of the follow-up sessions lasted approximately 10 min. apiece.

## Results

Sign recall was quantified using a binary coding scheme (1 = correct; 0 = incorrect/skipped). Total number of signs recalled correctly for each participant and condition were converted into proportions, in order to control for unscorable responses caused by technical errors in running the recall task (which accounted for less than 5% of the data). In order for a sign to be coded as correct, it must have been performed using the same hand (dominant/non-dominant, as specified per participant on a post-experimental questionnaire), and must have had the same hand shape and movements as the correct ASL sign, as modeled by the signer.

To address the question of whether learning condition affects sign recall, proportional data were submitted to repeated measures ANOVAs, using participant and sign as fixed factors. These analyses revealed significant main effects of learning condition,  $F_{pp}(3, 87) = 7.16, p < .001, \eta_p^2 = .29$ ;  $F_{sign}(3, 45) = 14.07, p < .001, \eta_p^2 = .48$ , and recall interval,  $F_{pp}(1, 29) = 10.99, p = .004, \eta_p^2 = .38$ ;  $F_{sign}(1, 15) = 18.16, p = .001, \eta_p^2 = .55$ , but failed to reveal a significant condition-by-interval interaction,  $F_{pp} > 1$ ;  $F_{sign} > 1$ ; see Figure 3. Bonferroni-corrected post-hoc analyses showed greater recall accuracy for signs learned via enactment than via mental imagery ( $p = .04$ ), motion ( $p = .06$ ), and

Figure 3: Percent of signs produced correctly by learning condition and recall interval (error bars represent SE).

Table 1: Mean number of signs produced correctly by sign type and recall interval.

Sign type	Recall interval		
	5 min.	1 week	4 weeks
Iconic	.74 (.36)	.66 (.24)	.62 (.28)
Metaphorical	.78 (.24)	.55 (.24)	.50 (.29)
Arbitrary	.60 (.26)	.56 (.28)	.44 (.27)

comprehension ( $p = .05$ ), as well as greater recall accuracy after an interval of 5 minutes than 1 week ( $p < .01$ ) and 4 weeks ( $p < .001$ ). These results indicate that enactment facilitates the acquisition of novel signs by hearing adult learners unfamiliar with sign language across both short and long learning-test intervals.

To address the question of whether iconicity affects the learning and recall of ASL signs, sign type (iconic, metaphorical, arbitrary) was entered into a repeated measures ANOVA, using sign as a fixed factor. This analysis failed to reveal a main effect of sign category on recall,  $F(1, 17) = 1.13$ ,  $p = .35$ ,  $\eta_p^2 = .12$ ; see Table 1. This result indicates that, similar to deaf children, hearing adult learners do not benefit significantly from iconicity when learning novel signs.

## Discussion

The current study investigated the roles of iconicity and enactment on the acquisition of ASL signs by hearing adult L2 learners. The results revealed that enactment facilitated sign learning more effectively than visualization of sign referents, performance of meaningless hand movements, or simple sign comprehension. However, the results failed to demonstrate that iconic signs are learned more effectively than arbitrary signs. Considered as a whole, these results suggest that enactment enhances ASL sign recall and production in hearing learners through the creation of motorically-rich lexical traces.

Unfortunately, the results of the current study do not provide insight into why adult L2 learners fail to benefit from the iconicity inherent in some signs, and in sign language in general. One possible explanation is that, like children, adults go through a developmental stage in the initial stages of language learning in which they are unable to associate the visuospatial properties of iconic signs with the affordances of their referents. Although adults are generally familiar with the affordances of common objects, it is possible that this inability to associate them with their corresponding signs derives from insufficient linguistic context, rather than from insufficient domain-general knowledge, which has been proposed to explain children's insensitivity to iconicity. When learning their first set of signs, adults unfamiliar with ASL are unable to relate their semantic and phonological properties to other similar signs, which may negate their ability to recognize iconicity. Alternatively, hearing adults' experience with spoken languages, in which iconicity is sparse, may lead them to

assume that language is not iconic, causing them to ignore any physical correspondences between signs and their referents. Finally, the novelty of processing language in the visuospatial modality may place a heavy cognitive load on adult L2 learners unfamiliar with sign language, negating any benefits that iconicity may have bestowed. Needless to say, future research is necessary to test between these possibilities and to clarify the cause of this null effect.

The advantage produced by enactment of signs during learning indicates that the motor system plays a key role in L2 lexical acquisition, particularly for sign language. Of note, only *meaningful* motion (i.e., sign enactment)—not arbitrary motion (i.e., X-shaped motions)—enhanced sign acquisition. This result is consistent with embodied theories of cognition, which maintain that the mental representations underlying language derive from meaningful interactions between our bodies and the world (Barsalou, 1999). It is also consistent with work showing that meaningless repetitive motion can disrupt the formation of visuospatial representations (Vandierendonck, Kemps, Fastame, & Szmalec, 2004). The observation that enactment is more effective at promoting sign learning than visualization of referents via mental imagery indicates that meaningful engagement of the motor system results in richer, more robust mental representations of signs, which are more likely to be retrieved successfully, particularly by inexperienced learners.

In conclusion, the results of this study demonstrate that adult L2 learners can take advantage of enactment, but not iconicity, to facilitate their acquisition of sign language. As such, they indicate that the hands cue the mind in sign language acquisition, rather than vice versa, demonstrating the power and depth of the body's cognitive capacity in relation to the acquisition of a novel second language.

## Abstract

In this study we examined the cognitive processes involved in engineers and lawyers-type problems, using a novel method (i.e., asking for liking ratings). We were particularly interested in how participants process information about personality descriptions and base rates, which are provided in the problems. In line with previous research, we found that people detect the conflict between descriptions and base rates. Nevertheless, when instructed to reason logically, instead of relying on base rates, participants resolved the conflict by showing higher preference for description-based responses.

**Keywords:** conflict detection; dual-process theories; engineers and lawyers problem; heuristics and biases; instruction manipulation; liking ratings.

Dual process theories of reasoning and decision making (e.g., Evans & Over, 1996; Stanovich, 1999) propose that higher order cognition is based on two qualitatively different types of process. Type 1 (i.e., heuristic) processes are assumed to operate fast and automatically with little demand of cognitive capacity, whereas Type 2 processes are slow, conscious, and demanding of computational resources. The tasks used in the heuristics and biases literature (see e.g., Kahneman, Slovic & Tversky, 1982) can be answered by giving a heuristic-based response, or a response which corresponds to a normative rule of probability (although some theorists have questioned the assumption that giving probability-based responses to these problems is more normative than giving description-based responses – see e.g., Hertwig & Gigerenzer, 1999). Kahneman and Frederick (2005) used these tasks as illustrations for Type 1 and 2 processes at work. For example, consider the classic engineers and lawyers problem (Kahneman & Tversky, 1973; see Table 1.). In the original (conflict) problem, base rate information, which strongly favors lawyers, is presented together with a stereotypical description of an engineer. When participants are asked to decide if the person is more likely to be an engineer or a lawyer, they tend to give the response which corresponds to the description.

An interesting question is whether participants experience a conflict while they solve these tasks, or if they just give the first response that comes to mind. Dual-process theorists (e.g., Evans, 2006) assume that, as Type 1 processes operate quickly and automatically, all participants are inclined to give a Type 1 response by default.

Nevertheless, some individuals (usually the ones of higher cognitive ability – see e.g., Stanovich & West, 2000) are able to inhibit this initial response tendency, and give a response which is based on Type 2 computations. Thus, participants who eventually give a normative response are expected to experience a strong conflict between Type 1 and 2 response tendencies. However, what happens in the case of the majority of the participants who give a heuristic response (which is supposed to be delivered by Type 1 processes)? Do they experience any inner struggle, or do they simply give the first response that comes to mind without ever considering probabilistic information?

In a number of recent studies De Neys and colleagues (e.g., De Neys, Cromheeke & Osman, 2011; De Neys & Glumicic, 2008) used different versions of the engineers and lawyers problem (see Table 1 for illustrations). Besides the original version, they also developed a *non-conflict* task where base-rates and the description pointed to the same response, and they also used a *neutral* task where base rate information was presented together with a description which had no relevance to the choice options. Note that *neutral* problems typically elicit the response of “both options are equally likely” (which is considered a heuristic response). The reason that participants ignore base rates even when they are not provided with any other useful information is, presumably, that they try to base their response on the description (which they automatically assume to be relevant, although it is not). Thus, providing an irrelevant description is enough to draw participants’ attention from the base rates.

De Neys and Glumicic (2008) stated that even people who eventually give a description-based response show signs of conflict detection, although they are not consciously aware of this. They demonstrated that whereas in verbal protocols there was no mention of experiencing a conflict, less explicit measures showed signs of differential processing of base rates in conflict and non-conflict problems.

The purpose of the present study was to investigate further how people process base rate-information in the presence of base rate-congruent, incongruent, and neutral descriptions. In the experiment that we report below we used the problems developed by De Neys and Glumicic (2008) which we slightly modified to make them more appropriate for UK participants. However, instead of asking participants to generate a response, we provided them with a response (which we called a statement), and we asked them

Table 1: Different versions of the engineers and lawyers problem (based on De Neys & Glumicic, 2008).

<i>Conflict: Incongruent description and base rates</i>	
<p><b>(Part 1:)</b> In a study 1000 people were tested. Among the participants there were 5 engineers and 995 lawyers. Jack is a randomly chosen participant of this study.</p> <p><b>(Part 2:)</b> Jack is 36 years old. He is not married and is somewhat introverted. He likes to spend his free time reading science fiction and writing computer programs.</p>	
Statement (heuristic): <b>Jack is an engineer.</b>	Statement (non-heuristic): <b>Jack is a lawyer.</b>
    	
Don't like it at all.	Don't like it. Don't know. Like it. Like it very much.
<i>Non-conflict: Congruent description and base rates</i>	
<p><b>(Part 1:)</b> In a study 1000 people were tested. Among the participants there were 995 sixteen-year olds and 5 fifty-year olds. Ellen is a randomly chosen participant of this study.</p> <p><b>(Part 2:)</b> Ellen likes to listen to hip hop and rap music. She enjoys wearing tight shirts and jeans. She's fond of dancing and has a small nose piercing.</p>	
Statement (heuristic): <b>Ellen is sixteen.</b>	Statement (non-heuristic): <b>It is equally likely that Ellen is sixteen or that she is fifty.</b>
<i>Neutral: Base rates plus neutral description</i>	
<p><b>(Part 1:)</b> In a study 1000 people were tested. Among the participants there were 4 who live in Manchester and 996 who live in Liverpool. Chris is a randomly chosen participant of this study.</p> <p><b>(Part 2:)</b> Chris is 28 years old. He has a girlfriend and shares an apartment with a friend. He likes watching basketball.</p>	
Statement (heuristic): <b>It is equally likely that Chris lives in Liverpool or that he lives in Manchester.</b>	Statement (non-heuristic): <b>Chris lives in Liverpool.</b>

to evaluate the statement, using a 5-point rating scale of smiley faces, ranging from “don’t like it at all”=1 to “like it very much”=5 (see Table 1). This procedure was modelled on Topolinski and Strack (2009a). Liking ratings are sensitive to both conscious and unconscious influences (e.g., explicit preferences, affective priming, etc.), and they are ideal for detecting subtle changes in participants’ judgments (cf., Morsanyi & Handley, 2012). Thus, even if participants are unaware of being influenced by base rates / descriptions, these influences should be reflected in their liking ratings. Moreover, liking ratings convey more information than response choices. For example, it is possible that although a participant shows a strong preference for a certain response option, they also evaluate other options positively.

In order to explore the role of Type 1 and 2 processes in people’s judgments and in utilizing base rates and descriptions, we implemented an instruction manipulation (see e.g., Klaczynski, 2001). Half of the participants were asked to rely on their intuitions, whereas the rest of the participants were instructed to think logically. From a dual-process perspective, intuitive instructions should encourage Type 1 processing, whereas logical instructions should increase the influence of Type 2 processes. Indeed, previous research (e.g., Chiesi, Primi & Morsanyi 2011; Ferreira,

Garcia- Marques, Sherman & Sherman, 2006) showed that instructions affected participants’ susceptibility to reasoning biases. Thus, we expected that whereas in the intuitive condition participants would be strongly affected by descriptions, logical instructions should increase the tendency to rely on base rate information. Nevertheless, this should only happen if participants are consciously aware of the conflict, and if they judge that base rates are more relevant to making sound judgments than descriptions.

Another question that we wanted to investigate was whether heuristic responses are associated with higher liking ratings than non-heuristic responses. In a recent paper (Thompson & Morsanyi, 2012) we proposed that heuristic responses might be hard to resist, because of the positive affective valence that they carry. Specifically, we suggested that as heuristic responses are generated fluently and effortlessly, and fluent processing is associated with positive affect (see Topolinski & Reber, 2010 for a review), participants will prefer a heuristic mode of processing, because heuristic responses “feel right”. In order to test the assumption that liking ratings are closely related to participants’ actual choices, we presented the problems with an option, and they were asked to rate it according to how much they liked it. After performing a different task,

participants were (unexpectedly) presented with the problems once more, but this time they had to select a response from three options. Given the associations between heuristic (i.e., Type 1) processing, positive affect and confidence, we expected that initial liking ratings would be good predictors of subsequent choices.

In summary, the aim of the present study was to better understand the processes underlying performance on engineers and lawyers-type problems. Given the high rate of heuristic responses, we were particularly interested in whether participants experienced a conflict while solving the tasks. We employed a novel paradigm (i.e., asking for liking ratings) to investigate the effect of base rates and descriptions, and we combined it with an instruction manipulation, in order to explore the role of Type 1 and 2 processes in participants' judgments. Additionally, we wanted to test the assumption that heuristic responses are associated with positive affect. Finally, we also predicted that the affective valence of choice options would be closely related to how likely individuals will be to opt for a response when they are offered a choice between different responses.

## Methods

### Participants

The participants were 62 students (54 females, mean age 21 years 2 months) from the University of Plymouth, UK who participated in the study for ungraded course credit. Participants were randomly allocated either to the intuitive ( $n=32$ ) or to the logical ( $n=30$ ) instruction condition.

### Materials

The participants were presented with 12 problems: 4 *conflict* problems (i.e., where the description of the person was incongruent with base rates), 4 *non-conflict* problems (where descriptions and base rates were congruent), and 4 *neutral* problems (with irrelevant descriptions). The problems were presented in two parts (using a "moving window" procedure – see de Neys & Glumicic, 2008, Experiment 2). The base rates were presented first (together with the information that the person was randomly selected from a large sample – marked as Part 1 in Table 1), then participants had to press the space bar, and this information disappeared, and the description of the person (Part 2) appeared together with the statement about the person and the rating scale for liking ratings. Participants could review base rate information by pressing a radio button on the computer screen. The problems were presented in a random order, which was different for each participant. The statement that participants had to rate either corresponded to the base rates or to the description (or both), or it simply said that the person was equally likely to belong to either category (see Table 1 for examples). In order to reduce content effects, we created two task sets, where for the same problem participants were either offered a heuristic (i.e., description-based), or a non-heuristic response (see Table 1

for illustrations). Finally, in the second part of the experiment, participants were presented with the same problems again, using the same presentation format as in the first part. However, instead of providing liking ratings for one response option, participants had to choose from three responses (i.e., 1. the person belonged to one category – e.g., engineers; 2. the person belonged to the other category – e.g., lawyers; or 3. it was equally likely that the person belonged to either one or to the other category).

### Procedure

Participants solved the problems on the computer. First they were presented with instructions, and they were informed that they could review the first part of the problem. Additionally, in the intuitive condition participants were told: "*When you make your liking ratings, rely on your intuition and feelings. Give the first rating that comes to mind, without any conscious reflection, and do this as quickly as you can.*" In the logical condition the instructions ended like this: "*When you make your liking ratings, take the point of view of a perfectly logical person. Think about your answer very carefully. Don't rush. You can take as much time as you want.*" Subsequently, the participants were presented with a practice problem, and then they had to work through the 12 experimental problems. After this, they had to perform a different (unrelated) task for about 5 minutes. Finally, they were presented with the problems again. This time they had to choose from three options, rather than evaluating a response which was offered to them. In the second part of the experiment participants were instructed to consider the problems carefully, but they were not explicitly asked to reason intuitively or logically. This part also started with a practice problem.

### Results

First, as a manipulation check, we compared the average time that participants spent solving each problem across the intuitive and logical conditions (collapsed across all tasks). As expected, participants in the intuitive condition responded more quickly ( $M=17820$  ms,  $SD=4235$  ms) than participants in the logical condition ( $M=23872$  ms,  $SD=7223$  ms;  $t(60)=4.06$ ,  $p<.001$ ).

We also wanted to see whether we could replicate the pattern reported by De Neys and Glumicic (2008) regarding participants' inspection of base rates. Specifically, these authors reported that participants were more likely to opt for reviewing base rate information if the base rates were in conflict with the description of the person, as opposed to when there was no such conflict. In our analyses we included not only conflict and non-conflict problems, but also problems with neutral descriptions, in order to see whether problems with base rate-incongruent and neutral descriptions are processed differently. Finally, we were also interested in whether the tendency to review base rates differed across the two instruction conditions.

Participants in the intuitive condition reviewed on average 11% ( $SD=.22$ ) of the base rates in the case of

Table 2: Participants' liking ratings across the different types of task, and different statements.

	Incongruent		Congruent		Neutral	
	<i>Heuristic</i>	<i>Base rate</i>	<i>Heuristic/ base rate</i>	<i>Equally likely</i>	<i>Heuristic/ equally likely</i>	<i>Base rate</i>
intuitive	3.19 (.74)	2.66 (.76)	3.63 (.61)	3.14 (.95)	3.16 (.83)	3.27 (.84)
logical	3.47 (.82)	2.42 (.97)	3.60 (.93)	3.32 (.92)	3.68 (1.03)	3.22 (.85)

conflict, 8% ( $SD=.21$ ) in the case of non-conflict, and 9% ( $SD=.21$ ) in the case of neutral problems. The corresponding numbers in the logical group were 23% ( $SD=.24$ ), 14% ( $SD=.18$ ), and 28% ( $SD=.29$ ), respectively. A 3x2 mixed ANOVA with problem type (conflict/non-conflict/neutral) as a within-subjects factor and condition (intuitive/logical) as a between-subjects factor indicated a significant effect of problem type ( $F(2, 120)= 4.04, p=.020, \eta_p^2=.06$ ), and a significant effect of condition ( $F(1, 60)= 6.77, p=.012, \eta_p^2=.10$ ). The problem type by condition interaction was not significant ( $p=.114$ ). That is, in general participants in the logical condition were more inclined to review base rates. Follow-up analyses also showed that participants were more likely to review base rate information if descriptions were not in line with base rates, regardless of whether descriptions were conflicting or neutral. Indeed, the tendency to review base rates did not differ between conflict and neutral problems.

Next we analyzed participants' liking ratings (see Table 2). In order to gather further support for the claim that participants were sensitive to the conflict between the descriptions and base rates, we compared their liking ratings for description-based (i.e., heuristic) responses across problems where base rates and descriptions were congruent (non-conflict), and where these were incongruent (conflict). A 2x2 mixed ANOVA with condition (intuitive/logical) as a between-subjects, and problem type (congruent / incongruent) as a within-subjects factor indicated a significant effect of problem type ( $F(1, 60)= 5.95, p=.018, \eta_p^2=.09$ ). The effect of condition, and the condition by problem type interaction were not significant. That is, participants, regardless of condition, liked description-based responses more if these were not in conflict with base rates.

Another issue that we were interested in was whether participants' liking ratings were higher for heuristic responses than for non-heuristic responses. To investigate this question, we first collapsed ratings across *conflict* and *neutral* problems. As we described in the introduction, in the case of both types of task there is a general tendency for participants to disregard base rates. This is assumed to be the consequence of an automatic (i.e., heuristic) tendency to generate responses that correspond to (or take into account) the descriptions (cf. Kahneman & Frederick, 2005).

The average ratings for heuristic and base rate responses in the intuitive condition were  $M=3.17$  ( $SD=.51$ ) and  $M=2.96$  ( $SD=.63$ ), respectively. The corresponding ratings in the logical condition were  $M=3.58$  ( $SD=.60$ ) for heuristic,

and  $M=2.82$  ( $SD=.78$ ) for base rate responses. In line with our predictions, a 2x2 mixed ANOVA with response type (heuristic/base rate) as a within-subjects and condition (intuitive/logical) as a between-subjects factor indicated that participants liked heuristic responses more than base rate responses ( $F(1, 60)= 19.80, p<.001, \eta_p^2=.25$ ). Additionally, there was a significant interaction between response type and condition ( $F(1, 60)= 6.32, p=.015, \eta_p^2=.10$ ). Interestingly, this interaction showed that there was a greater difference between ratings for heuristic and base rate responses in the case of participants in the logical as compared to the intuitive condition. That is, participants who invested more time and effort into providing their liking ratings were more biased by the descriptions. Nevertheless, participants in both conditions provided higher liking ratings for responses which are supposed to be based on heuristic (i.e., Type 1) processing than for non-heuristic (i.e., Type 2) responses.

Finally, we wanted to investigate how closely the liking ratings were related to participants' actual response choices in the second part of the experiment (this analysis was conducted at the level of tasks; see Figure 1). The correlation between liking ratings and the probability that a participant selected a given response was significant both in the intuitive ( $r(384)=.20, p<.001$ ) and in the logical condition ( $r(360)=.38, p<.001$ ), and the association was significantly stronger in the logical condition, as indicated by a Fisher  $r$ -to- $z$  transformation ( $z=2.67, p=.008$ ).

Figure 1: The probability of selecting a response as a function of liking ratings in the two conditions (broken line: intuitive condition).

## Discussion

In the present study we employed a new method (asking for liking ratings) to investigate the cognitive underpinnings of performance on engineers and lawyers-type problems. Liking ratings can be used to investigate both conscious and unconscious preferences, and they are very sensitive to subtle changes in participants' judgments.

Arguably, the most interesting finding is that although participants' probability judgments were biased by the person's description both in the intuitive and in the logical condition, this bias was stronger in the logical group. This is in contrast with earlier studies which generally reported a decrease in biases as a result of logical instructions (e.g., Chiesi et al., 2011; Ferreira et al., 2006). This finding is also in contrast with the assumption that in heuristics and biases tasks people automatically generate an initial heuristic response, which is either accepted without modification, or it is suppressed by conscious and effortful reasoning (e.g., Evans, 2006). Instead, it seems that, at least in the case of the engineers and lawyers problem, although most people show an initial (weak) preference for heuristic responses, this preference becomes significantly stronger when they invest more time and effort in the evaluation of the response options.

Indeed, a similar pattern has been observed in the case of the Wason selection task, using eye tracking methods (Ball, Lucas, Miles & Gale, 2003). In the selection task people tend to focus on a response (usually the one, which is considered the intuitive response) almost immediately after they are presented with the options, but then they spend a longer period considering this response before making their eventual choice. This pattern has been cited as evidence that although Type 2 processes are employed in the selection task, they are merely used to rationalize an initial, Type 1 response (Evans, 2006). Nevertheless, there is evidence that people do engage in a conscious reasoning process when they make their choices in the selection task, although this does not necessarily result in finding the normative solution (cf., Handley, Newstead & Neilens, 2011). Indeed, spending more time on evaluating a compelling response option might increase reasoners' confidence in the correctness of the response (see e.g., Thompson & Morsanyi, 2012).

The increased bias in the logical condition suggests that conscious reasoning processes play an active role in the engineers and lawyers problem. Instead of just approving intuitive response tendencies, they magnify the initial bias. Indeed, this process might involve the active rejection of base rates as a potential basis of judgment. In fact, participants not only rated the responses which corresponded to base rates lower than the responses which were in line with the descriptions, but their ratings for base rate responses were also slightly negative.

With regard to conflict detection, our results support earlier findings (e.g., de Neys & Glumicic, 2008) which suggested that participants experience a conflict when base rates and the description of the person cue different responses. However, we should note that providing a neutral

description resulted in similar levels of base rate-inspection as providing base rate-incongruent descriptions. Thus, base rate inspection could be taken as a sign of uncertainty or decreased processing fluency, rather than of "conflict detection". As we found no evidence for a difference between the intuitive and logical groups in "conflict detection" (as indexed by reviewing base rates, and the difference between liking ratings for description-based responses in conflict and non-conflict problems), it remains unclear if participants are conscious of the conflict. We could expect that offering a response which corresponds to the base rates in a conflict task makes base rate information more salient. Nevertheless, participants' evaluations of these options were slightly negative, which indicates that even if they were aware of the potential significance of base rates (and the conflict between base rates and descriptions), they still preferred to base their judgments on the descriptions. Thus, it is unlikely that the reason that only a small minority of participants give normative responses to the engineers and lawyers problem is that participants only detect the conflict unconsciously, and, as a result, their conscious responses remain unaffected by this.

As expected (cf., Thompson & Morsanyi, 2012), heuristic responses were liked more than probability-based responses. This corresponds to the general pattern that most participants select or generate a heuristic response when they are presented with the engineers and lawyers problem (see e.g., De Neys & Glumicic, 2008; Kahneman & Tversky, 1973). This pattern is also in line with the idea that heuristic processing is associated with positive affect, and this affective component might contribute to participants' tendency to accept these responses. Indeed, initial liking ratings were significantly related to participants' response choices. The finding that this relationship was stronger in the logical group suggests that these participants indeed considered the options more carefully than participants in the intuitive condition (given that response choices in the second part of the study were based on careful consideration).

Although affective reactions might contribute to both liking ratings and response choices, it is also possible that the liking ratings were unrelated to participants' affective states, and participants simply indicated with their liking ratings the extent to which they found a particular response correct or appropriate. Other studies (e.g., Topolinski & Strack, 2009b; Morsanyi & Handley, 2012) demonstrated through effective priming and emotion-misattribution manipulations that liking ratings are sensitive to participants' affective states. Nevertheless, future studies should seek to provide more direct evidence for the link between affect, liking ratings, and heuristic responses. One method which seems particularly suitable would be to measure the activation of facial muscles which are associated with smiling and frowning, using electromyography (see Topolinski, Likowski, Weyers, & Strack, 2009), while participants evaluate heuristic and non-heuristic response options.

In summary, our findings provide new insight into the cognitive processes involved in the engineers and lawyers problem. Most importantly, these results indicate that conscious thinking might contribute to the biases often observed in judgment and reasoning. Indeed, there is a growing body of evidence to indicate that responses which are assumed to be based on heuristic or automatic (i.e., Type 1) processing often require cognitive effort. Generating these responses might even be more effortful than producing other responses, which traditional dual-process approaches associated with effortful, Type 2 processing (see e.g., Handley, Newstead & Trippas, 2011; Morsanyi & Handley, 2008). These findings, together with criticism which is based on more theoretical considerations (e.g., Keren & Schul, 2009; Osman & Stavy, 2006), pose a challenge to dual-process theories of reasoning.

# Inferring aspectuality on French sentences: a minimalist approach

Damien Munch (Munch@Telecom-Paristech.fr) and  
Jean-Louis Dessalles (Jean-Louis.Dessalles@Telecom-Paristech.fr)  
INFRES, Institut Telecom ParisTech, 46 rue Barrault  
75013 Paris FRANCE

## Abstract

Current models of temporality in language are either inaccurate or too complex to be cognitively plausible. We present a cognitive model of the computation of aspect in French. Our approach emphasizes the importance of minimalism for cognitive plausibility: structures and computation are kept simple and combinatorial explosion is avoided. Though the model and its current implementation remain partial for now, our approach opens the way to a generic and cognitively plausible method for the determination of aspect.

**Keywords:** Cognitive minimalism; Natural Language Processing; Temporal aspect; Temporal reasoning

## Introduction

Humans are experts in the communication of temporal information. The coherence of discourse relies on the correct expression of time and aspect, both in narratives (e.g. to mark causality) and in argumentative discussions (think of an alibi). Though significant progress has been achieved in modeling temporal processing, current models are either inaccurate or too complex to be cognitively plausible. In the present paper, we stick to the idea that a plausible model should rely on a minimum number of principles. The paper presents new elements in that direction.

Linguists have established various categorizations of aspect, tense and modality (Vendler, 1967; Comrie, 1976; Veters, 1996, among others). They explain variations of meaning by postulating the existence of rich semantic structure stored in lexical entries. For example, Comrie (1976), based on (Vendler, 1967), associates binary attributes such as achievement, accomplishment, semelfactive or activity to verbs. The challenge is to infer aspect, such as repetition and perfectivity, and to predict semantic incorrectness from the combination of attributes when processing a sentence. One problem is to limit the number of attributes that lexical entries may instantiate in their structure. Another problem is to show that the chosen lexical attributes are sufficient.

In addition to fixed attributes attached to the lexical entries, some logicians and computer scientists introduced a *procedural* component in their models of temporal interpretation. To process *tense*, Reichenbach (1947) introduced a minimalist model based on three dynamical coordinates: Event, Reference and Speech. Despite its impressive description power, this model does not account for tense in nested clauses (Hwang & Schubert, 1992) and it fails to explain the behavior of some tenses in other

languages than English (Dowty, 1979; Comrie, 1985). Since then, Reichenbach's model has been steadily improved. The three coordinates have been changed for intervals and/or have been increased in number (Comrie, 1985; Gosselin, 1996; Elson & McKeown, 2010).

There have been attempts to process *aspect* in a minimalist way as well. Recent TimeML versions (Sauri & al., 2009) consider four attributes: Progressive, Perfective, Perfective\_progressive and None. Smith (1991) proposes a model based on only three viewpoints: Imperfective, Perfective, and Neutral. Ghadakpour (2004) uses only two viewpoints, called Figures and Grounds.

Lexical models, in which temporal knowledge is stored in static lexical attributes, face the problem of *attribute defeasibility*. For instance, the verb "to hit" is supposed to have the Punctual attribute; therefore, "she hit the wall for one minute before leaving" receives a repetitive interpretation (several knocks); however, "The small galaxy hit (collided with) the Milky Way for ten million years before collapsing" can receive a non-repetitive interpretation, in contradiction with the supposed Punctual attribute of the verb.

Procedural models, in which lexical entries are given computation power, are able to deal with context. For instance, in Gosselin's (1996) and Schilder's (2004) models, the function assigned to *en* (in French) or *in* (in English) checks whether the complement of the preposition involves duration. Schilder's model even checks whether the phenomenon happened in the past or not. Procedural models, however, are not parsimonious as long as they do not set limits to the computational power of words. For instance Person's (2004) implementation of Gosselin's model of French temporality associates a specific computing rule to each tense and each temporal marker (preposition, temporal adverbs, ...). Similar procedural approaches, in which temporal lexemes are given significant computation power, are proposed by others authors like Saussure (2003) and Schilder (2004). Though these models try to remain parsimonious *in fact*, they are not parsimonious *in principle*. Models in which words may have unlimited power (*i.e.* they may perform any computation like Turing machines) do not qualify as cognitive models, not only because they lack parsimony but also because they cannot explain how children learn the mechanisms of temporality of the surrounding language.

Models of temporality face another problem. The temporal meaning of a sentence cannot be deduced only from temporal information stored in lexemes. Moens and Steedman (1988) have shown that the mental

representations corresponding to events are not reducible to tense and aspect. They are closer to concepts such as causal sequences, preparatory processes, goals and consequent states. According to these authors, temporal attributes stored in the lexicon cannot capture the richness of interpretation that is accessible to humans. Temporal interpretation would involve causal relationships that lie beyond strict linguistic processing. Models such as Event Calculus (Shanahan, 1999), modeled by Mueller (2004), do take background knowledge into account. The problem, for such models, is to circumscribe the effect of context, not only to avoid unrealistic processing time, but also to keep the systematic character of some temporal phenomena.

Our aim is to design a cognitively plausible model of temporality that avoids the previously mentioned difficulties (attribute defeasibility, unlimited computational power and unlearnability, prohibitive processing time, loss of systematicity). We favor a minimalist approach, in which both structures and procedures are kept minimal. In what follows, we will first list a limited set of examples in French that we use as benchmark. Then we will see how Gosselin's and Schilder's models behave on such examples. We chose these two models because they use concepts similar to ours, such as *viewpoint*, *anchoring* and *granularity*. We will then describe our model and its single procedure: *tMerge*. We conclude with a discussion in which we assess the plausibility and the generality of our approach.

### Temporal correctness

Table 1 shows a few examples that have been tested for acceptability. We asked thirty-five French native speakers to answer multiple choices questions about forty-one sentences in French. These sentences were designed to test all combinations of tense, event type and time adverbials. They were proposed in random order and participants were allowed to stop whenever they want. We got an average of twenty answers by sentence. All sentences have the same form: verb phrase + prepositional phrase. Participants were asked the following questions:

- Is the sentence correct / incorrect ("one wouldn't say that") ?
- Does the event occur several times (repetition) / only once (possibly with breaks) ?
- Is the event finished / not finished / don't now ?
- Is the event taking place during the whole period indicated by the prepositional phrase / during only part of it / don't now ?

Participants could provide two sets of answers for a given sentence if they thought there were two meanings.

Table 1 shows some of the results. The binary values *unique/multiple*, *perfective/imperfective* and *whole/slice* refer to coded answers to questions b-d. Percentages for a given sentence correspond to participants who found the sentence correct. They may add up to more than 100% when several interpretations were given.

Table 1: Tested sentences

- |  |
|--|
| <p>(1) Elle mangera du gâteau en février.<br/> <i>She will eat (be eating) cake in February.</i><br/> (30%) <b>unique/perfective</b> and <b>slice</b> of February<br/> (80%) <b>multiple/imperfective</b></p> <p>(2) * Elle mangera du gâteau en 30 minutes.<br/> * <i>She will eat (be eating) cake (or from the cake) within 30 minutes.</i><br/> (30%) <b>unique/perfective</b></p> <p>(3) Elle atteindra le sommet en février.<br/> <i>She will reach the top in February.</i><br/> (76%) <b>unique/perfective</b> and <b>slice</b> of February</p> <p>(4) Elle mangera (à la cantine) pendant deux mois.<br/> <i>She will be eating (at the canteen) for two months.</i><br/> (100%) <b>multiple/imperfective</b></p> |
|--|

Table 2 shows classical sentences (examples 5-8) that were not included in the test.

Table 2: Sentences variations

- |  |
|--|
| <p>(5) Elle atteindra le sommet en 30 minutes.<br/> <i>She will reach the top within (the next) 30 minutes.</i><br/> <b>unique/perfective</b></p> <p>(6) * Elle atteindra le sommet pendant 30 minutes.<br/> * <i>She will be reaching the top for 30 minutes.</i></p> <p>(7) Elle atteindra le sommet pendant le prochain mois.<br/> <i>She will reach the top during the next month.</i><br/> <b>unique/perfective</b> and <b>slice</b> of the next month</p> <p>(8) Elle mangera du gâteau pendant les 30 prochaines minutes.<br/> <i>She will eat (be eating) cake during the next 30 minutes.</i><br/> <b>unique/perfective</b></p> |
|--|

The challenge is to account not only for the acceptability or incorrectness of sentences, but also for the judgements about repetition, perfectiveness and wholeness. The next section examines how Gosselin's and Schilder's models perform on this kind of examples.

### The computation of aspect

Gosselin's (1996) model represents perfectivity by considering intervals with two different types of boundaries: *intrinsic* and *extrinsic*. These boundaries are retrieved from the aspectual type of events (telicity, punctuality, dynamicity). For instance "manger du gâteau" ("to eat cake") will take extrinsic boundaries because its aspectual type is supposed to be *semelfactive* (this information is provided by some external cognitive processing).

Repetition appears during conflict resolution, when the granularities of two intervals are different. For instance in example (1), “manger du gâteau” and “février” (February) do not have the same granularity; the conflict is solved by iterating the interval of “manger du gâteau”.

Conflict resolution also involves instructions which can move one or both boundaries of an interval. This will lead to shrinking, expanding or moving one of the conflicting intervals. Slices in our examples would result from shrinking the interval of the adverbial phrases (“février”, “le prochain mois”).

In example (2) (“manger du gâteau en 30 minutes”), “manger du gâteau” is represented by an interval [B1,B2] with *extrinsic* boundaries, whereas “30 minutes” is represented by an interval [ct1,ct2] with *intrinsic* boundaries. Step b (Figure 1) succeeds, but step c fails because the two intervals have incompatible boundaries types.

Though Gosselin’s model seems to work fine, it is at the expense of simplicity. Specific instructions are assigned to ‘operators’, that is, to every lexeme with a temporal meaning, such as tenses and temporal prepositions. Figure 1 shows the instructions associated to the preposition “en” + *duration*. The problem is not only the actual complexity of such instructions, but also the fact that this complexity is not bound in principle.

- |   |
|---|
| <p>a) associate an interval [ct1,ct2] to the temporal adverbial</p> <p>b) <math>ct1 &lt; ct2</math> (non-ponctual adverbial, boundaries are dissociated)</p> <p>c) [ct1, ct2] CO [B1,B2] (adverbial coincides with the event)</p> <p>d) [I,II] ACCESS [B1,B2] (boundaries of the event must be ‘accessible’ by the reference interval ; <math>I \leq B1</math> and <math>II \geq B2</math>)</p> <p>The interval of the event [B1,B2] must be intrinsic (when “pendant” + duration need extrinsic boundaries).</p> |
|---|

Figure 1: instructions for “en” + *duration*, adapted from Gosselin (1996)

Schilder (2004) uses neither intervals nor boundaries in his model. Events are given one of the four aspectual values defined in TimeML (Sauri & al., 2009): Perfective, Progressive, Perfective\_progressive and None.

Schilder’s model can detect granularity incompatibilities, though it is not clear whether they are solved by operations like slice or repetition.

To deal with the examples of Tables 1-2, he proposes two different functions for each temporal preposition, depending on whether the complement is anchored or not. Figure 2 shows instructions for “in” (note that this function applies to the English or German “in”). In example (5), the event “reach the top” occurs at ‘timestamp’ TS, which is the ‘Document timestamp’ (DTS) *plus* the given duration (DUR) “30 minutes”. The granularity (G) of the event is given by

the document timestamp (Figure 2). Note that this computation does not seem to be always valid in English (for instance, in “She will defeat her opponent in 30 minutes”, meaning “She will play during 30 minutes and win”, the duration of the event should be DUR and not DTS).

<p><i>Anchored</i>: TSDUR</p> <p><i>Unanchored</i>: If Tense = Past then DUR else TSP1G where <math>TS = DTS + DUR</math> and <math>G = \text{gran}(DTS)</math></p>
---

Figure 2: function used by “in”, adapted from Schilder (2004)

Contrary to Gosselin, Schilder chooses to assign functions to all lexemes, not only the ‘temporal’ ones. On the other hand, processing is somewhat simpler, as it treats prepositions as unary instead of binary operators, as proposed by Pratt & Francez (2001). However, Schilder model has the same drawback as Gosselin’s: *each lexeme* is given a dedicated function. As long as there is no indication about how to limit the computational complexity of these functions, models cannot be considered minimalist.

## A minimalist model

In this paper, we present a model which is minimal in terms of structures, procedure and memory use. We rely on one single fixed-sized semantic structure, called *temporal Semantic Structure* (tSS), and one single non-recursive operation, called *temporal merge* (tMerge). Note that the use of the term *merge* (related to Chomsky, 1995) instead of *unification* is debatable (Jackendoff, 2005). To achieve this reduction, we decided to exclude several operations from the temporal processing proper, in line with (Moens & Steedman, 1988), considering that they required access to other cognitive modules (general knowledge and perception abilities, syntax, determination). These operations include:

- time location (whether a situation is located in time or not)
- temporal granularity (or order of magnitude) consistency checking
- causality and anteriority checking
- self-similarity checking
- phrase syntactic hierarchy

For our purposes, these operations need not be represented in a cognitively realistic way, as they are considered external to the model. We implemented them in a basic form in our perception module. We now describe the two central components of the model, tSS and tMerge.

## The Temporal Semantic Structures (tSS)

The tSS is the only structure processed in the model. A tSS is a non-recursive structure. It contains three attributes: an

*image reference* (ImageID) and two *switches* (*Viewpoint*, *Anchoring*).<sup>1</sup> These attributes may be uninstantiated at a given step of the processing.

**ImageID** The image identifier is a reference to a perceptive representation. The term 'image' includes any perceptive representation, either stored or constructed. The mere use of *ImageID* in the tSS allows us to grossly simplify several processes which are supposed to be performed in an external module. That module (called '*Perception*') is loosely defined as including anything which does not pertain to syntactic processing or to temporal processing proper (as defined in our model). This includes all forms of memory and all forms of knowledge, such as the granularity or the date of events. It also includes the ability to decide about anteriority and about self-similarity.

**Viewpoint** The *Viewpoint* switch may take two values, *figure* (f) and *ground* (g) (Ghadakpour, 2003). It may be defined in the lexical entry (for example, the French 'imparfait' (imperfect tense) requires a *ground*). However, it is most often determined during temporal processing. Viewpoints are a key element of our model. They provide information about how the speaker regards the temporal phenomenon at a given stage of processing: either 'from the outside' and considering the overall event (*figure*), or 'from within' (*ground*) (exactly as for space). These two values correspond to standard aspect values: perfective and imperfective. However, we consider the viewpoint as a *switch* that may change value during processing.

**Anchoring** The anchoring *switch* indicates whether *Perception* is able to provide some (absolute or relative) location for the perceptive image. The Anchoring *switch* may take two values: *anchored* (a) and *unanchored* (u). For example "(any) 30 minutes" will be unanchored, but "these 30 minutes" will be anchored. Some lexemes are ambiguous in this respect: "in February" may mean that we deal with a specific (anchored) or a recurring (unanchored) period. Anchoring bears a close relation to determination. "The concert" is likely to designate an anchored time period, whereas "a concert" refers to an unanchored time period.

### The temporal merge operator (tMerge)

The tMerge procedure (Figure 3) is launched whenever a phrase is recognized by the syntactic analysis. In other words, the syntactic and semantic analyses are fully synchronous. tMerge receives two tSS as input, plus the indication that one (the head) dominates the other (the complement). It returns a unique tSS as result. These elements appear as H, C and R respectively in Figure 3 (tSS are indicated in square brackets). Even if we deal here with temporal merge exclusively, we assume that the semantic merge operation performed in several other specialized modules (spatial relationships, determination, perception).

(1) The essential part of tMerge consists in a *basic merge* operation (bottom of figure 3): corresponding *switches* in the two input tSS are merely matched for compatibility to produce R.

(2) When basic unification succeeds, unification proceeds to the Perception module (see figure 3) where it generates a new image (this process, omitted from our model, merely concatenates images identifiers). The perceptive merge may apply *viewpoint* constraints to the resulting tSS depending of the nature of the phenomenon: *indivisible* events are bound to be *figures*, whereas *self-similar* events must be

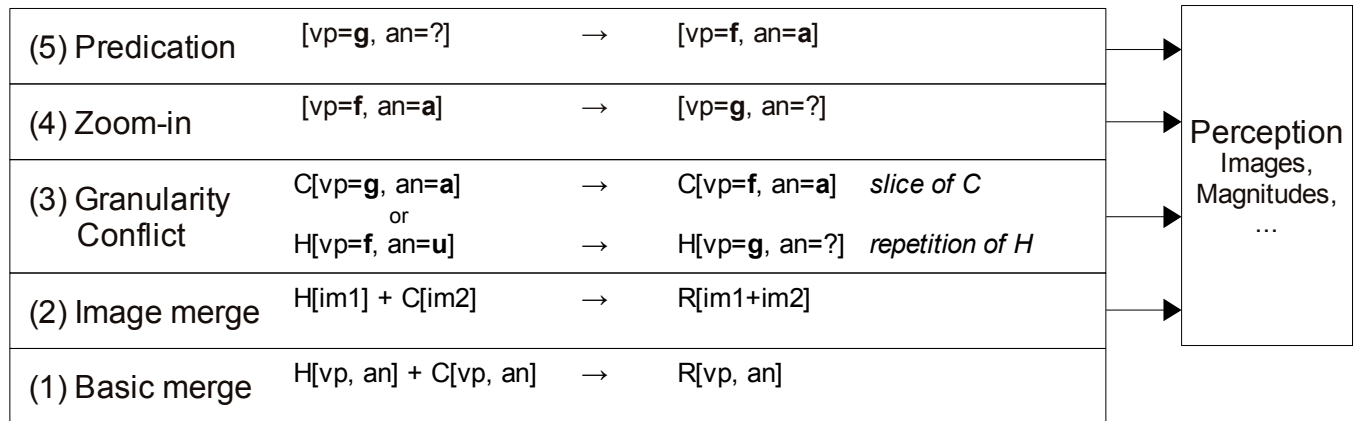

Fig 3: tMerge steps

<sup>1</sup> For the sake of simplicity, we omit *switches* related to tense.

*grounds*. The perceptive merge also checks for granularity compatibility. All the other operations of figure 3 aim at rescuing basic merge and perceptive merge in case of failure.

(3) The *Granularity conflict* rescue operation is triggered in examples like: “She will eat the cake in February”, where the orders of magnitude are hour *vs.* month. Depending on viewpoint and anchoring constraints, the complement element will be *sliced* (she will eat cake once at some point in February) or the head will be *repeated* (she will be eating cake repeatedly throughout February).

(4) The *Zoom-in* rescue operation may switch a viewpoint that is blocking unification from *figure* to *ground*. It can only apply if the input tSS is *anchored*, if it has an instantiated imageID (for example we can zoom-in on “this month” but not on “30 minutes”), and if Perception is able to create a zoomed image (as in “she reached the top in ten hours”, where one must imagine some definite ultimate climbing phase lasting ten hours).

(5) The last rescue operation is *Predication*. Its effect is to switch one tSS to an *anchored figure*. It requires that *imageID* be instantiated and it can be used only once in a sentence.

The model, characterized by the tSS and the tMerge operation, claims to be minimalist. tSS are not recursive (*i.e.* a tSS does not contain or refer to another structure of same nature, contrary to feature structures like those used in HPSG for instance). A tSS has a fixed length and cannot grow. Moreover, the tMerge operator is ‘amnesic’, which means that the input tSS are lost after the resulting tSS has been computed. This prevents the model from using unrealistic memory resources in uncontrollably growing structures. Many models are monotonic, which means that the structures they process can only grow in size and complexity during processing, becoming unrealistic for large inputs (Ghadakpour, 2003). Our model is non-monotonic and therefore avoids this problem.

Our model has been implemented in Prolog. The program provides all admissible solutions for an input sentence and signals incorrect sentences.

## Examples

The model and its implementation account for all sentences of our test, including the examples listed in Tables 1 and 2. It detects “incorrect” sentences; it correctly predicts repetition, slice and perfective and imperfectives aspects. Examples (1) and (2) are detailed below.

(1) Elle mangera du gâteau en février  
(*She will eat/be eating cake in February*)

The determiner “du” introduces a *ground* viewpoint. On the other hand, “en” is associated with a *figure*. Let’s consider the step where the two phrases “manger du gâteau” (“to eat cake”) and “en février” (“in February”) are to be unified.

Head: “manger du gâteau” (“to eat cake”)  
[im/i\_eat\_cake, vp/g, an/?]  
Complement: “en février” (“in February”)  
[i\_february, vp/f, an/a]

The *basic merge* (figure 3, (1)) detects a viewpoint conflict. The conflict could be solved either by zooming-in on “en février” (figure 3, (4)) or by predicating “manger du gâteau” (figure 3, (5)), but then the perceptive merge (figure 3, (2)) will detect a granularity difference. We must predicate “manger du gâteau” and zoom-in on “en février” in both case. This leaves us with two solutions.

In the first solution, the *figure* of the head is repeated, and a *ground-ground* merge becomes possible. In the second solution, the complement is sliced and a *figure-figure* merge becomes possible. Slicing is allowed by the fact that “February” is anchored (figure 3, (3)). We thus get the two following interpretations:

Result 1: “manger du gâteau (plusieurs fois) en février” (“to eat cake several times throughout February”)

[i\_eat\_cake\_february, vp/g, an/u]

Result 2: “manger du gâteau” (une fois) en (un moment de) février” (“to eat cake once at some point in February”)

[i\_eat\_cake\_february, vp/f, an/u]

(2) \* Elle mangera du gâteau en 30 minutes

(\* *She will eat (be eating) cake (or from the cake) within 30 minutes.*)

As previously, the tSS of “manger du gâteau” receives a *ground* viewpoint. By contrast with example (1), there is no granularity conflict, but the complement “en 30 minutes” is not anchored. Let’s consider the step where the two phrases “manger du gâteau” (“to eat cake”) and “en 30 minutes” (“within 30 minutes”) are to be unified.

Head: “manger du gâteau” (“to eat cake”)  
[i\_eat\_cake, vp/g, an/?]  
Complement: “en 30 minutes” (“within 30 minutes”)  
[i\_30\_minutes, vp/f, an/u]

There is no way to solve the viewpoint conflict: the complement cannot be zoomed-in because it is unanchored. Predication cannot be used to solve the *viewpoint* conflict, since it creates an *anchoring* conflict. The model returns an error, as expected.

## Conclusion

We have shown how some of the mechanisms of French aspectuality could be predicted using a minimalist model. We share various notions and mechanisms with Gosselin’s and Schilder’s models, including anchoring, granularity checking and dynamic conflict resolution. Our model departs from theirs by the fact that lexical structures are fixed instead of including algorithms. There is only one procedure in our model: tMerge, which is not attached to the

lexicon and can be synchronized with syntactic analysis. Our model is able to detect and solve aspectual effects such as repetition and slice, to identify the perfectivity and progressivity of events, and to detect incorrect sentences. The output of the model is congruent with the majority judgment among the participants we tested.

The notion of semantic *incorrectness* is relative, as a substantial number of participants considered these sentences as acceptable (e.g. 30% for example (2)). Acceptability seems to depend on several factors that are to be investigated: differences in the kind of computations performed in *Perception*, or differences in judging as correct sentences that wouldn't be uttered by a native speaker but that could still make sense. Another possible source of variation among participants may be judgments of relevance. For instance, "Elle mangera du gâteau en 30 minutes" (understood as: "She will eat cake within a period of 30 minutes") may be acceptable in a context in which any consumption of cake is supposed to require more than thirty minutes. We are currently investigating these phenomena.

Though we are confident in the fundamental principles and in the overall architecture of the model, we need to check its validity against a much larger variety of phenomena, not only in French but also in other languages. For instance, we are currently investigating how the English *progressive* "V-ing" (Deo, 2009) can be explained as a sub-categorization of the *ground* viewpoint depending of perceptive information. These investigations may bring us to adapt and augment the model, while hopefully keeping its minimalist character.

## Abstract

Both transitive reasoning and analogy-making are present at very early stage of human development and the question arises whether the two developmental trajectories interact with each other. We are presenting an experiment with 4 years old children to test the hypothesis that the analogy-making capabilities can scaffold and facilitate the development of transitive inference and the empirical data support this hypothesis.

## Introduction

Transitive inference is the simplest form of deductive reasoning that combines two premises  $R(a,b)$  and  $R(b,c)$  and makes the conclusion that  $R(a,c)$ . For example, if John is stronger than Peter, and Peter is stronger than Bill, then necessarily, John is stronger than Bill. Piaget (1921) was the first psychologist who introduced the topic of transitive inference in the developmental framework. He and his collaborators claimed that the ability of transitive reasoning is developed relatively late during the stage of concrete operations (Inhelder & Piaget, 1958, 1964): first at the age of 8 about size relations like “bigger than”, and even later on about other relations like “heavier than”.

The developmental trajectory of transitive reasoning has been extensively studied and disputed in the literature and many psychologists found evidence that this ability is present much earlier in the development than it was assumed by Piaget. Thus since 1970s the research in the area was dominated by the debate about the age at which children can be considered to make transitive inferences. According to Trabasso (1977) and Halford (1993) this age depends on the specific procedure that tests the ability and under certain circumstances even children at the age of 4 can exhibit this capacity. McGonigle and Chalmers (1977) challenged the field by demonstrating that monkeys can also make transitive inferences. More recently it has been demonstrated that rats (Roberts & Phelps, 1994), pigeons (von Fersen et al, 1991, Lasareva & Wasserman, 2006), and even fishes (Grosenick, Clement & Fernald, 2007) do make transitive inferences. It has been argued that transitive inference is important for the survival because it allows the animals to determine social dominance of other animals without getting into mortal fights.

A very similar debate has also dominated the field of analogical reasoning development. Inhelder and Piaget (1958, 1964) claim that analogical reasoning is a type of

reasoning which develops during the formal operation stage i.e. after 11 years of age. However, like in the field of transitive inference, modern researchers have demonstrated that analogy is present at very early age if not from birth (Goswami, 1991, 2001, Kotovsky & Gentner, 1996). And again there is now some evidence that Chimpanzees (Gillan, Premack, & Woodruff, 1981; Oden, Thompson & Premack, 2001), Baboons (Fagot & Parron, 2010), Capuchin monkeys (Truppa et al, 2010, 2011), and even New Caledonian Crows (Taylor et al., 2007) can make analogies.

This research suggests that both transitive inference and analogy-making are very old evolutionary and are also present from very early age in human beings and the question arises whether the development of the two capabilities interact with each other.

Kokinov (1990, 1992) suggested that in fact deductive, inductive and analogical reasoning might be produced by the very same mechanisms. His proposal is that the analogical reasoning mechanisms are the basis and they are then used for deduction and induction as well. He obtained some experimental support for this proposal using adults. Halford (1993) suggested that deductive reasoning development is based on the already developed analogical reasoning capacities, but did not present empirical evidence for his claim. Goswami (1995) tried to find support for that idea by providing analogies to children in the class inclusion problem, but could not find an effect of the analogy. Based on the two proposals above Mutaſchieva and Kokinov (2008) designed an experiment to test whether analogy can actually help children make better transitive inferences and obtained positive results. However, the doubt remained whether this is really transitive reasoning. The current paper presents an experimental study that replicates and further extends these initial findings making sure that children are making proper transitive inferences.

Another topic of hot debate is the methodology of measuring transitive inference capabilities. Various authors have suggested various procedures and it might be that they measure different aspects of the transitive reasoning abilities. Inhelder and Piaget (1958, 1964) used the original definition of transitive inference with three objects where the premises are presented as two comparisons and the question is about the relation between the two objects unseen together. Later on, however, Bryant and Trabasso (1971) and McGonigle and Chalmers (1977) have used a form of the task with 5 items in a series with extensive training of some pairs and asking about others that are

unseen before. This procedure was meant to eliminate the potential memory problem that children can have remembering the premises. Pears and Bryant (1990) finally eliminated the training phase since there was severe criticism about the role of this training plays.

Sternberg (1980) introduced another version of the three object task, namely if A is shorter than B, and B is shorter than C, which is the shortest? We are using this version in our study. However, there is serious potential problem here. As Piaget emphasised crucial for the transitive inference is the understanding of the relativistic nature of the relations, i.e. that relations, unlike properties which are constant characteristic of an object (e.g. if the object is red it remains red during the whole experiment), are dynamically changing depending on the specific object you are comparing it to. For example, object B may be bigger than object A and at the same time be smaller than C, i.e. being “bigger” is not a property of the object itself. Inhelder and Piaget (1958, 1964) claim that this ability is mastered much later in life – in the stage of concrete operations, while prior to that stage children think that relations are absolute properties of the objects – properties like “larger” and “smaller” are mutually exclusive and it is not possible to attribute them to one and the same object.

In order to test whether children have actually obtained this relativistic understanding of relations and thus exhibit proper transitive inference we have designed a new procedure in which we first show children two separate relations like A is stronger than B, and B is stronger than C, then we ask which is the strongest. Let suppose that the child correctly responds that A is the strongest. Then we add a new object D and say that D is stronger than A and ask children which is the strongest object now. Alternatively in half of the trials we add a new object E and say that C is stronger than E and ask the child which is the strongest now. If children understand correctly the nature of the transitive inferences they have to switch to the new object D in the former case, but keep insisting that A is the strongest in the latter case. We believe this is a stronger and more conservative test of transitive inferences capacity and have introduced it in the current study.

There is another innovation in the test procedure. Since it is natural for children, we speak of how one animal is stronger than another one (e.g. this bear is stronger than this bear). If the animals were visually available than no inferences would be needed and children would visually find the strongest animal, that is why we are presenting the animals hidden in boxes and children have to remember that the bear in this box is stronger than the bear in that box. In addition, to make the task even more complicated we presented the three boxes not in a linear order, but in a triangular configuration. This complicates the task of children according to the “spatial model” (DeSoto, London & Handel, 1965, Huttenlocher, 1968) which assumes that transitive inferences are made based on a linear spatial mental model built in the process of understanding of the premises. As you will see, however, the triangular configuration is important for our manipulation and makes it possible to compare every two objects equally easy.

Finally, the manipulation in the experiment is the introduction of an analogy between the three (or four) boxes in the triangle (rectangular) configuration and a train that is taking turn. In the train the stronger animals are pulling the next ones. In this way we are trying to ground the abstract knowledge of children about “being stronger” with their familiar experience of being able to pull. This is further supported by using physical “draw-bars” between the wagons of the train. In both the experimental and control groups there is a second set of animals on the table which belongs to the experimenter and these animals are not hidden, i.e. the child can visually judge which is stronger than which and which is the strongest. We know from previous studies (Mutafchieva & Kokinov, 2007a, 2007b) that the child can possibly make a mapping between the two sets of animals (the experimenter’s and their own) and we assume that this should facilitate the inference process. The difference is that in the experimental group the train analogy is introduced, while in the control group it is not.

## Experiment

The goal of the present experiment was to find out whether an analogy with a familiar domain that is grounded in children’s physical experience (like the train analogy of pulling) would facilitate the transitive inference while we measure also children’s understanding of the relativistic nature of relations.

### Hypothesis

Our hypothesis was that when provided with the train analogy children would improve their performance on the transitive inference task and would demonstrate understanding of the relativistic nature of relations.

### Design

The experiment had a mixed design.

The *between-subject factor* had two levels:

- **Control condition:** one visible and one hidden set of objects were presented, but no analogy was provided;.
- **Analogy condition:** one visible and one hidden set of objects were presented, and each set was described as a train with wagons that are connected with draw-bars.

The *within-subject factor* was the **number of objects** participating in the object series:

- First measurement – after presenting the two sets of **three objects**.
- Second measurement – after adding a **fourth object** to each set.

Children in both conditions participated in both measurements of the within-subject factor.

The dependent variable was the number of correct responses to the transitive inference tasks and since there were five trials in each session the value could vary from 0 to 5.

## Stimuli

Eight animals of the same type were used in each trial: 8 bears, 8 swans, 8 mice etc. In the first measurement 6 animals were presented, divided in two sets of three animals of the same type – one set of 3 animals for the experimenter and one for the child. There was a big, medium and small animal in each set. The corresponding objects from the two sets were of different absolute sizes - for example the biggest mouse from the experimenter's set and the biggest mouse from the child's set had different sizes. In the second measurement a fourth animal of the same type was added to each set. In addition, in the Analogy condition six draw-bars were used to connect the wagons of the train – three for the experimenter's set and three for the child's set (Figure 1a and 1b, correspondingly).

Figure 1a. Example of the stimuli used in the Analogy condition in the first measurement. The biggest object from the upper set was the same absolute size as the medium object from the lower set. The objects from the child's set were hidden under white boxes (Fig. 2)

Figure 1b. Example of the stimuli used in the Analogy condition in the second measurement after adding the fourth object.

In this experiment the stimuli were presented in a triangle configuration. Different sets of stimuli were used in every trial with different spatial arrangements and absolute sizes as well as different animals. The objects from the child's set were covered with white boxes of equal size (Figure 2 and Figure 3, correspondingly).

Figure 2. Example of the stimuli used in the Analogy condition in the first measurement before adding the fourth object. The experimenter's set could be seen in the upper side of the table.

Figure 3. Example of the stimuli used in the Analogy condition in the second measurement after adding the fourth object, which in this case is smaller (weaker) than the smallest one.

## Procedure

Each child participated in two individual experimental sessions. Each session included three training trials and five test trials. In the training trials the experimenter gave the child feedback in order to make sure that he/she correctly understood the instruction.

The instruction for the Control group in the test trials of the first measurement session was (in Bulgarian language):

*"I have three bears and you have three bears. Out of these two of my bears this is stronger than this one (pointing to the biggest and the medium bear in the experimenter's set), and from these two of my bears this is stronger than this (pointing to the medium and the smallest bears from her set). Out of these two of your hidden bears, this one is*

stronger than this one, and this one is stronger than this one. Please tell me, where is your strongest bear hidden?"

The instruction for the second measurement for the Control group had two versions depending on whether we added a stronger or a weaker fourth animal. The first one was as follows:

*"Now close your eyes because I will make a trick. Now look, I added another bear to my animals which is stronger than this one (pointing to the formerly biggest animal from her set). I also added another bear to your animals. The new bear is hidden under this box and now this bear is stronger than this one (pointing to the formerly biggest animal from the child's set). Now, please tell me where is your strongest bear hidden?"*

The second version for the Control group in the second measurement was the same except the fact that the fourth added animal was weaker than the weakest one.

The corresponding instruction for the Analogy group in the test trials was the following:

*"I have three bears and you have three bears. Out of these two of my bears (pointing e.g. to the biggest and the medium bear in the experimenter's set) this one is stronger than this one and I will put this draw-bar in such a way that the stronger bear could pull the weaker one. Out of these two of your hidden bears, this one is stronger than this one. Please, put this draw-bar in such a way that the stronger bear could pull the weaker bear. Now, out of these two of my bears (pointing e.g. to the medium and the smallest bear from the experimenter's set) this one is stronger than this one and I will put the draw-bar in such a way that the stronger bear could pull the weaker one. Out of these two hidden bears this is stronger than this. Please, put this draw-bar in such a way that the stronger bear could pull the weaker one. Now look, my bears look like a train in a turn and your bears look like another train in a turn. Please tell me where is your strongest bear hidden?"*

The instruction for the two versions of the second measurement for the Analogy group was the same except that the added fourth animal was connected to the smallest or the biggest animal by a new draw-bar. We randomized the sequence in which the fourth strongest or weakest animal was added. An important fact about this experiment was that the child had never seen the objects in his/her set and it was not possible to solve the task by remembering the absolute sizes of the stimuli.

## Participants

49 children were studied in this experiment. 25 of them formed the Control group, 24 formed the Analogy group.

The average age of the children was 4 years and 5 months ranging from 4 years and 1 month to 4 years and 11 months.

## Results and discussion

The data are presented in Figure 4. The mean for the Control Group in the three objects trials is 2.56 (out of 5), and in the four objects trials is 2.04. There is a slight decrease in this group. The corresponding means for the Analogy group are 3.46 for the three objects trials and 3.58 for the four objects trials. The chance level for the three objects trials is 1.66 and for the four objects trials is 1.25.

Figure 4. Mean scores (which vary from 0 to 5) for each measurement for each group. There is a clear Analogy effect  $F(1, 47) = 12.478$ , partial  $\eta^2 = 0.21$ ,  $p = 0.001$

A repeated measures ANOVA has been run with within group factor the number of objects and between group factor the presence or absence of analogy. There is an effect of the Analogy manipulation and the performance of the children in the Analogy group is significantly better than the performance of the children in the Control group ( $F(1, 47) = 12.478$ , partial  $\eta^2 = 0.21$ ,  $p = 0.001$ ). Pair-wise comparison shows that there is significant difference between the two groups in both the first measurement with sets of three objects ( $F(1,47)=4.142$ ;  $p=0.047$ ) and in the second measurement with sets of four objects ( $F(1,47)=22.548$ ;  $p<0.001$ ).

Analysis of the within subject factor shows that there is no difference between the two measurements of each child ( $F(1,47)=1.267$ ;  $p=0.266$ ) which means that there is no significant improvement or decrease of the results of each child after adding the fourth object. Children are equally good in solving transitive inference tasks with three and four objects. The interaction between the two factors is also not significant  $F(1, 47)=2.547$ ,  $p=0.072$ ).

Additional analysis shows that there is a significant difference between the children's performance in each measurement and the corresponding chance level in both groups. The difference between first measurement and chance level of 1,66 in the Control group is  $T(24)=7,709$   $p<0,001$ , a similar difference could be found when comparing the second measurement with the chance level of 1,25 in Control group ( $T(24)=12,134$ ;  $p<0.001$ ). For the Analogy group the results are similar ( $T(23)=11,985$ ;  $p<0.001$ ) when comparing the score of first measurement with the chance level of 1,66, and ( $T(23)=12,716$ ;  $p<0.001$ ) when comparing the score of the second measurement and chance level of 1,25). These results could be interpreted that in both measurements in both groups children are significantly better than the chance level in solving the transitive inference tasks.

## General Discussion

The results showed that both groups are significantly better than the chance level in both measurements which means that children are able to solve transitive inference

tasks to some degree. These findings are consistent with the results of Bryant and Trabasso (1971) and Pears and Bryant (1990) which showed that young children could solve transitive tasks when memory limitations were overcome or when the relations were visible for the child at the moment of decision making.

We can also claim that children showed an understanding of relativistic nature of relations because the results from the second measurement are also significantly better than the chance level in both groups. In three of out of 5 trials one and the same object is “stronger than” in the first measurement and is “weaker than” in the second measurement. So, the child had to reverse the answer in order to respond correctly. Children succeeded to overcome this difficulty and demonstrated an understanding that relations are not object’s attributes and have a relative nature.

Most importantly, there is a main effect of the Analogy manipulation and children in the Analogy condition demonstrated significantly better performance than the children in the Control condition (both with three and four objects). This shows that analogy making could play an important role in accumulating experience and development of the transitive reasoning ability. This is in accordance with Halford’s (1993) claim that deductive reasoning development is based on analogical reasoning and with Kokinov’s (1990, 1992) proposal that the same mechanisms could underlie both types of reasoning.

How can we explain the specific effect of the train analogy in this experiment? One possible explanation is that children know that the strongest car that pulls all other cars in the train is the locomotive which is the first wagon in the train. Thus when asked “Where is the strongest bear hidden?” they think of the configuration of boxes as a train and try to find where is the locomotive. Then they use the draw-bars in order to determine where the locomotive is. This explanation relies on their common knowledge of trains and the causal model of its movement. A second possible explanation is that children are mapping their hiding boxes to the experimenter’s set of visible animals; they determine perceptually which the strongest visible animal there is and map it back to the strongest animal hidden in their corresponding box. The question is why children cannot do this in the control condition, and the answer could be that the analogy with the train and the visible draw-bars in both “trains” help children in doing the mapping. This is in accordance with the results obtained in an earlier experiment showing that the train analogy and the use of draw-bars help children make the analogical mapping (Mutafchieva & Kokinov, 2007b). Finally, it could also be argued that the analogy does not play any role here and simply the presence of the draw-bars in both sets makes it easier for the children to do the mapping and find which box corresponds to the strongest animal in the experimenter’s set. Although we cannot rule out this possibility, we believe that this is not very probable since in this earlier experiment (Mutafchieva & Kokinov, 2007b) the results from a

condition with draw-bars without the introduction of the train analogy did not help children in doing the analogical mapping and this group was indistinguishable from the control group. Thus it seems that the draw-bars become meaningful and usable for the children only after they are considered as part of the causal model of the train.

It is also possible that the draw-bars simply facilitated children in remembering the relations between the four objects and these physical representations were visible for the child at the moment of decision making. As explained above, however, we believe that the draw-bars alone will not do the trick. Especially since the children in both groups seemed to successfully remember the premises which could be seen from their answers to the control questions asked. Of course, we need further experimentation in order to distinguish between all these (and other) explanations.

The main conclusion for the moment is that children in our experiment demonstrated an ability to make transitive inferences and understanding of relativistic nature of relations. In addition, the train analogy in combination with draw-bars as physical representations of relations facilitates this children’s ability to make transitive inferences. These first data suggest that analogy could be an effective mechanism for learning to do transitive inferences supporting Halford’s theory that deductive reasoning development is based on analogy-making development.

## Acknowledgments

The research reported in this paper has been supported by the ANALOGY project (6<sup>th</sup> FP, NEST program, contract 29088) and by the European Office for Aerospace Research and Development under grant FA8655-10-1-3061. We would like to thank Ana Doncheva and Margarita Pavlova for helping in the data collection process.

# Cognitive Styles in Two Cognitive Sciences

James Myers (Lngmyers@ccu.edu.tw)

Graduate Institute of Linguistics, National Chung Cheng University  
Minhsiung, Chiayi 62102 Taiwan

## Abstract

Miller (1990) suggests that communication between linguistics and psychology is hampered for essentially cognitive reasons: linguists favor simplifying explanations while psychologists favor causal explanations. This paper reformulates this suggestion as three testable hypotheses. First, scientists vary in cognitive style from rationalist/nomological to empiricist/mechanistic. Second, linguistics is primarily a rationalist/nomological science, while psychology is primarily an empiricist/mechanistic one. Strikingly, even among nativists, linguistic and psychological research still contrast along the rationalist/empiricist dimension. Third, cognitive styles are relatively intractable, as suggested by empirical evidence that they are associated with intrinsic individual differences and by formal arguments that highlight their self-isolating nature.

**Keywords:** philosophy of science; epistemology; linguistics; psychology; individual differences.

## Introduction

Linguists and psychologists have often noted a persistent lack of mutual respect across their two disciplines (Johnson-Laird, 1987; Jackendoff, 1988; Miller, 1990; Carlson, 2003). Miller (1990, p. 321) ascribes this impasse to different ways of thinking, which we will call cognitive style:

What is holding up the free flow of ideas back and forth between linguists and psychologists? For what it is worth, my own view is that linguists and psychologists subscribe to different theories of explanation. Linguists tend to accept simplifications as explanations. [...] For a psychologist, on the other hand, an explanation is something phrased in terms of cause and effect, antecedent and subsequent, stimulus and response.

The present paper reformulates Miller's suggestion as the hypotheses in (1)-(3), then tests them.

- (1) Scientists vary in cognitive style from more rationalist and nomological to more empiricist and mechanistic.
- (2) Linguistics is primarily a rationalist/nomological science, while psychology is primarily an empiricist/mechanistic one.
- (3) Individual cognitive styles are relatively intractable.

By "cognitive style" we mean to cover both one's personal epistemology (theory of knowledge) and one's metaphysics (theory of reality). Rationalist epistemology emphasizes the role of reason in attaining knowledge, while empiricism emphasizes the senses. A nomological metaphysics explains

in terms of general laws, while a mechanistic explanation is expressed in terms of causal systems.

The overarching notion explored in this paper is that individual scientists tend to lean towards rationalism or empiricism, and towards nomological or mechanistic explanations, and that these leanings are reflected in their chosen scientific (sub)disciplines. Thus we expect to see reliable tendencies at both the individual and discipline level, but exceptions are not impossible.

Given the brevity of this paper and the ambitious nature of the hypotheses, this study cannot fully verify or falsify them. Obvious limitations include our focus on just two dimensions of scientific thinking (see, e.g., Hacking, 2002, for others), and the poorly understood relationship between individual and disciplinary styles (i.e., to what extent scientific styles are cognitive or social).

Each hypothesis is taken up separately. Support comes from published research in linguistics, psychology, and the history and philosophy of science.

## Cognitive Styles across the Sciences

Hypothesis (1) can be unpacked into three subhypotheses:

- (1a) Scientists vary from nomological to mechanistic.
- (1b) Scientists vary from rationalist to empiricist.
- (1c) Scientists in nomological sciences tend to be more rationalist, whereas those in mechanistic sciences tend to be more empiricist.

Regarding (1a), physicists favor nomological explanations, seeking the axioms underlying nature (exemplified in the Euclid-inspired style of Newton's *Principia*). Philosophers of physics sometimes write as if all science is inherently nomological (e.g., Scheibe, 2001), but in fact, physicists are atypical: chemists, biologists, geologists and other scientists generally concentrate on uncovering causal mechanisms, not general laws. As a typical example of a mechanism, Machamer, Darden, & Craver (2000) cite the transmission of chemical signals across a synapse, which involves entities (neurons, neurotransmitters) and activities (the releasing and binding of chemicals) in events that begin, progress, and end in space and time.

The ultimate reason for cross-disciplinary differences in explanatory metaphysics seems to be reality. The systems studied in fundamental physics are simple enough for simple laws to work well, and being fundamental, no lower-level causal explanation is possible. By contrast, chemical, biological, and geological phenomena merely need to be consistent with physics; historical contingences make them impossible to deduce from physics alone.

Yet there also seems to be a cognitive aspect to the preference for certain explanation types. Strikingly, scientists outside physics often demand mechanisms before accepting a pattern as scientifically significant, no matter how robust the observations. A classic example is the skepticism that greeted Alfred Wegener's theory of continental drift. This theory elegantly explained the fit between the coastlines of South America and Africa, among numerous other observations, but it was not accepted (revised as plate tectonics) until a plausible mechanism was discovered many decades later (Cohen, 1985).

As for (1b), cognitive scientists are used to thinking of rationalism as synonymous with nativism, but the focus here is instead on what Wole ski (2004) calls methodological rationalism (apriorism; nativism is genetic rationalism), as opposed to methodological empiricism (aposteriorism). Rationalism in this sense is associated with deduction from general axioms, while empiricism is associated with induction from specific tokens. More specifically, our focus is not on the views of professional philosophers, but the personal epistemologies (Muis, Bendixen, & Haerle, 2006) of practicing scientists.

Physicists are uncontroversially the most rationalist of scientists, having always tied their work to mathematics (as reemphasized by Galileo and Newton). Despite the physics-centric view of science among some philosophers, scientists in other disciplines view themselves quite differently. Surveys reviewed in Muis et al. (2006) find that while theoretical physicists group with mathematicians in scoring high for rationalist epistemology, chemists and biologists score high for empiricism.

The rationalist/empiricist contrast is not identical to the nomological/mechanistic contrast. Descartes claimed to use pure reason to deduce a theory of physics in which magnets attract via screw-like particles (Westfall, 1971). Similarly, natural selection has lawlike properties (Bock, 2010), even though arguments for it typically involve induction from masses of observations, as in Darwin's *Origin of species* (in sharp contrast to the deductive style of Newton's *Principia*).

Yet consistent with (1c), rationalists seem to have a natural affinity for laws and empiricists for mechanisms. Physicists since Newton have rejected mechanistic physics as question-begging, and biologists tend to see natural selection as a causal mechanism (Skipper & Millstein, 2005). More generally, while nomological approaches appeal to rationalists by being elegant and deductive, mechanisms appeal to empiricists because they are imageable as diagrams, posit causal interactions of the sort familiar from experience, and accommodate a diversity of induction-supporting observations through the cumulative elaboration of mechanical elements and architectures.

In a passage reminiscent of Miller (1990), Shapin (1996, p. 117) highlights the personal nature of cognitive styles:

Do you want to capture the essence of nature and command assent to representations of its regularities?  
Do you want to subject yourself to the discipline of

describing, and perhaps generalizing about, the behavior of medium-sized objects actually existing in the world? [...] The one is not necessarily to be regarded as a failed version of the other, however much partisans may defend the virtues of their preferred practice and condemn the vices of another.

Shapin illustrates this contrast with Newton and his contemporary Boyle, today known as the father of chemistry. When Newton first introduced his optical experiments to the Royal Society, he placed his observations in a deductive context: "I shall rather lay down the *Doctrine* first and then, for its examination, give you an instance or two of the *Experiments*, as a specimen of the rest" (quoted in Shapin, 1996, p. 114, italics in the original), adding that he had shown that the science of colors was "mathematical" with "as much certainty in it as any other part of optics," as "evinced by the mediation of experiments concluding directly and without any suspicion of doubt" (Shapin, 1996, p. 115). By contrast, Boyle's goals were simply to describe his experiments explicitly enough for others to experience them vicariously, if not replicate them and observe the results first-hand. Thus he wrote that he dared to "speak confidently and positively of very few things, except of matters of fact" (quoted in Shapin, 1996, p. 102). He even refused to express mathematically the gas law that today bears his name or to call it a law. Boyle also invented today's scientific reporting style, which clearly separates experimental description from interpretation.

### Cognitive Styles in Linguistics and Psychology

To paraphrase Shapin, we do not regard linguistic methodology as a failed version of psychological methodology, or vice versa. Rather, hypothesis (2) merely claims that there is a deep philosophical difference.

Miller (1990, p. 321) illustrates this difference as follows:

[A] grammarian who can replace language-specific rewriting rules with X-bar theory and lexicalization feels he has explained something: the work formally done by a vast array of specific rules can now be done with a simple schema. [...] To an experimental psychologist, X-bar theory is not an explanation; rather, if it is true, it is something to be explained.

More generally, linguistic explanations take the form of nomological grammars, which many linguists believe are themselves subject to universal laws. Evidence is slight by psychological standards, relying on a small number of clear cases; generality is assumed unless later shown otherwise. By contrast, psychological explanations take the form of processing systems, supported with empirical overkill by linguistic standards. Psychologists also follow Boylean reporting style, whereas linguists, like philosophers, freely interleave examples and analyses.

The contrasting philosophies underlying these practices are sometimes made explicit in rhetorical volleys aimed

across disciplinary borders. For example, Chomsky (2002, p. 102) claims that "the only field that has methodology courses, to my knowledge, is psychology," implying that psychologists still maintain the discredited notion of empirical discovery procedures. The psychologists Edelman & Christiansen (2003, p. 60) counter that linguists fail in their duty "to demonstrate the psychological (behavioral), and, eventually, the neurobiological, reality of the theoretical constructs," i.e., to demonstrate mechanisms.

Favoring mechanisms makes psychology an entirely typical science (outside of physics), but why does linguistics favor the nomological approach? Even though Chomsky is an easy target, linguists have always treated language nomologically. Bloomfield (1926) proposed a *Principia*-like axiomatic system for linguistic theory, and Chomsky (1966) links his own approach with Renaissance grammarians, who, in turn, built on the Aristotelian view of language as logic. Even before Aristotle and beyond Europe, Pāṇini developed an elaborate formal grammar of Sanskrit that presaged generative linguistics in important ways.

One motivation for nomological linguistics may be language itself: like physics, language is simple enough to be fruitfully described with simple laws. Yet unlike physics, a mechanistic approach to language is also fruitful, given that its processing involves causes and effects. Miller (1990, p. 321) tacitly admits the multifaceted nature of language when he addresses the question of why linguists and psychologists study it so differently, noting that "[s]ome have answered this question in terms of the competence-performance distinction: linguists and psychologists talk about different things," while "[o]thers have answered this question in terms of the structure-function distinction: linguists ask different questions of the same thing."

In fact, both of the alternative explanations he cites can be subsumed under cognitive style. Competence (grammar) is static linguistic knowledge, described in terms of structures; performance is language processing, described in terms of functions. Grammar is intrinsically atemporal, despite the confusion sometimes caused by the term "generative" (see Neeleman & van de Koot, 2010, for a computational argument that grammar must be atemporal). Hence grammar cannot be modeled mechanistically, since causal mechanisms necessarily operate in time (Machamer et al., 2000). This obligates grammarians to use nomological explanations, which, given hypothesis (1c), makes grammatical research particularly appealing to rationalists.

The central role of atemporality in nomological/rationalist approaches to language is highlighted by the turn that came with Saussure, the first modern linguist to explicitly advocate the primacy of synchronic grammar. The rise of structuralist linguistics in his wake was accompanied by a simultaneous rejection of psychological approaches to language, exemplified by the shift from the Wundtian philosophy of Bloomfield (1914) to the psychological agnosticism of Bloomfield (1933).

Since cognitive style is a property of individual scientists, methodological rationalists like Chomsky coexist in

linguistics with methodological empiricists like the corpus linguist Geoffrey Sampson. While Chomsky (2002, p. 102) praises "the Galilean move towards discarding recalcitrant phenomena if you're achieving insights by doing so," Sampson (2001, p. 1) asks linguists "to apply the same empirical techniques which have deepened our understanding of other observable aspects of the universe during the four centuries since Galileo." (Tellingly, both invoke Galileo: as noted by Shapin, 1996, scientists tend to take their personal cognitive style as defining science itself). Other non-rationalist approaches to linguistics include functionalism (e.g., Nichols, 1984), where causal mechanisms are central.

Psychologists also vary in cognitive style, with some attracted to nomological schools like rational analysis (Chater & Oaksford, 1999), or, earlier, Gestalt psychology. Yet other psychologists are quick to criticize such approaches for being insufficiently mechanistic, as seen in the peer commentary on Oaksford & Chater (2009), or in the comment by Bruce, Green, & Georgeson (2003, p. 127) that Gestalt laws have left us "with a set of descriptive principles, but without a model of perceptual processing."

The difference in cognitive style between (grammar-oriented) linguists and (most) psychologists is highlighted by the surprising fact that even when psycholinguists are genetic rationalists, they remain methodological empiricists. Compare Chomsky's nativism with that of the psychologist Steven Pinker. The poverty of the stimulus argument (Chomsky, 1986) deduces nativism from the premises that knowledge is rich but input to the learner is poor. This is a rational argument: Chomsky ascribes it to Plato, implying the irrelevance of two millennia of evidence. Moreover, contrary to a common misunderstanding (see, e.g., Chomsky & Katz, 1981), Chomsky does not induce universal grammar from grammatical universals.

By contrast, the prominence of these two arguments is exactly reversed in Pinker (1994). Pinker does rehearse a version of the poverty of the stimulus argument, but immediately afterwards he adds, "Chomsky's claim was tested in an experiment..." (p. 42). The remainder of Pinker's book is a long catalog of empirical evidence for nativism from a variety of sources, including cross-linguistic universals, in a style more like *Origin* than *Principia*.

The Chomskyan Jenkins (2000, p. 31) confirms that even if "no converging evidence at all of the kind Pinker detailed in his book [...] had turned up yet", we would still "be justified in accepting Chomsky's arguments that the 'basic design of language is innate,' to use Pinker's words", since "the argument from poverty of the stimulus [is] strong enough".

### The Intractability of Cognitive Style

Hypothesis (3) is supported by two independent arguments. For the benefit of different types of readers, one is empirical and one is rational. The empirical argument is based on evidence that cognitive style is associated with intrinsic individual differences. The rational argument is based on

formal analyses demonstrating the impossibility of choosing between cognitive styles either empirically or rationally.

### Individual Differences in Cognitive Style

The polarization of disciplinary styles can be explained in part by the social and cognitive factors driving group polarization more generally (Isenberg, 1986). Yet scientists do not merely absorb the cognitive style of their mentors and peers.

For example, the physicist Max Planck (quoted in Scheibe, 2001, p. 69) wrote:

What led me to my science and what fascinated me from a young age was the, by no means self-evident, fact that our laws of thought agree with the regularities found in the succession of impressions we receive from the external world, that it is thus possible for the human being to gain enlightenment regarding these regularities by means of pure thought....

Similarly, though Einstein described himself, thirty years after the fact, as having been changed "by the problem of gravitation" from "skeptical empiricism" into "a believing rationalist" (quoted in van Dongen, 2010, p. 57), his contemporary writings show that he had already rejected traditional empiricism before starting to work on gravitation (Howard, forthcoming).

Group dynamics also fail to explain why individual scientists can differ in cognitive style within a science. The physicist Dirac (1968) notes that "[w]hether one follows the experimental or the mathematical procedure depends largely on the subject of study, but not entirely so. It also depends on the man" (p. 22). Among his fellow theoretical physicists, he cites Heisenberg as exemplifying the former style, and Schrödinger (and himself) the latter.

Is cognitive style a matter of personality? Diamond & Royce (1980) explicitly argue that personal epistemology does correlate with personality traits, though unfortunately there has been little follow-up (cf. Muis et al., 2006). For example, Pashler, McDaniel, Rohrer, & Bjork (2009) cast serious doubt on the notion of intrinsic learning styles, but putative contrasts like visual versus verbal learning have nothing to do with empiricism versus rationalism.

More relevant are the many studies that reveal individual variation in reasoning. For example, in the Wason card selection task, where people are asked to test for violations of conditional propositions of the form if  $p$  then  $q$ , most fail to test cases of not- $q$ , even though finding not- $q$  given  $p$  would falsify the proposition. Oaksford & Chater (2009) review a series of experiments and mathematical models suggesting that most people approach the Wason task using Bayesian (i.e., essentially inductive) reasoning. This implies that the minority who give the normatively correct answer are using deductive reasoning. Since performing correctly is positively correlated with general intelligence (Stanovich & West, 2000) and working memory capacity (Copeland &

Radvansky, 2004), a facility with deduction seems to be an intrinsic individual trait.

Cognitive style may also be linked to another feature known to show individual variation: tolerance of uncertainty (Neuberg, Judice, & West, 1997). Deduction provides certainty (Euclid cannot be falsified), while induction does not (a black swan may be lurking around the next corner). Given this, it is unsurprising that Wilkinson & Migotsky (1994) found that the belief that knowledge depends on observations and data (which they label empiricism) is associated with the belief that knowledge is relative and context-dependent, whereas the belief that knowledge depends on logical and analytical thinking (which they label rationalism) is not associated with relativist tendencies.

When taken to an extreme, the intolerance of uncertainty is a hallmark of obsessive-compulsive disorder and autism spectrum disorders like Asperger syndrome (Sadock & Sadock, 2007). Indeed, autism is linked to mathematical (i.e., deductive) talent (Baron-Cohen, Wheelwright, Burtenshaw, & Hobson, 2007), and students with familial autism are more likely to choose a mathematics-intensive college major (Campbell & Wang, 2012). Complementarily, Péliissier & O'Connor (2002) found that participants diagnosed with obsessive-compulsive disorder had significantly more difficulty than matched controls in tasks that required induction, whereas both groups performed equally well with deductive tasks. Consistent with the above findings, the rationalists Newton (James, 2003) and Dirac (Farmelo, 2009) have been diagnosed (post hoc) with Asperger, whereas the more empiricism-inclined Darwin earned a very high score from historians for openness to experience (Shermer, 2002).

In short, scientists are unconsciously pushed in one or the other direction along the rationalism/empiricism continuum even before their entry into science. Cognitive styles are thus expected to be relatively immune to persuasion.

### Cognitive Styles and Logical Traps

Whether rationalists or empiricists, scientists all face the problem of induction. Since observations are always consistent with (infinitely) many theories, scientists rely on strategies like Ockham's razor to narrow their options. However, even when Ockham is satisfied, rationalists are free to favor laws and empiricists to favor mechanisms.

The implications of this problem can be investigated in the context of formal learning theory. This approach is most familiar to cognitive scientists in its application to language acquisition, but it also helps inform the philosophy of science (e.g., Kelly, 2000). One lesson is that the challenge faced by scientists is much harder than that faced by infants. Infants may have evolutionarily provided "inside help" guiding them to linguistic knowledge, but scientists are not so lucky. Even if scientific decisions are innately biased, these biases are not guaranteed to lead to scientific truth.

Because of this distinction between children and scientists, formal learning theory leads to opposite conclusions in the two cases. Gold's theorem (Gold, 1967) provides a simple

illustration of this. Any finite set of strings is compatible both with a finite language consisting solely of the attested strings and with a language generated by rules that generate the attested strings plus infinitely many more. However, if the learner is biased to posit only one language type, and the strings are generated by a previous learner with the same bias, successful language learning is guaranteed. Some creatures may achieve this by being innately biased towards finite languages, but presumably humans do so via an innate bias for infinite ones.

But now consider a different scenario. A scientist collects utterances from a human, which we assume has an infinite language, and from an alien with a finite language consisting of symbol strings up to length three. The human is observed to have many more string lengths than the alien, but like the child learner, the scientist can only ever have access to strings of finite length, hence finite sets of strings, even for human utterances. If the scientist is biased towards nomological explanations, an infinite language (e.g., the grammar  $a^*$ ) will be incorrectly posited for the alien as well. If the scientist is biased towards less analytical hypotheses (i.e., is empiricist), the human will be ascribed an alien-like language (i.e., a list of strings).

One may object that the scientist can escape from this dilemma by collecting evidence about what is ungrammatical. Unlike the child learner, the scientist may run an experiment, for example "asking" the alien if some string is "acceptable" (e.g., via some processing task). Suppose the alien accepts  $a$ ,  $aa$ ,  $aaa$ , but rejects  $aaaa$ ,  $aaaaa$ ; surely that demonstrates that it has a finite language. Yet as Johnson (2004) points out, even negative evidence can only come in finite sets. Rejection of  $aaaaa$  does not preclude the acceptance of  $aaaaaa$ .

Kelly (2007) illustrates his proof that Ockham's razor minimizes backtracking with a scenario in which an Ockham-obeying scientist posits all and only the particles that have been emitted by a machine so far, exactly parallel to our string-listing empiricist. Yet the nomological analysis is not only intuitively simple, but also requires no backtracking. If no string longer than three is uttered for a sufficiently long time, we can merely add a constraint to the grammar; we are not compelled to give up the infinite  $a^*$  component. Thus both approaches obey Ockham's razor.

Nothing in the above discussion depends on specific features of Gold's theorem; the problem arises from the general problem of induction. Thus even in more realistic scenarios, the two approaches cannot be distinguished either empirically or rationally.

## Conclusions

This paper has argued that linguists and psychologists talk past each other primarily because they have different epistemic and metaphysical commitments that are beyond conscious control.

Miller (1990, p. 322) predicts that it will be hard for linguists "to make clear to psychologists that simplifying explanations can be satisfying, once you grow accustomed

to them." Despite its tentative nature, the present study has provided ample reason to take Miller's prediction seriously. The predominance of the empiricist/mechanistic approach across the sciences suggests that it may be easier for linguists to appreciate psychological explanations than the other way around. Nevertheless, linguistics will always have a core of nomological rationalists. Given the multifaceted nature of language, this is perhaps just as it should be.

## Abstract

The purpose of this study is to investigate the process of improvisational contemporary dance. To achieve this goal, we combine two types of methodology: analysis of data from interviews with dancers and analysis of their dance performances. Our findings reveal that while dancing, in order to create their movements, improvisational dancers interact with various stimuli that come from inside and outside of themselves (for example, images and feelings that they entertain during their dancing, and the music, space and audience of their dance performances). Through such interactions, dancers organize movements in their performances extemporarily, using various expressive techniques (for example, changing speed or image intentionally and seeing themselves from the viewpoint of a third person).

**Keywords:** Improvisation; Contemporary dance; Creativity

## Introduction

What happens in artists' minds when they generate their expressions or works? Recently research interest in artistic creation has been growing. There have been some empirical studies in psychology and cognitive science focused on artistic creation (e.g., Yokochi & Okada (2005) on Chinese ink painting, Tsuchikura (2010) on movie making, Tayanagi (2010) on jazz music, and Goan & Tujita (2007) on stage direction). Of the various forms of art, this study seeks to reveal the process of artistic creation empirically by focusing on dance, in particular improvisational contemporary dance.

Improvisation plays a critical role in the process of artistic expression. Sasaki, a scholar of aesthetics, has pointed out the importance of improvisation as follows: "In the exact moment of their generation, expressions in the artistic genres, such as fine arts, music, and drama are not generated based on predetermined plans, but based on impromptu activities" (Sasaki, 1995). Thus, it can be considered that improvisation exists as an essential part of the process of artistic expression.

Improvisational dance is one form of artistic expression in which such a process of improvisation saliently appears. Because improvisational dance presents audiences with the process of dance creation itself, making dance movements based on predetermined plans or repeating movements during dance performance is meaningless. Therefore, the

process of improvisational dance contains the essence of artistic creation and expression.

Previous studies in the domain of dance have pointed out the importance of improvisation in the creation of dance works, and the importance of impromptu expressions themselves (Fukumoto, 2007; 2009; Hosokawa, 2011; De Spain, 1997; Ribeiro & Fonseca, 2011; Soma & Hosokawa, 2007; Tsujimoto, 2010). Reviewing previous studies focused on how historically eminent dancers used improvisation to express themselves or create their dance works, Tsujimoto (2010) emphasized the significance of improvisation in dance. Tsujimoto (2010) also described an anecdote that when dancing extemporarily, the dancer's body instantly responded to stimuli from dance partners, the surrounding environment, and sensations born within the body. Through reviews of previous studies, Ribeiro & Fonseca (2011) also reported dancers' experience while dancing extemporarily. They suggested that improvisational dance is formed by "the interaction of the body with the environment and the affective and cognitive systems" (Ribeiro & Fonseca, 2011). Although these studies offer useful insights, these findings are based on reviews and anecdotal evidence, rather than on empirical evidence. They did not empirically investigate what stimuli dancers interact with in the process of improvisation or how dancers create their works.

In contrast, using information from reviews of a dancer's works, interviews with her, and field experiments, Hosokawa (2011) studied the process and skills of improvisational dance, focusing on Kei Takei, a famous contemporary dancer. On the basis of the results of the study, Hosokawa (2011) suggests that Kei Takei generates movement sequences intuitively based on her physical skill, and polishes movement sequences to develop her dance work in keeping with her dance philosophy. De Spain (1997) constructed a theoretical model about the process of solo dance improvisation through interviews and introspective reports with improvisers of dance. De Spain's model broke down the elements of improvisation into the categories of physical operands/operators, cognitive/affective operands/operators, determination, and attention. "The model also emphasized the importance of considering the existing state and flow of the improvisation at the moment of new action/interaction" (De Spain, 1997). Although Hosokawa (2011) and De Spain (1997) revealed

the process of improvisational dance, these studies focused only on the case of solo dance and their results are based mainly on verbal evidence such as interviews. In order to fully understand the process of improvisational dance in reality, it is necessary for us to analyze dance performance data in addition to interview data. Since the main medium for dancers to express what they want to express is their bodies, it is essential for researchers to analyze improvisational dance performances to understand how such a medium is used effectively. Therefore, we investigate the process of improvisational contemporary dance combining two types of methodology, analyses of data from interviews with dancers, and analyses of their dance performances.

Hence, this exploratory study aims at empirically investigating the improvisational process of contemporary dance by solo and duo dancers. Specifically, this study examines the relationship between dancers' internal processes and their dance performances, through: (1) interviews with dancers about what they pay attention to

while improvising; (2) fieldwork analyses of actual dance performances with introspective reports by the dancers.

## Study 1 Interviews with Dancers

In this interview study, we investigate what dancers think when they are dancing extemporarily.

### Methods

**Participants.** Ten professional contemporary dancers who have experience in improvisational dance participated in this study. (We use aliases A to J for these participants.)

**Procedure.** We conducted semi-structured interviews with the dancers about what they think when they are dancing extemporarily. The interviews were held between August and October 2010, with each interview lasting 90-120 minutes. All the interviews were recorded with a digital audio recorder, and the first author additionally took notes.

We asked the dancers about what they were thinking and what they valued when they were dancing extemporarily by

Table 1: Categories and definitions of dancers attention while dancing extemporarily

Category			Definition
Interaction with oneself	Internal experience	Message	To dance being aware of the message
		Feeling	To express the feeling that the dancer entertains while dancing
		Images	To dance retaining images that come into the dancer's mind while dancing
	Physical experience	Physical sensation	To enjoy the physical sensations that spring forth from the dancer's own body while dancing
Interaction with the outside	Stimuli from outside	Music	To dance being inspired by the music
		Space	To dance being inspired by the space
		Audience	Dialogue with the audience to touch their hearts or to surprise them
		Other dancers	To dance being inspired by other dancers
Means of expression	Confidence in oneself	Trust in inner experience	To move based on what the dancer feels without applying preformulated dance movements
		Trust in physical experience	To move following one's movements without conscious thought
	Expressive techniques	Switching	To change speed, rhythm, image or texture of movement intentionally
		Development	To develop movements or stories
		Seeing oneself from the viewpoint of a third person	To be conscious of how the dance looks to the audience
		Coordination with other dancers	To move together with other dancers, similarly, contrastingly or separately
	Personal decisions	Choice	To choose the most appropriate expression based on one's own feeling and the environment
		Continuation	Continue the current movement until satisfied

themselves and with other dancers. All the interviews were conducted in Japanese.

**Preparation for data analysis.** We analyzed the data by adapting the KJ method, a method to analyze the qualitative data. In detail, using the following procedure, the recorded interviews were prepared for analysis: 1. Transcription; 2. General understanding of the contents; 3. Identification of statements regarding attention or behaviour during extemporary dance; 4. Labelling of the statements with respect to dancers' attention or behaviour during extemporary dance; 5. Generation of categories by gathering similar labels together; 6. Consideration of the relationships between categories. We segmented the statements based on the speakers' turns, and coded all the segmented units based on what the dancer paid attention to while dancing extemporarily. In some cases, multiple codes are used for a single unit. Later, we assembled categories with similar meaning to create final categories.

During the coding process, several researchers and graduate students majoring in cognitive science checked the validity of the categories and revised inappropriate parts of labels and categories made by the first author.

## Results and Discussion

Table 1 is a collection of categories based on the interview data relating to what dancers pay attention to while dancing extemporarily. The statements were divided into three major categories, [interaction with oneself], [interaction with the

outside] and [means of expression]. Additionally, [interaction with oneself] was divided into <<internal experience>> and <<physical experience>>. The categories under <<internal experience>> are <message>, <feeling> and <images>. The category under <<physical experience>> is <physical sensation>. [Interaction with the outside] includes <<stimuli from outside>>, <music>, <space>, <audience> and <other dancers>. Topics associated with [means of expression] include the following three subcategories, <<confidence in oneself>>, <<expressive techniques>> and <<personal decisions>>. Subcategories under <<confidence in oneself>> are <trust in inner experience>, <trust in physical experience>; those under <<expressive techniques>> are <switching>, <development>, <seeing oneself from the viewpoint of a third person>, <coordination with other dancers>; those under <<personal decisions>> are <choice> and <continuation>. Table 2 shows which dancers referred to each category. In improvisational dance, dancers first pay attention to [interaction with oneself] and [interaction with the outside] and then, using [means of expression], they create a dance performance based on information from these interactions. Thus, when a dancer is dancing extemporarily, s/he interacts with factors such as <message>, <feeling>, <images>, <physical sensation>, <music>, <space>, <audience>, or <other dancers>. By combining this interaction with <<confidence in oneself>>, s/he creates physical movements as a dance performance.

Table 2: Dancers who referred to each categories

Category / dancers	A	B	C	D	E	F	G	H	I	J	total
Message	○	○		○	○		○	○		○	7
Feeling		○		○	○				○		4
Images									○		1

Music		○	○	○	○	○	○	○	○	○	9
Space		○		○	○		○	○			5
Audiences			○		○		○	○	○		5
Other dancers	○	○	○	○	○	○	○	○	○	○	10
Trust in inner experience	○		○	○				○	○		5
Trust in physically experience	○	○	○	○	○	○	○	○	○	○	10
Switching		○					○	○	○		4
Development			○			○			○	○	4
Seeing oneself from the viewpoint of a third person	○	○	○	○	○	○	○	○	○	○	10
Coordination with other dancers	○	○	○	○	○	○	○	○	○	○	10
Choice									○		1
Continuation						○					1

Dancers choose such interactions flexibly by listening to their feelings and responding to their surroundings. Dancers continue the interaction that they chose until they are satisfied with their own decisions. Thus, in improvisational dance, dancers pay attention to many things that normally go unnoticed (their own feelings, physical sensations, the music, space, other dancers etc.) and they create dance movements by responding carefully to these.

In order not to let the interaction cease and so to create dance works that are fixed at a certain time and place, dancers use expressive techniques, such as <switching>, <development>, <seeing oneself from the viewpoint of a third person> and <coordination with other dancers>. Improvisational dancers present to audiences the process of dance creation as a dance work. Therefore, in addition to producing movements, it is also necessary to organize them into dance pieces.

In other words, while dancing, in order to create their dance, improvisational dancers interact with various stimuli that come from inside and outside of themselves (for example, images and feelings that they entertain during their dancing, and the music, space and audiences of their dance performances). Dancers use these interactions for their expression by responding to them sincerely and carefully. Through such interactions, dancers organize movements in their performances extemporarily, using various expressive techniques (for example, switching; changing speed or image intentionally and seeing themselves from the viewpoint of a third person).

The next important questions are how much interaction occurs and with which kind of stimuli in improvisational dance, and how these interactions affect the development of dance. In order to answer these questions, Study 2 examines dancers' internal processes and behavioural processes through introspective reports and analyses of performances.

## Study 2 Field Experiment

What exactly do dancers think and feel while dancing in a performance? In Study 2, we conducted a field experiment to capture the relationship between the introspective reports mentioned above and actual dance performances. The analysis of reflection focuses on which stimuli dancers pay attention to during the performance. Also, in the case of duo dance performance, a dance partner is an additional stimulus in the circumstance. We will analyze how a dance partner's movements affect the dancers' movements in duo dance performance.

## Method

**Participants and procedure.** We conducted a field experiment to analyze the improvisational dance performance of two expert dancers (H and M, both with more than 10 years of dance experience) on 5 November, 2010. After having them dance solo performances, we asked them dance together. We recorded the performance with four video cameras. Additionally, directly after the performance, we showed the video of the performance to

the dancers and asked them to reflect on how they felt, thought and moved during the performance.

The same music was used for both solo and duo performances. The theme H chose for her dance was, "Did you know that manifesto means to leave a handprint? To leave a handprint", and the theme M chose for his dance was "Inside a framed picture". H's solo ran 4 minutes 18 seconds. M's solo ran 4 minutes 17 seconds. Their duo piece ran for 4 minutes 30 seconds. In the duo performance, the dancers each maintained their own theme from their solo work. The only difference this time was that they had to dance with a partner who was expressing a different theme.

### Preparation for data analysis.

**Introspective reports:** After transcribing the introspective reports, we coded the statements based on what kind of stimuli and interactions occurred using the categories from Study 1.

**Performance analysis:** In order to objectively analyze the dance performance, we first focused on the vertical change of the centre of gravity of the dancers. Specifically, we coded each video frame (30 frames = 1 second) focused on the centre of gravity (1 lying down, 2 sitting, 3 kneeling, 4 standing, 5 stretching up, 6 jumping). We calculated the average score for the change in the centre of gravity, by dividing the score for the successive changes by the total time (in seconds).

## Results and Discussion

**Introspective reports.** After transcribing all of the introspective reports, we identified the contents of the performances that the verbal reports indicated. Then we identified which stimuli the dancers interacted with. We coded the data according to the categories used in Study 1. Because it was difficult to distinguish between "images" and "message", we coded the statements relating to both of these terms as "theme". Therefore, the categories for the statements are "theme", "physical sensation", "feeling", "dance technique", "music", "other dancers", "audience", and "space". Figure 1 shows how the objects of the dancers' attention change throughout the performance second by second. The columns in Figure 1 indicate "oneself" ("theme", "physical sensation", "feeling", "dance technique") and "outside" ("music", "audiences", "space") in the case of solo performance and "oneself" ("theme", "physical sensation", "feeling", "dance technique"), "other dancer", and "other factors" ("music", "audience", "space") in the case of duo performance.

The results show that H paid attention to "theme" in 81% of the solo performance time, and M did so in 86%. Therefore, it is clear that among the various stimuli, interaction with "theme" plays a central role in the development of the solo performance. Meanwhile, in duo performance, 80% of H's performance and 94% of M's performance were focused on the "other dancer", indicating that attention to the "other dancer" plays a central role in the development of the duo performance.

1: Whether the lines are right or left has no significance. This is only because the dancers referred to more than two categories at the same time.  
 2: Whether the lines are right or left has no significance. This is only because the dancers referred to more than two categories at the same time.

pattern	category
	theme
	physical sensation
	feeling
	dance technique
	music
	other dancer
	audience
	space

Figure 1: Change per second for the different categories

Table 3 : The average values for the position of the centre of gravity per second

	H		M	
	solo	duo	solo	duo
Part 1				
Sum of changing values	66	53	12	44
Duration of music (s)	64	64	64	64
<b>Average value</b>	<b>1.03</b>	<b>0.83</b>	<b>0.19</b>	<b>0.69</b>
Part 2				
Sum of changing values	43	45	45	54
Duration of music (s)	95	95	95	95
<b>Average value</b>	<b>0.45</b>	<b>0.47</b>	<b>0.47</b>	<b>0.57</b>
3 part				
Sum of changing values	53	91	41	44
Duration of music (s)	99	111	98	111
<b>Average value</b>	<b>0.54</b>	<b>0.82</b>	<b>0.42</b>	<b>0.40</b>

**Performance Analysis.** The music used in this performance was composed in such a way as to be easily split into three distinct sections. Therefore, by dividing the overall performance into three sections, we checked the change in the dancers' centre of gravity. The first section of the music (therefore the first section of the dance performance) took 64 seconds and the second took 95 seconds. The third section of the dance performance was determined by the time when the dancers finished the dance. The third section of H's solo took 99 seconds, and M's took 98 seconds. That of the duo performance took 111 seconds. The results of the centre of gravity analysis are shown in Table 3.

During the first section of the duo performance, the dancers somewhat adjusted their own movements to their partner's. H's score for the change in the centre of the gravity was higher (1.03) in the solo performance, and became lower (0.83) in the duo performance. M's score changed in the opposite direction (from 0.19 to 0.69). This result is consistent with the introspective data. According to the introspective reports, when paying attention to the dance partner, dancers sometimes adjusted their dance movements to the partner's and sometimes created a contrast during the first section.

In the second section, the two dancers' scores for the centre of the gravity were similar (0.47 for H and 0.57 for M). The introspective report is consistent with this finding

in the sense that both dancers thought that they were following their partner's movements. There was also little difference in the scores between solo and duo performances, which may be attributed to the slow music in this section.

In the third section, H's score was 0.82, while M's was 0.40. In the introspective report, each of the dancers stated that they had focused on the stimuli that s/he wanted to interact with, while paying attention to her/his dance partner. In particular, H was more influenced by the interaction with the music and the audience, while M interacted more with his own feelings. The fact that both of the dancers were concentrating on their own dance in this section seems to explain the difference between the dancers' scores.

These results suggest that dancers' dance movements in the duo performance are affected by the interaction with the other dancer's movements, as well as other stimuli such as their own feelings and music.

### General Discussion

In this study, based on interviews and introspective reports, we find that dancers take interactions with various stimuli seriously when improvising dance. Paying attention mainly to their own theme in solo performance and to the other dancers in duo performance, dancers use expressive techniques to construct an improvisational dance performance. In addition, from the performance analysis in Study 2, we find that dancing with another dancer changes a dancer's movements. From the data on changes in the centre of gravity, it is shown that other stimuli also affect the dance performance.

These findings are consistent with the claim by dance scholars Tsujimoto (2010) and Amagasaki (2004) that when dancing extemporarily, the dancer's body instantly responds to stimuli from dance partners, the surrounding environment and sensations born within the body. This study offers empirical evidence for such an anecdotal statement. In other words, through analyses of both verbal and performance data, this study reveals dancers' interaction with the internal process and the external environment in actual solo and duo performances.

This research also reveals that dancers use various expressive techniques to organize their dance movements as a dance piece. These findings are consistent with the claim by the dance scholar, Hosokawa (2011). However, this study offers concrete examples of these expressive techniques. Since there have not hitherto been any empirical studies focused on improvisational dance, our research makes a contribution to this field of research. Our findings suggest that new artistic expressions beyond a dancer's own repertory are born through interactions with the various stimuli at the actual moment of creation.

### Acknowledgments

We would like to express our gratitude to all the participants for having spent so much time on the interviews and dancing. We also received many insightful suggestions from

them on this research through discussions on dance and through dancing together.

# Learning Containment Metaphors

Sushobhan Nayak (snayak@iitk.ac.in)

Amitabha Mukerjee (amit@iitk.ac.in)

Indian Institute of Technology Kanpur

Kanpur, UP 208016 India

## Abstract

We present a computational approach that traces the developmental process, from containment image schemas to metaphors, in four phases: a) perceptual discovery of image schemas, b) associating perceptual arguments and the relation with linguistic units, c) discovering a linguistic structure encoding the schema, and finally d) enriching the semantics of the schema via extended language usage (via a corpus). In the first three phases, we use no prior knowledge about either the perceptual or language domains; in the corpus analysis, we use the WordNet ontology. Our input is an animation based on the Heider-Simmel video, together with a small corpus of transcribed commentaries. From the image sequence, we cluster the visual angle subtended by a landmark, and find that one cluster reflects containment. This is then correlated with the sentences from the adult commentaries uttered contemporaneously with containment situations, yielding strong object-nouns and relation-preposition associations. For discovering linguistic constructs, we use no knowledge of grammatical category or syntax but find recurring patterns using the approach of (Solan, Ruppin, Horn, & Edelman, 2002). Knowing the units involved, we can identify several phrasal patterns (e.g. “X moved into”, “in the Y”). We then search a corpus with the “in the Y” schema to identify container words. We find that the most common class involving containment is location (66%), followed by group membership (20%), time, and cognition (17% each). These may be thought of as language-based non-spatial enrichments for the image schema.

**Keywords:** containment metaphor; grounded concepts; selectional preference

## Introduction

Containment metaphors arise in infancy and may help organize the adult conceptual system (Mandler, 2010). The earliest structures (*image schema*) may arise initially in perception, but are then enriched by language in several ways, and extended to various non-spatial categories. Thus, a sentence such as “I put a lot of energy *into* washing the windows.” reflects the schema ACTIVITIES ARE CONTAINERS in the influential Conceptual Theory of Metaphor (CTM) (Lakoff & Johnson, 1980).

While such extensions of the initial spatial schema become conventionalized in a linguistic group, they retain the grounding. So while starting with the final text is not very useful, the grounded interpretation gives it much more flexibility. A computational study of the process would a) suggest mechanisms for understanding this process, and b) may itself be useful computationally - e.g. by providing an interpretation via simulation using the original grounding.

While much computational work has been done on metaphors, there appears no work that attempts such a vertical sweep from the initial perceptual schema to a language corpus. The emphasis within the NLP paradigm has been

on identifying and analyzing metaphors. The earliest *rule-based* attempts - e.g. (Fass, 1991) were based on hand-coded knowledge and metaphors were identified as a violation of selectional restrictions in a given context (e.g. “my car drinks gasoline”).

Other approaches use syntactic and co-occurrence statistics across large corpora to identify metaphors. We may call these attempts *corpus-driven*; work here may include Shutova, Sun, and Korhonen (2010) who demonstrate metaphor paraphrasing using noun-verb clustering, or Kintsch (2000) who effectively uses Latent Semantic Analysis to interpret metaphors like “My lawyer is a shark”. Cormet (Mason, 2004) is able to find mappings given separated datasets for two domains, e.g. it finds LIQUID  $\rightarrow$  MONEY once provided with LAB and FINANCE specific corpora to train from. Corpus-based approaches keep the metaphor mapping implicit, i.e. while the system can identify many metaphorical usages, the source domain has no grounding. Even distinguishing source from target domain is difficult, e.g. TIME co-occurs more often with SPEND than MONEY. Also, due to a primary reliance on verbs, it becomes difficult to treat ontological metaphors like CONTAINER that are more preposition dependent. Most importantly, purely linguistic approaches are hard to extend - e.g. container metaphors may invoke other attributes of the schema (e.g. ‘stir excitement’, or “the idea jumped out”).

A third category of work, which we may call *embodied modeling* (Narayanan, 1997), is more cognitively motivated. A model is learned from a tagged training set simulating pre-motor cortical representation of movement (Bailey, 1997); this is then mapped to other domains to interpret metaphoric usage such as “India releases the stranglehold on business”. The embodied approach is appealing and elegant, but is hard to scale up because new training data for learning the schema have to be manually created, and the syntactic structures require knowledge of the language.

In this work, we present a grounded model where initial image schemas are discovered from untagged video, and are then associated with textual commentary without using any prior language models. We focus on n-gram models, and on discovering merged paths through the sentence graphs (Solan et al., 2002). Once we have a basic construct, we can enrich the schema by exposing the learner to lots of language situations, which is simulated here by considering the 1-million word Brown corpus.

## Motivation

This work combines ideas of metaphorical extension from the seminal work of Lakoff and Johnson (1980) together with the

developmental ideas from Mandler (2010). Both suggest a strong role for spatiality in adult conceptual structures. Containment is discriminated by infants by the age of 2.5 months, and becomes “accessible” by 5.5 months, when it is used for multiple activities including visual and manual exploration (Spelke & Hespos, 2002). This may imply the presence of a mental structure incorporating arguments like a container and at least one trajector, and a function that given a configuration, accepts it as an instance of containment. This structure, which may be called an initial image schema, is eventually mapped to language, when containment is acquired before support (IN before ON before UNDER). This acquisition reflects an awareness not only of the preposition, but also for the linguistic argument structure that maps the image schema. But after this point, linguistic usage adapts the concept in ways that are specific to the linguistic-cultural context (Spelke & Hespos, 2002). Extensions emerge involving new structures that transfer the relationship to new domains, not only in language, but also in thought. Over increasing exposure, many of these extensions become conventionalized, many of which are listed in the CTM corpus.

To get a baseline check, we compiled 85 containment metaphors from Lakoff and Johnson (1980); of these, 65 involve prepositions in/into/out (IN a lot of trouble, INTO the century); the remaining 20 involve verbs explode, erupt, fill or adjectives full, empty - which profile other aspects of the containment schema (fullness, enclosed-ness etc).

Given this picture of the metaphor acquisition, extension, and conventionalization process, our goal is to try to model this embodied developmental process computationally, right upto the point where language affects and changes the image schema. In this process, we would like to minimize the domain knowledge available to the system; we assume only a large set of statistical learning tools, and a preference for smaller explanatory structures. Of course, we cannot model many important factors like social, interactive aspects.

The next section focuses on how an uninformed agent, with a capability for statistical learning, may acquire the containment schema as a cluster in its sensory space. The following sections discuss the discovery of linguistic units (and  $n$ -grams), the discovery of linguistic constructions associated with containment, and finally, the mapping to a large corpus.

## Learning Containment from Perception

Linguistic concepts are cognitively characterized in terms of *image schemas*, which are schematized recurring patterns from the embodied domains of force, motion, and space (Langacker, 1987; Lakoff & Johnson, 1980). The precise structure of an image schema remains quite unclear, with different authors using differing characterizations. In this work, we take an image schema to consist of two related structures. First is the list of arguments which participate in the associated relation or activity. The other is a characterization of the situation in terms of a function defined over some feature space, so that situations satisfying this function may

Figure 1: *Multimodal input: 2D video “Chase”*: Three shapes, big-square([BS]), small-square([SS]) and circle([C]) interacting with each other and the static box([box]).

be considered as instances of the image schema. We wish to learn such an image schema given a simple video as input (Figure 1), where three objects - a big square ([BS]), a small square ([SS]) and a circle ([C]) are moving around, interacting with each other and going in and out of a static [box] via a **door**. Though the objects deform a bit while rotating, and also occasionally overlap, it is relatively straightforward to segment them.

The linguistic database consists of a co-occurring narrative with 36 descriptions of the video. These narratives exhibit a wide range of linguistic variation in terms of linguistic focus, lexical choice and construction. In an earlier work in learning prepositions and nouns from the same multi-modal data, we used dynamic bottom-up attention to correlate objects seen in the video with their linguistic counterparts (*nouns*) (Mukerjee & Sarkar, 2007). In this work, we further consider the subset of utterances which have a temporal overlap with the frames during which a containment situation prevails.

## Acquiring Containment Prepositions

In spatial reasoning, there have been several attempts at defining spatial relations involving continuum measures defined over different geometric features on object pairs. Regier (1996), a seminal work in preposition grounding, uses angle measures and a connectionist network to correlate videos and prepositions. The work, however, is limited in the sense that Regier uses videos annotated with single words like IN, OUT, THROUGH etc. while we hope to learn these schemas by clustering the untagged video. Also, because his videos are tagged with prepositions, he never has to work to discover the preposition; we have to discover these units from the unconstrained unparsed narrative. Mukerjee and Sarkar (2007) use the same dataset as ours, but use a measure based on visual proximity - the *Stolen Voronoi Area* - to cluster space using Kohonen Self Organising Maps (SOMs). We initially tried these two approaches and find that in an unsupervised clustering task ( $k$ -means with 6 classes), these earlier models do not work well for distinguishing the inside and outside of irregular (L- or U-shaped) containers (1st row, Fig 2). In a supervised scenario they show good results training with sophisticated neural-nets over multiple epochs, but our goal is to try not to use supervision data.

Another feature implicated in place learning in animals is *visual angle* (Rolls et al., 1999) - the angle subtended by a landmark on the retinal image. We attempted to improve on the previous features by using a single feature - the total

angle subtended by a landmark at the object position. With this measure, we find that when the resulting feature space is clustered, one of the clusters works quite well for identifying the IN-schema. Computing this feature involves computing the angle that the landmark, **[box]**, would subtend at each point in the space; the result is measured and clustered using  $k$ -Means ( $k = 6$ ). We can see in Fig 2 (bottom row left) that one cluster completely covers what may be thought as the inside of **[box]**, whereas the the outside is graded between a number of clusters. If we accept this as a characterization for an image schema for containment, then the distribution of visual angle in this cluster will serve to represent this relation. To test whether this model, learned from the single **[box]** shape, really represents the *category* of containment relations, we generalize and evaluate it over a number of other shapes. The results of applying the same learned distribution to three novel shapes is shown in Fig 2(bottom row). We find that regions with varied levels of ‘IN-ness’ have been separately grouped, validating our choice of features. While for closed convex shapes the measure has a clear demarcation of ‘inside’(360° angle), it gives a more graded assessment for open figures as well, such as the open-top square in Fig 2(2nd row, 4th fig).

Figure 2: *k*-Means Clustering of Space. a) Voronoi and Angle features (top row) and b) Visual Angle feature (bottom row). The inside of all the containers has been clearly identified as a separate cluster only in the latter case.

At this stage, the system computes the visual angle subtended at an object position, for a landmark (the box or some other shape). The two arguments participating in this computation are the container and the trajector, though the system does not use these terms; these relationships are implicit in the feature computation. If the visual angle falls within the distribution associated with containment (the *IN-cluster*), it is accepted as an instance of this relation. Thus the system has both the arguments, and the acceptance function characterizing the image schema. This acquisition is pre-linguistic, from perceptual data alone. When a pre-discovered object, say **[BS]**, lies in IN-cluster, we have the argument structure **{[BS] IN [box]}** or **IN([BS],[box])**. After learning the unit IN, we can attempt to map this perceptual argument structure to linguistic syntactical structure, thereby discovering aspects of syntax.

## Linguistic Elements Describing Containment

We now detail the discovery of linguistic elements pertaining to containment through correlation of the commentary with the acquired schemata. We restrict our analysis to utterances occurring while **[BS]** is in the *IN-cluster* w.r.t. **[box]**. Since the commentaries are unconstrained and there is no syntactic information, every uttered word is a possible label. Given an uttered unit  $w_i$ , the probability that it refers to schema  $s_j$ , is given by:

$$P(s_j|w_i) = \frac{P(w_i|s_j)P(s_j)}{P(w_i)} \propto \frac{P(w_i|s_j)}{P(w_i)} = A_{ij}^r$$

This metric, the *relative association* ( $A_{ij}^r$ ), is prone to give erroneous results for infrequent units, while working well for high frequency words. For example, it gives an association value of 1 for a word that has been uttered only once in the whole commentary. To counter this trend, we also subscribe to mutual information between states  $s_j$  and words  $w_i$ , which eliminates the possibility of uninformative rare words being assigned a high score. The word-object association is then estimated using the product of mutual information of word  $w_i$  and state  $s_j$  with their joint probability,

$$A_{ij}^m = Pr(w_i, s_j) \log \frac{Pr(w_i, s_j)}{Pr(w_i)Pr(s_j)}$$

where  $A_{ij}^m$  is the *mutual association*. We use this measure because if  $W(= \cup_i w_i)$  and  $S(= \cup_j s_j)$  are two random variables then their Mutual Information  $I(W, S)$  would be

$$I(W, S) = \sum_i \sum_j Pr(w_i, s_j) \log \frac{Pr(w_i, s_j)}{Pr(w_i)Pr(s_j)} = \sum_i \sum_j A_{ij}^m$$

$A_{ij}^m$  is, thus, the contribution of each word object pair. The results are shown in Fig 3. Notice that *in*, *inside* and *into* emerge as the three dominant monograms (their frequencies in the containment subset are 28, 26 and 15 of 1100 words).

Before moving onto syntax discovery, we observe that the nouns corresponding to the three objects in the video, had been acquired earlier using an attentional correlation model (Mukerjee & Sarkar, 2007). These will be used in the next section: “big square” for **[BS]**, “little square” for **[SS]**, and “circle” for **[C]**.

## Deriving Syntactical Structure

Discovering syntactical structures of a containment preposition like IN will enable us to discover other labels for objects participating in containment. For example, if we know that only object  $A$  with label  $l_A$  is in container  $B$  with label  $l_B$ , the *perceptual* arguments of IN are **{trajector:A, container:B}**. Now, suppose at the same time we hear the utterance: ‘ $l_A$  goes into  $l_C$ ’. If we know the linguistic argument structure associated with IN, then we can have a high confidence from this single instance that  $l_C$  is most likely another label for the container  $B$ . Once internalized, this process would help the agent recreate context in a novel discourse, by simulating the action and

Figure 3: Association of words with the containment cluster. Both the association measures, as used previously for noun-label learning, are shown. The **red** bars indicate the *Relative Frequency* measure while the **green** bars are for the *Mutual Information* Measure.

identifying probable trajectors and landmarks via the syntactic argument structure. In the example above, if we don't know what 'goes' refers to, some idea of this may be formed by realizing that it is something that *A* and *B* may be participating in. This goes along with Siskind (1996)'s *constraining hypotheses with partial knowledge*: "When learning word meanings, children use partial knowledge of word meanings to constrain hypotheses about the meanings of utterances that contain those words."

We start our discovery of syntactic structure by analyzing bi- and tri-gram correlations, which are associated with the same metric as in the monogram case. We observe that the prominent bi-grams are `inside the`, `into the` and `in the`. The tri-grams that emerge are `inside the box`, `in the box` and `into the box`. These associations could help learn the label of not only the containment schema, but also the container itself. Note that the attention based model for learning nouns cannot learn the container/box, which is never dynamically salient. Thus, its label is not known. However it is prominent in these containment sentences, and discounting the frequent word `the` in trigrams such as "`{ inside | in | into } the box`", we may associate `box` with the **[BOX]**, treating it as a label for the container. We also note the presence of other fragments (`big square goes` and `is trying to`) as prominent trigrams; but these are present only in this context, and will be diluted as the agent looks at other containment situations. But despite some glimmers, the *n*-gram approach is not very illuminating regarding the construction encoding for containment.

A richer model of syntactic structure has been developed over many years by Edelman and his group, implemented as the tool ADIOS (Solan et al., 2002). In this approach, a graph called Representational Data Structure (RDS) is constructed from the morphologically segmented input sentences. It then repeatedly scans and modifies the RDS in an attempt to merge edges and come up with a more compact description of the input. In the process, a number of syntactic clusters and constructions are discovered without any prior knowledge of grammatical categories. Examples of some of the patterns

found are:

$$\left[ \begin{array}{c} \left[ \begin{array}{c} \textit{ball} \\ \textit{door} \\ \textit{box} \\ \textit{square} \end{array} \right] \\ \textit{the} \\ \left[ \textit{circle} \right] \end{array} \right] \rightarrow \left[ \begin{array}{c} \textit{move} \\ \textit{came} \\ \textit{got} \end{array} \right] \rightarrow \textit{into}$$

$$\left[ \begin{array}{c} \textit{in} \\ \textit{inside} \\ \textit{into} \end{array} \right] \rightarrow \textit{the} \rightarrow \textit{box}$$

Clearly, these structures are discovering some relevant patterns for containment, including the group `in | into | inside` which was also observed in the trigram model. The noun cluster - with `box` and `door` is also an impressive discovery. But most effective is the fact that `box` is identified as a label appearing after the IN while the trajector appears before.

One of the uses of this structure would be the discovery of synonyms. For example, consider the sentence `large square moves into the box`, which is being uttered as the agent perceptually knows that **[BS]** is moving into IN-cluster, activating schema `IN([BS],[box])`. By aligning this with the linguistic input, `large square` is learned as a referent for **[BS]**, i.e. a synonym for "big square". Also, an unit appearing frequently in the trajector position in the discourse is "it", which has no constant referent; it is possible now to discover that this is a unit which may refer to multiple objects. Further analysis may reveal that "it" is strongly correlated to the most recently observed trajector - and thus our system may begin its journey of understanding anaphora, another computationally promising domain in language.

## Metaphorical Mappings from Language Usage

We have alluded to learning metaphorical maps through association before. We are in a position where we have grounded concepts of agents taking part in an event, and the concept of containment, through a mapping for linguistic element IN. Consider the following occurrences:

1. What state is the project IN? IN-STATE (project, state)

2. He did it IN three minutes. IN-TIME (he, 3min)

Here, the abstract concepts of STATE, TIME etc. are understood in terms of a container, thanks to their syntactic association with linguistic instances of “IN a BOX (container)”, for which the learner has a physical basis. It’s therefore prudent to assume that metaphorical concepts would occur in similar lexico-syntactic environments in language usage. We have demonstrated the ability of the agent in discovering the ‘container’ through ADIOS; the question we would like to address now is, would it also be able to discover the object of containment in a novel context with sentences of myriads of different structure? We investigated it by running ADIOS on IN-containing sentences of Brown corpus. We find that it can, indeed, distinguish ‘containers’ from other elements of a sentence, as evidenced by the following pattern:

$$in \rightarrow the \rightarrow \begin{bmatrix} building & war & fight & car \\ group & death & woods & cellar \end{bmatrix}$$

While discovery of ‘container’ elements would be the first evidence of mapping of abstract concepts to the ‘container’, the mappings would be prominent only if further evidence abounds in language, so that learning due to false evidence is minimized. The *propensity* of a concept to be described as a ‘container’ can be gauged through the regularity of its occurrence in the object position of IN. In literature, **selectional preference (SP)**(Resnik, 1993) is used abundantly to measure regularities of a verb w.r.t. the semantic class (*subject, object* etc.) of its argument. It has been used previously for word-sense disambiguation(Resnik, 1993) and metaphor interpretation(Mason, 2004). While it has only been used for finding verb-preferences, we will adapt it to include prepositional preferences, so that we are able to learn containment metaphors. While verbs have different syntactic relations like *verb-object* or *subject-verb*, the prepositions we are considering, have only one relation to the trailing noun, that of Object of Preposition (*pobj*)(according to the Stanford Parser(Marneffe & Manning, 2006)). Therefore, the formulation from Resnik (1993) is slightly modified. The *selectional association* of class  $c$  for predicate  $p$ (IN) is defined as:

$$A(p, c) = \frac{1}{S(p)} P(c|p) \log \frac{P(c|p)}{P(c)}$$

where,

$$S(p) = D(P(c|p)||P(c)) = \sum_c P(c|p) \log \frac{P(c|p)}{P(c)}$$

and,

$$P(c|p) = \frac{freq(p, c)}{freq(p)} = \frac{\sum_{w \in c} count(p, w)}{freq(p)}$$

where  $count(p, w)$  is the number of time word  $w$  occurred, and  $classes(w)$  is the number of classes it belongs to.

Table 1: Selectional association strength of different classes

Class	SA	Class	SA
location	0.658	act	0.058
group	0.201	artifact	0.077
time	0.175	object	0.055
cognition	0.164	food	-0.030
state	0.145	animal	-0.042

WordNet (Feinerer & Hornik, 2011) is our knowledge-base for class  $c$ . WordNet was developed as a system that would be consistent with the knowledge acquired over the years about how human beings process language. To represent the early learner’s limited concept-repository, only top level classes of WordNet are considered. We use the Brown Corpus as the sample space to determine the selectional preferences. All the sentences involving the containment concepts, i.e. all 21,480 sentence-parts with words *in/into/inside* were extracted. The sentences with IN were converted to the functional form of IN(*pobj*) in a rather simple way: the first occurrence of a noun after IN in the tagged corpus was assigned to the concept. For example, the sentence fragment *into a hot cauldron* is converted to IN(cauldron).

The most occurring ‘container’ words were *world, way, order, years, case, states* etc. The resultant associations are shown in Table 1. Notice that Location class has the highest association for container schema, activating a LOCATIONS ARE CONTAINERS mapping. Group class also has a strong association to containers, representative of the notion that groups or teams are visualized as containers (*in a group, in a team*). Time, Cognition and State also show high associativity, while Food and Person class demonstrate a significantly negative mapping. The negative numbers only represent the weakness of mapping, and should not be treated as repudiating existence of the same. The association measures only demonstrate that some mappings are used more in language, and consequently, are stronger in our cognition than others. In fact, in the original metaphor list(Lakoff & Johnson, 1980), the most prominent mappings to container are those of Cognition(15%), State(14%), Location(7.3%), Group(8.6%), Time(5.4%) and Act(4.8%), somewhat representative of their strength acquired from the whole corpus. Similarly, the least occurring classes in the list too are Plant(0.3%), Animal(0.3%) and Food(1%). Some examples of sentences from both the Brown corpus and metaphor list are presented below:

- STATE/COGNITION AS A CONTAINER
  - Meredith began falling in love. (Brown)
  - We’re IN a mess. (Lakoff & Johnson, 1980)
- TIME AS A CONTAINER
  - We’re well into the century. (Lakoff & Johnson, 1980)
  - There comes a time in the lives of most of us when we want to be alone. (Brown)
- LOCATION AS A CONTAINER

- If you’ve travelled in Europe a time or two , ... (Brown)
- ...and begin to feel at home in the capitals of Europe... (Brown)
- ACT AS A CONTAINER
  - How did you get into window-washing as a profession? (Lakoff & Johnson, 1980)

## Conclusion

In this work, we proposed a plausible method for a primitive artificial agent with multi-modal input handling and feature extraction capability, to internalize linguistic concepts of containment. Containment metaphors are a primary way in which humans understand abstract concepts of state/emotion etc. and it’s therefore necessary for a cognitive system to be able to do so if it’s to acquire human level intelligence. Through a grounded system and selectional preference of IN, we also showed how the model can internalize conventional metaphors in vogue in English.

In the work, we have used some novel ideas, like that of modifying selectional preference to include prepositional bindings, which is, to our knowledge, unexplored in literature. Also, through simple methods of spatial feature extraction, unsupervised clustering and word-cluster association, we have been able to extract the idea of containment.

Nonetheless, this work can benefit from much improvisation. The image schema for containment that we provide, is a very crude one. While it’s possible to extend it to more general scenarios, as has been demonstrated, we haven’t investigated its limitations on non-convex shapes. That, however, hardly undermines our contribution here since in non-convex shapes, even adults find it difficult to separate regions into inside/outside, and it largely becomes an outcome of some context. Furthermore, our aim was to show that even with so meagre a sense-world (that of one video and associated commentaries), an artificial agent can get some semblance of human-like notions of containment and employ them to inculcate metaphorical mappings in its system. Instead of 81 seconds of learning, however, the human learner has days and months and years of exposure, and clearly this can lead to the construction of extremely rich and diverse schemata.

While we have handled concepts that easily fall into a container mould due to usage of IN, we have not been able to model other container metaphors that have different attributes, like the 20 out of our list of 85 that depend on verbs and adjectives related to substance. Simulating all that is indeed a Herculean task in this limited set-up. We intend to look into these aspects and also, to matters of finding more mappings using WordNet’s synsets (at present we are using only the lexical files – synset usage would lead to discovery of more maps, but it would also make the process noisy) in our future work.

# Interaction of Word Learning and Semantic Category Formation in Late Talking

Aida Nematzadeh, Afsaneh Fazly, and Suzanne Stevenson

Department of Computer Science

University of Toronto

{aida,afsaneh,suzanne}@cs.toronto.edu

## Abstract

Late talkers (LTs) — children who show a marked delay in vocabulary learning — have also been shown to differ from normally-developing (ND) children with respect to the semantic organization of their learned vocabulary. We use a computational model of word learning to study how individual differences between LTs and NDs give rise to differences in abstract knowledge of categories emerging from learned words, and how this affects their subsequent word learning. Our results suggest that the vocabulary composition of LTs and NDs differ at least partially due to a deficit in the attentional abilities of LTs, which also results in the learning of weaker abstract knowledge of semantic categories of words.

## Introduction

Late talkers (LTs) are children with a marked delay in word learning at an early age, some of whom go on to exhibit specific language impairment (SLI). Early identification of LTs at risk for SLI is especially important, since early intervention can produce significant changes in the language development of these children (Desmarais, Sylvestre, Meyer, Bairati, & Rouleau, 2008). Many psycholinguistic studies have thus focused on understanding signs of late talking, as well as factors contributing to it (Paul & Elwood, 1991; Thal, Bates, Goodman, & Jahn-Samilo, 1997; Rescorla & Merrin, 1998; Ellis Weismer & Evans, 2002; Rowe, 2008; Stokes & Klee, 2009).

An important observation about late-talking children is that they seem to not only learn *more slowly* than their normally-developing (ND) peers, but also to learn *differently*. For example, the vocabulary composition of LTs shows greater variability, e.g., in terms of how consistently certain properties, such as shape, are associated with particular categories, such as solid objects (Jones & Smith, 2005; Colunga & Sims, 2011). More generally, the vocabulary of LTs has been shown to exhibit less semantic connectivity than that of NDs (Sheng & McGregor, 2010; Beckage, Smith, & Hills, 2010). The greater variability and the weaker connectivity in the vocabulary of LTs call for further investigation since they might be reflective of underlying cognitive deficits in these children.

Psycholinguistic evidence suggests that children’s word learning improves when they form some abstract knowledge about what kinds of semantic properties are relevant to what kinds of categories (Jones, Smith, & Landau, 1991; Colunga & Smith, 2005; Colunga & Sims, 2011). This abstract knowledge is argued to emerge by generalizing over the learned words. Stated otherwise, words that have been learned contribute to generalized abstract knowledge about word meanings and semantic categories, which then guide subsequent word learning. It is possible that because of the differences in the vocabulary composition of LTs and NDs, the two groups

of children also form different abstract knowledge of categories, which causes differences in their word learning (as suggested by Jones & Smith, 2005; Colunga & Sims, 2011).

We investigate this possibility by examining within a computational model the precise interaction between early word learning and knowledge of semantic categories of words. We do so by extending an existing model of cross-situational word learning (Fazly, Alishahi, & Stevenson, 2010). As in Nematzadeh, Fazly, and Stevenson (2011), we simulate the difference between ND and LT learners as a difference in the ability of the cross-situational learning mechanism to attend to appropriate semantic features for a word. Within this framework, we propose a new model that forms clusters of words according to their learned semantic properties, and that uses this knowledge in guiding the future associations between words and meanings. We show that the semantic clusters of words are qualitatively very different for our ND and LT models; moreover, the two learners exhibit striking differences in terms of the usefulness of their learned clusters for subsequent word learning. Through computational modeling, we thus suggest an interaction between the impaired ability of LTs to form informative abstract semantic categories, and the observed delay in their vocabulary acquisition.

## The Computational Model

### Overview of the Word Learning Model

The model of Fazly et al. (2010) is a cross-situational learner that incrementally forms probabilistic associations between words and their semantic properties. The input to a child is simulated as a sequence of utterances (a set of words), each paired with a scene representation (a set of semantic features, representing what is perceived when the words are heard):

**Utterance:** { *she, drinks, milk* }

**Scene:** { ANIMATE, PERSON, FEMALE, CONSUME, DRINK, SUBSTANCE, FOOD, DAIRY-PRODUCT }

Given such an input pair, the model adjusts its probabilistic representation of the meaning of each word. First, the model determines, *based on its current probabilistic knowledge of word–meaning associations*, which semantic features in the scene are more and less likely to be associated with each word in the utterance. Using that assessment of word–feature alignment in the current input, the model then updates its probabilistic representation of the meaning of each word.

In this way, the model uses cross-situational evidence to gradually improve its representation of the meaning of each word  $w$  as a probability distribution,  $p(\cdot|w)$ , over all semantic features: i.e.,  $p(f|w)$  is the probability of feature  $f$  being part

of the meaning of word  $w$ . At the heart of this process are two calculations which we briefly summarize here (see Fazly et al., 2010, for more detail). The *alignment probability* determines how strongly a word  $w$  and a feature  $f$  are associated in the current (multi-word) utterance  $U$  at time  $t$ , in proportion to the model’s current hypothesis of how likely the feature is part of the meaning of the word:

$$a_w^{(t)}(w|f) = \frac{p^{(t-1)}(f|w)}{\sum_{w' \in U_t} p^{(t-1)}(f|w')} \quad (1)$$

In order to collect this knowledge across all cross-situational uses of the word and feature, the model maintains an incrementally accumulated sum of these alignments that captures the overall strength of the association between  $w$  and  $f$ :

$$\text{assoc}^{(t)}(w, f) = \text{assoc}^{(t-1)}(w, f) + a_w^{(t)}(w|f) \quad (2)$$

The second key formula to the operation of the model is the *meaning probability* that uses the association scores to update the meaning of each word after processing an input pair:

$$p^{(t)}(f|w) = \frac{\text{assoc}^{(t)}(f, w) + \lambda(t)}{\sum_{f' \in \mathcal{M}} \text{assoc}^{(t)}(f', w) + \beta \cdot \lambda(t)} \quad (3)$$

where  $\beta$  is the number of expected distinct features,  $\mathcal{M}$  is the subset of those features that have been observed, and  $\lambda(t)$  is a smoothing function which we formulate in a way that captures the developing ability of the model to attend to input, as follows.

Research has shown that children’s ability to attend to relevant features of a perceived scene improve over time (e.g., Mundy et al., 2007). Moreover, LTs have been observed to show difficulty with the communicative abilities that enable children to direct appropriate attention on relevant aspects of a scene (e.g., Rescorla & Merrin, 1998). In recent work (Nematzadeh et al., 2011), we demonstrated that we can use the  $\lambda(t)$  function to simulate how quickly or slowly the attentional abilities of a learner develop over time. Specifically, the  $\lambda(t)$  function determines how much weight is given to unobserved word–feature pairs, with greater weight reflecting immature attentional skills in which the learner fails to focus on the observed (appropriate) meaning features. In the model,  $\lambda(t)$  is designed to decrease over time, to simulate gradually improving attentional processes that can appropriately focus on the observed word–feature pairs. We modeled the difference between ND and LT learners by having a  $\lambda(t)$  function for the latter that decreases much more slowly, corresponding to delayed development of appropriate attention to the input. Here we adopt that same formulation,<sup>1</sup> but extend the model as follows to consider the role of attention and its interaction with semantic category formation in word learning.

<sup>1</sup>Our ND and LT simulations here use the same settings for  $\lambda(t)$  as what we referred to as ND and LT<sub>5</sub> in our previous work.

## Learning Semantic Categories of Words

We extend the word learning model above by incorporating the ability to form clusters of words based on their learned semantics, and to use the resulting semantic categories in subsequent word learning.<sup>2</sup> These abilities represent a first step in integrating the model’s word learning with formation of conceptual categories. These extensions to the model are key to further examination of the cognitive mechanisms that might underlie the weaker semantic connectivity observed in the vocabulary of LTs. Specifically, while Nematzadeh et al. (2011) showed that learned words of their ND learner had greater semantic coherence than those in the LT learner, the model did not actually form semantic clusters of words, nor use semantic relations among words to help in word learning.

Our new model, at certain points in time (depending on the simulation), groups the words it has observed into clusters based on the similarity among their learned meanings. Given two words  $w$  and  $w'$ , we determine their degree of semantic similarity by treating their learned probability distributions over the semantic features,  $p(\cdot|w)$  and  $p(\cdot|w')$ , as input vectors to the cosine function. These cosine values guide the grouping of words using a standard unsupervised hierarchical clustering method. The clusters of semantically related words can then be analyzed to see how the factors that simulate ND and LT learners in the model contribute to different quality of semantic categorization, as observed by Sheng and McGregor (2010) and Beckage et al. (2010), among others.

Moreover, the semantic clusters enable us to build further on the explanation of late talking as arising from attentional differences in learners (as proposed in Nematzadeh et al., 2011). Specifically, we assume that learned semantic categories enable children to generalize their knowledge of related words, which can help focus subsequent word learning on relevant semantic features in the input. In our model, knowledge about the semantic category of a word can be used as an additional source of information about which semantic features are more likely to be aligned with the word in a given input. For example, features such as EDIBLE and FOOD should be more strongly aligned to a word referring to a kind of fruit than to a word referring to a kind of vehicle.

We achieve this in our model by aligning a word  $w$  and a feature  $f$  in an input utterance–scene pair according to both word-level and category-level information, the latter drawing on the incrementally created semantic clusters. We adopt the formulation used by Alishahi and Fazly (2010) to combine word and category information in the alignment probability:<sup>3</sup>

$$a^{(t)}(w|f) = \omega \cdot a_w^{(t)}(w|f) + (1 - \omega) \cdot a_c^{(t)}(w|f) \quad (4)$$

<sup>2</sup>We continue to refer to the clusters that our model learns both as *clusters*, to emphasize that they are learned in an unsupervised manner, and as *semantic categories*, to emphasize their connection to children’s knowledge of abstract categories.

<sup>3</sup>The approach of Alishahi and Fazly (2010) differs from ours: (1) They examine the role of syntactic categories (e.g., noun or verb) in word learning while we look at semantic categories. (2) They use predefined correct assignments of words to such parts of speech, but our clustering is based on the model’s learned semantic knowledge.

*apple*: { FOOD:1, SOLID:.72, ..., PLANT-PART:.22,  
PHYSICAL-ENTITY:.17, WHOLE:.06, ... }

Figure 1: Sample true meaning features & their scores for *apple*.

The first component of the above formula,  $a_w^{(t)}(w|f)$  is the word-based alignment, given in Eqn. (1) above. The second component,  $a_c^{(t)}(w|f)$ , is an analogous category-based alignment (described below). The  $\omega$  term is a weight (between 0 and 1) that determines the relative contribution of the two alignments; here we use a balanced weighting of 0.5.

Where the word-based alignment captures the association between a feature and a single word, the category-based alignment,  $a_c^{(t)}(w|f)$ , assesses the overall association between the feature  $f$  and the words in  $\text{cluster}(w)$ , the cluster assignment determined by the model for word  $w$ . This alignment is calculated by replacing occurrences of  $p(f|w)$  in Eqn. (1) with  $p(f|\text{cluster}(w))$ . We again follow Alishahi and Fazly (2010) in defining  $p(f|\text{cluster}(w))$  as the average of the meaning probabilities of the words in the cluster:

$$p^{(t)}(f|\text{cluster}(w)) = \frac{1}{|\text{cluster}(w)|} \sum_{w \in \text{cluster}(w)} p^{(t)}(f|w) \quad (5)$$

where  $|\text{cluster}(w)|$  is the number of words in the cluster.

## Semantic Representation in the Model

### The Representation of a Scene

The input data for our model consists of a set of utterances paired with their scene representations. As in Nematzadeh et al. (2011), the utterances are bags of lemmatized words, taken from the child-directed speech (CDS) portion of the Manchester corpus (Theakston et al., 2001, from CHILDES MacWhinney, 2000). The corpus is transcripts of conversations with 12 British children, ages 1;8 to 3;0. We use half the data as the development set, and the rest for final evaluations.

The corresponding scene representation for each utterance must be artificially generated, since no semantic annotation of the contextual scene exists for any large corpus of CDS. First, we create an input-generation lexicon containing the “true” meaning  $t(w)$  for each word  $w$  in our corpus:  $t(w)$  is a vector over a set of semantic features, each associated with a score. An example lexical entry is given in Figure 1; the creation of this lexicon is described below.<sup>4</sup> Next, to generate the scene  $S$  for an utterance  $U$ , we probabilistically sample an observed subset of features from the full set of features in  $t(w)$  for each word  $w \in U$ . This imperfect sampling allows us to simulate the noise and uncertainty in the input, as well as the uncertainty of a child in determining the relevant meaning elements in a scene. The scene  $S$  is the union of all the features sampled for all the words in the utterance.

### The Representation of Word Meaning

We focus on the semantics of nouns, since they are central to work on the role of category knowledge in word learning. Our previous work (Nematzadeh et al., 2011) used a

<sup>4</sup>It should be emphasized that the input-generation lexicon is not used for learning by the model; it is used only to create the input.

psycholinguistically-plausible set of features for this purpose (Howell et al., 2005); however, they were only available for a limited number of nouns. Here we develop an improved semantic representation for nouns that enables a more extensive test of our clustering method and associated processing involving semantic relatedness among words.

We construct the lexical entry  $t(w)$  for each noun  $w$  drawing on WordNet<sup>5</sup> as follows. For each synset in WordNet, we select one member word to serve as the semantic feature representing that synset. The initial representation of  $t(w)$  consists of the set of such features from each ancestor (hypernym) of the word’s first sense in WordNet.<sup>6</sup> We use the same features as in previous work to initialize  $t(w)$  for other parts of speech (Nematzadeh et al., 2011; Alishahi & Fazly, 2010).

To complete the representation of  $t(w)$ , we need a score for each feature which can be used in the probabilistic generation of a scene for an utterance containing  $w$ . We assume that general features such as ENTITY, that appear with many words, are less informative than specific features such as FOOD, that appear with fewer words. Hence, we aim for a score that gives a higher value to the more specific features, so that more informative features are generated more frequently.

We formulate such a score by forming semantic groups of words, and determining for each group the *strength* and *specificity* of each feature within that group; multiplying these components gives the desired assessment of the feature’s informativeness to that group of words.<sup>7</sup>

First, we form noun groups by using the labels provided in WordNet that indicate the semantic category of the sense; e.g., the first sense of *apple* is in category *noun.food*. (For words other than nouns, we form single-member groups containing that word only.) Next, for each feature  $f$  in  $t(w)$  for a word  $w$  in group  $g$ , the score is calculated by multiplying  $\text{strength}(f, g)$  and  $\text{specificity}(f)$ :

$$\text{strength}(f, g) = \frac{\text{count}(f, g)}{\sum_{f' \in g} \text{count}(f', g)}$$

$$\text{specificity}(f) = \log \frac{|G|}{|g : f \in g|}$$

where  $|G|$  is the total number of groups, and  $|g : f \in g|$  is the number of groups that  $f$  appears in;  $\text{strength}(f, g)$  captures how important feature  $f$  is within group  $g$  (its relative frequency among features within  $g$ );  $\text{specificity}(f)$  reflects how specific a feature is to a group or small number of groups, with larger values indicating a more distinctive feature. For each word  $w$ , each feature  $f$  in  $t(w)$  is associated with the score for  $f$  and  $g$  (where  $w \in g$ ); the resulting scores are then

<sup>5</sup><http://wordnet.princeton.edu>

<sup>6</sup>A native speaker of English annotated a sample of 500 nouns with their most relevant sense in our CDS corpus, revealing that the first WordNet sense was appropriate for 80% of the nouns. One regular exception was nouns with both ‘plant’ and ‘food’ senses, such as *broccoli*, which were predominantly referring to food. For these, we always use the ‘food’ sense.

<sup>7</sup>Our score is inspired by the tf-idf score in information retrieval.

re-scaled so that the maximum score is 1, to be appropriate for the probabilistic generation of the input scenes.

## Experimental Results

In our previous work (Nematzadeh et al., 2011), we showed in computational simulations that LT learners not only learn fewer words than an ND learner, but that the LTs also have a less semantically-connected vocabulary, a result in line with the findings of Beckage et al. (2010). Here, using our extended model with its improved semantic representation, we first analyze the learned clusters of words for our two learners, to confirm that the semantic category knowledge of the LT learner is of substantially poorer quality. We also investigate the differential effects of the learned clusters for the two learners in subsequent word learning. It is known that word learning in children is boosted by their knowledge of word categories (Jones et al., 1991). Here, we interleave the two processes of semantic clustering and word learning in our model, and examine the patterns of word learning over time, for the two learners, with and without category knowledge. Our hypothesis is that the ND learner not only forms higher quality semantic clusters of words compared to the LT learner, but that its (more coherent) category knowledge contributes to improved word learning over time.

### Analysis of the Learned Clusters

We examine the quality of the semantic clusters formed by each learner (ND and LT). We train the learners on 15K utterance–scene pairs, and perform a hierarchical clustering on the resulting learned meanings of all the observed nouns. To provide a realistic upperbound as a point of comparison for the two learners, we also cluster (using the same clustering algorithm and similarity measure) the true meanings of the nouns. These “TRUE” clusters indicate how well the nouns can be categorized by the clustering method on the basis of their true (in contrast to learned) meanings. In all cases, we set the number of clusters to 20, which is the approximate number of the actual WordNet categories for nouns.

To measure the overall goodness of each of the three sets of clusters (TRUE, ND, and LT), we compare the clustering to the actual WordNet category labels for the nouns, as follows. (The WordNet category labels reflect human judgments of semantic categories, since they are provided by manual annotation.) We first label each cluster  $c$  with the most frequent category assigned by WordNet to the words in that cluster, called  $\text{label}(c)$ . We then measure  $P(\text{recision})$ ,  $R(\text{ecall})$ , and their harmonic mean,  $F(\text{-score})$ , for each cluster, and average these over all clusters in a set. Given a cluster  $c$ ,  $P$  measures the fraction of nouns in  $c$  whose WordNet category matches the cluster label;  $R$  is the fraction of all nouns whose WordNet category is  $\text{label}(c)$  that are also in  $c$ . We report the average  $P$ ,  $R$ , and  $F$  scores for the TRUE, LT, and ND clusters in Table 1.

As expected, the  $F$  score is the highest for the TRUE clusters, which result from the same clustering algorithm but applied to noise-free semantic representations. In comparison, the ND learner has somewhat lower  $F$  scores, as well as  $P$  and

TRUE			ND			LT		
$P$	$R$	$F$	$P$	$R$	$F$	$P$	$R$	$F$
.77	.71	<b>.66</b>	.79	.53	<b>.51</b>	.88	.19	<b>.24</b>

Table 1: Average  $P$ ,  $R$ , and  $F$  scores (shown in boldface), for the TRUE, LT and ND clusters after processing 15K input pairs.

$R$  scores, compared to the TRUE clusters. By contrast, the LT clusters have a very low  $F$  score. These results confirm that, in contrast to the ND learner, the LT learner is unable to use its learned knowledge of word meanings to form reasonable categories of words, confirming that nouns in the vocabulary of the LT learner have less semantic coherence than those of our ND learner. Moreover, the unusual nature of the clusters formed by the LT learner (in contrast with ND) is further confirmed by its very high  $P$  and very low  $R$  scores compared to the TRUE clusters. Detailed examination of the clusters reveals that LT has learned a large number of small clusters (leading to high precision), but also a few large semantically-incoherent clusters (leading to very low recall).

### Incorporating Categories in Word Learning

Here we investigate the role of category formation in a naturalistic word learning setting. Specifically, we interleave the two processes by allowing the model to use its semantic clusters in word learning. To simulate the simultaneous learning of categories and word meanings, the model builds clusters from its learned noun meanings after processing every 1000 input utterance–scene pairs. It then uses these clusters when processing the next 1000 pairs (at which point a new set of clusters is learned). After the first 1000 input pairs, the model calculates the alignment probabilities using both word-based and category-based knowledge, as in Eqn. (4).

For each noun in an utterance, if it has been observed prior to the last clustering point, the model uses the cluster containing the noun to calculate the category-based alignment. But a novel (previously unobserved) noun has not yet been assigned to a cluster. However, it is recognized that children can use contextual linguistic cues to infer the general semantic properties of a verbal argument (Nation et al., 2003). For example, a child/learner knowing the verb *eat* might be able to infer that the novel word *dax* in “she is eating a dax” is likely referring to some ‘edible thing’. We assume here that a learner can use the context of a novel noun to identify its general semantic category. In our model, we simulate this inference process by giving the model access to the WordNet category label of the novel word. Recall that each noun sense in WordNet is assigned a category label that provides information about its general semantics. The model can then choose a learned cluster for the novel noun by identifying the cluster whose assigned label matches the WordNet category of the noun. If more than one cluster has the same label as the category of the novel word, the cluster with the highest precision is selected. If the learner does not have a matching cluster, no category information is used for the novel word.

We process 15K input pairs overall, and look at the aver-

Figure 2: Change in the average Acq score of all nouns over time; ND-CAT and LT-CAT use category formulation during learning.

age acquisition score (Acq, defined below) of nouns for each learner, with and without category knowledge, as a function of time (the number of input pairs processed); see Figure 2. The Acq score for a word  $w$  shows how similar its learned meaning  $l(w)$  is to its true meaning  $t(w)$ :

$$\text{Acq}(w) = \text{sim}(l(w), t(w)) \quad (6)$$

where  $\text{sim}$  is the cosine similarity between the two vectors.

A comparison of the curves in Figure 2 reveals several interesting patterns. First, the use of category knowledge substantially improves the word learning performance of ND, whereas it has no effect at all on the (poorer) performance of the LT learner. These results further elaborate the findings of our analysis of the learned clusters: the clusters learned by the ND are a better match than those of the LT with the manually-annotated categories provided by WordNet; moreover, they are able to contribute helpful information to word learning, where the LT clusters are not.

Thus, the LT clusters are not only in principle of lesser quality, they are in practice less useful. Also, the positive effect of category knowledge for ND increases over time, suggesting that the quality of its clusters improves as the model is exposed to more input. This mutually reinforcing effect of semantic category formation with word learning underscores the importance of studying the interaction of the two.

### Category Knowledge in Novel Word Learning

Results of the previous section suggest that the ability of a learner to form reliable categories of semantically-similar words may be closely tied to its word learning performance. In particular, we expect category knowledge to increase the likelihood of associating a word with its relevant semantic features when there is ambiguity and uncertainty in the cross-situational evidence. For example, when a child hears “The wug will drink the dax” while observing an unknown animal and a bowl of liquid in the scene, the child must rely on information sources other than the cross-situational evidence to infer the possible meanings of the two novel words. (That is, the child must infer that *wug* as a drinker is more likely to

Figure 3: Changes in the novel word learning over time

be the unknown animal.) We predict a substantial benefit of category knowledge when observing a word for the first time, since this is when there’s the least cross-situational information available to a learner about the particular word and its features. Here we examine the effect of category knowledge on the learning of novel words over time, within the naturalistic setting of the utterance–scene pairs of our corpus, focusing on those inputs that include previously unseen words.

We train the model on 15K input pairs, but restrict evaluation to the learning of novel words. Specifically, we look at the difference in the Acq score of words at their first exposure, for the ND and LT learners, each with and without using category knowledge. To do this, we look at utterances containing at least two nouns, at least one of which is novel.<sup>8</sup> For each such input utterance, we record the resulting Acq score of all novel words in the utterance, and take their average. For each learner, we also examine the pattern of change in these average scores over time, as shown in Figure 3.

The results show that after 2K input utterances, there is no difference between using and not using categories for each of the learners (i.e., comparing ND-CAT and LT-CAT to ND and LT, respectively). This is because none of the learners has formed sufficiently good categories yet. After 8K utterances, ND-CAT performs much better than ND, showing the benefit of using category knowledge in learning novel words in an ambiguous setting. By contrast, for the LT learner, the Acq score of the novel nouns does not increase when using category information (LT-CAT) even with additional exposure to the input. Another interesting pattern is that for the ND learner, the average Acq score does not increase between 8K and 15K input utterances. However, when using categories (ND-CAT), this score increases over time. Although the ND model has learned additional words after 15K inputs, knowledge of more words alone does not result in improved learning of novel words. By contrast, the increasing semantic category knowledge in ND-CAT over time leads to greater improvements in learning the meaning of novel nouns.

<sup>8</sup>If the utterance only has 1 novel noun, the task is too easy because the features of nouns and other parts of speech do not overlap.

## Conclusions

One possible explanation for the language deficiencies of late-talking children is inadequacies in their attentional and categorization abilities (Jones & Smith, 2005; Colunga & Sims, 2011). In this paper, we have investigated (through computational modeling) two interrelated issues: (1) how variations in the development of attentional abilities in normally-developing (ND) and late-talking (LT) children may interact with their categorization skills, and (2) how differences in semantic category formation could affect word learning. We have extended a model of word learning that incorporates an attention mechanism (Nematzadeh et al., 2011) to incrementally cluster words, and to use these semantic clusters in subsequent word learning.

Psycholinguistic findings have noted that the vocabulary of LTs shows both a lack of appropriate generalization (Jones & Smith, 2005; Colunga & Sims, 2011), and less semantic connectivity (Beckage et al., 2010; Sheng & McGregor, 2010). We find here that the clusters formed by our LT model indeed show more inconsistency and less coherence compared to our ND learner. In addition, unlike our LT learner, our ND model can use its learned knowledge of word meanings to form semantically-coherent and informative categories, which in turn contribute to an improvement in subsequent word learning. Moreover, the LT learner has particular difficulties in learning novel words, while the ND learner gets increasingly better over time when it draws on category knowledge. The inability of an LT learner to form reasonable semantic clusters limits its ability to generalize its knowledge of learned words to new words. This could be a substantial factor in the LT's delayed vocabulary acquisition.

The model presented here treats semantic category learning and word learning as two interacting but independent processes. In particular, the mechanism for incorporating category knowledge into word learning simply adds this knowledge as another factor in guiding the formation of word-feature associations. Our ongoing work is exploring a unified mechanism in which category knowledge is integrated into the attentional mechanism of the word learning model. Such an approach will enable us to further explore how specific correlations between semantic properties and abstract categories (such as shape-solid object) emerge from the input (for LTs and NDs), and how these affect subsequent word learning.

## Abstract

A computational model of selective attention has been previously used to provide a concrete and comprehensive account for perceptual load findings in visual search tasks (Neokleous, Koushiou, Avraamides, & Schizas, 2009). Here, the same model was used to simulate findings from an experiment in which perceptual load effects were attributed to distractor dilution (Benoni & Tsal, 2010). By modeling at the neural level the continuous inhibitory interactions that take place among visual stimuli competing for cortical representation, the model reproduced successfully the behavioural pattern of results. The model thus offers a biologically-plausible way to reconcile findings that contradict Perceptual Load theory with those that support it.

**Keywords:** Computational Modeling, Spiking Neural Networks, Perceptual Load Theory, Dilution.

## Introduction

The *Perceptual Load* theory was proposed by Lavie and Tsal (1994; Lavie, 1995) to resolve the early vs. late debate concerning the locus of attention (e.g., Broadbent, 1958; Deutsch & Deutsch, 1963). It posits that selection of stimuli may take place early or late depending on the perceptual load of the task.

In a paradigmatic study of perceptual load Lavie and Cox (1997) had participants carry out a *high load* or a *low load* visual search task. In the high load task participants searched for two target letters (X and N) among 5 similarly-shaped letters arranged in a circular array. In the low load task, they searched for these targets among five instances of the letter O. In both conditions, a distractor letter, which participants were asked to ignore, was presented to the left or to the right of the array. Depending on condition, the distractor letter could either be congruent with the target (i.e., the same letter as the target), incongruent (i.e., the other target), or neutral (i.e., the letter “L”). Results revealed that in the low load task participants took longer to identify the target in the presence of an incongruent

distractor compared to when the distractor was congruent or neutral. In contrast, in the high load task, no difference between the three distractor conditions was found. Lavie and Cox (1997) argued that distractor interference was absent in the high load task because all attentional resources were consumed by the task leaving none to process the irrelevant distractor. In contrast, in the low load task only minimal resources were devoted to the task allowing spare resources to spill over to the processing of the distractor. Thus, the Perceptual Load theory posits that selection is early under high load conditions and late in low load conditions.

Despite its appeal, the Perceptual Load theory has been criticized on various grounds. First, a number of studies have provided findings that seem at odds with the theory (Eltiti, Wallace, & Fox, 2005; Johnson, McGrath, and McNeil, 2002; Torralbo & Beck, 2008). For example, Johnson et al. (2002) showed that cueing the target location with a 100%-predictive central cue in a low load visual search task eliminates distractor interference despite the fact that it does not alter the load of the task. Neokleous et al. (2009) reported the same result using an 80%-predictive peripheral cue. Second, Torralbo and Beck (2008) argued that the theory is unsatisfying because it does not provide a clear definition for perceptual load, and because the concept of exhaustive capacity cannot be easily reconciled with what is known about brain mechanisms.

To provide a more concrete formulation of the Perceptual Load Theory we have previously presented a biologically-plausible computational model, capable of simulating both the basic pattern of findings from Lavie and Cox (1997) and findings considered contradictory to the theory (e.g., Johnson et al., 2002). The model offered an explicit account for the possible neural mechanisms that give rise to perceptual load findings without relying on vague terms such as high and low load. The model simulated the data by modeling at the neural level the continuous inhibitory interactions that take place among visual stimuli competing for cortical representation. The strength of these inhibitory interactions is determined by the saliency of stimuli whereas top-down

signals are allowed to bias this competition by amplifying neural activity that matches the current goals.

Recently, Benoni and Tsal (2010) proposed a theoretical account for perceptual load effects that resembles the one implemented in our model. In their *Dilution* account, Benoni and Tsal (2010; see also Tsal & Benoni, 2010; Wilson, Muroi, & MacLeod, 2011) claim that the distractors in the visual search tasks employed by Lavie and Cox (1997) are processed regardless of load. However, distractor interference in the high load condition is eliminated due to diluting effects exerted by non-target letters in the search array towards the distractor.

Benoni and Tsal (2010) provided support for the Dilution account by showing that distractor interference is absent in a low load condition with high dilution (Exp.1). In this condition, participants searched for a red target in an array with three additional green letters or a green target in an array with three additional red letters, while ignoring a larger white distractor presented adjacently to the array. In the high load-high dilution condition the 4 letters of the search array, including the target, were displayed in the same color, either red or green. Finally, in a low load-low dilution condition the red or green target was presented without any accompanying letters in the search array.

Results showed that, as predicted by the Perceptual Load theory, (1) overall latencies were shorter for the low load-low dilution than the high load-high dilution, and (2) distractor interference was present in the low load-low dilution condition but not in the high load-high dilution condition. However, in contrast to the predictions of the Perceptual Load theory, no distractor interference was observed in the low load-high dilution condition despite the fact that latencies in this condition were as short as those of the low load-low dilution condition. Benoni and Tsal (2010) interpreted this finding as evidence that the perceptual load effects reported in the literature previously are caused by dilution.

Although the Dilution account aspires to offer a more concrete explanation of perceptual load effects than the Perceptual Load theory itself, it is also somewhat vague in some respects. For example, Benoni and Tsal (2010) argued that dilution requires the mere presence of non-target letters "...whose features are visually similar to those of the distractor" (p.1293). It is not very clear what constitutes a visually similar feature and how exactly a task can be categorized as high-dilution or low-dilution. Benoni and Tsal (2010) employed a low load task in which the target was presented alone in the search array thus no dilution was possible. However, Lavie and Cox (1997) have used a low load task in which the target is presented among flanking O's. Are O's expected to exert diminished dilution effects or none at all?

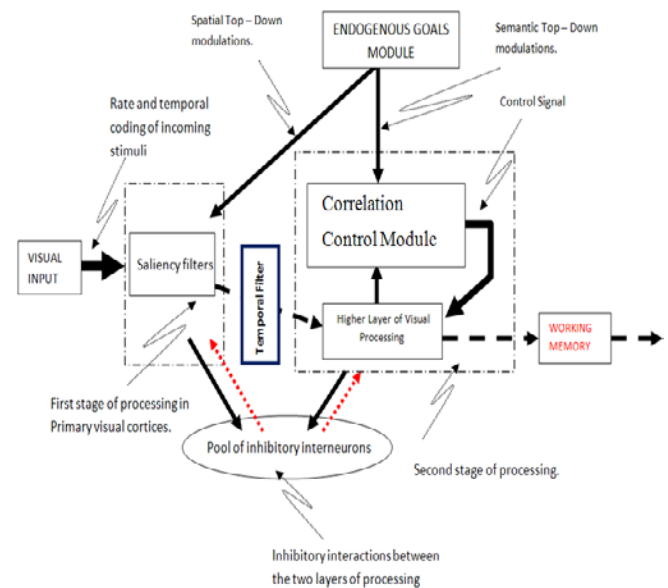

Here, we use the same computational model we described in Neokleous et al. (2009) to simulate the findings from Benoni and Tsal (2010; Experiment 1). The model requires neither a definition of load nor an explicit differentiation of tasks in terms of dilution. Also, in contrast to the Dilution

account in which inhibitory signals originate only from non-target letters in the search array and are directed only towards the distractor (i.e., the target is considered immune to inhibition), our model allows for inhibitory signals among all stimuli in the display.

## The computational model

The computational model has been previously used in similar form to simulate findings from the attentional blink phenomenon (Neokleous, Avraamides, Neokleous, & Schizas, 2009) and the relation between attention and consciousness (Neokleous, Avraamides, & Schizas, 2011). It is comprised of integrate-and-fire (I&F) neurons combined with coincidence detector (CD) neurons and simulates attention as a continuous stream of neural activity that is initially based on bottom-up information and gradually incorporates biases from top-down processes.

The model (Fig.1) involves two stages of processing implemented as spiking neural networks (SNN). The first stage involves the initial bottom-up competitive neural interactions among visual stimuli and corresponds to early visual areas in the occipital regions of the brain (e.g., V1, V2). The second stage of processing extends the neural pathway towards working memory and allows for relevant top-down information to exert an influence on neural activity.

**Figure 1.** The modules of the computational model of visual selective attention.

In the first stage of processing, the initial representations of visual stimuli are created in the model on the basis of a saliency map. The modulation of visual activity by saliency in the early stages of visual processing is supported by neurophysiological findings that in area V1 of the visual cortex a neuron's response can be significantly suppressed

or enhanced by stimulation in the vicinity of its receptive field (Nothdurft, Gallant, & Van Essen, 1999; Wachtler, Sejnowski, & Albright, 2003; Shibata et al., 2008). In our model, we adopted a saliency map algorithm proposed by Koch and Ullman (1985). This algorithm was implemented by Walther and Koch (2006) into a Matlab toolbox (Saliency Toolbox - <http://www.saliencytoolbox.net>), that is used in the model to produce saliency values for spatial locations in the visual field. These values are produced based on a simple transformation algorithm that converts grayscale pixel values into frequency of spikes to establish the initial firing rates of the neurons that encode visual stimuli (Fig.2).

During the first stage of processing, neural activity can be modulated by spatial top-down factors. For example, when a cue is used to prime the location of a stimulus ahead of presentation, the neural activity corresponding to the stimulus is amplified. This implementation is based on findings from several studies showing that cues may enhance the neural activity of neurons that encode visual stimuli (e.g., Shibata et al., 2008; Silver, Ress, & Heeger, 2007).

**Figure 2.**Initial firing rate computations based on a saliency map algorithm.

The second stage of processing simulates the modulation of neural activity that represents visual stimuli by activity that maintains information about the targets as specified by the set of instructions (e.g., “Find x or y in the central array”). Support for such modulations stems from studies showing that neural activity in area V4 of the cortex influenced by top-down activity (e.g., Moran & Desimone, 1985; Reynolds & Desimone, 2003). The top-down effects in the second stage of processing are implemented in the model in a way that produces both rate amplification and synchronization of neural activity as suggested by neurophysiological evidence (e.g., Fries, Reynolds, Rorie & Desimone 2001; Gregoriou, Gotts, Zhou & Desimone 2009). That is, according to the model, attending a stimulus enhances the firing rates of neurons that correspond to that

stimulus and at the same time forces them to fire in a more synchronous rhythm. Similarly, the firing rates of neurons that correspond to unattended stimuli are suppressed.

The main components in the second stage of processing of the model have been inspired by Crick and Koch’s (1990) theoretical analysis on the role of attention and neural synchronization for the establishment of awareness. Crick and Koch (1990) based on neurophysiological findings showing that visual stimuli can elicit synchronized activity in the visual cortex, suggested that a prerequisite for the presence of neural synchronization is to have synchronous impulses in selected neuronal populations. Therefore, they proposed that visual selective attention may function in a way that it causes changes to the temporal structure of the neural spike trains that represent the information to be selected, and that this temporal structure may facilitate the transfer of the encoded information to working memory.

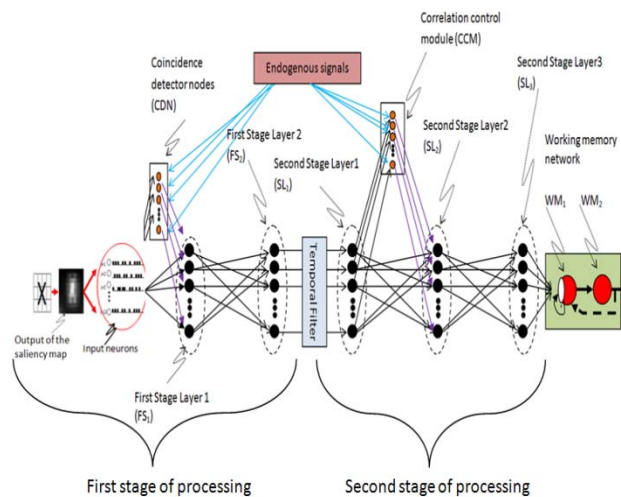

The idea presented by Crick and Koch (1990) was later supported by experimental evidence. In a comprehensive review, Womelsdorf and Fries (2007) presented evidence showing how attention selectively modulates the neurons that represent the attended stimulus feature or spatial location in a way that it synchronizes their responses. For example, Bichot, Rossi and Desimone (2005) recorded the neuronal spiking responses and LFPs in the visual area V4 of macaque monkeys and demonstrated that the allocation of attention towards a particular feature synchronizes the responses of selective sensory neurons, tuned to the attended feature. They suggested that feature salience is not only demonstrated with an increasing firing rate, but also by selectively synchronizing specific neuronal responses based on the similarity between feature preferences and the attended stimulus feature.

To incorporate these ideas in our model, templates that contain features of visual search targets are created and maintained in the endogenous goals module of the model and are used to evaluate the resemblance between any incoming visual input and a target. The evaluation of each stimulus takes place by computing the correlation between spike trains representing the stimulus and the spike trains maintaining target identity in the endogenous goals module. This is performed in the Correlation Control Module (CCM) of the model (Fig.1). However, before the neural activity of each incoming stimulus is processed in the CCM, it passes through a temporal filter that reorganizes the timing of spikes without altering the average firing rate. This mechanism is implemented in the model according to a pre-defined probability that reflects the degree of resemblance between the features of the incoming stimulus and those of a target. Thus, only the spike train patterns of a stimulus that shares features with the target will significantly change and become closer to the distinct spike train pattern of the target. The temporal filter mechanism used in the model is in line with Crick and Koch’s (1990) suggestion about the impact of selective attention on neural synchronization.

During the progression of neural activity through the two stages of processing, the encoded stimuli compete for access

to working memory (WM) through forward and lateral inhibitory interactions (from the pools of inhibitory interneurons), resulting into modulation of the strength of their neural response (Fig.3). This implementation is based on neurophysiological findings showing that competition for neural representation in visual areas V1 and V2 is initiated when two or more stimuli fall within the receptive fields of the same or nearby cells (Reynolds & Chelazzi, 2004; Reynolds & Desimone, 1999).

**Figure 3.**Top-down and bottom-up interactions during the progression of neural activity in the two stages of processing.

These interactions during the progression of neural activity produce enhancement and synchronization of neural activity that eventually lead to the selection of a particular stimulus for further processing.

## Computational Simulations

The computational model described in the previous section was used to simulate the pattern of findings reported by Benoni and Tsal (2010). Three aspects of the model are important for simulating the data: (1) spatial top-down signals enhance the neural activity of the neurons whose receptive fields fall within the area of the search array, (2) the saliency analysis produced different values for stimuli in each condition of the experiment (Fig.4) and led as a result to different initial firing rates, and (3) stimuli whose neural representation matches that of a target template held in the endogenous goals module are biased regardless of whether they appear, at a given trial, in the search array or as a distractor.

**Figure 4.**The three conditions and the output of the saliency map algorithm.

These aspects of the model allow the target to “win” the race to working memory but with different speed depending on the combination of load/dilution (low load-low dilution, low load-high dilution, high load-high dilution) and distractor compatibility (congruent vs. incongruent).

Fifty simulation trials were run for each of the combinations of load and compatibility. Median latencies from the model are shown in Fig.5. As seen in the figure, the model successfully produced the pattern of latencies reported by Benoni and Tsal (2010). Specifically, a compatibility effect (i.e., slower latency for incongruent vs. congruent distractors) was produced in the low load-low dilution condition only. Latencies were overall shorter in the low load-high dilution condition than in the high load-high dilution condition, but no difference between congruent and incongruent distractors was present in either condition. It should be noted that although the model successfully produced the patterns reported by Benoni and Tsal (2010), it was in all conditions slower than human participants by 150-200ms. However, it should also be pointed out that the simulations were run with exactly the same parameter settings that were previously used to simulate the findings of Lavie and Cox (1997; see Neokleous et al., 2009). That is, no effort was made to fit the behavioral data by tweaking the parameters of the model.

In the next section we discuss how exactly the model simulates the behavioral data.

## How the model simulates the experimental data

### High Load-High Dilution Condition

In this condition the saliency analysis produced similar values for the target and the non-target letters in the search array. Saliency was somewhat higher for the distractor due to its larger size. As the task instructs participants to focus on the search array, the effects of spatial top-down signals were modeled by raising the firing rate for the four letters of the array. The higher neural activations for these letters resulted in greater inhibition from the letters of the search array (both target and non-target letters) towards the

distractor. As a result, the neural activity of the distractor was significantly reduced from the very early stages of processing, thus reaching the second stage of processing with low activation. Due to its low activation, the distractor, regardless of being congruent or incongruent with the target, could not influence much the response latency.

Besides inhibition exerted towards the distractor, the non-target letters of the search array produced strong inhibitory signals towards each other and towards the target. As a result, the neural activity of the target was reduced and the time needed to pass the set response threshold was increased. This accounts for the long response latencies observed in this condition.

**Figure 5.** Experimental data for the conditions reported by Benoni and Tsal (2010) compared to the simulation results from the computational model.

#### *Low Load -Low Dilution Condition*

Due to the absence of non-target letters in the search array of the low load-low dilution condition, the target and the distractor had about the same saliency. In fact, due to its larger size, the distractor initially had a somewhat higher saliency value than the target. The neural activity of the target was, however, amplified as it fell within the area that participants are instructed to attend. Although inhibitory interactions take place between the target and an incongruent distractor, both enter the second stage of processing with enough activation to produce a match with the goal templates held in the endogenous goals module. While a congruent distractor assists the target's processing, an incongruent distractor inhibits it. This results into (1) overall shorter latencies than in the high load condition, and (2) longer latencies for trials with incongruent than congruent distractors.

#### *Low Load-High Dilution Condition*

The low load-high dilution is the critical condition for differentiating the Dilution account from the Perceptual Load theory. The saliency analysis resulted in a higher value for the target letter than for the non-target letters of the search array because it was presented in a different color. In addition, the neural activity for all letters in the search array

was amplified to model top-down spatial effects. As a result, the target accumulated substantial activation which allowed it to exert strong inhibition towards the other elements of the display, including the distractor. As in the high load condition, the distractor reached the second stage of processing with low neural activation and was thus unable to exert strong influence on the processing of the target. The main difference between this condition and the high load condition, is that here, because of the initial amplification of the target's neural activity, the neural activations of the non-target letters in the search array were suppressed which allowed the target to be processed easier and faster.

## **Discussion**

The computational model of selective attention that was described in the present paper was previously implemented to account for the basic pattern of findings from the Perceptual Load paradigm (Lavie & Cox, 1997). The model was capable of simulating not only the basic pattern of load findings, but also findings that were considered contradictory to the theory (Johnson et al., 1992). Here, the same model, with no tuning whatsoever, was able to reproduce the pattern of findings from a study manipulating dilution (Benoni & Tsal, 2010).

Although the Dilution account of Benoni and Tsal (2010) resembles the functioning of the model we had presented earlier (Neokleous et al., 2009), its premises are not entirely in line with the way our model reproduces the behavioral data. According to the Dilution account, the representation of the distractor in high dilution conditions and in the typical high load conditions is degraded by inhibitory signals exerted from the non-target search array letters towards the distractor. Although we agree that such inhibitions take place, our model posits that in some cases, such as the in low load-high dilution of Benoni and Tsal (2010), the major source of inhibition on the distractor originates from the target. In contrast to the Dilution account, our model allows for inhibitory signals among all elements of the display. The amount of inhibition that any stimulus exerts on others depends on the strength of its neural activity, which according to the model, is based on its initial saliency and the biasing from top-down factors.

The computational model presented here is an attempt to provide a comprehensive and concrete account for Perceptual Load findings based on what is currently known about the neural mechanisms of selective attention. The way the model is implemented allows for modeling a wide range of empirical data related to perceptual load effects. Future empirical research will allow us to test predictions from the model and evaluate its validity.

## Abstract

We learn culture-specific weights for a multi-attribute model of decision-making in negotiation, using Inverse Reinforcement Learning (IRL). The model takes into account multiple individual and social factors for evaluating the available choices in a decision set, and attempts to account for observed behavior differences across cultures by the different weights that members of those cultures place on each factor. We apply this model to the Ultimatum Game and show that weights learned from IRL surpass both a simple baseline with random weights, and a high baseline considering only one factor of maximizing gain in own wealth in accounting for the behavior of human players from four different cultures. We also show that the weights learned with our model for one culture outperform weights learned for other cultures when playing against opponents of the first culture. We conclude that decision-making in negotiation is a complex, culture-specific process that cannot be explained just by the notion of maximizing one's own utility, but which can be learned using IRL techniques.

**Keywords:** cultural decision-making; negotiation; ultimatum game; inverse reinforcement learning.

## Introduction

Social scientists have often observed that people from different cultures behave differently in interactive situations (Camerer, 2003; Roth, Prasnikar, Okuno-Fujiwara, & Zamir, 1991). There are several different possible explanations for this, including

1. one culture is better than another at optimizing outcomes;
2. there is some kind of convention (Lewis, 1969) or equilibrium at work, such that people behave differently because the context is different, particularly their expectations about how others will behave. For example people in Japan or England drive on the left while people from America and Europe drive on the right, because that is the safest, most efficient way given how other drivers will behave, even though the goals of safety and efficiency are the same, and neither is innately better at achieving these goals;
3. the cultures have different goals, which lead to their optimizing different functions.

Most classical economic game-theory accounts of decision-making, e.g. (Neumann & Morgenstern, 1944), look at a monolithic notion of utility and maximizing

expected utility as the key to rationality. This, in effect, denies the third explanation above. For very simple games, where it is relatively easy to calculate the payoffs, the first possibility seems hard to believe, thus we are left with the hypothesis that differences in behavior are based on applying common utility principles to different problems. Others, e.g. (Gal, Pfeffer, Marzo, & Grosz, 2004), have claimed that there are many factors that contribute to the behavior of humans in social situations. This makes the third explanation plausible, if people from different cultures have different relative weights for the different factors. But this leads to a further question of how to determine those different weights. In (Nouri & Traum, 2011) we presented one such model of decision-making that culture-specific virtual agents were able to use to play the Ultimatum Game (see the following section) with each other or with people. The model used Hofstede's multi-dimensional model of culture (Hofstede, 2001) to determine the relative weights of different factors. However, in that work the weights were set manually using our intuitions about how to apply the literature, which involved a number of relatively arbitrary decisions.

In this paper we attempt to learn the weights using Inverse Reinforcement Learning (IRL) (Abbeel & Ng, 2004). To our knowledge no one has used IRL before in the Ultimatum Game or generally to learn patterns of behavior in negotiation. We also perform two experiments to try to get at the question above of what is the best explanation for the observed behavioral differences across cultures. On one account, it is the different goals that lead to different behavior. In this case we would predict that we learn different goals for different cultural patterns and that these goals would be better at generating observed behavior than other possible goals. On another account, we would expect the same set of goals to be satisfactory for any population, and differences in behavior to result from the different environments that are encountered. Our results show that the learned weights are better able to match observed distributions of culture-specific behavior than either arbitrary weights, a simple model based on economic gain, or in most cases the weights learned for other cultures. This suggests that cultures vary in goals, not just conventional circumstances but also that we can successfully use IRL techniques to learn population-specific goals for this type of game.

The structure of the paper is as follows. First we briefly present the Ultimatum Game and studies that show different behaviors for different culture groups. Then we describe our decision-making model and we present an overview of Reinforcement Learning (RL) and IRL. After that we talk about our experimental setup and present our results. Then we discuss our results and propose ideas for future work, and finally we conclude.

## Culture and the Ultimatum Game

We use the Ultimatum Game as a testbed for our model. The Ultimatum Game involves two players bargaining over a certain amount of money (in our experiments, \$100). One player, the proposer, proposes a division, and the second player, the responder, accepts or rejects it. If the responder accepts, each player earns the amount specified in the proposal, and if the responder rejects, each player earns zero. At perfect equilibrium, according to economic game theory, the proposer receives all or almost all of the money and the responder accepts all offers made to them. This classic experimental economics game has received a great deal of attention since the initial experiment by (Güth, Schmittberger, & Schwarze, 1982). Results from these studies often deviate from the predictions of game theory (Henrich, 2000; Camerer, 2003). In fact there is considerable variation of offers and rejection rates across studies (Henrich, 2000; Buchan, Croson, & Johnson, 1999), and it has been reported that people from different cultures behave differently in this game. For example (Roth et al., 1991) studied the Ultimatum Game in four countries (US, Japan, Israel, and former Yugoslavia). They found that the offers in US and Yugoslavia were higher than the offers in Japan which were higher than the offers in Israel. (Henrich, 2000) compared the behavior of 18-30 year old Machiguenga men of the Peruvian Amazon with UCLA students and found significant differences, i.e. the offers of the latter were higher than the offers of the former. (Buchan et al., 1999) studied the differences in comparable student populations in Pennsylvania and Tokyo and observed that the offers of the former were lower than the offers of the latter.

All the above studies clearly show that culture can play an important role in negotiation and in particular in the Ultimatum Game. The question however is what role: different goals, or different conventions, and whether we can learn to emulate culture-specific behavior.

## Our Decision-Making Model

Our decision-making model presented in (Nouri & Traum, 2011) considers a number of different metrics for evaluating a given situation, even for something as simple as division of money in an economic game such as the prisoner’s dilemma (Camerer, 2003) or the Ultimatum Game (Güth et al., 1982). Each of the metrics can be calculated from a basic payoff matrix. The metrics we considered for the Ultimatum Game include: *Self* (the agent’s own gain); *Other* (the gain of another); *Self/Other* (the relative gain of the negotiators); *Minimum* (lower bound of any participant - the aim of Rawls’

theory of justice (Rawls, 1971)). Each of these metrics can be given one or more valuations, choosing an optimum point and scale. The agent has a vector of weights, one per valuation, indicating the relative importance of that valuation. The total value for each choice is the sum of the product of values and weights for each valuation as shown in equation (1):

$$Value(Choice_i) = \sum_{j=1}^n (W_j * V_j(Choice_i)) \quad (1)$$

An advantage of this multi-valuation approach is that it can model an agent who cares (possibly to different extents) about different aspects of the situation, such as self-interest, collective interest, and fairness. In (Nouri & Traum, 2011) we also adapted this model to take into account Hofstede’s dimensions (Hofstede, 2001), i.e. *Individuality* (IDV), *Power Distance* (PDI), *Long Term Orientation* (LTO), *Masculinity* (MAS), *Uncertainty Avoidance* (UAI). Thus our generalized model shown in (2) breaks down the elements of the weight vector into one component per dimension, and thus an overall matrix of  $n$  valuations and  $m$  ( $=5$ ) dimensions.

$$Value(Choice_i) = \sum_{j=1}^n ((\prod_{d=IDV}^{UAI} W_{j,d}) * V_j(Choice_i)) \quad (2)$$

In this paper our focus is to learn the weights of (1) but our ultimate goal is also the learning of the weights of equation (2) that take into account Hofstede’s dimensions (see the discussion section).

## Reinforcement Learning and Inverse Reinforcement Learning

An agent’s policy is a function from contexts to (possibly probabilistic) decisions that the agent will make in those contexts. Reinforcement Learning (RL) is a machine learning technique used to learn the policy of an agent (Sutton & Barto, 1998). For an RL-based agent the objective is to maximize the reward it gets during an interaction. Because it is very difficult for the agent, at any point in the interaction, to know what will happen in the rest of the interaction, the agent must select an action based on the average reward it has previously observed after having performed that action in similar contexts. This average reward is called *expected future reward*. RL is used in the framework of Markov Decision Processes (MDPs). An MDP is defined as a tuple  $(S, A, P, R, \gamma)$  where  $S$  is the set of states (representing different contexts) which the agent may be in,  $A$  is the set of actions of the agent,  $P : S \times A \rightarrow P(S, A)$  is the set of transition probabilities between states after taking an action,  $R : S \times A \rightarrow \mathcal{R}$  is the reward function, and  $\gamma$  a discount factor weighting long-term rewards. At any given time step  $i$  the agent is in a state  $s_i \in S$ . When the agent performs an action  $\alpha_i \in A$  following a policy  $\pi : S \rightarrow A$ , it receives a reward  $r_i(s_i, \alpha_i) \in \mathcal{R}$  and transitions to state  $s_{i+1}$  according to  $P(s_{i+1}|s_i, \alpha_i) \in P$ . The quality of the policy  $\pi$  followed by the agent is measured by the expected future reward also called  $Q$ -function,  $Q^\pi : S \times A$

→  $\mathcal{R}$ . Details are given in (Sutton & Barto, 1998). There are several algorithms for estimating the  $Q$ -function and we use  $Q$ -learning (Sutton & Barto, 1998). However,  $Q$ -learning requires thousands of interactions between the agent and the environment in order to learn the optimal policy. In the case of a multi-party interaction, such as dialogue or the Ultimatum Game, the environment also needs to represent the decisions and actions of another participant. For this reason we need to build another agent, called a simulated user (SU) (Georgila, Henderson, & Lemon, 2006), that will behave as part of the environment and will interact with the policy for thousands of iterations to generate data in order to explore the search space and thus facilitate learning. Note that the SU generates a variety of actions for each state based on a probability distribution but does not learn from the interaction.

With RL, the reward function should be defined. Designing a good reward function is not trivial and not always possible. There are tasks where it is not clear what constitutes a good reward function. Inverse Reinforcement Learning (IRL) (Abbeel & Ng, 2004) aims to learn a reward function (not necessarily the true reward function) from a set of data recording interactions between the agent and the environment. This data is called *expert data*. The reward function  $R$  can be expressed as follows:

$$R_w(s, \alpha) = w^T \phi(s, \alpha) = \sum_{i=1}^k w_i \phi_i(s, \alpha) \quad (3)$$

where  $s$  is the state that the agent is in and  $\alpha$  the action that it performs in this state, and  $w^T$  is a vector of weights  $w_i$  for the feature functions  $\phi_i(s, \alpha)$ . Note that these feature functions are specified manually and the weights  $w_i$  are estimated by IRL.

In particular we use the imitation learning algorithm (Abbeel & Ng, 2004). The imitation learning algorithm is an iterative process. Initially we have a random policy  $\pi_i$  that by interacting with the SU generates data. Then this data is compared with the expert data and the weights  $w_i$  are calculated. Based on these weights a reward function is estimated and RL is performed to learn a new policy  $\pi_{i+1}$  which generates a new set of data by interacting with the SU. Then this new data is compared with the expert data and new weights are calculated, a new reward function is computed and so forth. The iteration stops when the distance between the data generated from the interaction of the latest policy with the SU and the expert data is lower than an empirically set threshold.

## Experimental Setup

We use data of the distribution of offers and acceptances or rejections for four different cultures (US, Japan, Israel, and former Yugoslavia) reported in (Roth et al., 1991). For each culture, we generate SU-proposers and SU-responders by using probability functions that match the reported data. (Roth et al., 1991) provide this data for the first and last round of the game. In our setup the game lasts 5 rounds. For the rounds in between we interpolate the first and last round values using

weights that vary depending on the round. For example, for round 4 we give a higher weight to the last round values and for round 2 a higher weight to the first round values. For each culture we generate “expert” data by having the SU-proposer interact with the SU-responder for that culture. We then apply IRL to learn weights of different motivational factors for each of these cultures and roles (proposer and responder), by iteratively playing against the appropriate SU. We then use the weights as a reward function, using RL, to learn policies for a proposer and responder for each culture. We evaluate success of the learned policies by how closely they match the expert data. We compare our learned policies with two baselines: RL models trained with either a random reward function or a reward function based on maximizing the wealth of the agent. We also compare the policies learned for a particular culture with the policies learned for the other cultures and the human expert data of the other cultures.

Our state definition includes information about the accumulated wealth gain of the agent (AccSelf), i.e. the wealth gain that the agent has gathered starting from the first round of the game, the accumulated wealth gain of the SU (AccOther), the wealth gain of the agent in the current round (Self), the wealth gain of the SU in the current round (Other), and also different representations of their relative gain (Self/Other) and the minimum gain (Min). We also take into account the round of the game. There are 11 actions that the proposer can perform (offer=0, offer=10, ..., offer=100). The initial context can be different for each round depending on the accumulated wealth of the agents, and the resulting reward is uncertain, depending on the action of the responder. For the responder, there are only two actions (accept, reject), but again there are many possible different start states to consider depending on the accumulated wealth of the agents (the reward is deterministic based on the state and action chosen).

The feature functions that we use are binary, i.e. the value of the feature function  $\phi_i(s, \alpha)$  is 1 when  $\phi_i$  is true for state  $s$  and action  $\alpha$ . So to form the feature functions  $\phi_i(s, \alpha)$  each feature is paired with all the available actions. Table 1 lists the features that we use to represent the type of context that we consider in each state. Thus for the proposer the feature function  $\text{Self} \geq 10 - \text{offer} = 10$  is 1 when the self gain of the proposer is  $\geq 10$  and the proposer has made an offer of 10, which means that this feature function is going to be 0 at the time of the offer (because at that point Self is always 0), 1 after this offer has been accepted, and 0 after this offer has been rejected. We also use additional features related to the accumulated wealth that are not depicted in Table 1 due to space constraints. In fact every possible value of AccSelf or AccOther can form a feature, e.g. AccSelf=150, AccOther=200, etc. Thus for the proposer the feature function AccSelf=150-offer=20 is going to be 1 when the accumulated wealth of the proposer is 150 and the proposer has made an offer of 20.

As we can see from the previous discussion our model is considerably different from the original SU model (human data) that just uses a probability distribution per round. First,

Table 1: Features used for IRL.

Self $\geq 0$	Other $\geq 0$	Self/Other $> 2$
Self $\geq 10$	Other $\geq 10$	Self/Other $> 1$
Self $\geq 20$	Other $\geq 20$	Self/Other $= 1$
Self $\geq 30$	Other $\geq 30$	Self/Other $< 1$
Self $\geq 40$	Other $\geq 40$	Self/Other $< 1/2$
Self $\geq 50$	Other $\geq 50$	Min(Self,Other) $= 0$
Self $\geq 60$	Other $\geq 60$	Min(Self,Other) $= 10$
Self $\geq 70$	Other $\geq 70$	Min(Self,Other) $= 20$
Self $\geq 80$	Other $\geq 80$	Min(Self,Other) $= 30$
Self $\geq 90$	Other $\geq 90$	Min(Self,Other) $= 40$
Self $= 100$	Other $= 100$	Min(Self,Other) $= 50$

our model is deterministic for each state but keeps track of additional state information, such as accumulated gains for each side. Thus we can still get a range of different offers and responses from our agents, depending on the learned policy for each state (including the accumulated gain) and the probability of those states. Second, our model for a specific culture includes a reward function, which is specific to that culture distribution. Third, the reward function could potentially be applied to other problems (see the discussion section), whereas we would have to collect human data to create a SU for a new problem.

We perform two experiments. The goal of the first experiment is to show that the reasoning behind the actions of the proposer is better modelled as a complex tradeoff of multiple goals, and cannot be explained merely by learning the behavior patterns of the partners. Thus for the proposer and the responder and the 4 cultures we learn 3 policies using RL; one based on a random reward function that assigns arbitrary weights (weak baseline), one where the reward function is based only on wealth (strong baseline), and one based on IRL. If only the data patterns mattered and not the reward function, we should see comparable performance between policies trained using the weak baseline reward functions and policies using the learned ones. Surpassing this weak baseline would be evidence that reward functions matter. The strong baseline follows classical economic game theory predictions. If everyone really does have this as a reward function and differences in behavior are due to learned differences in convention rather than goals, we should see this reward function able to match the observed behavior of different populations. On the other hand, if the IRL reward functions lead to better models than the strong baseline, that is evidence that multiple factors are taken into consideration.

The purpose of the second experiment is to show that the weights learned with IRL really are culture-dependent, i.e. that they work better for the culture that the weights were learned from than models learned for other cultures. To show that we use IRL to learn the reward function for the 4 cultures and then we use these reward functions to learn policies for each culture (for example for

the US culture we have policy-rewardUS-trainUS, policy-rewardJapan-trainUS, policy-rewardIsrael-trainUS, policy-rewardYugoslavia-trainUS). Then we test the 4 policies against SUs from the same culture that they were trained on (in this case, US). If the goals for different cultures really are different, then one would expect that policy-rewardUS-trainUS would better match the expert US data than policies learned using weights from other cultures.

To measure how closely the distributions generated with the 3 models match the human expert data we use Kullback-Leibler divergence.<sup>1</sup> The Kullback-Leibler (KL) divergence between two probability distributions  $P$  and  $Q$  is defined as follows:

$$D_{KL}(P||Q) = \sum_{i=1}^n P(i) \log_2 \frac{P(i)}{Q(i)} \quad (4)$$

where  $n$  is the number of points in the distribution that we consider. Because KL divergence is asymmetric we calculate  $D_{KL}(P||Q)$  and  $D_{KL}(Q||P)$  and then we take the average. The lower the KL divergence the closer the distributions.

## Results

In Table 2 we can see the KL divergences that we get when we compare our model and the two baselines with the human expert data for the proposer and responder policies of the 4 cultures. To avoid local optima or just being lucky with the random rewards, we ran both our model and the weak baseline (based on a random reward) multiple times and for each run we calculated the KL divergence. In Table 2 we report the median value of all computed KL divergences. In Figures 1 and 2 we can also see a graphical representation of our comparisons for the Japan proposer policy and the US responder policy. As we can see in all cases our IRL-based model outperforms both the weak and strong baselines. This verifies our hypothesis that decision-making is a complex process that cannot be attributed just to reacting to data or the sole factor of self-gain. It also shows the power of IRL for accurately modelling negotiation.

Table 2: KL divergences for IRL and the two baselines for all cultures and roles.

	Proposer			Responder		
	random	wealth	IRL	random	wealth	IRL
US	3.95	19.82	<b>2.84</b>	0.61	0.37	<b>0.10</b>
JP	4.01	4.86	<b>0.74</b>	0.64	0.25	<b>0.16</b>
IS	3.68	16.11	<b>1.29</b>	0.58	0.27	<b>0.13</b>
YU	9.28	3.49	<b>1.73</b>	0.57	0.26	<b>0.11</b>

The next question is whether our models are really capturing performance of people from the cultures that they were

<sup>1</sup>We also looked at Cartesian distance, but in all cases the best matching policy for the expert data was the same, so we report only KL-divergence, due to space restrictions.

Figure 1: Comparison of random reward, wealth reward, IRL-based reward and human data for the Japan proposer policies tested with Japan SU-responders.

Figure 2: Comparison of random reward, wealth reward, IRL-based reward and human data for the US responder policies tested with US SU-proposers.

trained for. We examine this question in two ways. First we look at the KL divergences between all learned models and all original data sets. This is shown in Table 3. We can see that most of the time the model for each culture matches the data set from that culture better than other data sets. On the other hand there are several exceptions, for example, US proposers do better on Yugoslavia data than US data, and US responders perform well on all human data. We can also look at this table from a different perspective, as a way to compare various models (learned from data of different cultures) with the same human data. Here we can see that in most cases the data set is best modelled by the culture trained on it. However, there are a few exceptions, for example, Israel proposers are a better model of the Israel data than US and Yugoslav proposers, but a worse model of the Israel data than Japanese proposers. US proposers are not a very good model of the US data. US re-

sponders are the best model for US data, Japanese responders are a good model of the Japan data (equally good to US and Israel responders), Israel and Yugoslav responders are a good model of the Israel and Yugoslavia data respectively, but not as good as US responders. These results are encouraging and show that our models do not just beat the weaker baselines of wealth and random rewards, but also in most cases learn to model a culture better than models learned with different cultures. As we saw there are a few cases in which the results were not optimal. We believe that there could possibly be some convergence issues, even though our IRL algorithms ran for over 1000 iterations and our KL divergences are based on many runs, or perhaps, we need a larger set of features and constraints between features. Given that we take into account in our state accumulated wealth as well as rounds, our state space is fairly large. These are issues for further investigation.

Table 3: Cross-culture results, comparison with human data from different cultures (KL divergences). Best values are in bold (horizontally) and italics (vertically).

	Proposer				Responder			
	Human Data				Human Data			
	US	JP	IS	YU	US	JP	IS	YU
US	2.84	3.11	4.61	<b>2.71</b>	<i>0.10</i>	<i>0.13</i>	<i>0.08</i>	<b>0.06</b>
JP	<i>1.05</i>	<b>0.74</b>	<i>1.06</i>	1.96	0.27	<b>0.16</b>	0.18	0.24
IS	1.82	2.04	<b>1.29</b>	4.27	0.25	0.14	<b>0.13</b>	0.20
YU	2.21	2.83	5.76	<b>1.73</b>	0.15	0.27	0.20	<b>0.11</b>

In Table 4 we can see the results of experiment 2, where we use weights learned with one culture to learn policies by training on other cultures.<sup>2</sup> The results generally verify our hypothesis that the learned weights are culture-specific: with only two exceptions, the policy based on the reward function learned for that culture outperforms policies based on reward functions for all the other cultures. In the case of the US and Japanese responders, it appears that the policy trained with the Israel reward performs just as well as the policy using the learned reward function for US and Japanese responders, respectively. However the converse does not hold: the Japan and US reward functions do not work well for the Israel policies. These issues need to be investigated further.

## Discussion

Our results show clearly that there are various factors that may affect one’s decision and these factors may vary significantly depending on the culture of the decider. They also show the power of IRL for uncovering the decision-making mechanism of negotiators. (Turan, Dudik, Gordon, & Wein-gart, 2011) argue about the potential advantages of using IRL for learning the goals and motives of negotiation participants.

<sup>2</sup>We used only some of the many reward functions for each culture to learn policies for other culture data. In this table we show results for the reward functions that are closest to the median values reported in Table 2, but in some cases they are not identical.

Table 4: Cross-culture results, learning policies using rewards calculated from different cultures (KL divergences).

Policy/Role	Reward functions			
	US	JP	IS	YU
US Proposer	<b>2.84</b>	7.32	14.13	11.78
US Responder	<b>0.08</b>	6.77	<b>0.08</b>	19.10
JP Proposer	7.71	<b>1.58</b>	4.89	14.25
JP Responder	14.94	<b>0.11</b>	<b>0.11</b>	15.25
IS Proposer	3.92	5.93	<b>1.27</b>	19.52
IS Responder	7.62	6.95	<b>0.10</b>	13.08
YU Proposer	3.32	7.90	19.84	<b>1.73</b>
YU Responder	7.51	8.16	0.12	<b>0.06</b>

They use scenarios from group negotiation research and discuss how IRL could hypothetically be applied to such scenarios, but they have not actually used IRL for negotiation.

With IRL we calculated the weights for a number of features (see Table 1). These weights can be used in equation (1). However, in order to use equation (2) we need to find some kind of mapping between these weights and Hofstede’s dimensions. Our ultimate future goal is once we have Hofstede’s dimensions for a culture to be able to calculate these weights automatically. That would be very useful in cases where we do not have data to calculate the weights directly from but it is indeed a very ambitious goal. Other future work involves examining whether the reward function learned for one game or role can transfer to another. We also aim to experiment with larger numbers of RL and IRL iterations and runs, different exploration parameters, different state representations, and different features.

## Conclusion

We used IRL to learn a model for cultural decision-making in negotiation. This model takes into account multiple individual and social factors for evaluating the available choices in a decision set. Our model assigns different weights to these factors based on the modelled culture. We applied this model to the Ultimatum Game and we showed that weights learned from IRL surpass both a weak baseline with random weights, and a strong baseline that only seeks to maximize the agent’s own gain. Our model outperformed both baselines by generating behavior that was closer to the behavior of human players of the game in 4 different cultures. We also showed that the weights learned with our model for one culture outperform weights learned for other cultures when playing against opponents of the first culture.

Our results verify our hypothesis that decision-making in negotiation is a complex, culture-specific process that cannot be explained just by the notion of maximizing one’s own utility. We showed that cultures vary in goals, not just in conventional circumstances but also that we can successfully use IRL techniques to learn culture-specific goals.

# State effects of action video-game playing on visuospatial processing efficiency and attention among experienced action video-game players

Takashi Obana (a0068245@nus.edu.sg)

Maria Kozhevnikov (psymaria@nus.edu.sg)

Department of Psychology, National University of Singapore

## Abstract

Although researchers have speculated action video gaming might induce the state of “flow experience”, most previous experimental studies have focused primarily on the long-term (trait) effects of action video gaming, while overlooking possible short-term (state) effects characterizing the “flow” state. The goal of the current research was to investigate the state effects of action video games on visual-spatial processing efficiency and visual-spatial attention. We compared the baseline performance of experienced action video game players on two visual-spatial tasks and Attention Network Test with their performance on these tasks immediately after action video-gaming. The findings indicate half an hour of action video-game playing temporarily boosted participants’ performances on tasks that require visual memory, spatial transformations (mental rotation), and executive network of attention. The existence of such enhanced cognitive states implies the possibility of consciously accessing the latent resources of our brain and boosting our attentional and visual capacity upon demand.

**Keywords:** enhanced cognitive states, visual-spatial processing efficiency, attention, action video game

## Introduction

Phenomenological research suggests the existence of mental states in which overall mental functioning, as well as specific cognitive processes (e.g., attention, perception) can be enhanced for limited durations (Csikszentmihalyi, 1990; James & Marty, 1982; Maslow, 1999). Csikszentmihalyi (1997) termed such experiences “flow experiences” (p. 29), which are characterized by “complete focus” (p. 31) where “attention becomes ordered and fully invested” in the activity (p. 31). Despite the wealth of phenomenological evidence, these enhanced mental states are largely neglected in cognitive psychology research. Kozhevnikov, Louchakova, Josipovic, & Motes (2009) were the first to report experimental evidence on the existence of enhanced cognitive states as an aftereffect of focused meditation. In particular, they found that meditation that required holding the focus of attention on an internally generated image of a religious deity temporarily boosted participants’ performance in a number of visual-spatial working memory tasks. Kozhevnikov et al. (2009) suggested that a key characteristic of the induction of enhanced cognitive states, at least in the visual domain, is the intense voluntary focus of visual attention on a chosen object, which activates prefrontal-temporal and prefrontal-parietal connections in the brain, thus facilitating an enhancement of visual-spatial working memory.

A number of researchers have speculated that action video gaming might also induce the state of “flow experience”

(Chiang, Lin, Cheng, & Liu, 2011; Klasen, Weber, Kircher, Mathiak, & Mathiak, 2011; Sherry, 2004; Weber, Tamborini, Westcott-Baker, & Kantor, 2009) due to “cognitive absorption”, deep immersion, intense focus, and merging action with awareness (whereby awareness is only focused on activity) required during video-game play. Experimental studies, however, have thus far focused primarily on the trait effects that result from action video gaming (Bavelier & Green, 2003; Castel, Pratt, & Drummond, 2005; Dye, Green, & Bavelier, 2009; Green & Bavelier, 2006a, 2006b; Li, Polat, Makous, & Bavelier, 2009).

What characteristics of FPS enable these changes in cognitive performances to occur has been discussed in detail (Spence & Feng, 2010). However, despite its abundance in literature, playing FPS is seldom seen as a source of intense visual focus. While playing FPS might leave a lasting change in cognitive performances, the nature of cognitive states induced by intense visual focus remains to be unstudied. In the current study, action video game playing is seen as one way of inducing sustained intense visual focus. The aim of this study is to investigate the nature of cognitive states induced by intense visual focus by utilizing various psychological measurements.

Among the different cognitive processes affected by meditation which might be temporarily enhanced as a result of intense visual focus are different components of visual-spatial cognitive processing (Kozhevnikov, et al., 2009) as well as attentional components (Tang et al., 2007). In the present study we compared the baseline performance of experienced action video game players on two visual-spatial tasks (Mental Rotation Task and Visual Memory Task) as well as on the Attention Network Test measuring executive, orienting, and alerting components of attention with their performance on these tasks immediately after FPS video gaming.

## Method

Twenty-eight action video-game players (24 males) who have 4 to 20 years of experiences (Mean = 10), aged from 20 to 27 (Mean age = 23) were recruited for the study by advertising in National University of Singapore. One participant’s data was deleted due to procedural error. Two participants’ data were treated as outliers.

The participants of the current study played the action video-game *Unreal Tournament 2004* (referred to as FPS henceforth) by Atari. The video-game uses first-person point of view and require monitoring of the entire visual field (extent from fixation about 16° height × 29° width).

The participants were administered two computerized tasks assessing different aspects of visual processing: a visual memory task (VMT, MM Virtual Design, 2004) that assessed their ability to maintain images of complex static objects in visual working memory and a mental rotation task (MRT, Shepard & Metzler, 1971) that assessed their ability to dynamically transform and compare two spatial objects.

The VMT (MM Virtual Design, 2004) consisted of two parts. There were six test trials in the first part of the VMT. On each trial, participants were exposed to a single image (see Figure 1a) that appeared for 5 seconds. This display was replaced by an array of six images: five distractors and the previously shown image. Participants were asked to determine which image in the array was the previously shown image. There were 18 test trials in the second part of the VMT. On each trial, participants viewed an array of seven images (see Figure 1b) that appeared for 8 seconds. This array was replaced by another array of seven images: six of the previously studied images and one novel image. Participants were asked to judge which image in the second array was not present in the first.

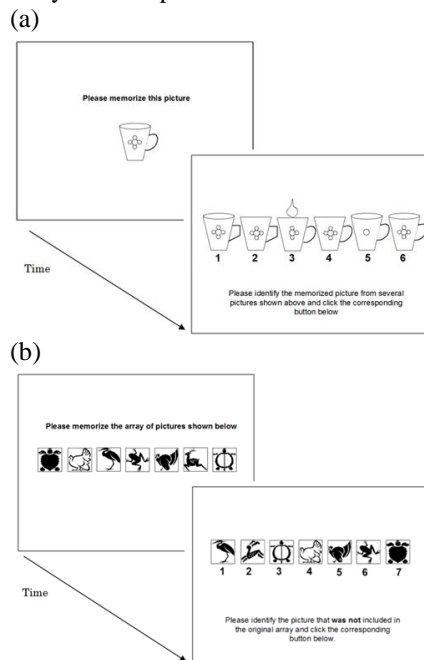

Figure 1: Examples of items from the visual memory test.

On each trial of the MRT, participants viewed a pair of two-dimensional pictures of three-dimensional forms (see Figure 2). The forms in each pair were rotated relative to each other around the x-, y-, or z-axis. Across trials, the amount of rotation ranged from 40° to 180°, in 20° increments. Participants judged whether the forms in the pair were the same or mirror-reversed. There were 36 test trials.

Figure 2: Example of a test trial from the Shepard & Metzler mental rotation task.

The Attention Network Test (ANT) was designed by Fan et al. (2002) to evaluate three attention networks: alerting, orienting and executive attention (see Figure 3). First, the alerting attention signifies the ability to make use of the presented cue. It represents individual's vigilance or alert state of preparedness to respond to the cue while attention is prompted to be diffused. Second, orienting attention is measured by the use of spatial cue. It signifies individual's ability to direct attention to specific location. Third, executive attention represents individual's ability to selectively attend to the significant stimuli while filtering out the distracting stimuli. It is measured by the incongruent targets.

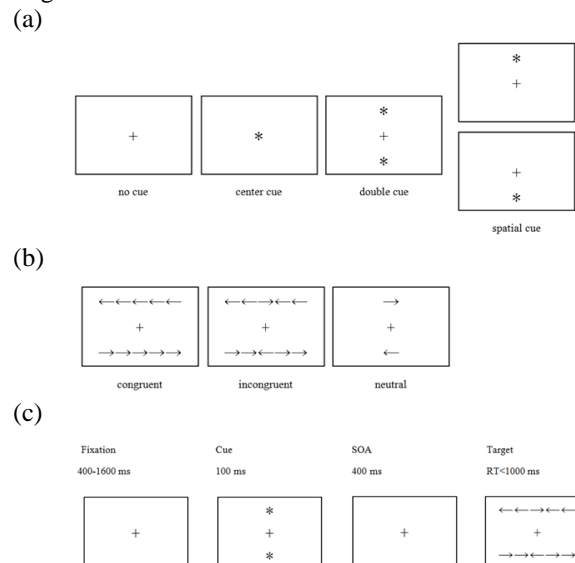

Figure 3: Attention Network Test (ANT). (a) The four cue conditions; (b) The three target conditions; and (c) an example of stimulus presentation sequence.

All the participants were tested individually, in a testing session lasting from 2.5 to 3 hours. First, as a pretest, all the participants completed the ANT, MRT, and VMT, the order of which was counterbalanced across participants.

After completing the pretest, all the participants were playing a video-game for 30 mins. Then, we randomly assigned the participants to the two following groups (see Figure 4).

Figure 4: The time sequences of the different groups.

Above are the experimental procedures for group A (N=13) and B (N=12). In the beginning of the whole procedure, ANT, MRT, and VMT were given to all participants as pretests. The order of MRT and VMT was counterbalanced across participants. After the pretests, participants were asked to play FPS for 30 minutes. Right after that, the posttests 1 were administered. When participants are done with their posttests, 30 minutes of rest periods were given. After 30 minutes have elapsed, the whole sequence ended with posttests 2.

The informal interviews were conducted during the rest period. Participants were asked how they generally felt right after playing the FPS.

Posttest 1 was given to the participants to investigate the changes in their performance right after playing the action video-game that is to measure whether they exhibited enhanced cognitive state or to see if the action video-game has enhancing effect in short term. Posttest 2 was administered to the participants in order to see whether the state dissipates with time.

If to assume that the enhanced states do exist, they are of limited duration. The states dissipate quickly (about 20-25 min, according to the reports of meditators from Kozhevnikov et al. (2009) so it was impossible to give to the same participants all the visual and attentional tests in one session (overall time to complete all tests is more than 30 minutes) that is why some participants received only MRT and VMT (total duration; 10 to 15 minutes) after playing the videogame while others received only ANT (total duration; 25 to 30 minutes).

Second, we did not want to give to the same participants the same test three times (there is a possibility that they will remember some of the responses by the third time) in a row, due to a large practice effects. Thus for posttest 2 we used test(s) which was(were) not given in posttest 1.

## Results

First, we analyzed participants' descriptions of how they felt right after 30 mins of playing FPS by using the simplified version of phenomenological method (Giorgi, 1985). The recurring themes were "better focus", "faster reaction", "being more alert", and "heightened arousal level". Equally used description was feeling "tired" (7/28). Number of participants reported that playing FPS makes them psychologically alert but physically tired (6/28). It was reported that the state of alertness after playing FPS eventually dissipates in time. One participant who was very

observant to his inner state, reported he was able to react to ANT task much faster and more accurately right after playing FPS, but he could feel this state disappear upon finishing the first block of ANT (after 10 min). Thus, the state might be of short duration, approximately 10 min for 30 mins of FPS playing.

Second, we analyzed performance on the VMT and MRT. In order to avoid confounds arising from speed accuracy trade-offs, a measure of visuospatial processing efficiency for each imagery test was computed for mental rotation and visual memory tasks, similar to the previous literature (Kozhevnikov, Louchakova, Josipovic, & Motes, 2009).

Figure 5 presents the results for visual memory processing efficiency. A 2 (time: pretest vs. posttest)  $\times$  2 (Condition: after video-game vs. after rest) mixed-model ANOVA yielded a significant main effect of time,  $F(1, 25)=8.43$ ,  $p<.001$ , suggesting that there was a significant improvement in performance from pretest to posttest for all participants. The main effect of group was also significant,  $F(1, 25)=6.22$ ,  $p<.05$ , indicating that participants who took the VMT posttest after the videogame (VMT after video-game) performed significantly better than the ones who took posttest after the rest period (VMT after rest). The interaction between time and group was also significant,  $F(1, 25)=8.43$ ,  $p<.01$ . A follow-up ANOVA revealed a significant increase in efficiency from the pretest to the posttest for VMT after video-game,  $F(1, 13)=35.00$ ,  $p<.001$ , and a no significant increase for VMT after rest,  $F(1, 12)=2.52$ ,  $p=.14$ . These results indicate that there is an improvement in visual memory task performance, in posttest compared to pretest, only right after playing videogame. However, this improvement is no longer observable if the posttest is taken about half an hour after playing videogame.

Figure 5: Processing of efficiency on the visual memory pre- and posttests as a function of group. Error bars show  $\pm 1$  SEM.

For comparison, on Figure 5 we also plotted the results for deity meditation group from Kozhevnikov (2009) study, where VMT was also given using pre-post test paradigm to different groups of meditators. Among all the groups of meditators, only *deity yoga* meditators (DY) showed the significant increase in VMT efficiency from pretest to posttest ( $F(1, 14)=26.41$ ,  $p<.001$ ). The comparison of effect size reveals participants in VMT after video-game ( $\eta^2=.73$ ) and DY ( $\eta^2=.65$ ) group are quite similar. Although the contents of focused objects are different, both playing FPS and DY involves the acts of intense visual focus.

Figure 6 presents the results for MRT efficiency. A 2 (time: pretest vs. posttest)  $\times$  2 (group: after video-game vs. after rest) mixed-model ANOVA yielded a significant main effect of time,  $F(1, 24)=16.54$ ,  $p<.01$  suggesting that there was a significant improvement in performance from pretest to posttest for all participants. However, main effect of group was not significant,  $F(1, 24)=.01$ ,  $p=.91$ . The interaction between time and group was marginally significant,  $F(1, 24)=3.23$ ,  $p=.085$ . A follow-up ANOVA revealed a significant increase in efficiency from the pretest to the posttest for MRT after video-game,  $F(1, 12)=13.87$ ,  $p<.01$ , and only marginal increase for MRT after rest,  $F(1, 12)=3.39$ ,  $p=.09$ . These results indicate that there is an improvement in mental rotation task performance, in posttest compared to pretest, only right after playing video-game. However, this improvement is no longer observable if the posttest is taken about half an hour after playing video-game.

Figure 6: Processing of efficiency on the mental rotation pre- and posttests as a function of group. Error bars show  $\pm 1$  SEM.

For comparison, on Figure 6 we also plotted the results for deity meditation group from Kozhevnikov (2009) study, where MRT was also given using pre-post test paradigm to different groups of meditators. Among all the groups of meditators, only deity yoga meditators (DY) showed the significant increase in MRT efficiency from pretest to posttest ( $F(1, 14)=19.36$ ,  $p<.001$ ). The comparison of effect size again reveals participants in MRT after video-game ( $\eta^2=.54$ ) and DY group ( $\eta^2=.58$ ) are quite similar.

The result (interaction) for MRT comparing after video-game vs. after rest group was only marginally significant. This could be caused by the presence of ceiling effect. Since VGPs seem to exhibit exceptionally high spatial abilities from the beginning (Fig 6), the MRT was not able to reflect the effect of action video-game playing.

For ANT, three networks – executive, alerting and orienting – were calculated by subtracting the average RTs of specific condition from other condition (Fan et al., 2002).

ANT is composed of three test blocks, with each block taking approximately 10 minutes to complete. So that overall duration of the test is 30 min. However, as the qualitative data show, the duration of the enhanced states might be limited, and dissipate in 10 min as one of our participants reported. Since ANT took about 2 to 3 times longer compared to VMT or MRT (25 to 30 minutes vs. 10 to 15 minutes respectively), it is possible that by the time participants reached second block of the posttest, the

enhanced state started to dissipate. Thus, for each of the attentional network, we performed two analyses: 1) we compared ANT pretest with participants' performance on the first block on ANT posttest only, and 2) we compared performance on ANT pretest and ANT posttest (including all three blocks for both pretest and posttest).

Figure 7 presents the results for executive network. For better comparisons, the results for each of the three blocks of the ANT posttests are presented separately. A2 (time: pretest vs. posttest block 1)  $\times$  2 (Condition: after video-game vs. after rest) mixed-model ANOVA did not yield a significant main effect of time,  $F(1, 25)=0.48$ ,  $p=.50$  suggesting that there was no significant improvement in performance from pretest to posttest block 1 for all participants. The main effect of group was not significant either,  $F(1, 25)=1.48$ ,  $p=.24$  indicating that overall performance of participants' executive network did not differ from pretest to posttest block 1. However, the interaction between time and group was significant,  $F(1, 25)=9.84$ ,  $p<.01$ . A follow-up ANOVA revealed a significant increase in executive network efficiency from the pretest to the posttest block 1 for ANT after video-game,  $F(1, 12)=5.38$ ,  $p<.05$ , and a marginally significant decrease for ANT posttest block 1 after rest,  $F(1, 13)=4.36$ ,  $p=.06$ .

Figure 7: Executive network pre- and posttests as a function of condition. Higher reaction time denotes less efficient executive network. Error bars show  $\pm 1$  SEM.

Then, we conducted a 2 (time: pretest vs. posttest all 3 blocks)  $\times$  2 (Condition: after video-game vs. after rest) mixed-model ANOVA did not yield any significant main effects ( $p>0.2$ ). Similar to the previous case, only interaction between time and group was significant,  $F(1, 25)=7.73$ ,  $p<.05$ . A follow-up ANOVA revealed a significant decrease for ANT 3 blocks after rest,  $F(1, 13)=6.65$ ,  $p<.05$ , and no significant difference in executive network efficiency from the ANT pretest to the posttest all 3 blocks right after video-game,  $F(1, 12)=1.50$ ,  $p<.25$ .

These results indicate that there is an improvement in conflict resolution performance, in posttest compared to pretest, only about 10 minutes (during performance on block 1) right after playing video-game, and then the performance starts to degrade for both groups, as it could be seen from Figure 7.

For the orienting network and alerting network, there were no evidences that playing action video-game improved

network efficiency right after playing action video-game compared to after resting ( $p > 0.1$ ).

Taken together, the results of present study show that the enhanced cognitive states do exist. As the results of ANT (executive network) show, this state is transient and it dissipates quickly. The result shows that the residual effect of 30 min of action video-game playing can hold for at least 10 mins when the degree of visual focus intensity is strong enough.

## Conclusions

The findings of this study indicate that half an hour of FPS video game playing temporarily boosted participants' performances on tasks that require visual memory, spatial transformations (mental rotation), and executive network of attention. The effect of enhanced performance disappeared and returned to the baseline level for all the tasks after 30 minutes of rest. Furthermore, based on ANT data and participants' reports, these performance improvements might last no longer than 10 minutes after video-game playing. Thus we suggest that FPS action video game playing can give an access to relatively short temporary cognitive states characterized by drastically enhanced performance on visual-spatial and executive attention tasks.

Although some researchers (e.g., Weber, et al., 2009) speculated that the experience of flow might be related to the functioning of alerting and orienting networks during video-gaming (due to their importance in achievement/maintaining the alert attentional state as well as efficient orienting of attentional resources to spatial locations where the event takes place), our experimental results do not support this suggestion. The only attentional network which significantly improved during the enhanced state is the executive network. It is possible to infer that during enhanced states, attentional focus becomes "sharper" and of greater resolution, and thus, encoding of visual-spatial information as well as discrimination between target and flankers becomes more efficient. Meditation has a similar effect on attentional networks: Tang et al. (2007) showed an improved performance only in executive network as a result of short-term meditation.

The result of experiment 2 confirmed that intense visual focus induced by action video game playing enhances the efficiency of presented visual information processing.

Furthermore, our results show the significant increase in performance on such visual-spatial tasks as mental rotation and visual memory test during the enhanced cognitive state, similar to what has been reported by Kozhevnikov et al (2009) as a result of focused meditation. In our study, playing FPS required intense visual focus on many elements in the display such as "abrupt-onset events" (Spence & Feng, 2010, p. 93) and "significant objects" (p. 93) that must be discriminated and selected. Similar to DY meditation where the subject focuses on imagining himself/herself as a deity, focused visual attention seems to be crucial for inducing enhanced states. Indeed not all video-games seem to have a similar affect on visual attention (Bavelier & Green, 2003;

Feng, Spence, & Pratt, 2007; Green & Bavelier, 2006a, 2006b, 2007; Li, et al., 2009). For example, compared to FPS, puzzle video-games such as Tetris are shown not to have enhancing effect on spatial attention. Similarly, as it was shown by Kozhevnikov et al. (2009), not all types of meditation lead to enhanced cognitive states, but only those that require intense visual focus as DY. Other types of meditation, such as Open Presence which required "evenly distributed attention that is not directed toward any particular object experiences" (p. 646) did not produce an enhanced cognitive state. In addition focused attention, an interesting aspect of both FPS and DY is that both of them require egocentric (first-person perspective) spatial imagery. DY requires egocentric embodiment (visualizing oneself as a deity and not just focusing on an external image) and FPS "provides a natural egocentric compatibility between the visual input and the motor output" (Spence & Feng, 2010, p. 99). It is possible that a combination of focused attention and egocentric spatial imagery processes might be the key to inducing enhanced cognitive states. Future research should address this question by directly comparing the accessing of enhanced cognitive states using visual concentration on egocentric vs. allocentric visual-spatial images.

It should be noted, however, that although both DY meditation and videogaming seem to boost temporarily visual-spatial memory and attention, we should be very cautious to make any conclusions about similarity of enhanced cognitive states induced by meditation vs. video-gaming. First, it is known that meditation leads to emotional stability while video-gaming increases aggression and emotional desensitization (Anderson et al., 2010; Bushman & Gibson, 2011). Second, our participants in informal interview reported depletion of their attentional resources right after the enhanced states while monks reported "refreshed feeling" accompanying them long after meditation. Thus, while both focused meditation and action video-gaming playing might both boost visual-spatial cognitive processes, the nature and temporal dynamics of these enhanced states might be very different.

The fact that enhanced cognitive states do exist has significant practical implications for different domains of human performance. Csikszentmihalyi (1990) described the tremendous energy of enhanced cognitive states using a metaphor of atomic energy, which could be used for a variety of purposes. Knowing the means and the mechanisms behind cognitive enhancements would allow us to generalize related findings to help different cognitive problems (e.g. memory loss, attentional problems). Although it is transient, a temporary boost in visuospatial processing efficiency or attention can also greatly enhance the performance during the critical periods of our lives (e.g. training soldiers before going to battlefields). Furthermore, they can help us boost creativity (Csikszentmihalyi, 1996) or could be of particular use for learning.

## Abstract

There are conflicting hypotheses for the causes of Dyslexia in reading and writing difficulties, such as the phonological deficit hypothesis, double deficit hypothesis, magnocellular deficits hypothesis etc. The cause of the difficulties may vary between individuals. Moreover, most of these hypotheses consider only a single disability, despite the fact that factors related to reading and writing may affect the difficulty in various ways. We conducted this study to identify individual differences in the effect of Dyslexia. The participants were 12 Japanese children who were diagnosed with learning disabilities or suspected to be learning disabled. In this study, we considered how phonological awareness, visual perception, and phonological processing are related to reading and writing abilities in the Japanese language. In addition, we checked "handwriting ability." This study shows that reading and writing difficulties are caused by a variety of factors and that there are individual differences in the difficulties.

**Keywords:** Reading and writing Difficulties, Dyslexia, Individual differences, Japanese education

## Introduction

In Japan, official reports claim that 6.3% of elementary and middle school students enrolled in normal classes experience learning difficulties (MEXT Japan, 2002). This means that each class has two or more students with actual or potential learning problems, making learning disabilities an issue that should be urgently addressed to provide these students with special learning assistance. Students with

learning difficulties have more than one problem in reading, writing, listening, communicating, calculating, planning, and memorizing. In particular, support for reading and writing are very important. Difficulty with reading negatively affects all learning domains, thereby hindering academic performance in all subjects. A person's inability to read well can also generate an inferiority complex that results in the loss of his or her motivation to learn, which, in turn, may be linked to symptoms leading to juvenile delinquency (Kimberly & Richard, 2006; Siponmaa, Kristiansson, Jonson, Nyden et al., 2001). The inability to read also influences friendships outside of the classroom (Stanovich, 1986) and children's ability to process feelings of anger (Kazdin, Rodgers, Colbus, & Siegel, 1987; Moffitt & Henry, 1989). All of these factors suggest that addressing reading difficulties should be a priority for helping children with learning difficulties.

To support them, it is important to know the causes of the difficulty. Moreover, there are different manifestations of developmental dyslexia in different languages (Miles, 2000). Researchers (e.g., Landerl, Wimmer & Frith, 1997; Paulesu, McCrory, Fazio, Menoncello et al., 2000; Paulesu, Demonet, Fazio, McCrory, 2001; Wydell & Butterworth, 1999) argue that the discrepancy in the prevalence of reading impairments in different languages might be primarily due to inherent differences in the structure/characteristics of each orthography, specifically the way in which phonology is computed from it. In the alphabetic languages in which a

finer “grain” processing of orthography-to-phonology mapping is required, such as English or Danish, developmental dyslexia forms a large minority group. For these facts, to support Japanese children, it is necessary to know the characteristics of Japanese children’s reading and writing difficulties.

There are conflicting hypotheses for developmental dyslexia, reading and writing difficulties, such as the phonological deficit hypothesis (Shaywitz, 2003; Shaywitz & Shaywitz, 2005), double deficit hypothesis (Wolf & Bowers, 1999; Wolf & Bowers, 2000; Faust & Sharfstein-Friedman, 2003), magnocellular deficits hypothesis (Livingstone, Rosen, Drislane, & Galaburda, 1991), and so on. However, most of these hypotheses only consider a single disability. Other studies that discuss the issue with many factors don’t consider individual differences (e.g., Uno, Wydell, Haruhara, Kaneko et al., 2009). However, all factors related to reading and writing may affect the difficulty in various ways. This paper hypothesizes the influence of individual differences is suspected to add to the difficulties.

The core ability of reading and writing skills is phonological processing. Phonological processing is the ability to see or hear a word, break it down into discrete sounds, and then associate each sound with letter/s that make up the word. The prerequisite skills for phonological processing are the ability to analyze the phonological structure of sound and the ability to recognize its characters. According to the phonological model, the difficulty results from an impaired ability to segment spoken words into phonologic parts and link each letter to its corresponding sound (Shaywitz, 2003; Shaywitz & Shaywitz, 2005). Phonemes are small units of sound that can be conceptualized as the building blocks of words (for example, the word cat is comprised of three phonemes: k, aaaa, and t). That is the ability to analyze phonological structure. The Japanese language is based on a subsyllabic unit, the mora (Otake, Hatano, Cutler, & Mehler, 1993). According to magnocellular theory, the difficulty results from abnormalities of the magnocellular component of the visual system, which is specialized to quickly process temporal information (Stein & Walsh, 1997). That is the ability to recognize character. Furthermore, not only cognitive ability, but also the ability to correctly produce sound is necessary for reading. And handwriting abilities are necessary for writing letters correctly. Therefore, it is also important to possess these abilities. Moreover, in reading, there are two strategies, one is a lexical strategy based on whole word recognition and another a sub-lexical processing strategy based on a grapheme-to-phoneme conversion (Wydell & Butterworth, 1999). This means that if we want to know the ability of phonological processing in reading, we have to check not only word tests, but also non-word tests.

Additionally, Wydell & Butterworth (1999) established “the Hypothesis of Granularity and Transparency.” Through this hypothesis, they maintain that orthographies can be described by two dimensions: “transparency” and

“granularity” and argue that: (1) any orthography where the print-to-sound translation is one-to-one or transparent will not produce a high incidence of phonological dyslexia, regardless of the level of translation, i.e., phoneme, syllable, character, etc. This is the “transparency” dimension, and (2) even when this relationship is opaque and not one-to-one, any orthography whose smallest orthographic unit representing sound is coarse, i.e., a whole character or whole word, will not produce a high incidence of phonological dyslexia. This is the “granularity” dimension. Any orthography used in any language can be placed in the transparency-granularity orthogonal dimension described by this hypothesis. This is illustrated in Figure 1. The hypothesis argues that any orthography that falls into the shaded area in Figure 1 should not produce a high incidence of phonological dyslexia. Given the characteristics of Japanese orthography, both Japanese Kana and Kanji can be placed in the shaded area. For example, in Japanese Kana, the granularity of the smallest orthographic unit representing phonology is finer than the whole word, but coarser than the grapheme and its orthography-to-phonology translation relationship is at the level of syllables and one-to-one. For Kanji, on the other hand, the unit of granularity is much coarser, i.e., a character or a whole word and the relationship between orthography and phonology is very opaque, hence Kanji can be placed in the shaded area.

Granular Size

Figure 1: Hypothesis of granularity and transparency and orthography-to-phonology correspondence made by Wydell & Butterworth (1999).

In this study, we targeted the difficulties in Kana (Hiragana and Katakana), the most basic character in Japanese. We considered phonological awareness, visual

perception, and phonological processing which relate to reading and writing abilities in Japanese. In addition, we checked the ability of “expression of handwriting.” We conducted this study to bring out the effect of individual differences on the disability.

## Method

### Participants

The participants were 12 children (eight boys and four girls) who were recruited by the doctor of the Nagoya City Child Welfare Center and Nagoya Central Care Center for Disabled Children. The doctor believed that all had difficulty in reading and writing which harbored the possibility that they had developmental dyslexia. Table 1 presents participant profiles.

Table 1: Participant profiles.

Child	Grade	Gender	Dual diagnosis	
A	6	M	PDD	
B	5	M		AD/HD
C	4	M		
D	4	M	PDD	
E	4	M		AD/HD
F	3	M	PDD	
G	3	F	PDD	
H	3	F	PDD	
I	3	F	PDD	AD/HD
J	3	M		
K	3	M	PDD	AD/HD
L	3	F		

*Note.* M = Male, F = Female, PDD = Pervasive Developmental Disorder, ADHD = Attention Deficit/Hyperactivity Disorder.

In December 2010, seven children were enrolled in third grade, three in fourth grade, one in fifth grade, and one in sixth grade. All of them were enrolled in regular elementary school classes. Every child was either diagnosed as having learning disabilities or suspected of being learning disabled by the doctor. Five children exhibited symptoms that coexisted with pervasive developmental disorder, two with attention deficit/hyperactivity disorder, and two with both pervasive developmental disorder and attention deficit/hyperactivity disorder. The Wechsler Intelligence Scale for Children-Third Edition (Wisc-III) Full Scale IQ scores ranged from 79 to 112, with a mean IQ score of 97.8. Verbal IQ scores ranged from 72 to 120, with a mean IQ

score of 100.7. Performance IQ scores ranged from 80 to 120, with a mean IQ score of 95.1. No children stuttered and all could correctly produce sounds.

### Measures

**Phonological awareness task:** Each participant performed two phonological awareness tests: isolation of unvoiced sounds test and segmentation of choked sound test. Isolation of unvoiced sounds requires recognizing the individual unvoiced sounds in words, for example, “Tell me the second sound of the word you hear.” The experimental stimuli of isolation of unvoiced sounds test were 10 words of five characters like “ka-ta-tsu-mu-ri,” in Japanese “かたつむり.” The participants were asked to identify the second sound in three words, the third sound in four words, and the fourth sound in three words. The achievement scale was above 8/10. Segmentation of choked sound requires recognizing the number of sounds in words, for example, “Tell me how many sounds in the word you hear.” The experimental stimuli of segmentation of choked sound test were 10 words of six choked sound words and four unvoiced sounds words. These words had three to six characters. We analyzed only the choked sound words. The achievement scale was above 4/6. We performed these tests by checking references from the test performed by Hara (2001).

**Visual perception task:** Each participant performed three subtests of the Japanese version of the Developmental Test of Visual Perception (DTVP; Frostig, 1977): figure ground, position in space and spatial relations. Perceptual age was determined by the test. Scaled Scores (SS) of each test was determined using the DTVP. If the perceptual age was younger than the calendar age, SS was equal to or less than eight. Individual tests are not sufficiently different to measure separate abilities (Olson, 1968), and all of the tests are thought to be related to visual perception. In this study, participant passed the task if his or her score showed more than eight in every three scores of subtests. Otherwise, the participant failed the task.

**Phonological processing task:** Each participant performed six reading tests to examine their phonological processing ability. Four tests were subtests of the Screening Test of Reading and Writing for Japanese Primary School Children (STRAW; Uno, Haruhara, Kaneko, & Wydell, 2006): Hiragana character reading test, Katakana character reading test, Hiragana word reading test, and Katakana word reading test. These tests consist of 20 known words. The other two tests were the Hiragana non-word reading test and Katakana non-word reading test. These tests consist of 10 non-words. The achievement scale of each test was more than or equal to 90%. If a child’s score of the word reading test was above the achievement scale, but the character reading test or non-word reading test was below the achievement scale for at least one condition of Hiragana or Katakana, he or she can use the lexical strategy based on whole word recognition but

cannot use the sub-lexical processing strategy which is based on a grapheme-to-phoneme conversion. In this case, he or she was assumed to fail the phonological processing task. If a child's score of all the tests was above the achievement scale, he or she was assumed to have passed the phonological processing task.

**Handwriting ability task:** Each participant performed one subtest of the Japanese version of the Developmental Test of Visual Perception (Frostig, 1977): eye-motor coordination. Perceptual age was determined by the test. SS of the test was determined using the DTVP. If the perceptual age was younger than the calendar age, SS showed equal or less than eight. Participants passed the task if his or her score showed more than eight of the subtests.

## Procedure

Participants were tested individually in a quiet room at the Nagoya City Child Welfare Center. Each participant was seen more than five times over one week, each time for approximately 40 minutes. To exclude the factor of PDD or ADHD, we organized the physical environment (e.g., Treatment and Education of Autistic and related Communication handicapped Children). In each test errors were recorded. Also, each child's responses were videotaped for later reviewing. Children were told that these were not academic achievement tests, and that only the investigators would see their results. The data was collected from May 2010 to December 2010.

## Results

### Phonological awareness task

Every child passed the isolation of unvoiced sounds test. In the segmentation of choked sound test, only one child, F, failed. That means that only one participant had difficulty in phonological awareness.

### Visual perception task

Only two children, B and L, passed the task and the other 10 failed. This means that 10 children had problems in the recognition of characters in some way.

### Phonological processing task

Four children, A, B, H, and I passed all tests and therefore passed the phonological processing task.

Eight children failed the phonological processing task. Four children, C, D, E, and J failed only the Katakana non-word reading test, while L failed both the Katakana non-word reading test and the Katakana character reading test. They appeared to read the words of Katakana, but seemed to have a weak ability for phoneme-to-grapheme conversion in Katakana. Two children, G and K, failed both the Hiragana and Katakana non-word reading tests. They appeared to read the words of Kana (Hiragana and Katakana), but seemed to have a weak ability for phoneme-to-grapheme conversion in

Kana (Hiragana and Katakana). One child, F, passed only the Hiragana character reading test. She appeared to have read the words of Hiragana, but seemed to have a weak ability for phoneme-to-grapheme conversion in Hiragana. In addition, she couldn't complete all of the Katakana tests.

## Handwriting ability task

Four children, C, G, K and L, passed the task and eight failed. These eight children's writing movements may be related to their writing difficulties.

## Discussion

Table 2 presents the results of each test for each child and the type of characteristics in reading and writing difficulties. One child, F, is type 1 and failed all the tests. Three children, D, E, and J, are type 2 and passed only the phonological awareness test. Three children, C, G, and K, are type 3 and failed in visual perception and phonological processing. Three children, A, H, and I, are type 4 and failed in visual perception and handwriting ability. One child, B, is type 5 and failed only in handwriting ability. One child, L, is type 6 and failed only in phonological processing.

Table 2: Type of characteristics in reading and writing difficulties.

Type	PA	VP	PP	HA	Child	Grade
<b>1</b>	F	F	F	F	F	3
<b>2</b>	P	F	F	F	D	4
<b>2</b>	P	F	F	F	E	4
<b>2</b>	P	F	F	F	J	3
<b>3</b>	P	F	F	P	C	4
<b>3</b>	P	F	F	P	G	3
<b>3</b>	P	F	F	P	K	3
<b>4</b>	P	F	P	F	A	6
<b>4</b>	P	F	P	F	H	3
<b>4</b>	P	F	P	F	I	3
<b>5</b>	P	P	P	F	B	5
<b>6</b>	P	P	F	P	L	3

Note: PA = Phonological awareness, VP = Visual perception, PP = Phonological processing, HA = Handwriting ability, F = Failed, P = Passed

By examining individual levels for the four elements, as shown in Table 2, it becomes apparent that reading and writing difficulties are not caused by a single disability, but

rather by a combination of factors. Furthermore, the combination of individual elements is different. This means that students with learning disabilities need separate support even they have the same symptoms or reading and writing difficulties.

In the four elements, a higher percentage of children were considered to have problems with visual perception. Type 4 children passed the phonological processing task even though they failed the visual perception task. This result may be caused by Japanese education methods. The simultaneous oral spelling method is a good way for dyslexic children to acquire reading and writing skills (Thomson, 1996). Typical Japanese education methods, however, utilize simultaneous oral spelling techniques. Japanese has multiple characters that are similar to each other. Also, there are many strokes in Japanese Kanji. Therefore, we need to study the influence of visual perception on difficulties in reading and writing Japanese in the future.

The groundbreaking discovery of our study was that there were many children who have poor handwriting abilities. Stroke order is believed to very important in Japanese education.

However, if there is difficulty in handwriting, it may be hard for these children to write in handwriting stroke order. When considering the difficulty of writing, handwriting ability wasn't considered. However, from the viewpoint of quality of life, it is necessary to know a child's handwriting ability in an assessment. If a child has poor handwriting ability, he or she should be supported and taught that the stroke order is not necessarily important. In Japan, it is an accepted practice to learn characters from a set of reading and writing lessons. However, this method is not good for children who have poor writing abilities, in particular type 5 children, like child B, who have difficulty only with handwriting. These children need support in the form of separate reading and writing practice.

In this study, only child F failed the phonological awareness task. This supports the granularity dimension of "the Hypothesis of Granularity and Transparency." However, some children failed the phonological processing task because they failed the Katakana test. In particular, child L, a type 6, passed other tasks like the phonological awareness task, visual perception task and handwriting ability task. Why is there difficulty only in the Katakana phonological processing? Kana is a one-to-one from a character standpoint, but not a one-to-one transparent from a sound standpoint. This is illustrated in Figure 2.

Considering this, granularity and transparency and orthography-to-phonology correspondence of KANA will appear as presented in Figure 3.

For type 6 children, like child L, the Japanese syllabary table may be a good education support tool. The Japanese syllabary table may be utilized as a type of location map of phonemes (Seki et al., 2004). If children have already learned Hiragana, using the Katakana syllabary table may help them learn Katakana characters.

Figure 2: Transparency dimension of Kana from character and sound standpoints.

Figure 3: Granularity and transparency and orthography-to-phonology correspondence of KANA

In this study, we demonstrated that reading and writing difficulties in the Japanese language attributed to learning disabilities are caused by variety of factors and that there are individual differences in the difficulties. We also demonstrated that an assessment of handwriting ability is necessary to identify the proper types of support for

problems. Furthermore, we demonstrated that Kana is not one-to-one transparent from a sound standpoint. This research will have a large impact on education methods and techniques in Japan.

### Acknowledgments

## Abstract

When many factors must be considered for decision-making, people dynamically change their emphasizing points, along with their understanding of these factors and the relationships between them. In previous work, we proposed a method to dynamically estimate emphasizing points (DEEP) based on utterances, physiological indices, and proposal selections. To evaluate this method in actual interactions, we conducted controlled WoZ (Wizard of Oz) experiments using Embodied Conversational Agents (ECAs), which interactively provide controlled information for decision-making. Using ECAs, we compare our method to an existing method, which estimates emphasizing factors through the “gradual method”. We confirm that our method can accurately estimate dynamic changes of emphasizing points, and that participants were more satisfied with the final proposal from the ECA that used DEEP.

**Keywords:** verbal and nonverbal behavior; physiological indices; preferential structure estimation.

## Introduction

When many factors must be considered for decision-making, we dynamically and interactively change the factors that we emphasize (which we call “emphasizing points”). We also change our understanding of these factors and relationships between them. For example, in travel planning, we have to synthetically consider factors, such as place, budget, members, and schedule. We often make such plans interactively with our friends and travel agency staff.

The interaction between conversational partners influences how we understand the factors and the relationships between them during the decision-making process. Therefore, their emphasizing points are often dynamically changed when faced with new information. However, the important factors may not only be the most recent points emphasized, but the process of interaction may also change the emphasizing points. People have to re-estimate the changes in their emphasizing points throughout the interaction.

In interactive decision-making with dynamic changes to emphasizing points, humans provide active demands and passive responses through verbal expressions, nonverbal reactions, proposal selection, and physiological state (Ohmoto,

Kataoka, Miyake, & Nishida, 2011). In the previous work, we analyzed the interaction process, and verbal and nonverbal behavior during the interaction to propose an estimation method of interaction using utterances, nonverbal behavior, physiological indices, and proposal selections.

The purpose of this study is to evaluate whether our proposed method based on dynamic estimation of emphasizing points (DEEP) is useful to participants in interactive decision-making and whether the proposed method can provide satisfactory proposals for participants. To test this method, we used Embodied Conversational Agents (ECAs), because it is difficult for human agents to achieve rigorously controlled interaction with participants based on our proposed method. Specifically, we conducted an experiment that compares the results of interactive decision-making with two types of ECAs; one provided proposals based on our method and another based on an existing method that gradually estimates emphasizing points based on verbal expressions and proposal selections.

The paper is organized as follows: Section 2 discusses work on interactive systems. Section 3 briefly explains DEEP, which dynamically estimates emphasizing points. Section 4 describes the experiment for comparing two types of estimation methods and then presents the results. Section 5 discusses the achievements and limitations of the proposed method. Section 6 concludes and discusses future work.

## Related work

Some researchers have developed systems that can provide proposals to satisfy user’s demands. These systems gradually estimate user’s demands throughout the interaction.

Kitamura et al. (Kitamura et al., 2008) developed the “Laddering” Search Service System that matches users queries with search targets by communicating with users throughout the interview. They assume that user’s emphasizing points do not change during the interaction.

Aydogan et al. (Aydogan & Yolum, 2007) proposed an architecture in which both consumers and producers use a

shared ontology to negotiate services. Through repetitive interactions, the provider accurately learns consumers' needs to provide better-targeted offers. The system learns consumers' needs over long-term interactions.

Kurata (Kurata, 2010) proposed a computer-aided tour planning system. The system provides several tour plans and asks the user to provide feedback. The feedback is utilized by the system for inferring the user's preferences and then for revising tour plans. This cycle is repeated until the user is satisfied with the final plan, with the hopes that this method gradually leads to a more satisfying experience of computer-aided tour planning. The system can then estimate user's emphasizing points. However, the user has to manually change emphasizing points when the user wants to change her/his emphasizing points during the interaction. Moreover, the user cannot modify their emphasizing points when he/she does not have knowledge about the planning.

Previous work revealed that user demands and needs could gradually be estimated through repetitive interactions. However, most of the research did not consider that user's demands and needs could change throughout the interaction. In contrast, we assume that emphasizing points can change over the interaction and we dynamically estimate these changes. We focus not only on active demands verbally expressed and proposal selections, but also on passive responses expressed by backchanneling, and nonverbal reactions.

It is, however, difficult to estimate human internal states through nonverbal information, especially when passively interacting with others. Therefore, we use physiological indices for estimating human internal states during interaction. There are various studies on estimating human internal states by measuring physiological indices (e.g. (Iwaki, Arakawa, & Kiryu, 2008)). There are also several studies that use these measured physiological indices for effective human-agent interaction.

Bosma et al. (Bosma & Andre, 2004) proposed a method that takes into account users' emotional state to disambiguate dialogue acts. They restrict to pedagogical agents that offer a text-based natural language interface for assisting the user in text communication. They estimated levels of arousal and valence by using physiological indices: skin conductivity response (SCR), heart rate, muscle activity, and respiration rate.

Prendinger and Ishizuka (Prendinger & Ishizuka, 2005) developed an interview agent which takes physiological data (skin conductance and electromyography) of users in real-time, interprets the data into emotions, and addresses the user's affective states in the form of emphatic feedback. In addition, they evaluated the agent by using SCR and heart rate. The empathic feedback has a positive effect on the interviewee's stress level while hearing the question.

As mentioned above, physiological indices are useful for estimating human internal states in interaction even when users passively interact with others. The proposed method uses physiological indices, SCR, electrocardiograms (LF/HF values), and skin temperature of fingers, to detect mental

stress, such as pleasure, excitement, and tension. The method estimates emphasizing points by using these physiological indices, as well as verbal expressions, and nonverbal responses.

We have discussed the achievements and limitations of previous work related to our objective of estimating emphasizing points for interactive decision-making. Because of the difficulty in detecting passive responses during interactions, most prior work estimated user demands and needs gradually through repetitive interactions that required active demands from users. Therefore, we propose a method that dynamically estimates emphasizing points by using physiological responses, which could detect human internal states even during a passive interaction, *in addition to* verbal expressions, and nonverbal responses. In this study, we apply the proposed method to actual interactions and experimentally evaluate whether proposals that use physiological responses are useful for participants' decision-making and for achieving satisfactory results in the interaction.

### **Dynamically estimating emphasizing points**

For our purpose, we conducted preliminary analyses to elicit useful information for dynamically estimating emphasizing points (DEEP) in human-human interaction (Ohmoto et al. 2011). As a result of the analyses of videos and physiological indices, we could suggest a method to DEEP which is explained next subsection. We proposed a method to DEEP based on the observation of human-human interaction in preliminary analyses, so, we think that the proposed method is one of methods realizing DEEP. In this section, we briefly explain the proposed method to DEEP based on verbal reactions, body movements, and physiological indices, when participants are given two proposals and asked for his/her selection and demands.

DEEP, in this paper, is applied to the situation in which many factors, including unknowns, for must be considered for decision-making. In this situation, a user interacts with a system based on DEEP and the system advises some useful proposals for user's decision-making. A proposition process in an interaction is as follows: First, the two most appropriate proposals at that point are explained from a DEEP system. After the proposition, the system asks the user what his/her demands were and which proposal is better. The DEEP system pays attention to the user's reactions and answers during the explanation and questions. The system then estimates the emphasizing points. The user repeats this process until one of the propositions satisfies the user's end goal.

### **Overview of DEEP**

The degree of emphasis for an emphasizing point is rated on a scale from zero to five. The rating is changed based on the following three factors during the explanation.

- **Verbal reactions**

Either of the two following reactions occurs.

- Listed words appear in answers or demands.

- The participant provides backchanneling phrases, which express acknowledgement, surprise, or understanding, such as “ah,” “oh,” “aha,” “I see,” and “I understand.”

- **Body movements**

The participant repeatedly nods three times or more.

- **Physiological indices**

Either of the two following responses occur (refer to (Miyata, 1998), (Lin, Omata, Hu, & Imamiya, 2005), (Iwaki et al., 2008) and (Nakazono, Hada, Ataka, Tanaka, & Nagashima, 2008)).

- SCR increases more than 10% compared to resting level.
- LF/HF value (electrocardiograph measurement) is more than 6.0.

Verbal reactions, body movements, and physiological indices, are used as criteria for determining when a new factor is discovered and should be emphasized, and for determining when a user’s degree of emphasis of a particular factor increases or decreases.

**Rules for changing estimated emphasizing points during explanation** The estimated emphasizing points are changed by the participant’s responses when a DEEP system explains the proposals.

- **Discovery of a new factor to be emphasized**

When any one of the three criteria appears during an explanation, the system decides that the factor should be slightly emphasized, and increases the degree of emphasis from zero to two. When any two or three criteria are present, the system increases the emphasis from zero to three.

- **Increasing or decreasing degree of emphasis**

When any one of the three criteria appears, the system decides that the factor should be emphasized, and increases the emphasis of the factor by one. When there are physiological reactions, but no verbal reactions, or body movements, the system decides that the factor should be emphasized less, and decreases the emphasis of the factor by one.

**Rules for changing estimated emphasizing points from active demands** The system asks whether a user has any demands. From the user’s response, the system determines what the user’s demands are and what changes there are to emphasizing points. The system uses assumed keywords in the user’s response to determine demands and changes to demands. Assumed keywords are words that express assumed emphasizing points, demands, and basic words necessary to capture demands. Words that are not expected to be included in answers are ignored.

- **Discovery of new factors to be emphasized**

When the emphasis degree of the discovered factor is zero, the system increases the degree of emphasis from zero to three.

- **Increasing or decreasing degree of emphasis**

When the emphasis of the discovered factor is greater than zero and the system decides that the factor should be increased, the system increases the degree by one. When the system decides that the emphasis of the factor should be decreased and the degree is greater than zero, the system decreases the degree by one.

**Deciding a better proposal by the user’s choice between the two proposals** Given two proposals, the system asks the user which is better. If the proposal satisfied the user’s end goal, that is the final proposal. If not, based on the answer, the system determines which proposal more satisfies the user or decides either that both proposals equally satisfy or that neither proposal is satisfactory. When the system determines that both proposals equally satisfy the user, the proposal in which the lowest skin temperature was recorded is regarded as better. When the system determines that neither proposal satisfied the user, the system does nothing.

### **Selecting the next step based on DEEP results**

According to the criteria mentioned above, changes to user’s emphasizing points are estimated after the proposals are given and data is collected from the user’s reactions and response. After the estimation, the next two proposals are selected based on the estimation results.

The next proposals are selected using a table of orthogonal arrays in advance. Orthogonal arrays are a special set of Latin squares, which can be used to estimate main effects using only a few experimental runs. From the table, the two proposals that most satisfy user’s emphasizing points are picked. When many proposals in the table can satisfy a user’s emphasizing points, the two proposals nearest to the best proposal for a user’s choice are selected. When neither proposal will satisfy the emphasizing points, the two proposals furthest from the previous proposition are selected. The distances of proposals are calculated by cosine similarity.

## **Experiment**

The purpose of this experiment was to investigate whether the DEEP method could accurately estimate emphasizing points in which many factors, including unknown factors, must be considered for decision-making. In the experiment, we used human-like virtual agents (ECAs) to strictly control the verbal and nonverbal expressions of the agent, which could affect user’s impressions of the proposals presented. The ECAs were operated by a WoZ (Wizard of Oz) interface because accurate voice recognition can be difficult. The proposed method was compared with the gradual method, which was discussed above, and is described in more detail below.

### **Task**

Participants were asked to design a mobile robot using a robot parts catalogue. Each participant interacted with an experimenter for two sessions, in which they designed a different robot that achieved different tasks. The participant could

change the design concept of the robot during the session without informing the change to the experimenter. The task had 23 criteria that the robot must meet and there were various ways to design robots that realize the same purpose. Examples purposes in Situation A were "taking photos of beautiful scenery" and "introducing old temples and shrines," while in Situation B, examples purposes were "a mountain climbing race" and "a city obstacle race."

### The gradual method compared with DEEP

We compared the DEEP method with gradual method. In the gradual method, the ECA provides the two proposals nearest to the best proposal of the user. When the user decides that neither proposal will suffice, the two proposals furthest from the last two proposals. This method only uses user's selection between the two proposals and gradually approaches a satisfactory proposal. The method does not pay attention to the dynamic changes of user's emphasizing points during the interaction. Therefore, only the user's actual choice is taken into account. This method can provide a better proposal than previous one in most cases. This is a better point than the DEEP method. This method was regarded as a modified version of work by Kurata (Kurata, 2010).

### Outline of WoZ

The experimenter entered into the system data that contained verbal reactions, body movements, and physiological indices, because we could not robustly capture this data in real-time. Each ECA generated verbal and nonverbal behavior that had been previously designed by the experimenter based on the expected reactions.

Both ECAs accepted the results of user's choice. In addition, the ECA with DEEP accepts data as was described in previous section. Verbal reactions and body movements are determined via visual observation. Physiological indices were automatically measured and the experimenter annotated which words or explanations may have triggered the physiological responses. Each ECA used the entered data to decide the proposals presented in the next proposition.

### Experimental settings

The experimental setting is shown in Figure 1. The participant sat in front of a 100-inch screen displaying the ECA. The experimenter sat out of view of the participant and entered the stimuli via a WoZ interface. Two video cameras recorded the participant's behavior; one was placed on the screen for recording the participant's behavior, and another was placed behind the participants for recording the screen. The participant's voice was recorded by microphones. Polymate was used to measure SCR, the electrocardiogram, and skin temperature of fingers. The experimenter instructed the participant to keep their left arm on an armrest.

### Participants

26 students (20 males and 6 females) participated in the experiment. They were undergraduate students from 18 to 25

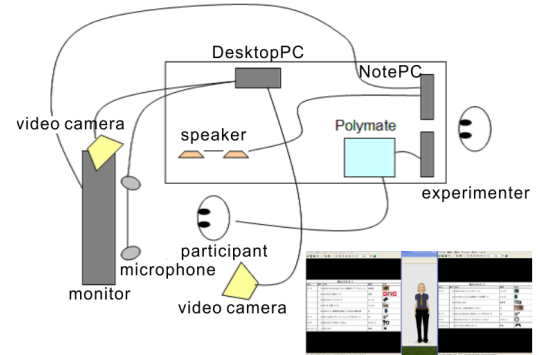

Figure 1: Experimental settings

Table 1: T-test results for accuracy in estimating emphasizing points

	proposed	gradual
average	2.1	1.0
standard deviation	0.69	1.0
t	2.49	
p	0.029*	

years old (an average of 20.6 years old). They did not know about robots but they were in science course. All of them interacted with both of ECA with DEEP and without DEEP.

### Procedure

After a brief explanation of the experiment, the experimenter began the experiment. Two sessions were conducted during the experiment. The experimenter randomly decided which ECA, DEEP or the gradual method, was used for the first session, and the other ECA was used for the second session. The participant repeatedly selected proposals provided by the ECA until he/she was satisfied his/her end goal for the robot. At the conclusion of each session, the participant completed a questionnaire regarding the ECA's evaluations.

### Results of accuracy in DEEP

We randomly picked seven participants before the experiment. These seven participants chose their top three emphasizing points out of 23 factors at the end of both session. The reason why we picked up a limited number of participants is that the choice of emphasizing points was very time consuming process because they had to understand the meanings of 23 factors and reflect on their decision-making. Therefore, we could gather a limited number of participants for the research. We then calculated concordance rates between the factors chosen by the user and the factors estimated by each ECA. We conducted a t-test to compare the concordance rates of DEEP with that of the gradual method. Results are shown in Table 1. Average values show the average number of matched factors.

Table 2: Chi-squared for the effect of method on dynamic changes

	changed	not changed
proposed	25	1
gradual	22	4
p	0.158	

Table 3: Sign-test for comparison of ECA method

	score (proposed > gradual)
average	1.0
standard deviation	1.9
p	0.013*

The results of a t-test confirmed that DEEP more accurately estimates emphasizing points than does the gradual method. We suggest that DEEP has sufficient performance for estimating emphasizing points because the average is high and the standard deviation is low. Therefore, by using verbal reactions, body movements and physiological indices, DEEP can correctly estimate the emphasizing points of each participant.

### Questionnaire results

The participants answered three rating questions on the ECA's behavior using a seven-point scale. The scale was presented as seven ticks on a black line without numbers, which we scored from -3 to +3.

Each of the three questionnaires contained two kinds of questions; one was on how much the ECA affected participant's thought ("how much" question), another was regarding which method had more affected participant's thought ("which" question).

**Changing emphasizing points and purpose of robot** Participants answered whether they dynamically changed their emphasizing points and purpose of the robot throughout the interaction ("how much" questions). We performed Chi-squared test to confirm that there was a significant difference between DEEP and the gradual method, and the results are presented in Table 2. Participants also answered which method caused more dynamic changes ("which" question); we performed sign-test to calculate the difference between the two methods, which is shown in Table 3 (when the gradual method caused most changes: -3 - when DEEP caused most changes: +3).

There is no significant difference between the "how much" scores, because both methods could cause dynamic changes during the interaction. This means that humans easily change their emphasizing points even when simple algorithms provide the proposal and explanation. Meanwhile, DEEP caused significantly more changes than did the gradual method. It is possible that participants pay attention to broader factors than contained in the mobile robot task because the proposed

Table 4: Wilcoxon signed-rank test results on user satisfaction of ECA's final proposal

	proposed	gradual
average	1.8	0.81
standard deviation	2.3	1.6
z	2.11	
p	0.035*	

Table 5: Sign-test results on which ECA provided the best proposal

	score (proposed > gradual)
average	1.1
standard deviation	2.3
p	0.038*

method was sensitive to changes in emphasizing points and modified subsequent proposals accordingly.

**Participant satisfaction of ECA's final proposal** Participants answered how satisfied they were with the ECA's final proposal ("how much" questions). The results of a Wilcoxon signed-rank test are shown in Table 4 (not at all: -3 - very much: +3). Participants also answered which method provided a more satisfactory proposal ("which" question). We performed a sign-test, and the results are shown in Table 5 (satisfy the final proposal of the ECA with gradual method: -3 - satisfy the final proposal of the ECA with DEEP: +3).

Both of Table 4 and Table 5 show that the ECA with DEEP provided a significantly more satisfactory proposal than the ECA with the gradual method. However, it is important to note that the standard deviation for the results of the ECA with DEEP in Table 4 and Table 5 are fairly large. We return to the implications of this result in the discussion.

**Naturalness of ECA's proposals** Participants answered how natural the sequence of proposals was ("how much" questions). We performed a Wilcoxon signed-rank test, and the results are shown in Table 6 (not at all: -3 - very much: +3). Participants also answered which method provided more natural proposals ("which" question). The results of a sign-test are shown in Table 7 (the ECA with gradual method provided most natural proposal: -3 - the ECA with DEEP provided most natural proposal: +3).

Both Table 6 and Table 7 show that the ECA with DEEP provided significantly more natural proposals than the ECA with gradual method. The each content of proposals were the same between the proposed method and gradual method. Therefore, naturalness must be attributed to presentation order and whether the proposals reflected their emphasizing points. The proposed method most likely provided more natural proposals because DEEP could quickly reflect changes in their emphasizing points.

Table 6: Wilcoxon signed-rank test results on naturalness of ECA proposals

	score (proposed > gradual)
average	0.89
standard deviation	1.7
p	0.027*

## Discussion

In this study, we evaluated one method for estimating emphasizing points based on verbal and nonverbal information and physiological indices. As a result, we confirmed that our proposed method improved the accuracy of estimating emphasizing points, has more latitude in changing emphasizing points, is natural, and participants are more satisfied with the final proposal. In addition, we find evidence that people often change their emphasizing points and purpose of the task during the interactive decision-making process.

The proposed method considers changes of emphasizing points. Therefore, the proposed method often provided proposals that included new combinations of factors which the participant did not specially emphasize. One participant reported "I was often surprised at the dynamic changes of the proposals." The surprise sometimes causes uncomfortable feelings so we will have to consider proposal history and provide additional explanations for the change.

The standard deviations in proposed method are relatively large. This means that the effectiveness of the proposed method is different across individuals. One of the reasons was that some participants' demands could not be satisfied by the ECA. In those cases, the ECA did not provide any notification of impossibility or alternatives. In many possible cases, the ECA with DEEP quickly responded to participants' demands, so, in some impossible cases, the participants who had impossible demands felt disappointed, as would be expected. Future work should include notification capabilities.

## Conclusion

In this study, we evaluated whether our proposed method, which estimates dynamic changes of emphasizing points based on verbal reactions, body movements, and physiological indices, is useful for interactive decision-making and for selecting a proposal that satisfies the user's end goal. For this purpose, we conducted an experiment that compared two

methods: our method and an existing method that gradually estimates emphasizing points based on participants' proposal choice. As a result, we confirmed that DEEP improved estimation accuracy, user satisfaction, and naturalness of proposals. We propose that interactive decision-making be based on estimation of emphasizing points.

One important issue that should be explored in future work is more clearly define the criteria for noting verbal and non-verbal behavior. Physiological indices are very useful for estimating internal states of human but measuring these indices may not be natural in many cases. In future work, we will try to replace physiological indices with synthetic use of some verbal and nonverbal behaviors.

## Abstract

The vowel-size relationship has been repeatedly reported: the vowels /a/ and /i/ elicit bigger/smaller images respectively. Previous studies reporting this relationship have required participants to make explicit decisions about the meaning of the target words including these vowels. In the present study, we attempted to re-examine the vowel-size relationship in two experiments using speeded classification tasks. The results of Experiment 1 indicate that participants associated the vowels with a bigger/smaller image even when they were not motivated to pronounce the vowels during the task. The results of Experiment 2 indicate that the proprioception of the absolute size of the mouth may not contribute to the vowel-size relationship. The process underpinning the vowel-size relationship is discussed.

**Keywords:** sound symbolism; vowel-size relationship; speeded classification; kinesthetic experience

## Introduction

The relationship between a word and its referent is said to be arbitrary, but many studies have reported relationships between them. This is referred to as “sound symbolism.” Among these studies, the vowel-size relationship has been repeatedly reported: the vowel /a/ is likely to make us imagine objects of bigger size whereas the vowel /i/ elicits images of smaller objects. Previous studies (e.g., Sapir, 1929; Newman, 1933; Tarte & Baritt, 1971) that reported this relationship have required participants to make explicit decisions about the meaning of target words including these vowels. For example, Sapir (1929) asked participants which table was bigger, /mal/ or /mil/, while Tarte & Baritt (1971) required participants to match CVC trigrams (e.g., /was/ or /wis/) with geometric figures of different sizes. However, these studies suffer from a weakness in the way the process underpinning the vowel-size relationship was investigated: participants had enough time to pronounce or simulate the target words during the task, which makes it difficult to determine which of the following two factors contributed to the vowel-size correspondence.

The first of these factors is the component formant frequencies of the vowels (Tarte, 1982). The second and third formants of the vowel /i/ are higher than those of the vowel /a/. Given that higher frequency sounds correspond to smaller images and lower frequency sounds correspond to bigger images (Gallace & Spence, 2006), frequencies of

vowels may explain why the vowel /a/ is likely to elicit bigger images and /i/ to elicit smaller images.

The second is the contribution of the kinesthetic experience of pronunciation (e.g., Newman, 1933). The vowel /a/ is pronounced with the mouth wide open and the tongue positioned low in the mouth. In contrast, the vowel /i/ is pronounced with the mouth slightly open, and the tongue positioned high in the mouth. Since the oral cavity is larger when pronouncing /a/ than when pronouncing /i/, the vowel /a/ is likely to elicit bigger images than the vowel /i/.

In the present study, we attempted to investigate the vowel-size relationship in a way that distinguished between these two factors. More specifically, in Experiment 1, we examined whether participants would associate the vowels /a/ and /i/ with bigger and smaller images, respectively, even when they were not motivated to pronounce the vowels during the task. In Experiment 2, we examined whether kinesthetic experience around the mouth (i.e., proprioception of the size of the oral cavity when pronouncing the vowels) on its own and without auditory experience could elicit bigger/smaller images.

To examine these problems, we used speeded classification tasks, which have been widely used in studies of cross-modal perception (e.g., Gallace & Spence, 2006). In this kind of task, participants have to discriminate between stimuli in one dimension while trying to ignore an irrelevant dimension, which enables us to see whether their response to the relevant dimension is influenced by the variation of the irrelevant dimension.

In Experiment 1, to investigate whether the vowels /a/ and /i/ elicit bigger/smaller images without the kinesthetic experience of pronunciation, we asked participants to judge the relative size of the target disk, while an irrelevant sound (the vowel /a/ or /i/) was presented simultaneously. If reaction times for judging the size of the target disk were influenced by the variation of the vowels, this would allow us to conclude that the acoustical features of vowels /a/ and /i/ elicit bigger/smaller images without kinesthetic experience.

In Experiment 2, to investigate whether the proprioception of the size of the oral cavity when pronouncing /a/ and /i/ could elicit bigger/smaller images on its own without the subject actually hearing any vowel sounds, we asked participants to judge the relative size of the target disk, while ensuring that they opened their mouths in the same way they would if pronouncing each

vowel. If reaction times for judging the size of the target disk were influenced by the variation in the way the participants opened their mouths, this would allow us to conclude that the kinesthetic experience alone elicits bigger/smaller images without auditory experience.

In the following, we will discuss the possible process underpinning the vowel-size relationship, taking both the above factors into account.

## Experiment 1

In Experiment 1, we attempted to investigate whether the vowels /a/ and /i/ elicit bigger/smaller images without the kinesthetic experience of pronunciation. In the experiment, participants were asked to judge whether a target disk was bigger or smaller than a standard disk. The target disk was presented following the standard disk. It was 10% or 20% shorter or longer in diameter compared to the standard disk. A task-irrelevant sound (/a/ or /i/) was sometimes presented simultaneously along with the presentation of the target disk. If it is the case that the vowel sounds (/a/ and /i/) elicit bigger/smaller images without the kinesthetic experience of pronunciation, the reaction times should have been shorter when the vowel-size relation is congruent (/a/ being presented when the target disk was bigger and /i/ being presented when it was smaller) than when it was incongruent.

## Method

**Participants** Thirty Japanese-speaking undergraduate students (14 males, 16 females; mean age, 22.2 years; range 20-36 years) took part in the experiment.

**Apparatus** The visual stimuli were presented on a laptop computer (Dell Inspiron 1526) with a 15.4-inch screen, or on a desktop computer (VAIO VGC-RA72P) with a 17-inch screen. Auditory stimuli were presented through headphones (Audio-Technica ATH-ANC7 or Sennheiser HDA200). The presentation of the stimuli and the recording of the participants' responses were controlled using Cedrus Superlab 4.0 software.

**Materials** The visual stimuli were the standard disk, the target disks, and the mask. The standard disk was gray and 3 cm in diameter, and the target disks were  $\pm 10\%$  and  $\pm 20\%$  of the diameter of the standard disk. The visual mask was a light-gray screen with dark-gray spray. Four different auditory stimuli were used for presentation of the vowels /a/ and /i/, respectively. The auditory stimuli were a recording of a Japanese female who had been asked to pronounce Japanese vowels. Her speech was recorded on a Roland R-09. The duration of each vowel was 300 ms. For the vowel /a/, the mean fundamental frequency was 240.3 Hz ( $SD = 2.16$  Hz), the mean first formant frequency was 780.3 Hz ( $SD = 46.1$  Hz), the mean second formant frequency was 1374.8 Hz ( $SD = 57.6$  Hz), the mean third formant frequency was 3077.5 Hz ( $SD = 241.7$  Hz), and the

mean intensity was 48.79 dB ( $SD = 2.48$  dB). For the vowel /i/, the mean fundamental frequency was 240.6 Hz ( $SD = 3.59$  Hz), the mean first formant frequency was 416.5 Hz ( $SD = 20.9$  Hz), the mean second formant frequency was 2712.3 Hz ( $SD = 67.6$  Hz), the mean third formant frequency was 3494.0 Hz ( $SD = 75.3$  Hz), and the mean intensity was 49.94 dB ( $SD = 2.43$  dB).

Figure 1: Illustration of the sequence of visual stimuli presented in each trial in Experiment 1 and 2.

**Procedure** The participants sat at a desk, 45 cm from the computer. It took about 10 minutes to complete the entire experiment.

Figure 1 illustrates the sequence of events in each trial. At the start of each trial, the word “Ready?” appeared at the center of the screen, and the participants could choose when to start by pressing the space key. At first, a fixation point was presented in the middle of the screen for 300 ms, followed by a blank white screen. After a 300-ms presentation of the blank screen, the standard disk was presented at the center for 300 ms, followed by the mask screen. The mask screen was presented for 500 ms and was followed by the target disk. The position of the target disk varied randomly (by up to  $\pm 0.3$  cm vertically and horizontally from the center of the screen) to prevent the participants from using superimposition cues to judge the relative size of the target disk. At the same time the target disk was presented, a vowel (/a/ or /i/) was presented in 20 trials for each vowel, and no sound was presented in the remaining 20 trials. The target disk was presented for 80 ms, followed by the mask screen. The mask screen stayed on the screen until the participant responded or until 3 seconds had elapsed, at which point the screen displaying the word “Ready?” appeared and the next trial was ready to begin.

The participants were asked to judge whether the target disk was bigger or smaller than the standard disk as rapidly as possible. The participants were instructed to indicate the relative size of the target disk by pushing “/” with the index finger of the right hand, or “\” with the middle finger of the right hand. Which key corresponded to “big” or “small” was counterbalanced across the participants.

Table 1: The means and standard errors of reaction times (in milliseconds) as a function of condition and size of the target disk in Experiment 1 and 2.

size	Condition					
	congruent		incongruent		control	
	RT		RT		RT	
	<i>M</i>	<i>SE</i>	<i>M</i>	<i>SE</i>	<i>M</i>	<i>SE</i>
Experiment 1						
+10%	408.7	29.6	423.9	25.8	397.9	23.7
+20%	375.6	18.2	410.2	20.2	381.3	21.9
-10%	469.8	29.4	492.8	41.0	482.3	36.6
-20%	387.5	18.6	423.1	26.7	397.5	21.6
mean	410.4	21.8	437.5	26.0	414.7	23.4
Experiment 2						
+10%	378.5	18.0	387.3	18.5	385.1	15.0
+20%	362.6	12.2	369.8	19.8	367.0	12.2
-10%	427.4	20.8	411.8	16.8	421.2	22.0
-20%	376.7	18.5	367.7	16.0	370.5	15.1
mean	386.3	15.5	384.1	15.2	385.9	14.6

The participants were informed that a task-irrelevant sound would sometimes be presented, but they were instructed to ignore it. The response times were calculated from the beginning of the second mask screen to the time of the decision. The participants completed 12 practice trials before the experiment to ensure that they clearly understood the task.

The experiment was composed of 60 trials, 15 trials for each size of the target disk ( $\pm 10\%$ ,  $\pm 20\%$ ). The order of trials was randomized for each participant. For each size of the target disk, five trials were presented with the vowel /a/, five trials were presented with /i/, and the remaining five trials were presented with no sound. Each of the trials was classified into three conditions, with 20 trials each: congruent condition (i.e., /a/ being presented when the target disk is bigger and /i/ being presented when it is smaller), incongruent condition (i.e., the opposite combination to the congruent condition), and control condition (i.e., no sound being presented along with the target disk).

## Results

The means and standard errors of reaction times as a function of the condition and size of the target disk are shown in Table 1. Because the error rate was quite low ( $M = 3.1\%$ ,  $SD = 2.9\%$ ), subsequent analysis was only performed on the reaction times.

**Reaction times** The reaction times for the wrong decision (3.1%) and above +3SD from the mean reaction times of each participant (1.2%) were excluded from the analysis.

We performed repeated measures of variance on the reaction times as a function of condition (3) and size of the target disk (4). The analysis revealed a significant main

effect of condition ( $F(2,58) = 7.08$ ,  $p = .002$ ), and a significant main effect of size of the target disk ( $F(3,87) = 10.89$ ,  $p = .001$ ),<sup>1</sup> but no significant interaction between condition and size ( $F(6,174) = .484$ ,  $p > .10$ ).<sup>1</sup>

A post hoc Bonferroni test of condition revealed significant differences between the congruent condition and the incongruent condition and between the control condition and the incongruent condition (all  $ps < .05$ ), with the slowest responses occurring in the incongruent condition. There was no significant difference between the congruent condition and the control condition. A post hoc Bonferroni test of size revealed significant differences between -10% and other sizes (all  $ps < .05$ ), with the slowest responses occurring in -10%. There were no significant differences between any pair of the remaining sizes (+10%, +20%, -20%).

In sum, reaction times were longer in the incongruent condition than in the congruent condition or control condition, and in -10% than in the other sizes.

## Discussion

In Experiment 1, we attempted to investigate whether participants would associate the vowels /a/ and /i/ with bigger and smaller images, respectively, without the kinesthetic experience of pronunciation, using a speeded classification task. The results indicate that they did. The participants responded more slowly in the incongruent condition than in the congruent condition or control condition. The vowel /a/ elicited bigger images and the vowel /i/ elicited smaller images without kinesthetic experience, which could interfere with the response of “big”

<sup>1</sup> A Greenhouse-Geisser adjustment was used to correct for violations of sphericity.

while hearing /i/ and with the response of “small” while hearing /a/. As Tarte (1982) pointed out, the component formant frequencies of vowels can explain the vowel-size relationship.

## Experiment 2

In Experiment 2, we attempted to investigate whether bigger/smaller images would be elicited only with the kinesthetic experience around the mouth when pronouncing the vowels /a/ and /i/ (i.e., the proprioception of the size of the oral cavity), without the subject actually hearing any vowel sounds, using the same task as Experiment 1. In the experiment, the participants completed the same speeded classification task with the kinesthetic experience of pronouncing vowels. We ensured that the participants opened their mouths in the same way they would if pronouncing each vowel by asking them to hold either of two types of solid object in their teeth: one was egg-shaped and the other was board-shaped. In order to hold the egg-shaped object with their teeth, participants had to open their mouth widely, and the resultant lip shape was similar to that when pronouncing the vowel /a/. On the other hand, holding the board-shaped object required participants to open their mouth slightly along the vertical axis and pull their lips sideways. This shape mimicked the lip shape when pronouncing the vowel /i/. If it is the case that the proprioception of the size of oral cavity elicits images of size without auditory experience, the reaction times should have been shorter when the participants were holding the egg-shaped object and the larger target disk was presented, and they are holding the board-shaped object and the smaller target disk was presented, compared with the opposite combinations.

## Method

**Participants** Twenty-four Japanese-speaking adults (13 males, 11 females; mean age, 26.8 years; range 22-42 years) took part in the experiment.

**Apparatus and Materials** The visual stimuli were presented on a laptop computer (Dell Inspiron 1526) with a 15.4-inch screen, controlled by Cedrus SuperLab 4.0. The visual stimuli were the same as Experiment 1. Two solid objects (egg-shaped and board-shaped) made from styrofoam were used to ensure the participants opened their mouths in the same way they would if pronouncing each vowel. The egg-shaped object was 5.5 cm in maximum diameter and 8 cm long, and the board-shaped object was 7.5 cm by 15 cm long and 0.5 cm thick. Twenty-four sets of the two objects were prepared so that each participant could use a new one.

**Procedure** As in Experiment 1, participants sat at a desk, and the experimenter instructed them to indicate the relative size of the target disk as soon as possible by pressing the keys. The sequence of the visual events in each trial was the same as Experiment 1.

The participants completed 12 practice trials before the experiment. The experiment was composed of six blocks of 72 trials, with a short break at the end of each block. Each block had 12 trials, three trials for each size of the target disk ( $\pm 10\%$ ,  $\pm 20\%$ ), and the order of the trials was randomized in each block for each participant. Six blocks were divided into three phases, which had two blocks each. In one phase, participants were instructed to open their mouth naturally, and hold the smaller side of the egg-shaped object in their teeth. In the other phase, participants were instructed to open their mouth slightly sideways, and hold the longer side of the board-shaped object in their teeth. In the remaining phase, participants were instructed to complete the task in the same way as the practice trials, i.e., to hold no object in their mouth. The order of the three phases was counterbalanced across participants. Each of the trials was classified into three conditions, 24 trials for each condition: congruent condition (i.e., the participants are holding the egg-shaped object and the larger target disk is presented, or they are holding the board-shaped object and the smaller target disk is presented, incongruent condition (i.e., the opposite combination to the congruent condition), or control condition (i.e., the participants are not holding anything when the target disk is presented).

## Results

The means and standard errors of reaction times and number of wrong decisions as a function of condition and size of the target disk are shown in Table 1. As in Experiment 1, because the error rate was quite low ( $M = 3.1\%$ ,  $SD = 2.9\%$ ), subsequent analysis was performed only on the reaction times.

**Reaction times** As in Experiment 1, the reaction times for the wrong decision (3.1%) and above +3SD from the mean reaction times of each participant (1.2%) were excluded from the analysis.

We performed repeated measures of variance on the reaction times as a function of condition (3) and size of the target disk (4). The analysis revealed a significant main effect of size of the target disk ( $F(3,69) = 14.8$ ,  $p < .001$ ),<sup>1</sup> but no significant main effect of condition ( $F(2,46) = .05$ ,  $p > .10$ ),<sup>1</sup> and no significant interaction between condition and size ( $F(6,138) = .438$ ,  $p > .10$ ).<sup>1</sup> A post hoc Bonferroni test of size revealed significant differences between -10% and the other sizes (all  $ps < .01$ ) with the slowest responses occurring in -10%, and a marginally significant difference between +10% and +20% with slower responses in +10% ( $p = .08$ ).

These results indicate that the condition did not affect the reaction times, although the size of the target disk affected them as in Experiment 1.

## Discussion

In Experiment 2, we attempted to investigate whether the proprioception of the size of the oral cavity could elicit

bigger/smaller images on its own without the subject actually hearing any vowel sounds, using the same task as Experiment 1. The reaction times did not differ significantly between in the congruent condition and in the incongruent condition. The results indicate that the proprioception of the size of oral cavity when pronouncing /a/ and /i/ may not, on its own, elicit the image of bigger/smaller sizes. However, it should be pointed out that in this experiment we controlled the absolute size of the oral cavity, in other words, we investigated the effect of the *static* kinesthetic experience of pronunciation. It is possible that the *dynamic* kinesthetic experience of pronunciation, that is, the temporal change of the relative size of the mouth, plays an important role in eliciting the image of bigger/smaller sizes.

It is also worth noting that the lack of uncertainty about the variation of stimuli in the irrelevant dimension may have weakened the effect of treatment (Gallace & Spence, 2006). In Experiment 1, there was an uncertainty about the variation of stimuli in the irrelevant dimension, induced by trial-by-trial variation. In contrast, in Experiment 2, the stimuli in the irrelevant dimension were fixed during each of the blocks.

In sum, the results in Experiment 2 indicate that the static kinesthetic experience (i.e., the proprioception of the absolute size of oral cavity) may not contribute to the vowel-size relationship, although it is possible that the dynamic kinesthetic experience could contribute to it. In addition, the lack of uncertainty about the variation of the irrelevant dimension may have weakened the effect of treatment.

## General Discussion

In the present study, we attempted to re-examine the vowel-size relationship in a way that distinguished between two possible factors, formant frequencies of the vowels (Experiment 1) and kinesthetic experience while pronouncing the vowels (Experiment 2), using the speeded classification paradigm.

The results of Experiment 1 indicate that the component formant frequencies of vowels on their own can explain the vowel-size relationship, and the results of Experiment 2 indicate that the static kinesthetic experience (proprioception of the absolute size of oral cavity) may not contribute to the vowel-size relationship.

However, in the results of Experiment 2, the possibility remains that the dynamic kinesthetic experience (the temporal change of the relative size of the mouth) might have elicited bigger/smaller images and had an influence on the results. Furthermore, we cannot completely eliminate the possibility that the dynamic kinesthetic experience may have affected the results of Experiment 1 from the viewpoint of motor theory (e.g., Liberman & Mattingly, 1985), which understands the perception of speech as vocal tract gestures. From this viewpoint, the dynamic kinesthetic experience automatically generated from hearing vowels may have affected the judgments of size, and supported the results of Experiment 1.

Taking the above into account, the vowel-size relationship can be mainly explained by the component formant frequencies and the static kinesthetic experience may not contribute to it, but the dynamic kinesthetic experience of pronunciation may play some role. Further research is needed to evaluate the role of component formant frequencies more exactly by controlling the kinesthetic experience more rigidly, and to investigate the role of the dynamic kinesthetic experience of pronunciation.

## Abstract

We explain the current version of a conceptual dictionary containing two hierarchies of verb concepts and noun concepts to be functioned in our narrative generation system. It is used for operating naturalness or validity of generated events and realizing or adjusting the intentional defamiliarization. Namely, this dictionary is a mechanism to be able to flexibly adjust a variety of generation from realistic narratives to fantastical narratives as well as the foundation for a narrative event and the elements. In the current version, verb concept dictionary has originally defined 5338 case frames and modified 1158 constraints and noun concept dictionary contains 121573 concepts including 5808 intermediate concepts.

**Keywords:** Narrative generation system; conceptual dictionary; verb/noun concept hierarchy; case frame; constraint.

## Introduction

This paper explains the development of a conceptual dictionary or hierarchical systems of concepts in the narrative generation system framework which is our main research theme. A basic unit for a narrative in the system is an event concept containing a verb concept and noun concepts and the information of these concepts is held in the conceptual dictionary. It is one of the central components in the system.

Narrative is the strongest method for organizing fragmentary knowledge human being has. We have been developing a narrative generation system as an intelligence tool for the creation of future literature & narrative (Ogata & Kanai, 2010). For digital art and entertainment such as computer game, perhaps narrative and story can become an important element in the same manner as traditional genres. Our research of narrative generation is done for the application to novel contents such as computer game and narrative generation based narrative or literature.

As a related work, Okada and Endo (1992) proposed a system to generate stories like Aesop fables. A story generated is a kind of simulation of the process that a main character or actor plots a sequence of planning actions. In contrast, our narrative generation system architecture is constructed as an organic

fusion of diverse narrative knowledge and techniques including planning, discourse structure, story grammar, script, discourse relation, and so on. Although the Aesop system has a feature as an application of conceptual dictionary research, our goal of the narrative generation system is pursuing the mechanism of narrative generation itself. Our extreme purpose is not developing conceptual dictionary itself, but creating narrative generation system. Therefore, a basic policy here is to use existing dictionaries as possible to customize and expand them according to the architecture and mechanism.

As a narrative generation study, Oz project (Bates, 1992) attempted the development of an interactive drama with dialogue and actions in autonomous agents. This system mainly focuses on the interactive techniques for the user's narrative experiments. In contrast, our system contains a variety of narrative and linguistic knowledge for generating deep and conceptual narrative structures. On the other hand, BRUTUS (Bringsjord & Ferrucci, 2000) is an interactive narrative generation architecture which has an integrative feature including story grammar, planning, and so on. However, it deals with only a specialized narrative theme, "betrayal". Whereas, we are intend to develop a more general mechanism for various types of narratives.

The goal of this paper is the proposition of a conceptual dictionary in the narrative generation system architecture we have been developing. The conceptual dictionary has two components of verb concept dictionary and noun concept dictionary and each system has a hierarchical structure based on single inheritance. A main issue in the development of conceptual dictionary is currently defining constraints, which means the knowledge for deciding the range of value for each case in an event as a basic unit in a narrative. A constraint is described in a verb concept and prescribes the possible range of noun concepts. In this paper, we describe the whole structure and some detailed parts of the conceptual dictionary by especially putting a focus on the description and role of constraints. Although this paper uses existing studies of conceptual dictionaries as a reference, in the combination with the domain of narrative generation system, a variety of novel and difficult issues emerges. For

example, realistic narratives and fantastical narratives respectively need different widths of conceptual constraint. This issue is directly treated in other papers (Zhang, Ono & Ogata, 2011, 2012). A characteristic of this study is an exploratory approach through the incremental system development, and it is hoped that models and theories progress through the repetition of design-implementation-experiment. The proposed conceptual dictionary in this paper provides a foundation for such incremental process toward more principled modeling.

## Narrative Generation and Conceptual Dictionary

In the macro design, the architecture of narrative generation system consists of conceptual generation phase and surface representation phase by natural language, visual media, and music. The former is divided into story as the narrative content to be narrated and discourse as the structure that a story is narrated. According to this framework, we have been developing various mechanisms and modules independently of each other. Currently, we are advancing the developing of an integrated narrative generation system in which a variety of modules are organically blended into a whole. The goal of this system is to execute the generation of narrative structures in some levels such as story, discourse, and surface representations in a unified method. Story and discourse are represented in formally same a tree structure description form. Each leaf node in the structure is corresponding to an event or state and each intermediate node is corresponding to a relation combining the child nodes including events, states, and the sub-structure. An event as a unit of conceptual representation is the most fundamental element of story and discourse. It is described in the form of case frame which is linked to a verb concept and some noun concepts in the conceptual dictionary. When story or discourse generation mechanism generates an event concept, the conceptual dictionary provides or constraints the semantic elements. A case frame for a verb concept is created and a constraint in the verb concept combining with noun concepts decides the semantic range of each noun concept in the case frame.

The proposed conceptual dictionary is actually positioned in a pilot version of integrated narrative generation system (Akimoto & Ogata, 2011b). It is implemented by Common Lisp with about 800 functions. The main macro modules are control mechanism, conceptual generation module, and surface representation module. The control mechanism calls each module according to a set of parameters as the goal of generation to automatically execute a generation process from story to expression. The conceptual generation module contains next modules to generate or transform narrative conceptual structure: a story generation mechanism including a single event generation mechanism using rhetorical techniques (Zhang, Ono & Ogata, 2011, 2012), a state-event transformation mechanism (Onodera & Ogata, 2012), an events sequence generation mechanism by story grammar based on Propp's narratology (Propp, 1969; Imabuchi & Ogata, 2011), and a discourse mechanism containing 13 kinds of narrative discourse techniques redefined Genette's narrative discourse theory (Genette, 1972; Akimoto & Ogata, 2011a). The surface representation mechanism consists of a sentence generation mechanism, an animated movie generation mechanism (Ogata, 2008), and a cyclical mutual transformation mechanism between conceptual narrative and music (Ogata, Akimoto & Seito, 2011).

Our narrative generation project is a longitudinal and exploratory study, and we have been employing both top-down approach relevant to the system's macro design and bottom-up one programming various modules in parallel. Although the above system is a kind of "bricolage" in the current state, the conceptual dictionary plays an important role in an organized integration of some modules developed independently. The standardizing of an event form and the reference of a common conceptual dictionary by various modules enables the combination as a whole narrative generation system. This is the most fundamental role of the conceptual dictionary and advanced topics of research for upgrading narrative generation emerge on the ground.

## The Structure of Conceptual Dictionary

As described above, the basic unit of a narrative is an event or an event concept described as a conceptual representation. A story and a discourse are represented as each tree structure (Figure 1). Each terminal node is corresponding to an event and each intermediate node is a relation for binding some the lower nodes. Each event is represented as a case frame with a verb concept and some noun concepts. We prepare next eight cases: agent (an subject in an action), counter-agent (an object in an action and a living thing), object (an object in an action and a no living thing), instrument (an tool used in an action), location (a place of an action), time (a pair of starting time and ending time of an action), from (a starting place of an action), and to (an ending place of an action). In addition, we prepare seven kinds of optional cases for treating such concepts which are not able to describe using above cases (Table 2).

The conceptual dictionary performs as a background for each event in narrative generation. It is divided into verb concept hierarchy and noun concept hierarchy. Both have a hierarchical structure based on is-a relations by the mechanism of single inheritance. A verb concept defines one or more case frames which become the templates of the event concept(s). In addition, it has the description of constraint condition (simply constraint) for limiting the range of each case's value. A constraint is defined by one or more noun concepts in noun concept hierarchy and means the range that an element in each case contained in a verb concept can refer inside the noun conceptual hierarchy. The current version of verb concept hierarchy has 5338 case frames and 4881 constraints. On the other hand, current noun concept hierarchy contains 121573 noun concepts including 5808 intermediate concepts.

In a verb concept, if noun concepts inside the range of constraint are used, a natural and possible event like "A knight fight an enemy" is formed. But, if noun concepts outside the range are used, an unnatural and impossible event like "A knight fight a windmill" is created. We show another example. In an event concept (eat (agent old-person) (object rice-ball)) ("an old-person eats a rice-ball"), when (eat (agent N1) (object N2)) is defined as the case frame corresponding to "eat" and the noun concept "food" is defined as the constraint of N2, the

Figure 1: An example of narrative conceptual structure

noun concept to inserted into N2 is the subordinate concept of “food” in the noun concept hierarchy. Therefore, we can confirm that this event concept is constructed inside the constraint.

By the way, fantastical events or physically impossible ones appear in narratives normally. One of concerns for us in our narrative generation project is to be able to flexibly generate from more realistic narratives or events sequences to more fantastical ones. Although the objective of this paper does not discuss the topic, it has been treated in the study of advertising scenario generation system as an application of the narrative generation system in our group (for details, Zhang, Ono & Ogata, 2011, 2012). One of main objectives of this research is to adjust the semantic range in a single event using the concept and techniques of “defamiliarization”. Its idea was acquired from a rhetorical analysis of actual television commercial films. The analysis defined three types of standard rhetoric, which are for generating events corresponding to ordinary events, and nine types of irregular rhetoric, which are for generating events corresponding to extraordinary events. We call twelve types of rhetoric “product introduction rhetoric (or technique)”. In advertising narratives, events with a product are represented through the rhetoric. The former types of rhetoric draw the processes of “manufacturing”, “purchasing”, and “usage” of a product. In contrast, the latter types of rhetoric perform a kind of deviance by techniques of defamiliarization for “the actor’s action”, “the state of product”, “the background or place”, “the actor himself (herself)”, and so on. Defamiliarization means a literary technique for changing a familiar object into unfamiliar one to reinforce the impression. For example, the impression of a familiar product is reinforced by the application of defamiliarization techniques to the objects and agents. This idea will be able to generalize to narratives other than the advertising narrative.

We show the overview of the processing flow. First, user selects a product name from a products list prepared by the developer and the number (1-3) of a type of standard rhetoric. Based on the information, the system generates an ordinary event by acquiring a verb concept and some noun concepts within the standard rhetoric for the product. These concepts are prepared according to each product. Next, when the user designates an irregular rhetoric, the system rewrites the ordinary event to an irregular or extraordinary event by applying the corresponding rhetorical technique. Conceptual dictionary is used in the application of irregular rhetoric. Specifically, the system replaces an original concept in the target event with another concept in the different category by changing the reference region in the noun concept hierarchy. For example, to generate an event with a product “car” according to “the defamiliarization of location” rhetoric, first, the system generates an event like “(drive (agent woman) (instrument car) (location plateau))” using a noun concept “car” inside the constraint. Next, the system replaces a noun concept corresponding to the location with another concept outside the constraint using the defamiliarization processing to generate an event at the strange place like “(drive (agent woman) (instrument car) (location seabed))”. The condition of this processing is that the constraint in regular rhetoric is limited in the actual range. In this research, the conceptual dictionary basically defines the standard semantic range for each noun concept in an event from the viewpoint of actual possibility or physical possibility principally. On the other hand, extraordinary or irregular events are constructed by several types of defamiliarization rhetoric based on a kind of

constraint relaxation. Although a weak point of the current version is that the defamiliarization techniques are randomly applied, we succeeded at the experimental implementation of a simple framework of defamiliarization processing using the conceptual dictionary.

In addition, a story generation system by McIntyre and Lapata (2009) generates stories by using a knowledge base about compositions of an event sentence and chains of events extracted from a narrative corpus based on co-occurrence of words. Stories are generated by a kind of tree search of possible stories. Here, the system has several scoring criteria for pruning low scored branches that are strength of connection of words in an event and words between adjacent events, interestingness, and coherence.

## Existing Conceptual Dictionaries

Table 1 compares existing Japanese conceptual dictionaries. “Goi-Taikei, A Japanese Lexicon” (Ikehara et al., 1999) is the largest scale Japanese lexical and conceptual dictionary for Japanese-to-English machine translation, which hierarchically organizes semantic attributes based on single inheritance. We mainly referred to it as a starting point to construct the overall structures of two hierarchies. The lexicon is basically a lexical dictionary, and because the definition of constraints and the granularity of noun concepts’ categories are too rough to directly use in the narrative generation system, we considerably refined their organizations and uniquely added case frames for verb concepts. Especially, for the purpose of complementing the shortage of intermediate concepts in the noun conceptual hierarchy to a large degree, we referred to “Japanese WordNet” (Bond et al., 2009). Although we used only Japanese lexicon and Japanese conceptual dictionaries as a reference, narrative has an aspect which transcends linguistic difference and we also need to them.

## A Verb Concept Hierarchy

Figure 2 shows the overall structure of verb concept hierarchy. Although the Japanese lexicon contains about 12000 verb concepts under 36 categories, the current version of our verb concept hierarchy contains 4260 verb concepts in 6 categories to represent physical state changes (“physical transfer”, “possessive transfer”, “change of attribute”, “change of body”, “body motion”, and “generation”). A verb concept defines a sentence pattern (“A Japanese Lexicon” contains about 12000 sentence patterns), which is the template for a sentence that takes a verb as the predicate, one or more sets of case frames, the constraints, and the superordinate concept (by an “is-a” relation). The number of case frames is 5338 for 4260 verb concepts.

In Figure 3, we show the form by an example of a verb concept’s description by Common Lisp. The information relating to a verb concept is stored into a variable. In this example, next information is stored into the variable: (1) A corresponding sentence pattern; (“N1 eat N2”), (2) Two case frames; (“(eat(2) (agent N1) (counter-agent N2))” and “(eat(2) (agent N1) (object N2))” (“(2)” means the second meaning of “eat” covering some meanings), (3) Constraints for each case, and (4) the information that the superordinate concept is a verb concept category (“body motion”).

## Defining Case Frames

In the description of a case frame, we decided adequate cases corresponding to respectively a noun concept based on the

Table 1: Existing conceptual dictionaries

	<b>EDR Electronic Dictionary</b> (National Institute of Information and Communications Technology, 2001)	<b>Japanese WordNet</b> (Bond et al., 2009)	<b>Goi-Taikei, A Japanese Lexicon</b> (Ikehara et al., 1999)
<b>Number of concepts</b>	About 410,000	57,238	About 3,000
<b>Number of words</b>	About 270,000	93,834	About 300,000
<b>Structure of concept hierarchy</b>	Multiple inheritance	Multiple inheritance	Single inheritance
<b>Feature</b>	Bilingual dictionary, collocation dictionary, corpus, etc. are recorded.	The words are divided into group by synonym (synset).	About 12000 sentence patterns corresponding to the meaning of verb concept are recorded.

sentence pattern and the constraints. We show an example of the definition based on a sentence pattern, “N1 eat N2”. The constraints of N1 and N2 are respectively “(human, animal)” and “(food, life)”. This means that N1 takes the subordinate concepts of “human” or “animal” and N2 takes the subordinate concepts of “food” or “life”. In the N2, we distinguish “a living thing” from “a nonliving thing” and define two types of case frames, “(eat(2) (agent N1) (object N2))” and “(eat(2) (agent N1) (counter-agent N2))”. Here, the constraints of N1 in two frames are “human” and “animal”. However, in the N2, the constraints of two frames are respectively “food” and “life”. As mentioned above, a verb concept sometimes holds some different case frames.

Currently, case frames for 174 verb concepts are not defined because it is difficult to find an adequate case for a noun

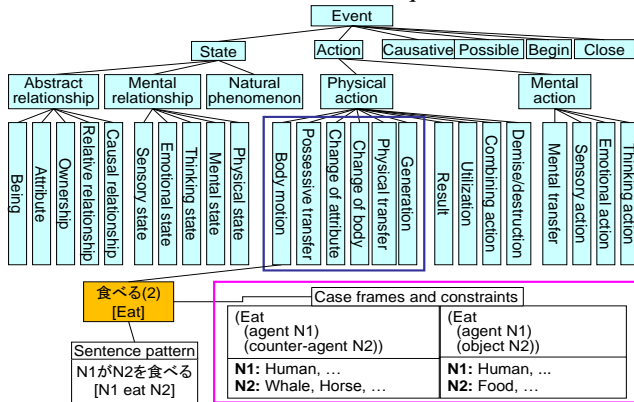

Figure 2: The overall structure of verb concept hierarchy

“飲料・たばこ<drink・cigarette>”))))
(is-a (身体動作<Body motion>))))

Figure 3: The description of a verb concept

concept within the current cases. Such noun concepts are categorized into following seven types: “adverbial concept”, “possessive case”, “event”, “purpose of action”, “experiencer”, “target of comparison”, and “idiom”. We show an example of “purpose”. In a verb concept, “go(3)”, the sentence pattern is “N1 go to N3 from N2 for N4” and the constraint of N4 is “(abstraction)” which shows the purpose of “go”. For instance, “a man goes to a mountain from a house for mowing”. If we interpret it as “to”, we can not distinguish N4 from N3 (“(place, field)”). Table 2 set straight above seven cases to be expanded and the relevant studies. Okada (1991) and Takeuchi (2011) show other case frames. The former uses ten types of cases. And, the latter uses 71 types of cases to represent the argument structure of verbs which defines the relationship between a verb and nouns in a sentence. Because the description of case frames by the reference may become too long and complex, we tentatively describe seven types of case frames with “optional” sign.

In addition, for example, FrameNet (Fillmore & Baker, 2010) and Japanese FrameNet (Ohara, 2008) define the semantics of a word by a semantic frame, which means the structured knowledge about a typical scene, constructed with the frame elements. And, VerbNet (Kipper-Schuler, Dang, & Palmer, 2000; Kipper-Schuler, 2005) is a hierarchical verb lexicon in which each class is described by semantic predicates, thematic roles, and basic syntactic frames. Their resources and above Takeuchi (2011) are advanced semantic knowledge to deal with the complex narrative knowledge unit. In the modular approach of our narrative generation system architecture, a common and a large amount of conceptual dictionary treats the semantic knowledge which has a comparatively simple structure and other mechanisms handle more complex semantic processing. For example, Onodera and Ogata (2012) resolve an action into two states and the relations to generate sequences of states which form a basis of a story. The above resources are more directly related to the part of such complex semantic processing.

## Editing Constraints

The result of a previous evaluation and consideration shows that if we adopt “actual naturalness” as the criterion, the definition of constraints become too difficult or ambiguous (Oishi & Ogata, 2011). So, as a basic policy, we define constraints in the range of physical possibility (in our daily life in common sense). We think this criterion is comparatively clear though it may actually contain difficult problems. In addition, constraints contained in “A Japanese Lexicon” have originally the purpose and role of conflict resolution for Japanese-English translation. For the context of narrative generation, they are too wide to adequately limit the semantic range for each noun concept to be generated. For example, in the case of “eat(2)”, the subordinate concepts of a constraint “food” corresponding to the N2 contain inadequate concepts such as “drink”. And, the subordinate hierarchy of “life” also contains “the animal on a legend”. One of primary purposes of the extension of hierarchy is to avoid such ambiguity and inaccuracy.

The method is divided into two parts. First is by hyponymy concepts and “furniture” is substituted with “chair” and “bed”. Second is by the partial exclusion of hyponymy concepts and “dead person” is excluded from “human” using a minus sign such as “-dead person”. Oishi and Ogata (2011) have modified 300 constraints by the methods. For noun concepts defined as constraints of all terms in these case frames, we investigated

Table 2: Towards the expansion of deep case definition

problem	example of sentence pattern	Okada (1991)	Takeuchi (2011)	New case
1) adverbial concept	N1がN2をN3にN4縮める (N1 shorten N2 by N4 to N3)	OC: complement of attribute	numeral / correspond to adverb	Adverb
2) possessive case	N1がN2のN3にへ 潜る (N1 go under N2)			Possessive
3) event	N1がN2をN3で 破る (N1 beat N2 at/in N3)		situation	Situation
4) purpose of action	N1がN2からよりN3へ/にまでN4に 出かける (N1 go to N3 from N2 for N4)		purpose	Purpose
5) experiencer	N1がN2に 疲れる (N1 get tired of N2)		experiencer	Experiencer
6) target of comparison	N1がN2をN3の 倍にする (N1 make N2 twice as much as N3)	OS: souse		Souse
7) idiom	N1はN2(を)がN3から 遠のく (N1 go to N3 less frequently)		usage	Ideom

the subordinate concepts and edit them according to the methods. For instance, for the constraints of N3 in “N1 return to N3 from N2”, we extended the original constraints “(location place building)” to “(lodging housing area -area(scope) -area(human\_activity) -land -world foot\_of\_mountain mountain\_pass valley ground island/cape shore -bank farm site point\_of\_compass edge distance house(body)[housing])”. However, this work spent a lot of time.

To improve the work efficiently and organically, we prepared a lot of “sets” that describe a group of constraints to be used commonly in similar plural case frames. For instance, a common set can be applied to the case frames consisting of a place a person can sit down and the set can be used to the opposite concepts such as “stand up” too. Specifically, to a set of noun concepts used as constraints, we give a name that the set means as a whole to apply it to the constraints for other case frames. For example, we give a name, “inhabitable location” to a set of constraints, “(lodging housing area -area(scope) -area(human\_activity) -land -world foot\_of\_mountain mountain\_pass valley ground island/cape shore -bank farm site point\_of\_compass edge distance house(body)[housing])”. The set of noun concepts is commonly used for the constraint of N2 in other events like “N1 move to/into N2”, and so on.

In this time, we extracted 26 kinds of sets from the modified constraints in 300 case frames and applied the sets to other 5037 case frames. As a result, we could apply the sets to one or more elements in 4581 case frames. The number of cases that are adequate sets to all elements was 1158. For example, in “N1 take out N2 from N3”, we could apply a set, “a person of such age who can take care by herself or himself” to N1 and “transportable object” to N2.

## A Noun Concept Hierarchy

Figure 4 is the overall structure of noun conceptual hierarchy. The current version contains 5808 intermediate concepts and 115765 terminal concepts. Many of the higher level concepts are based on the information registered in “general semantic attributes system (hierarchy) for nouns” in “A Japanese Lexicon”. On the other hand, the hierarchy of lower intermediate concepts is basically organized referring to “Japanese WordNet”. The terminal concepts are based on the words in the Japanese lexicon.

Next Figure 5 is the format for describing the noun concept hierarchy and the actual example by Common Lisp. The upper list means the serial number showing registered intermediate concepts, and variables into which the information for each intermediate concept is stored. An intermediate concept has a list of hyponymy concepts, a number of the depth in hierarchy, the serial number of the superordinate concepts, and the range of serial numbers of the hyponymy concepts. In the example,

“(seal sea-lion fur-seal sea-animal dugong bakushia)” is defined as the subordinate concepts of “sea-animal”.

The method of constructing the noun conceptual hierarchy is as follows. The referred Japanese lexicon contains 141870 words in 2710 attributes in “general semantic attributes system (hierarchy) for nouns”. Here, each attribute is corresponding to a concept in our conceptual dictionary. These words have homonyms like “狸” (“tanuki” in Kanji) and “タヌキ” (“tanuki” in Katakana), which means commonly “raccoon dog” in Japanese. In the narrative generation system, we divide the generation process into a conceptual level to make a narrative content and a surface representation level to make the variations by language and other representation media. The former uses a conceptual dictionary and the latter uses a language dictionary. To realize the mechanism, after we integrated two or more homonymous words into a single concept, we viewed all words as concepts to store 115765 concepts into the noun concept hierarchy.

In addition, to be able to set more detailed and elaborated constraints, we added intermediate concepts and refined the classification referring to “Japanese WordNet”. In the step that we integrated homonymous words into a single concept to register them as concepts, many terminal concepts were directly combined with the intermediate concepts. For example, “seal” and “raccoon-dog” are respectively the subordinate concepts of “beast”, and more detailed categories do not exist. If we want to define “aquatic mammal” as a constraint, we have to list all the terminal concepts. On the other hand, in “Japanese WordNet”, the concept of “aquatic mammal” exists as a subordinate category of “aquatic mammal”. Therefore, we added an

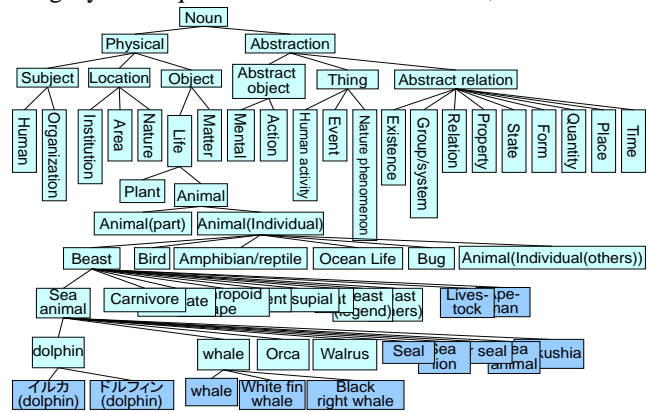

Figure 4: The overall structure of the noun concept hierarchy

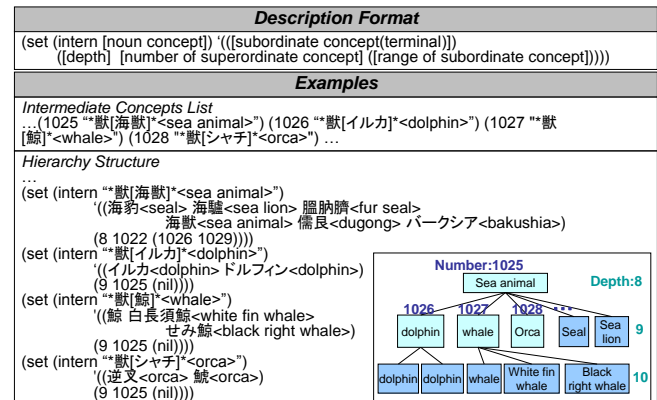

Figure 5: The format and an example of noun concept hierarchy

intermediate concept, “sea-animal”, under “beast”, and moved “seal” and “sea-lion” to the subordinate category.

### A Tentative Evaluation

For the concepts that constraint sets are applied, we attempted a confirmation of the validity of the constraints and the classification of noun concepts regarding to the constraints. The criterion is whether physically possible events can be generated by each constraint. For example, we determine that such event as “A salesgirl divorces her husband” is possible. In contrast, such event as “A spokesman is sailing on the paper” is impossible.

We prepared an experimental event generation program which selects a noun concept in the noun concept hierarchy for each case in the case frame at random according to the constraint. And, we generated 20 events by 100 case frames selected at random from 1158 case frames that all constraints were set. Three evaluators checked the generated 2000 events according to the criterion of possible/impossible. As a result, if 14/20 or more events were “physically possible”, we decided that the constraints in the case frame were comparatively adequate. When the results in the evaluators were different, we employed the result of majority. The success was 70 and the failure was 30. For 12 in the 30 failures, we could modify them by applying another set of constraint. For example, in the case of “N1 collect N2 from N3”, we may replace the set of “N2:object” from “goods, status, and notion to be able to send” to “goods to be able to send”. For the 15, we modified the constraints themselves. For example, in the case of “N1 sail N2”, we changed the constraint of “N2:location” to “(river waterway lake sea)” from “(river waterway lake sea sky)” which is corresponding to a set, “the place to be able to pass with ship and aircraft”. Other two ones are the description errors in case frames. Remaining 1 problem is the case that the verb concept itself is impossible like “N1 cast a spell on N2”. By applying the above criterion of evaluation, the difference of feelings by evaluators and the ambiguity of evaluation diminished more than previous criterion, natural/unnatural. This brings the simplicity of system development. However, there is also the difficulty that possible but ordinarily unnatural events can not be eliminated. Because it is difficult that the conceptual dictionary absorbs this sort of contextual knowledge, the solving needs to be given in the relation with the above-mentioned defamiliarization rhetoric. We are considering a basic framework that the conceptual dictionary gives comparatively simple and standard conceptual knowledge and a variety of narrative knowledge such as the defamiliarization operates and adjust more complex and advanced literary or artistic rhetorical techniques.

### Conclusions

We explained the current version of a conceptual dictionary containing two hierarchies of verb concepts and noun concepts to be functioned in our narrative generation system. It is used for operating naturalness or validity of generated events and realizing or adjusting the intentional defamiliarization. Namely, this dictionary is a mechanism to be able to flexibly adjust a variety of generation from realistic narratives to fantastical narratives as well as the foundation for a narrative event and the elements. In the current version, verb concept dictionary has originally defined 5338 case frames and modified 1158 constraints and noun concept dictionary contains 121573 concepts including 5808 intermediate concepts.

## Abstract

Elicited imitation (EI) is a testing method for learners' oral language proficiency. One common criticism aimed at EI is that performance might not require linguistic knowledge, but mere rote memorization. This study explores the issue by administering two tests to the same group of students studying English as a second language: (1) a working memory test, and (2) an English EI test. Participants came from a range of English language proficiency levels. Our goal was to test whether scores from these two treatments (English EI scores and working memory scores) would correlate significantly. If not, this would suggest that there is some difference in what they measure. The results did fail to show a significant correlation between working memory and English EI scores. On the other hand, there was a significantly positive correlation between students' English EI scores and their placement level.

**Keywords:** working memory; elicited imitation; oral language testing; explicit/implicit linguistic knowledge

## Introduction

Numerous methods exist for assessing language competence, ranging from written grammar examinations to live interviews with a native speaker. Some discussion revolves around the different types of tests: what they actually measure, and whether they directly assess linguistic knowledge and ability versus some other capability. One such testing method is commonly referred to as *elicited imitation* (EI). EI is a testing method in which researchers present a series of sentences to a person who then imitates each sentence by repeating it as accurately as possible. These responses are recorded and subsequently analyzed. Since 1967 EI has been used in linguistic research, particularly for studying language acquisition (Slobin & Welsh, 1973). Many have further proposed that EI tests can assist in measuring language ability (Connell & Myles-Zitzer, 1982; Vinther, 2002; Erlam, 2006). Others have argued (Hamayan, Saegert, & Larudee, 1977) that EI cannot measure language ability, and that listeners can simply repeat what they hear, without involving any linguistic processing. Such arguments claim that a person could repeat the utterance without understanding what it means, and without having any ability in that language. In this paper we report on a study meant to contribute more human performance data to this debate.

Addressing the issue of whether or not EI test-takers rely solely on rote repetition in responses requires some consideration of memory. We assume here an admittedly simple but traditional tripartite view of memory: long-term, short-term, and working memory (Cowan, 1996). Furthermore,

we will focus on only the third component, working memory (WM). WM contains the information held momentarily, as it is needed to analyze, solve a problem, or perform a task.

Working memory is the part of memory that would determine whether high performance levels on EI tests are a result of mere parroting or whether linguistic knowledge and competency are also needed. An EI test-taker who did not know English would have to hear the stimulus utterance, retain it in WM, and then repeat the utterance exactly to get a perfect score on the item. If the item were beyond their WM capacity, they would be expected to get only part of it correct at best, all of it wrong at worst.

Clearly WM and second-language (L2) ability are not completely independent. Some WM capacity is necessary to even be able to respond in an EI test (Doughty & Long, 2003; Robinson, 2005); some WM capacity is also necessary in all analytical and linguistic tasks. In this paper we probe the degree of overlap between them with two EI tests, one targeting English ability and the other WM capacity.

## Background: WM, language, and EI

Early research in working memory includes Miller's famous discussion of *immediate memory span* positing a "magic number" of  $7 \pm 2$  (Miller, 1956), meaning that a person could generally hold up to seven completely unrelated items in mind simultaneously. Several researchers have subsequently advocated the number  $4 \pm 1$  instead as the relevant metric defining the scope of average WM capacity (Cowan, 2001). Miller also introduced the process of *recoding* now more commonly referred to as *chunking*. Chunking takes multiple separate items and agglomerates them into patterns, reducing the number of items to remember and speeding up processing.

Another thread of research has sought to differentiate WM, which is highly evanescent, from other types of memory that are longer-lasting. For example, Baddeley and Hitch (1986) experimented to see if storing several numbers in working memory affected the ability to carry out comprehension tasks. It did not, suggesting that memory is stored in a different "place" from where processing and problem-solving occur, as one did not impede the other. A distinction is typically drawn between WM and short-term memory (STM): the latter is a form of memory that lasts for up to 10-30 seconds after one receives a stimulus (Cowan, 1996). Discussions of how language interacts with WM and STM also involve the articulatory loop, a time-constrained buffer that temporarily

stores information when comprehending and producing language. Issues of activation, decay, and interference all complicate and enrich investigation of these areas; to the extent possible we will abstract away from or simplify these factors in the work reported in this paper.

STM involvement in conversational language includes managing spontaneity, multiple interlocutors, conversational turn-taking, contextual factors, meta-awareness, and explicit language knowledge. Evaluating L2 conversational speech abilities typically involves oral proficiency interviews (OPI's) (Lehman & Tompkins, 1998) which are costly and challenging to grade since it involves skilled human interlocutors.

Our study differs from natural speech in that spontaneity does not occur, as it would in a traditional OPI. In an EI test, as opposed to natural conversation, there is a response, but it is imitative rather than a spontaneous utterance invented by the individual. STM is what holds the stimulus information when the response is being planned (Cowan, 1996).

Language acquisition researchers distinguish between *acquisition* and *learning*. Acquisition is done intuitively, similar to a child developing her native language abilities (Krashen, 1982). Competence, the result of acquisition, is also subconscious: we are generally not consciously aware of the grammatical rules of the languages we have acquired. Instead, we have a "feel" for correctness, and errors do not "sound" or "feel" right, even if we do not consciously know what rule was violated. Krashen associates language acquisition with *implicit learning*.

On the other hand, Krashen defines *language learning* as a conscious awareness of grammar, vocabulary, syntax, etc., and refers to this as *explicit learning* (Krashen, 1982). Ellis echoes Krashen's use of the terms implicit and explicit and extends them beyond the learning process to linguistic knowledge itself (N. C. Ellis, 2008). Thus explicit and implicit knowledge of language are distinct and dissociated, they involve different types of representation, they are substantiated in separate parts of the brain, and yet they can come into mutual influence in processing. Explicit knowledge of a language is form-focused rather than meaning-focused, and involves conscious thought. Presumably much of the implicit and explicit knowledge of a language are stored away in long-term memory (LTM) and marshaled as necessary by STM when required.

EI testing is interesting for a variety of reasons. First, it is time-constrained; the responses must be immediate, so extensive deliberation is not possible. The time constraint also prevents use of the articulatory loop to enhance WM, and thus scores on the EI test. Second, the test involves repetition instead of full-fledged conversational interaction so that deliberation about of grammatical form is less salient. These two elements—time limit and avoiding meta-awareness of form—are thought to shift EI tests towards the assessment of implicit language knowledge instead of explicit knowledge (R. Ellis, 2005).

Some combination of WM, STM, and LTM is pressed into

service for language-based interactions including simultaneous listening and comprehension. STM, like WM, is limited in its capacity and reactivity, so processing language must involve optimally combining layers of representation of meaning (morphemes, lexemes, lexical items, phrases, sentences), that allow STM to group items together, thereby expanding its ability to deal with the situation at hand.

Meaning is another important consideration in memory, language, and learning (Doughty & Long, 2003). Robinson (2005) noted that phonological WM capacity in particular is associated with L2 speaking abilities. DeKeyser notes the difference between *meaningful* versus *nonmeaningful* associations, each in its relation to memory capacity: meaningful form-function mappings associate constituents in a sentence according to lexical and grammatical principles of the language. Establishing meaningful relationships between abstract entities draws more on insight, whereas associating nonmeaningful co-occurrence of concrete elements logically draws more on memory (DeKeyser, 2005).

Utterances are constructed as intonation units, and substantive units are fairly strongly constrained to have a typical length of about four words in English, indicative of the cognitive limits on how much information can be fully active in the mind at any one time (N. C. Ellis, 2002). At the syllable level most information has already been chunked up, reflecting the phonemic, morphological, and lexical properties of the language: speakers rarely deliberate at the syllable level in languages they are proficient in. On this basis, one would expect a nonce syllable test would measure memory, and a "meaningful" (i.e. language-based) test would draw less on memory than the nonce test, and more on linguistic ability.

Previous research has also shown that knowledge of semantics, grammar, syntax, etc., affects verbal STM performance. This suggests that such linguistic working memory chunking also occurs during the process of verbal repetition. The articulatory loop is also implicated in both vocal and subvocal repetition of a phrase, which helps to maintain it in short-term memory. The connection is complicated by factors including articulation rate, semantic properties, grammar class, word frequency or familiarity, and word sequencing. Since chunking can happen at these linguistic levels as well, an interesting question is the interaction of linguistic versus articulatory loop chunking; current thinking is that the former can supersede the latter (Morra, 2000).

It follows that, due to WM limitations, correctly repeating longer utterances in an EI test is only possible via linguistic recoding. Hence WM tasks involving processing of nonce syllables will be different from WM tasks enhanced by language ability, and the difference indicates to what degree the EI tests are measuring language.

Elicited imitation (EI) and sentence repetition testing (SRT) are the most common terms used to refer to the same testing method. Though a thorough review of the extensive history in EI testing is not possible here, we mention some of the strands of work most relevant to our current experiment.

EI is the “...repetition of a model sentence presented in a context calling for imitation, as opposed to...spontaneous imitation of...utterances” (Slobin & Welsh, 1973). Bley-Vroman and Chaudron (1994) suggest that EI performance requires both linguistic processing and short-term memory. They sketch a 4-step process of EI performance; the test-taker: (1) hears the utterance; (2) forms their version of it in their mind (a *representation*); (3) stores this representation in short-term memory; and then (4) verbalizes their representation of the initial utterance.

EI has been instrumental in measuring first language acquisition. By studying the EI of adult speech in children, Slobin and Welsh (1973) conclude that the process requires linguistic processing, particularly since children cannot repeat beyond what they could produce spontaneously, unless the utterances were short enough to leverage immediate memory. He argues that the same conclusions hold for adult L2 learners.

A well known basic asymmetry in language capabilities exists between comprehension and production; this also underlies EI testing. Vinther points out whereas some test subjects may be able to understand the stimulus but not reproduce it accurately, on the other hand “the opposite situation, that subjects should be able to produce well-formed imitations of sentences they have not understood and are not able to remember, is highly improbable” (Vinther, 2002).

Prior literature also provides guidelines for EI testing. Jessop et al. outlined the advantages and challenges of using EI as an L2 acquisition assessment, providing suggestions for using EI effectively. This paper addresses the central problem they delineate: “In the 1970s, EI’s validity was challenged: the major criticism being the possibility of rote repetition in response to stimuli (i.e., participants may be simply parroting what they hear)” (Jessop, Suzuki, & Tomita, 2007). They call for more study to validate the use of EI in measuring L2 performance.

EI tests thus measure verbal STM performance in the sense that they measure knowledge of the various linguistic elements discussed above, rather than rote memory ability. It is also apparent that WM is essential to perform well on a language EI test. The question is how much do language EI tests overlap with working memory tests in what they measure? If the two do not correlate perfectly, then whatever does not overlap implies that the remaining portion, the part of the EI test that does not overlap with WM, is measuring something else. As suggested by previous research, that “something else” is knowledge of grammar, vocabulary, syntax, and other linguistic features. To quote one researcher, “Elicited imitation goes beyond rote memory and repetition; rather, sentences are assumed to be ‘filtered’ through one’s grammatical system” (Gass & Mackey, 2007). This would predict that highly proficient L2 learners will do better at EI tests since their knowledge and expertise will help overcome memory capacity and time constraints.

Conversely, an L2 EI test would function more similarly to a WM test for individuals who do not yet have any ability

in the language. This is because without necessary language competence, the individual will not be able to “chunk” and use other opportunistic linguistic strategies; syllables would instead sound like nonce syllables to the student. For longer sentences mere rote repetition will not be possible since WM capacity will be exceeded.

If there were a significant WM/EI correlation across the board, one could conclude that memory is dominating the measurement of language ability. This would support arguments that EI tests are mere “parroting”, and hence offer no contribution to measuring language ability. If, however, there is minimal correlation between WM scores and EI language test scores, the tests cannot be primarily memory tests. We also predict that some students who have approximately the same WM capacity but differing language ability will score differently on the EI language test. In summary, we claim that EI language tests, when constructed properly, primarily measure linguistic ability, and demonstrably do not measure an individual’s working memory to a significant degree.

## Testing EI and WM

We administered two tests to a pool of students: an English EI test and a WM test. For the EI test, we used our own pre-existing English instrument: EI Form D. It contains 60 questions of varying lengths and complexity, carefully designed and engineered to target different levels of proficiency. Half of the items were also paired with a comprehension task.

The comprehension task involved two illustrations appearing side-by-side on the screen after an EI stimulus sentence was given, but before the test-taker recorded their response. One illustration depicted the meaning of the stimulus sentence, and the other picture was irrelevant to the stimulus. Test-takers were to click on the relevant picture. Only then were they allowed to record their audio response. These tasks were intended to divert attention away from form, and shifting the focus to meaning.

We chose to create our own working memory test—as opposed to using a previously existing one—in order to assure that its content, format, and delivery method integrated seamlessly with the English EI test. Our WM test uses nonce syllables (Cowan, 2005) drawn from a pre-existing repository of nonce words (McGhee, 2010). Meaningless monosyllabic words such as “kish” were used directly, and longer ones were split into nonce syllables. Caution was exercised to ensure that the individual syllables were not homophones of actual English words, either in isolation or in sequence; this would have enabled chunking and hence complicated WM measure interpretation. The 55 nonce syllables were arranged into ten items of increasing length: item 1 has one syllable, and item 10 has 10 syllables.<sup>1</sup>

Half (i.e. five) randomly selected WM items were recorded

---

<sup>1</sup>A reviewer has observed—and we concur—that a more commensurate WM test would have had sentences with (nonce) syllable totals equalling those in the EI test sentences. Unfortunately we no longer have access to the subject population for another within-subjects test.

by a male voice, and the other by a female voice, presented in randomized order. Syllables within a single item were separated by pauses of approximately one second in length. Care was also taken to assure flat prosody when pronouncing the syllables, avoiding any intonational contours that might make them easier to remember in sequence.

We administered the English EI test in January 2011 to incoming adult students at the BYU English Language Center (ELC) as a part of an initial placement assessment. The ELC in essence has 6 grade levels, Levels 0 through 5. Students are placed at these levels based on multiple assessments of their abilities, including grammar, writing, and listening comprehension tasks. Our test was given at the same time as other diagnostic language tests. Our EI test results were not used in placing students in their ELC levels.

The 94 students were randomly divided into two equally sized groups (A and B). Group A took the 60-item English EI test with 30 items paired with distractor comprehension tasks. Group B was given the same 60-item English test, but with the other half of the 60 items paired with comprehension tasks.

The presentation order of English EI items was randomized within each set (questions with tasks, and questions without tasks, respectively) to eliminate any possible item-order effects. In the test both groups were presented the section without the tasks first, and afterwards the section with the tasks. Time allowed for responses for individual items was proportional to their length. Due to technical difficulties (microphone malfunctions, web server problems, etc.) about half of the students' tests had to be discarded.

A few months later, in March and April, as many of the original students as could be located were invited to take the 10-item working memory test. This resulted in 67 students; some students had left the program, and others were unavailable due to scheduling problems. Again, various technical difficulties resulted in tests that were lost or unusable. The final pool of data consisted of 40 students for whom we had a complete set of English EI and WM scores.

Both tests were scored by a percentage method, i.e. the overall score on the test is a percent of the total number of syllables the student uttered correctly over the total number of syllables in the stimuli of the test. As with our prior work, we had trained human graders (all native English speakers for this project) score the test recordings via a web-deployed user-friendly interface. The rater listens to the audio recording, and marks each syllable that is present with a "1," and each syllable in the utterance that the test-taker missed with a "0." Six individuals graded results for the 5,430 English test items (89 test-takers times 60 items per test), and the 890 working memory test items. Individual EI item scores were aggregated across each test.

## Results and Discussion

To ensure that the WM test was actually testing memory, we analyzed the scores of all participants for each item. All WM

scores ranged from 27.27% to 52.73% (mean and mode at about 40%), with one outlier at 20%. As indicated in Figure 1, average accuracy across students on 1, 2, and 3-syllable items were almost 100% as expected. At 4 syllables, the average score dropped to just below 80%. At 5 syllables the score fell below 50% (49.55%), reminiscent of the  $4 \pm 1$  WM "magic number". These findings suggest that our WM test was measuring WM capacity as intended. In addition, the boxplot shows that skewness on both tests was minimal.

Figure 1: WM scores histogram (left) and boxplots for both tests' scores (right).

We then ran three Pearson correlations across individuals to quantify relationships of interest; see Table 1.

Test	EI	ELC Level
WM	$r=.249, n=40, p=.121$	$r=.130, n=40, p=.430$
EI		$r=.786, n=40, p=.000$

Table 1: Pearson correlations between WM and EI scores and placement level.

The correlations between WM and EI scores and between WM scores and ELC level do not reach significance, though the correlation between EI scores and ELC level does.

Consider the scatterplot graphs in Figure 2: each plot-point represents an individual student who took both tests, modulo overlap. Graph (a) shows that most students have average WM scores (around 40% overall), but have very divergent EI test scores, ranging vertically throughout almost the entire spectrum of English language ability, from 1.9% to 84.97%. We also see students with below-average WM scores but average English EI scores; on the other hand, some students who did not do as well on the EI test have above-average WM scores.

Scatterplot (b) shows that the student at the highest ELC level (5) had a WM score of 41.82%, but was outperformed on the WM test by a student at the lowest ELC grade (0), who had a WM score of 47.27%.

Scatterplot (c) reveals a much clearer correlation, the only significant positive correlation we found: EI versus ELC placement level. Most of the points align much more closely with the diagonal.

Of the three students in Level 0 (the ELC's lowest beginning level), one of them scored the very lowest on the English EI test, correctly repeating only 1.9% of the syllables.

Figure 2: Scatterplots: (a) WM score vs. EI score; (b) WM score vs. ELC level; and (c) EI score vs. ELC level

This student's working memory score was perfectly fine, at 38.18%. Further, note that the lowest beginning level students could not break past the 30-40% barrier on the English EI test.

With their little-to-no knowledge of English, the lowest-scoring students were unable to repeat anything beyond their WM capacity. It seems reasonable to assume that below scores of roughly 30%, working memory tends to be the primary contributor to the test-takers' English EI results. Above 30%, knowledge of the language seems to have a greater influence, and working memory proportionately less so. This particular result follows our prediction—that the English EI test would primarily be an assessment of an individual's linguistic ability, and not an assessment of their working memory capacity—not as a rote memory test.

As mentioned above, most types of second language capacity tests assess explicit knowledge. Our test responds to Ellis' two criteria for measuring implicit knowledge: (1) the test must be time-constrained, and (2) the test must get at meaning, and, as much as possible, avoid focusing on form (R. Ellis, 2005). Our test was time-constrained: test-takers were only allowed a few seconds to respond. This did not give students a chance to analyze sentence structure or grammar, or indeed rehearse the item before repeating it.

Although we were not measuring actual language chunking in this test, if chunking by meaning enabled higher-level ELC students to perform better on the English EI test, then it may be that this test (or at least some of its items) allowed them to focus on meaning rather than form.

Shorter EI stimuli that fall within the constraints of working memory function more like a nonce syllable working memory test. This is especially true of students at Level 0, who have little knowledge of the language. But lengthier sentences are too long for WM capacity, and perhaps form-focused chunking does not sufficiently recode so many syllables into few enough chunks to retain in working memory. The longest sentences on the test can be remembered and uttered correctly more easily by those who can recode it into its

meaning, which accesses their implicit knowledge of the language. Otherwise these lengthier items become impossible for low-proficient learners to reproduce based on WM alone.

For example, one of the items on our English EI test, "Joe writes poetry," is short enough that working memory may have a greater correlation to scores on this particular item than the test overall. While due to its length it could be considered a working memory test item, its carefully designed grammatical features make it a test of at least some explicit linguistic knowledge.

Complex, lengthy items such as "When Jim entered the office he was immediately afraid of the uncommunicative boss." contain too many separate features for a person wholly dependent on explicit knowledge to maintain all the separate elements in STM and/or WM; a round-trip to implicit knowledge representations would be required. If such is the case, then specific items could be used to distinguish between working memory, explicit knowledge, and implicit knowledge of the language.

In summary, the lack of significant correlations between working memory and English EI scores and between working memory and ELC levels, and the significant correlation between English EI scores and ELC levels suggest that there is more to performance on EI tests than working memory capacity. Ellis proposed that EI tests could be developed to test for different types of knowledge, namely, explicit linguistic knowledge and implicit linguistic knowledge. He stated that time-limitations and a focus on meaning were necessary to construct an EI test that measured implicit linguistic knowledge. The test-takers' errors indicate that using items with specific grammatical features can distinguish between levels of ability. Beginning level test-takers had difficulty with even very short items, if they contained specific grammatical structures beyond their linguistic ability. Long sentences were also difficult or impossible for the beginning-level students, but doable for advanced speakers. These findings produce further research questions. Do utterances that are too long to repeat using average working memory capacity require chunking by

meaning to repeat correctly? If EI performance on longer sentences does access a translation into meaning, then according to Ellis' framework, these types of long utterances also test implicit knowledge. A further question still is, do test-takers even recall hearing those morphemes they were unable to accurately repeat, such as the word-final 3rd person singular "s" (e.g. "runs")?

### Conclusions and future work

The findings above indicate a lack of significant correlation between EI and WM scores for the same population. Though a direct causal relationship cannot be made to language use from this result, our measures do lend circumstantial support to the idea that WM testing does not primarily target linguistic ability, and hence directly or even significantly influence EI scores. This is in agreement with the findings of DeKeyser (2005) that elements without meaning (in this case, nonce syllables) draw on memory more than elements of meaning. Though some working memory is involved in language learning and production (Robinson, 2005), it was not shown here to be positively correlated with EI testing. This lends credence to the suggestion that the English EI test is testing linguistic knowledge.

There were a few limitations in the scope of this study, all of which can be overcome with further testing or analysis: (1) The sample size of forty test-takers is relatively small, though the largest we have seen yet for the task at hand. (2) We cannot guarantee that the nonce syllable sequences are meaningless in all of the non-English languages known by test-takers. (3) It would be informative to correlate other metrics (e.g. the participants' OPI scores) to working memory. (4) We have not yet analyzed the effect of the distractor tasks. (5) More detailed analyses of our results could be undertaken including such techniques as structured equation models or ANOVA analyses.

### Acknowledgments

We express our appreciation for support from the BYU Pedagogical Software and Speech Technology Research Group, the BYU Center for Language Studies, and the BYU English Language Center.

# Changing Discriminatory Norms Using Models of Conceptually-Mediated Cognition and Cultural Worldviews

Daniel Olsher (dan@intmind.com)

National University of Singapore

## Abstract

Cognitive modeling can provide immense social benefits, especially in the case of unconscious processes causing significant psychological and societal distress. One such process, discrimination against minorities, is typically grounded in unconsciously held stereotypes reflecting deep ignorance of the realities minorities face. Another, suicide terrorism, results in significant suffering for many communities. Related beliefs often arise from unquestionable values, norms and worldviews, however, making direct/conscious change appeals unworkable. Building upon cultural knowledge representation and cognitive modeling, this paper shows how change could be effected via cognitive operations on conceptual worldviews. After introducing a novel framework for modeling conceptually-mediated belief systems and techniques for guided dissonance reduction and network change, the paper applies these to anti-discrimination and terrorism reduction. Such work holds great potential for better aligning perception of minorities with the realities they face, reducing suffering, and disrupting psychological processes dependent on improper views of stigmatized minorities and other phenomena.

**Keywords:** Culture; Cognitive Models; Nuance; Knowledge Representation; Norm Change; Discrimination Reduction; Terrorism Reduction

## Introduction

Cognitive Science has the potential to provide immense social benefits, especially in shedding light on processes that are normally unconscious but which tend to cause significant psychological and societal distress.

One such process is discrimination, often grounded in stereotypes reflecting deep ignorance of the realities of what minorities are and what they face. Another is the process by which people decide to undertake violent action during conflict.

Because the beliefs underlying such processes often arise from norms, cultures, values, and other strongly unconscious, often nearly unquestionable, belief systems, direct conscious appeals are often unworkable and insufficient for effecting change.

In this paper, we consider how to construct procedures capable of achieving change in beliefs by modeling the beliefs people already hold (and the connections between them) and designing procedures tailor-made to effect change.

Incremental changes are most effective. The use of familiar concepts lowers fear, and as the status quo already appears to be 'reality', small changes to it are more likely to succeed. Direct/conscious attempts to change such beliefs often fall afoul of cognitive and social defense mechanisms, with excessive change causing dissonance, negative emotional outcomes, and ultimately, rejection.

This paper introduces a framework for modeling conceptually-mediated belief systems, a novel change

strategy entitled Directed Dissonance Reduction (DDR), a conceptually-mediated formulation of inoculation theory, and a brief discussion of techniques for modifying belief networks. Examples (including sample networks) are then given demonstrating how to apply these tools in the prejudice and terrorism reduction domains.

Beyond norm change, this research seeks to advance nuanced knowledge representation of worldviews, cultures, and norms as well as to advance our understanding of conceptually-mediated cognition.

## Core Representation Frameworks:

### COGVIEW and INTELNET

In this paper, the author's COGVIEW and INTELNET formalisms are used to model nuanced conceptual worldviews. Both formalisms are the subject of ongoing development, with this paper providing an early demonstration of their combined capabilities.

COGVIEW is a network-based framework for representing complex worldviews through 'fields' of interconnected concepts and energy flows. It serves as a base for simulating important psychological, conceptual, and cognitive semantics processes mediated by worldviews. COGVIEW reflects the insight that information originating from human cognitive processes is of a different type than that typically considered in the 'hard sciences'; namely, it is *deeply nuanced and inherently distributed*.

COGVIEW uses networks of concepts to store information. Networks are defined as collections of nodes connected with edges (or links). Energy originates from energy sources and flows across edges (capable of modifying the energy that flows across them). Each edge has an indicated direction in which energy traversing it will flow.

COGVIEW supports two levels of cognitive processing, the C(onscious)-Level and the U(nconscious)-Level. U-Level processing is not accessible to conscious awareness and is dominated by the effects of associational memory in that the primary activity taking place at this level is the spreading of energy between concepts and concept fields and the associative detection of congruence/similarity between various portions of the extended concept universe. Critically, 'rational' or 'logical' thought does not take place at this level and is therefore incapable of acting as a filter for change. Growing evidence (see Shermer, 2002) suggests that at this level, mere understanding may be cognitively tantamount to acceptance, requiring an active act of 'disbelief' to be overcome. 'Raw' concepts and a wide range of energies can be accessed directly here and immense amounts of energy easily shifted and deployed, as well as emotions triggered, all without conscious or rational intervention.

**Clashes** In COGVIEW, a *clash* occurs when energy flowing in one direction meets energy flowing in the other, an especially important occurrence when the positive or negative valences of clashing energies are opposed to one another.

Clashes represent the point at which conceptual incompatibilities become manifest, and when the ability and/or need to take some sort of meaningful action has been identified, that is, when the model makes a certain type of 'conclusion'.

The subnetwork within which a clash occurs will naturally be activated most when a result propagates to consciousness, and thus is the subnetwork from which the conscious knower will consider the 'insight' of the clash to have originated. Critically, this is true even (as is the common case) when the energy which caused the clash came from other concept fields. This phenomenon allows for persuasive processes in which the semantic/conceptual content of a clash is removed from its original context (usually one in which conscious processing would have caused the desired conceptual understanding to be rejected) and shifted to another context (i.e. another subportion of the conceptual cloud) wherein which the attribution of the clash output to that context is 'safer' (or more desired).

The sites of clashes often coincide with the most relevant and important (moral) 'issues' that a human would identify within particular conceptual fields. This phenomenon provides one source of evidence that specific COGVIEW networks are accurately reflecting certain real world semantics.

Arguably, clashes have a neural basis; for example, Lieberman, Schreiber, and Ochsner (2003, p. 689-690) suggest that "The C-system [conscious] (named for the "c" in reflection), consisting of the prefrontal cortex, anterior cingulate cortex, and medial temporal lobes, is recruited when the X-system [unconscious] fails to create coherent outputs from the different sources of input. ... According to this model, the C-system is usually involved only to the extent that the X-system fails to resolve the current set of inputs into a coherent output ... [I]f the conflict between different considerations is too large, the C-system will detect this tension in the X-system and become involved (Botvinick, Braver, Barch, Carter, and Cohen, 2000)."

## Tools for Effecting (and Inoculating Against) Belief Change

In this section we introduce tools for use both at the macro and COGVIEW network levels.

### Network-Level Tools

This section provides a very high-level listing (due to space limitations) of techniques for adjusting COGVIEW networks. While useful on their own, a high-level understanding of these techniques is also helpful in understanding Directed Dissonance Reduction.

1. **Break Link Between Two Concepts:** Disconnects energy sources from downstream concepts (can be accomplished via DDR).

2. Introduce new connections to compete for energy with pre-existing connections.
3. **'Attraction':** Prime concepts likely to attract energy and thus create more desirable energy flows. Priming of 'incompatible' concepts (those causing dissonance with other salient concepts) may cause confusion, weakening previous connections.
4. Use 'attractor cognitions', that is, new cognitions more pleasant than undesired ones. Protoypical examples: 'hot-button' concepts like 'family'. Energy from these may 'overwhelm' that of undesired concepts or paths.
5. **'Blocking cognitions'** capable of blocking flow along undesired paths. To accomplish, associate original path with something unpleasant, confusing, or fear-inducing. Highlight path nonoptimality by pointing out logical inconsistencies or suboptimal conclusions arising from the path.
6. **Create Links:** Repeatedly reference pairs of concepts together, point out semantic similarities, and/or create scenarios where concepts are always associated or required to be used together to accomplish a goal.
7. **Emphasize / De-emphasize Concepts:** De-emphasize through neglect - emphasize through repetition.
8. **Redirect Link:** Prime desired concepts and paths. Reinforce through Repetition and Need-To-Use. Repetition: use narratives or linguistic constructions continually invoking and refreshing the salience of desired concepts or paths. Need-To-Use: cognitions become more salient when they are necessary to accomplish important goals.
9. **Change Polarity** (what was once sending negative energy now sends positive, and vice versa): Represents significant changes in perspective. Overwhelm energy of one polarity with energy from a source of the opposite polarity.
10. **Re-Normalize:** Show that concept 'X' is actually much more like concept 'Y' than was originally believed to be the case.
11. **Stigma Disconnect:** Stigma is a highly potent source of negative energy. Stigma Disconnect breaks energy flows associated with stigma as early as possible and/or refits them with more positive energy sources.
12. **Concept Implantation and Reconstruction of Incorrect Concept Fields:** Entire concept fields may be incorrect, either in terms of content or in connections.

Associations may be reinforced if they cover entire concept chains - that is, from energy input nodes to output nodes, as this provides cognitive 'closure' and makes chains easier to process.

## Directed Dissonance Reduction

Dissonance reduction (Festinger, 1957) represents a powerful mechanism for effecting psychological change, capable of marshaling significant emotional and mental energies. In this section we reformulate this mechanism in terms of COGVIEW networks, and later demonstrate how it may be repurposed in service of both belief change and 'inoculation'.

DDR redefines dissonance reduction as a process of *positive energy maximization*, suggesting that people seek to maximize the most positive energy obtainable within their belief networks. Dissonance is understood as a threat to current energy maximization, and dissonance reduction as an attempt to create a new equilibrium. Motivation arises from discomfort, with motivation levels proportional to the potential amount of threatened energy change.

## Stages of Directed Dissonance Reduction

### Phase I. Design

Phase I analyzes subjects' COGVIEW networks and identifies clash nodes, important positive energy sources, and potential psychological defenses.

COGVIEW allows putative belief changers to identify where concepts and energy sources lie in relation to others and to determine what concepts to prime and interconnect in order to 'reach' desired energy sources.

### Phase II. Initiation (Build Initial Context)

Priming of concepts identified in Phase I takes place here. This phase may also seek to add new useful concepts or links, though strategies built significantly on pre-existing networks are likely to be more effective, reliable, and easier to implement in practice.

If subjects perceive that large negative changes in energy balance may result, denial may occur. In order to avoid this defense strategy, significant positive energy sources (such as FAMILY) may be identified and primed at this stage.

In some cases, negative energy sources may be primed, for example, if subjects believe that there is 'no problem' or that a potential dissonance-inducing stimulus is of little or no significance. A canonical example is the use of fear by terrorists to cause target populations to take their goals seriously. Another involves health appeals, in which subjects may not be convinced of the reality of possible threats.

### Phase III. Dissonance Introduction

In this stage, a stimulus - a single or small set of new links whose existence threatens the existing positive energy balance - is introduced, causing dissonance. These must be significant enough to threaten belief network energy maximization.

Care must be taken here to avoid resort to denial as a clash defense strategy; if the target is able to simply ignore the stimulus altogether, it will not be effective. Thus, stimuli should be factually accurate, important, and otherwise impossible to ignore.

### Phase IV. Directed Dissonance Reduction

Here, energy is introduced and links are adjusted so that dissonance will be resolved as desired. This stage attempts to direct the choice of energy maximization equilibrium; energy placed at clash sites is most beneficial.

## Phase V. Solidification

This phase solidifies energy at important clash points in order to enhance satisfaction and attitudes towards outcomes, as well as make it less likely that changes will be reversed or re-examined.

The more likely it is that the new energy balance will persist in future, the more anxiety will be reduced during the dissonance reduction process.

## Directed Dissonance Reduction Examples

We now provide two detailed examples of how DDR can be used in diverse domains.

### Coming Out

The first example illustrates the case of a son who comes out to his father, whose view of the situation is initially quite inaccurate. The goal of DDR is that the father maintain his positive associations and attitudes about his son.

Figure 1 provides a diagram of the father's COGVIEW network before DDR has taken place. Energy flows from the energy source nodes, following the arrows indicated in the diagram, with two properties: magnitude (amount) and valence (positive or negative). Whenever energy crosses a graph edge labeled 'NEG', the valence of that energy is reversed.

Energy derives from three sources. *Biological* energy arises from parental love, the need to guide children, parent-child and father-son bonding, the desire to raise well-adjusted children capable of participating in the wider world, and the psychological need to view oneself as a good parent. *Societal* energy arises from in-built needs to be seen positively by the community as a good parent and as someone who has raised a well-adjusted child. Lastly, *Cultural* energy draws on local imperatives to guide children, act as good parents, and raise moral children.

**Phase I (Design):** DDR goals are as follows: *break* the link between INCORRECT-BELIEFS-ABOUT-GAYS and GAY (Link *IncorrectBeliefs*) and *maintain* the link between IDEAL-SON and THE-SON (Link *IdealSon*). The unfavorable outcome is the opposite, that is, the breaking of link *IdealSon* and the maintenance of the *IncorrectBeliefs* link. Another undesired outcome could be the breaking of the link between THE-SON and FATHER - in other words, the father disowning the son.

Clash points occur at FAMILY, RAISING CHILDREN, and THE-SON. At FAMILY, positive energy (+50) comes from SOCIETY and significant negative energy from COMBINED-ENERGY (initially positive but reversed after crossing the NEG edge near INCORRECT-BELIEFS-ABOUT-GAYS). Without mitigation this will flow into IDEAL-SON, ultimately making this path one that contravenes DDR goals. If positive energy is introduced at this node through priming or statements such as 'your son wants to raise children and start a family', 'gay people want to start loving families', and/or associating FAMILY with significant positive energy, positive energy may 'overwhelm' the negative energy at the clash point. A similar technique may be applied at RAISING CHILDREN.

Figure 1: Father's COGVIEW Network before DDR

The clash located at THE-SON is particularly interesting, as it points to the exact dilemma faced by the father in this situation: either accept his son and break links to his incorrect beliefs or vice versa. Such correspondences can help verify how well COGVIEW networks fit the situations they represent.

Energy does not actually flow from INCORRECT-BELIEFS-ABOUT-GAYS to THE-SON until the dissonance-inducing cognition (linking GAY to THE-SON - the *ComingOut* link) is introduced, matching the reality of the problem being modeled.

Because THE-SON connects to FATHER, reminding the father that his son is a 'good' son will introduce positive energy into this node and make it more likely that he will not want to disown his son so that he may remain associated with this positive energy source.

Other positive energy sources include caring/compassion, parental attachment, the desire for enhanced well-being, the desire to focus on strengthening family and not break it apart, and so on. Other potential strategies could include creating new links between desirable nodes or changing the polarity of existing links between personal attributes (RESPONSIBLE, RESPECTABLE, etc.) and GAY or THE-SON.

**Phase II (Initiation):** In Stage II, the priming-related components of the Phase I design are carried out.

**Phase III (Dissonance Introduction):** In this stage, the link (from GAY to THE-SON), labeled as *ComingOut* above, is introduced by the son coming out to the father. Denial must

be avoided, which would appear as refusing to believe the son is gay.

**Phase IV: (Directed Dissonance Reduction)** At this stage, the full strategy designed at Phase I is implemented. Positive energy is inserted at FAMILY, RAISING CHILDREN, THE-SON, and so on. This stage makes use of link change strategies 1, 2, 3, 4, 5, 6, 7, 9, 10, 11, and 12 (see above).

The goal here is to make it more painful for the father to configure his belief network in a manner contrary to the goals of DDR - that is, if he breaks or maintains non-preferred links, the maximum energy balance (equilibrium) he will achieve will ultimately be lower than that if he configures his network as desired. As an example, if the father breaks the link from IDEAL-SON to THE-SON, he will cease to receive the benefit of the positive energy entering the node THE-SON from IDEAL-SON. A similar outcome will arise if he breaks the link between IDEAL-SON and THE-SON.

**Phase V (Solidification):** Operations remain at Phase IV until sufficient change has been effected. To test, we may ask the father how he feels about his son, tallying the total number of positive and negative qualities.

Further positive energy may be added to THE-SON by focusing on the father's need that his son and other family members be associated with positive attributes, and re-priming may be performed on FAMILY, CHILDREN, and so on.

## Terrorism Reduction

DDR also has significant application in the domain of terrorism reduction. DDR can support public communications de-

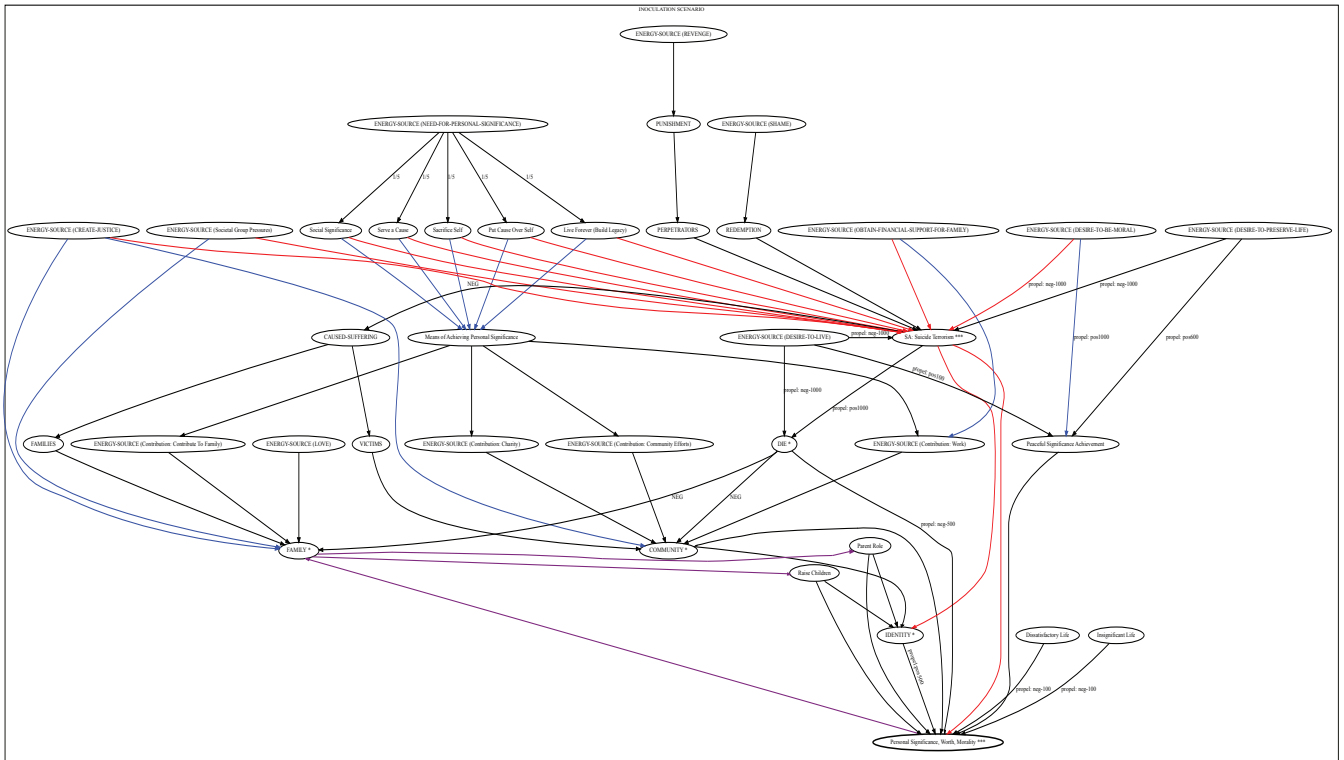

Figure 2: Citizen COGVIEW Network before Persuasion

signed to slow the adoption or 'taking root' of radical ideologies in susceptible individuals (termed 'inoculation'). Focus can also be placed on interrupting the flow from conception to the carrying out of acts.

We focus here on 'inoculation' against suicide terrorism, as it is a highly effective strategy capable of blocking entire event chains from occurring. Suicide terrorism's reliance on interlocking societal and personal value systems is an excellent fit for the COGVIEW+DDR approach.

We draw on Kruglanski et al. (2009)'s view of suicide terrorism as a quest for personal significance. We also draw on 'inoculation theory' (McGuire, 1961; Pfau et al., 1997), which suggests that subjects may be 'inoculated' against later attempts to change their beliefs by being exposed to weakened forms of counterarguments to their current positions. 'Beliefs' are understood here as COGVIEW links relevant to suicide terrorism and 'attempts to change beliefs' as attempts to convince others to undertake suicide terrorism.

Inoculation seeks to protect existing beliefs against change, assuming that people initially believe that suicide is wrong and that they should seek to make their life meaningful through appeal to family and activities rather than through terrorism.

Inoculation consists of two phases: *Threat* and *Refutational Preemption* (Pfau et al., 1997, 188-189). Threat motivates belief protection by demonstrating that beliefs (and energy maximization) can be threatened. Refutational Preemption inoculates against future threats by presenting weak-

ened forms of counter-arguments (which may ultimately be the same or different as what are eventually encountered, as the effect works in both cases.) (Pfau et al., 1997, 188-189) (McGuire, 1961, 330).

DDR assists (and induces) participants to 'create their own' counterarguments against persuasion attempts. As Pfau (1997, 189) suggests, "[i]t is the motivation provided to generate answers to potential counterarguments, as opposed to the specific information provided, that is responsible for [confering resistance]."

By highlighting anxiety related to energy equilibrium loss, DDR can help explain findings related to distraction and differential performance of inoculation as a strategy (see, for example Keating & Brock, 1974).

**Applying DDR** Threat occurs at Phases II and III of DDR, and Refutational Preemption at Phases IV and V.

**Phase I (Design - Threat):** Identify nodes expected to lose significant positive energy if persuasion occurs: FAMILY, COMMUNITY, IDENTITY, PERSONAL SIGNIFICANCE, WORTH, AND MORALITY and PEACEFUL SIGNIFICANCE ACHIEVEMENT. Also threatened is the *loop* between FAMILY and PERSONAL SIGNIFICANCE, WORTH, AND MORALITY. Loops such as these serve to simulate stability; the loss of stability represented by energy flowing within stable feedback loops is a significant loss in and of itself.

Simulate the introduction of negative energy into threatened

nodes (and loss of stability). This can be accomplished by calling attention to the following potential outcomes of energy loss:

**FAMILY:** Children without parents, not close to loved ones, loss of significance, judged as immoral, not supportive, broken family (leading to suffering, shame), ostracism, discrimination, prejudice, family suffering from revenge taken by others.

**COMMUNITY:** Chaotic communities, crime out of control, suffering, no rule of law, fear, bad example, children hurt, not growing up well, bad publicity for cause, martial law.

**IDENTITY:** Unclear about role in life, no personal meaning, unsure how to live life, deep instability, lose identity as good parent, good spouse, good member of community.

**PERSONAL SIGNIFICANCE, WORTH, AND MORALITY:** loss of face/worth to family, community, and friends, seen as wrong and immoral, family members feel societal shame, ashamed, unhappy due to lack of access when in need.

**PEACEFUL SIGNIFICANCE ACHIEVEMENT:** never-ending violence throughout the community, loss of life, family, and friends, international condemnation, loss of resources, great danger, great instability, fear throughout.

Loss of stability loop between **FAMILY** and **PERSONAL SIGNIFICANCE, WORTH, AND MORALITY**: great uncertainty, chaos, lack of predictability surrounding life.

**Refutational Preemption:** For this component we identify clashes at the following nodes: **SIGNIFICANCE ACHIEVEMENT: SUICIDE TERRORISM** (3 clashes), **PERSONAL SIGNIFICANCE, WORTH, MORALITY** (3 clashes), **FAMILY, COMMUNITY, DIE, and IDENTITY**.

Clash nodes are those most contested from a good-vs-bad moral perspective; at these sites worldviews may be modified significantly and immense shifts may occur. Clash points are marked with asterisks in Figure 2; the number of asterisks denotes the number of clashes occurring at any given node.

**Phases II and III** (Initiation and Dissonance Introduction) involve execution of the Threat component. Threat primes appropriate concepts and the existence of a threat in and of itself creates dissonance.

In Figure 2, blue links mark those that would be threatened and red links those that would be newly introduced should indoctrination succeed.

**Phase IV (DDR and Refutational Preemption):** The goal of DDR is to cause maintenance of blue links (those that are threatened) and rejection of red links (those that are indoctrination-related).

This can be accomplished by priming the clash nodes and significant energy sources that feed into them as follows: **PERSONAL SIGNIFICANCE, WORTH, MORALITY:** Prime **RAISE CHILDREN** and **PARENT ROLE** by highlighting importance of personal roles and positive emotions for all. Instinctual protecting, providing for. Prime **IDENTITY** through critical non-violent roles played by subject in the community.

**FAMILY:** Children with supportive parents in a stable home with a good reputation worthy of respect. The importance of the family as a unit *with the individual present to participate*

*within it.*

**COMMUNITY:** Stable communities conducive for leading a good, moral life, international support, and so on. Link strengthening, performed by simultaneously invoking **JUSTICE** and **COMMUNITY**, affecting the link between **CREATE JUSTICE** and **COMMUNITY**.

**DIE:** Prime **DESIRE-TO-LIVE** by cultural allusions to the importance of life, stories about what can be achieved during one's lifetime, meaning behind life, and so on. Mortality itself may be primed, but with undesirable follow-on effects.

Attempts may be made to introduce negative energy into **SIGNIFICANCE ACHIEVEMENT: SUICIDE TERRORISM**, though this is risky as it may be seen as a clumsy attempt to persuade, inducing change in an undesired direction.

The stability loop between **FAMILY** and **PERSONAL SIGNIFICANCE, WORTH, MORALITY**, will be automatically strengthened by introduction of positive energy to any constituent node, serving as further support for the status quo during DDR.

In the above, link-changing strategies 4,5, and 7 are employed.

## Conclusion and Next Steps

This paper has introduced strategies for modeling and changing beliefs and demonstrated examples of their application in the domains of prejudice and terrorism reduction. Further work will involve extended validation of the **COGVIEW** modeling framework and DDR technique, as well as development of further rubrics for using these techniques in critical real-world scenarios.

## Abstract

Considerable evidence supports the effectiveness of close comparison of examples as a means to promote the induction of schemas that support generalization, especially to novel cases that require far transfer. The ease of comparison would appear to be maximized by presenting the to-be-compared cases in close spatial and temporal proximity. However, findings from a number of recent studies have been interpreted as evidence that induction is fostered not by presenting training cases for a single category together (massed practice), but rather by presenting them in an interspersed fashion (spaced practice). We address this apparent paradox in a study in which people are asked to learn the “styles” of furniture designs from a small number of examples of different products (e.g., a bed frame) and then classify examples of entirely different products (e.g., a chandelier). We contrasted a learning procedure based on comparison of examples presented simultaneously with procedures involving processing of individual items, either massed or spaced. Study time was minimized, and generalization was maximized, when learning was based on comparison. In a further study we use structural equation modeling to assess the content of the schemas for visual styles that are acquired by comparison processes. We propose that comparison fosters induction, whereas spacing facilitates retention and retrieval.

**Keywords:** induction; schema induction; design; spacing effect; structural equation modeling

## Introduction

Early work on learning and transfer based on analogy provided strong evidence that close comparison of two examples of a complex category (e.g., problems that can be solved by using converging weak forces) supports subsequent transfer to novel cases that exhibit a similar relational structure (Gick & Holyoak, 1983). The inductive benefit of comparison can arise either as a deliberate learning strategy or as a side effect of applying one solved source problem to an unsolved target problem (Novick & Holyoak, 1991; Ross & Kennedy, 1989). The positive impact of comparison has been demonstrated for both adults (Catrambone & Holyoak, 1989) and young children (Brown, Kane & Echols, 1986; Chen & Daehler, 1989; Holyoak, Junn & Billman, 1984; Kotovsky & Gentner, 1996; Loewenstein & Gentner, 2001; Namy & Gentner, 2002; Star & Rittle-Johnson, 2009). Comparison has been shown to guide schema formation in teaching such complex topics as negotiation strategies (Loewenstein, Thompson, & Gentner, 1999, 2003), and also

may play important roles in language learning (Gentner, 2010; Gentner & Namy, 2006). The dominant interpretation of these findings has been that comparison processes foster the induction of a schema for a class of situations, which in turn will facilitate subsequent transfer to additional examples (Gick & Holyoak, 1983).

It would be natural to assume that comparison, and hence induction, will be facilitated by presenting multiple examples simultaneously, or in close temporal proximity. However, this assumption has been challenged. The extensive literature on memory and retention provides robust evidence of an advantage for spaced over massed practice (e.g., Cepeda, Pashler, Vul, Wixted & Rohrer, 2006; Ebbinghaus, 1885/1964). Most of this research has focused on memory for specific items, such as words on a list. However, Kornell and Bjork (2008) showed that the advantage of spaced presentation over massed presentation of training examples extends to a task requiring induction of artistic styles. Classification of new examples was more successful when examples of paintings by different artists were intermixed during training (spaced condition) than when examples of paintings by an individual artist were presented in immediate succession (massed condition). These findings have been interpreted as evidence that spaced presentations actually facilitate participants’ generalization. Similar benefits of spacing have been observed in studies of children’s category learning (Vlach, Amkowsky & Sandhofer, 2012; Vlach, Sandhofer & Kornell, 2008).

On the face of it, the evidence for an advantage of spacing in fostering generalization poses a paradox. If comparison promotes schema induction, and is easier when the examples to be compared are presented in close proximity, it might seem that spaced presentation should hinder rather than help induction; i.e., one might expect spacing to be “the enemy of induction” (E. Z. Rothkopf, quoted by Kornell & Bjork, 2008, p. 585).

However, although simultaneous or massed presentation might be helpful or even necessary for comparison, the mere fact that examples are juxtaposed does not ensure that learners will engage in active comparison. Effective comparison typically is elicited by specific instructions to compare cases and write down commonalities (e.g., Gick & Holyoak, 1983). The benefit of such comparison instructions has been shown to greatly exceed that of simply providing two cases together (even on a single page) without comparison in-

structions (Gentner, Loewenstein & Thompson, 2003; Thompson, Gentner & Loewenstein, 2000; see also Kurtz, Miao & Gentner, 2001). In order to assess the impact of different presentation conditions, it is therefore important to include a condition in which learners are clearly instructed to perform active comparison of examples.

Accordingly, in Study 1 we directly contrasted a learning procedure based on comparison of examples presented simultaneously with procedures involving processing of individual items presented sequentially, either massed or spaced. We used a novel paradigm in which people attempt to learn realistic styles of furniture and related home décor. After being shown a small number of examples of home décor items of a specific style, participants were asked to judge whether examples of new décor items are of the same style (see Figure 1). This task involves far transfer, since the generalization items included different types of décor items than the training items (e.g., after seeing a dresser, bed frame, fabric and pillowcase set during training, a generalization item required judging the style of a chandelier). Although the relevant cues that might provide the basis for forming a schema are presumably visual, the schema is likely to be quite abstract, and not tied to any single décor type. In Study 2 we employ structural equation modeling in an effort gain insight into the nature of the style schemas acquired via comparison processes.

## Study 1

### Method

**Participants** A total of 147 participants (49 in each of three training conditions) were recruited online through Amazon Mechanical Turk (<http://www.mturk.com>). This system has been demonstrated to produce reliable data in many experimental studies (e.g., Paolacci, Chandler, & Ipeirotis, 2010; Mason, & Suri, 2011). Each participant was paid 60 cents for completing the study, which took about 10 minutes. At the conclusion of the study, information was collected about participants' age, nationality, and possible color blindness. Participants (52 male, 95 female) were all residing in the United States, and ranged in age from 18–61 years ( $M = 31.5$ ). We tracked IP addresses to ensure that participants were not repeatedly sampled. The participants described above excluded those who failed to complete all of the conditions in the experiment, or reported color blindness.

**Materials** The materials were 14 color pictures of IKEA furniture and other home décor items (7 each of two styles) printed in the catalog of IKEA 2012 (<http://info.ikea-usa.com/Catalog/>). The training items for each style (termed Style X and Style Y) consisted of a drawer, a bed frame, fabric, and a duvet set. The tests items used in the subsequent generalization phase were a wall lamp, a (novel) bed frame, and a chandelier (see Figure 1).

**Procedure and Design** Three conditions, Comparison, Massed and Spaced, were manipulated across participants. In the Comparison condition, the four items of each style, X and Y, were shown together on the screen (randomizing

position of items, and counterbalancing order of styles as well as assignment of the labels X and Y to styles). Participants were asked to write down three commonalities for each style. In the Massed and Spaced condition, instructions focused attention on individual items rather than commonalities. In the Massed condition each example of a given style was presented separately, but consecutively; whereas in the Spaced condition examples of the two styles were alternated. In both of the latter conditions participants were asked to write descriptions of each individual item of home décor. Participants advanced through the study phase at their own pace, and their total study time was recorded.

After the study phase, participants were presented with three pairs of new pictures of home décor items. For each pair one was a product of Style X, and the other a product of Style Y (positioned randomly on the left or right). Participants used an 8-point scale to rate which item was from Style X (where a rating of 8 indicated certainty that an item was from Style X).

*Figure 1.* (A). Four examples of each style presented in study phase of Study 1. (B). Three pairs of new pictures presented to the participants in the test phase. (NB: assignment of the labels X and Y was counterbalanced.)

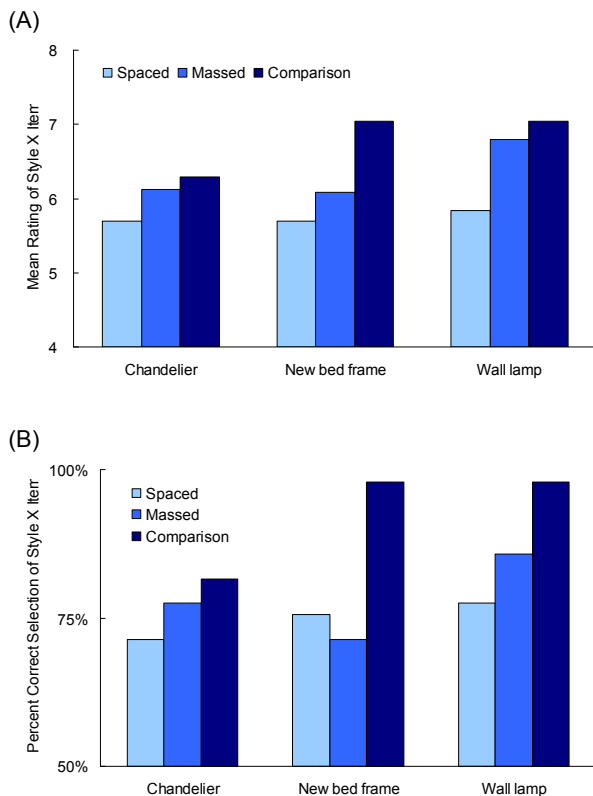

### Result and Discussion

Mean study times differed across the three conditions: 8.53 min (Spaced), 7.96 min (Massed), and 4.93 min (Comparison),  $F(2, 144) = 16.5$ ,  $MSE = 11.2$ ,  $p < .0001$ . Tukey tests showed that study time was lower for the Comparison condition than either the Massed or Spaced condition ( $p < .0001$ ), whereas the Spaced and Massed conditions did not differ reliably.

Figure 2A presents the mean ratings of the correct item representing Style X on the test phase, plotted such that

higher values (max = 8) indicate greater certainty that the correct item was indeed from Style X. A 3 x 3 mixed-factors ANOVA revealed a reliable effect of condition,  $F(2, 144) = 8.90$ ,  $MSE = 4.72$ ,  $p < .001$ . There was also a main effect of test item,  $F(2, 288) = 3.97$ ,  $MSE = 10.66$ ,  $p < .05$ , but the effect of condition did not vary significantly across items,  $F(4, 288) = 1.46$ ,  $MSE = 3.91$ ,  $p = .22$ . Collapsing over items, mean ratings were 5.74 (Spaced), 6.08 (Massed) and 6.79 (Comparison). Tukey tests revealed that generalization was more accurate for the Comparison condition than either the Spaced ( $p < .01$ ) or Massed condition ( $p < .05$ ), whereas the Spaced and Massed conditions did not reliably differ.

**Figure 2.** (A). Mean ratings of correct item from Style X for three pairs of new home décor items presented in test phase of Study 1. (B). Mean percentage of correctly selecting item from Style X for each of the three pairs.

We also calculated the percentage of correct choices by reducing the 8-point rating scale to a binary decision, breaking it at the midpoint (ratings of 1-4 vs. 5-8). As shown in Figure 2B, Comparison instructions yielded higher overall accuracy (93%) than either the Massed (78%) or Spaced (75%) condition. After aggregating across the three items, a one-way between-subjects ANOVA revealed a reliable effect of condition,  $F(2, 146) = 7.11$ ,  $MSE = 0.86$ ,  $p < .01$ . Tukey tests confirmed that generalization was more accurate for the Comparison condition than either the Spaced ( $p < .01$ ) or Massed condition ( $p < .05$ ), whereas the latter two

conditions did not reliably differ. The results of Study 1 thus provide clear evidence that comparison instructions designed to encourage induction of schemas for styles of home décor support more efficient learning and generalization than do presentation methods that focus attention on individual examples. The Comparison condition required less study time than either the Spaced or Massed conditions, yet yielded more successful generalization.

## Study 2

The results of Study 1 support the hypothesis that comparison instructions aid in inducing a schema for styles of furniture design, facilitating subsequent generalization. In Study 2 we examined the possible causal relationships between content of a style schema and generalization, using structural equation modeling to infer relevant latent variables. For modeling purposes only a single condition was run, with study, test, and evaluation phases. Participants first studied examples of multiple styles of home décor items, focusing on one particular style (called Style X), then judged which of new examples were from Style X, and finally rated descriptive words as to how well they fit their impression of Style X. The ratings of descriptors were used to estimate latent variables representing a schema for Style X, with the aim of predicting the generalization data from the test phase.

## Method

**Participants** A total of 175 participants (50 male, 125 female), ranging in age from 18–70 years ( $M = 32.4$ ), all residing in the United States, were recruited through Amazon Mechanical Turk. Participants were paid 60 cents for participating in the experiment, which took about 10–15 minutes.

**Materials** The materials were 23 pictures of IKEA home décor items, five representing each of five styles (labeled X, A, B, C, and D), selected from the same source as in Study 1. Style X (a specific style that was constant for all participants) was the focus of our modeling effort (see Figures 3–4). In addition, a list of 30 descriptive words was created for use in the evaluation phase (see Table 1). To create this list, 118 participants in an initial survey (also conducted on Mechanical Turk) were asked to generate words describing Style X (based on the same three examples used in the study phase of Study 2). Using these generated words as a starting point, we selected relatively high frequency and non-redundant words, and added several additional words (as distractors) that had *not* been generated to describe Style X.

**Procedure and Design** In the study phase, three pictures (a drawer, a bed frame, and a chandelier) were presented together for each style (see Figure 3). The study phase began with three steps that applied only to the examples of Style X (the style that was the direct focus of structural equation modeling). Participants (1) listed three common features of the examples of Style X; (2) described their “impression, feel, or sense of Style X” based on its common features; and (3) described the “personality” that Style X would represent

if it were thought of as a person. Next, participants saw all five examples of each type of home décor item (e.g., stools of each of the Styles X and A-D), and were asked to compare them and describe the difference between Style X and the other styles. This task was repeated for each of the three types of training items. The presentation order of pictures in Style X and the other styles was fully randomized.

During the subsequent test phase (see Figure 4), pairs of examples of four novel types of home décor items were presented (stools, wall lamps, duvet sets, and fabric). Each pair included one example of Style X and one example of some other style (Styles A-D). For each pair, participants rated which example was more likely to be from Style X, using the same 8-point scale as had been used in Study 1.

Finally, in the evaluation phase, participants were presented with the 30 descriptors in random order. Participants used a 4-point rating scale to evaluate how well word captured their impression of Style X (with a rating of 4 indicating that the descriptor “definitely” fit Style X).

Figure 3. Three examples of each style presented in study phase of Study 2.

Figure 4. Four pairs of new pictures presented to the participants in the test phase of Study 2. For each pair, the item in the left column is from Style X; that on the right is the foil, drawn from Styles A-D.

Table 1. Set of 30 descriptors used in evaluation phase of Study 2.

Words produced as descriptors of Style X	
feminine (25), old-fashioned (18), girly (17), traditional (9), plain (9), fancy (8), country (7), elegant (6), stylish (4), pretty (4), conservative (3), familiar (3), light (3), luxury (3), relax (3), cheery/active (2), romantic (2), soft (2), warm (2), modern (1), unisex (1)	
NB: number of respondents in initial survey (out of 118) who produced each descriptor in response to Style X is indicated in parentheses.	
Distractors (not produced in response to Style X)	
casual, cool, fashionable, formal, gorgeous, hard, masculine, natural, wild	

## Results and Discussion

Prior to conducting structural equation modeling, we checked descriptive statistics from the evaluation phase, identifying five descriptors with means ratings above 2.50 on the 4-point scale of applicability to Style X. We then performed exploratory factor analysis using these five scales, obtaining a promax rotation by maximum likelihood estimation using SPSS. Contribution ratios and eigenvalues were computed, and two factors were retained (eigenvalues > 1.0), which explained 60.0% of total variance. The inter-factor correlation between the two factors was 0.24.

We then performed structural equation modeling using EQS version 6.1 (<http://www.mvsoft.com/>) in order to identify apparent causal relationships between a style schema (based on the latent variables derived from ratings of descriptors) and the ability to discriminate examples of Style X on the test phase. The analysis identified a model with three latent factors that provided an excellent statistical fit to

the data,  $\chi^2(24) = 31.3, p = .14$ . The value of Root Mean Square Error of Approximation (RMSEA) was 0.04, and the value of the Comparative Fit Index (CFI) was 0.98.

The structural equation model is displayed in Figure 5. The factor labeled D (Discriminability) summarizes the ability to discriminate Style X from others on the test phase, based on the four items used to assess generalization of the knowledge about Style X acquired during the study phase. The D factor was in turn predicted by factors F (Femininity) and C (Classic), derived from the ratings of descriptors dur-

ing the evaluation phase. Specifically, factor F was associated with ratings of the words “feminine”, “fancy”, and “girly”, while factor C was associated with ratings of “traditional” and “old-fashioned”. The factor loadings for Factors F and C exceeded 0.50 and for factor D were over 0.20. Factors F and C had positive path coefficients between each other as well as to factor D. Intuitively, participants who associated Style X with descriptors indicative of a feminine and classic image were best able to discriminate examples of Style X from alternatives on the generalization test.

Figure 5. The model for predicting generalization of Style X to novel items on the test phase, derived by structural equation modeling in Study 2. Values of correlation coefficients are indicated. Error terms are denoted by subscripted *e*.

## General Discussion

Using realistic visual categories (styles of furniture and other home décor items) we showed in Study 1 that active comparison of examples of a category is more efficient (reduced study time and greater accuracy) in promoting subsequent generalization than is processing of individual examples, whether massed or spaced. These findings support the hypothesis that schema induction underlies successful generalization of a visual style. In Study 2 we attempted to assess the content of a design schema. Using structural equation modeling, we showed that after learning by comparison, generalization performance can be predicted by latent variables corresponding to relatively abstract concepts derived from descriptive terms.

Taken together, these findings support the usefulness of the concept of schema induction as a basis for generalization with complex categories. The results of Study 1, in particular, suggest that it would be a mistake to view spaced presentation *per se* as an optimal procedure for promoting induction and generalization. Not only did the Spaced condition yield poorer generalization (despite longer study time) than the Comparison condition, but it showed no advantage

(trend in wrong direction) relative to the Massed condition. Massed presentation, although not sufficient to reliably trigger comparison processes, may nonetheless make such processing more likely.

Based on other findings in the literature (e.g., Kornell & Bjork, 2008), there clearly are some conditions under which spacing improves later generalization performance, particularly in comparison to massed presentations that focus on encoding of individual items. In fact, comparison and spacing may well convey distinct and complementary benefits for categorization performance. In terms of the traditional stages of memory—encoding, retention and retrieval—schema induction can be viewed as a special type of encoding that focuses on abstraction of general cues to category membership, as opposed to encoding of individual training examples. We suggest that comparison facilitates schema induction during encoding, whereas spacing has its greatest impact on retention and retrieval. For complex categories of the sort used in the present studies, spacing likely makes schema induction more difficult; however, spacing may sometimes provide compensatory benefits in increasing retention and later retrieval of knowledge. This hypothesis suggests that generalization might be optimized by early

comparison of concurrently-presented examples, followed by subsequent spaced presentation of additional examples. Further research will be needed to explore the potential interactions between factors that guide induction of schemas and those that aid their retention and retrieval.

### Acknowledgments

Preparation of this paper was supported by a gift from Canon Incorporated, and by grant N000140810186 from the Office of Naval Research. We thank Airom Bleicher for assistance in running the studies.

## Abstract

This paper describes the current version of state-event transformation system to transform story lines and story worlds each other using a knowledge base and a conceptual dictionary. Moreover, we extend the basic framework to a circulative generation mechanism with a simple mutation function. Through the preliminary performance checks, we confirmed that the transformation of story worlds and story lines is approximately logically adequate and the circular process produces the diversity of stories. The proposed system is a module in an integrated narrative generation system and the pilot version is already implemented. In the context of the narrative generation system, the proposed system plays roles for expanding the variation of discourse to be generated and limiting possible narrative elements at any given time in a narrative generation process.

**Keywords:** Narrative generation system; story generation; state; action; conceptual dictionary.

## Introduction

In the context of natural language processing in the wide sense, the research of narrative generation system which aims at automatic generation of narrative texts by computer has been developing from 1960s. Meehan (1977) shows a classical approach and Bringsjord and Ferrucci (2000) is an example of the comparatively new result. Along with traditional literary genres, narrative and story will play important roles for digital entertainment genres such as computer game. The mechanism we propose in this paper is a part in an integrated narrative generation system we have studied as a project. The applicable goal is creating novel contents such as automatic generation game, which has not a fixed story, and narrative generation based narrative or literature, which is a form of novel containing narrative generation mechanisms. Moreover, narrative is the strongest method for organizing and structuring fragmentary information and a kind of collective knowledge in human being. The narrative generation system is also associated with a variety of issues such as the organic formation of fragmentary information, the diverse interpretation of an event or events, and so on (Ogata & Kanai, 2010).

In this paper, we deal with a part of mechanism for generating a story, which is a sequence of events to be narrated, in the narrative generation process. In concrete terms, we propose a system to make a correlation between state and event (action) which are main elements to construct

stories using a conceptual dictionary for noun/verb concepts and transformation rules. We analyze and classify the relationship between an action and the states in front and behind for 689 verb concepts to develop a mechanism that mutually transforms from an action to states or from states to an action and cyclically repeats the process. The action means an event in which a verb concept for an action is included as the central element. A temporal sequence of events is corresponding to a story. On the other hand, a collection of states means a static narrative knowledge supporting events.

## Narrative Generation and Proposed Mechanism

Three main modules of our narrative generation system are story generation mechanism, discourse mechanism, and surface expression mechanism. Story means a sequence of events to be narrated and discourse means the narrated structure of events, and both are described with conceptual representation. Expression contains surface representations including natural language, animated movie, music, and so on. The system has a conceptual dictionary and various narrative knowledge bases used mainly in story and discourse parts. Although our previous works was to develop the comparatively independent modules, we are currently starting to complete an integrated narrative generation system in which a variety of mechanisms are synthesized by standardizing data structure for event representation and constructing a conceptual dictionary to be used in a lot of modules commonly (Akimoto & Ogata, 2011). Figure 1 shows the overall structure of a pilot version of the system. The proposed system in this paper is corresponding to both “SL (story line)→SW (story world)” and “SW→SL” in the “Structural operation module”. As mentioned later in details, a story line is a sequence of events and a story world is a collection of states.

Figure 1: The overall structure of an integrated narrative generation system

A story is represented as a tree structure as shown in Figure 2. Three types of components in a story tree are relation, event, and state. An event forms a case frame with some elements such as agent, object, location, and so on. A relation semantically binds some events or the following part. The generation mechanism in this level is described in Ogata, Hori and Ohsuga (1994). The lowest layer of the tree is formed by states. A state means the precondition and the result of an event. Each state is represented with some kinds of frames describing the values of case frames in the corresponding event, namely it actually is a set of semantic data. We call the layer of states “story world” and the layer of events “story line”. An event produces two states and two states are corresponding to an event. This paper describes the detailed structures and proposes the mechanism of mutual transformation processing by refining and expanding previous studies (Nakashima & Ogata 2008; Onodera, Oishi & Ogata, 2011). In the context of narrative generation system, the primary roles of this mechanism are providing a function for generating narrative representations such as descriptions and explanations besides events sequences and a construction for limiting possible elements (like agent, object, and place) at any given time in a narrative generation process, using the detailed and explicit definition of states.

## Research Background

In the research of “the history of narrative” by philosophers (Noe, 2005), history is a kind of story to transform a chronicle as chronologically arranged events into a sequence of events sorted through the narrator’s filter. As described above, we divide a narrative generation process into the information to be narrated (story) and the narration itself (discourse and surface expression). It may be thought that the part of state and event in this paper is corresponding to the chronicle. One of the characteristics in our narrative generation system research is an interdisciplinary approach of the humanities such as narratology & literary theories and computer science such as AI. The materialization as a program of the conceptual idea and theory contributes to give the new tools of thought to such area. From this point of view, the problem is that what kinds of knowledge and techniques are used for executing the transformation from states as a chronicle to events as a story. Although we propose only the micro level’s technique in this paper, we are aiming at building the narrative generation system on such conceptual and philosophical foundation.

In AI, this paper is related to the function of planning that an agent automatically executes a goal through a goal oriented process. Planning technique, which is a strong foundation in many story or narrative generation systems (Mueller, 1990; Okada & Endo, 1992), generates stories or

Figure 2: The structure of a story

plot lines to reach a goal through the recursive division of the goal. Although the planning is a comparatively macro framework for story generation, in this paper, we pay attention to the part of micro transformation process between states and events without a specific goal. Therefore, it is not planning in a strict sense. As our narrative generation system adopts a kind of modular approach in which a variety of elements are organically integrated, the aspect of goal-based planning can be incorporated into the system as a different module.

Next, conceptual dependency theory by Schank (1975) is a classical study regarding to the semantic categorization of concepts and categorizes verb concepts into 11 types of fundamental concepts. It is difficult to faithfully categorize real diverse concepts in accordance with the theoretical framework. However, we will be able to partially apply it or the idea as a reference, regarding to the part of especially abstract actions. A verb thesaurus by Takeuchi (2011) also shows a detailed system of semantic classification of verbs. It classifies verbs into basic events (states and activities) and complicated events (verbs for state change). Verbs for transitioning among states in this thesaurus are corresponding to verb concepts for changing states in this paper. Although our research shows more detailed classification about the categories of moving of agent and object, we may be able to refer to this thesaurus’s classification about other categories, namely, human relationships, body information such as personal appearance and physical condition, psychological information such as emotion, change of hardness and shape of object, etc. In addition, FrameNet (Fillmore & Baker, 2010) and Japanese FrameNet (Ohara, 2008) define the semantics of a word by a semantic frame, which means the structured knowledge about a typical scene, constructed with the frame elements. And, VerbNet (Kipper-Schuler, Dang, & Palmer, 2000; Kipper-Schuler, 2005) is a hierarchical verb lexicon in which each class is described by semantic predicates, thematic roles, and basic syntactic frames. Because this research’s purpose is not building a conceptual lexicon itself and the implementation from the viewpoint of the narrative generation system, we do not aim at the direct use or the direct revision of above resources currently. However, for revising the knowledge base mentioned later, the more direct reference will be needed in the future.

Moreover, the proposed system uses a conceptual dictionary to transform between states and events. As an example of story generation systems by the use of conceptual knowledge base, McIntyre and Lapata (2009) proposed a system which generates stories by using a knowledge base of compositions of an event sentence and chains of events. Stories are generated by a kind of tree search of possible stories. The system has several scoring criteria for pruning low scored branches. Although this is a completed story generation system, the proposed system is a mechanism in a big framework of narrative generation system to be able to add various other mechanisms such as a selection function based on some specific criteria on the foundation of a simple basic mechanism.

## An Overview of the Mechanism

Figure 3 draws an image of the state-event transformation mechanism. The state of A (a place in this case) changes or

does not change based on an event. A state includes some kinds of information such as a place, an agent's features, and object or objects, and so on. These elements in a state are described by each frame. For example, an agent's frame contains name, location, time, possession, and so on. The each element is really corresponding to an instance as the substantiation of each element in a conceptual dictionary. On the other hand, an event is described by a conceptual representation form shown in Figure 4. When the system recognizes a change in the states of agent, object, place, and time, it infers an event using "state-event transformation knowledge base". In contrast, the system can also infer two states from an event using the same knowledge base. We call a set of states "story world" and a sequence of events "story line". In summary, in a story line, each event is represented with a case frame including agent, object, location, time, and so on. In a story world, each state is represented with a set of four types of frames of agent, object, location, and time corresponding to above cases. And, each frame is constructed with slots and the values. A state means static knowledge and an event means dynamic one generated by the change of two states. The system can also repeat a circulative transformation process between states and events. The objective is to add various changes to the flows of stories through the cyclical process. However, as the state change and events are the relationship of one-to-many, in the case of simple circulation, the change of story worlds remains small compared with the comparatively large change of story lines. To add a larger change to story worlds, a kind of simple mutational function is introduced. This system is implemented by Common Lisp as with other main parts in the narrative generation system.

The conceptual dictionary is a hierarchical system for verb and noun concepts developed referring to "Goi-Taikēi: a Japanese lexicon" (Ikehara et al., 1999) and "Japanese WordNet" (Bond et al., 2009) mainly. It contains about 12000 verb concepts and about 120000 noun concepts. In the current version in this paper, we limitedly treat only verb concepts relevant to the "physical transfer" and "possessive transfer". The each verb concept is described as a case frame form

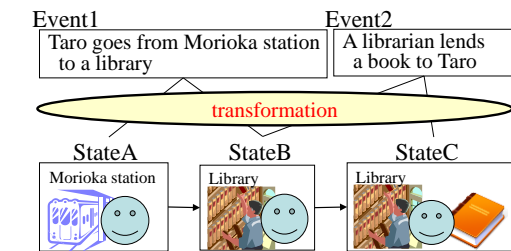

Figure 3: An image of the proposed mechanism

age1 goes loc2	Case	Function of case
(event 行く(1)[go(1)] (type action) (ID 1) (time (time1 time2) (agent age1) (counter-agent nil) (location loc1) (object nil) (instrument nil) (from nil) (to loc2))	type	Kind of event (action or happening) (Prince, 1987)
	ID	Identification of an event
	time	A pair of starting time and ending time of event
	agent	Agent of the action
	counter-agent	Object of the action (living thing)
	location	Occurrence of the event
	object	Object of the action (no living thing)
	instrument	Instrument or tool used by the action
	from	Starting position of the action
	to	Ending position of the action

Figure 4: The conceptual representation form of an event

shown in Figure 4. Oishi and Ogata (2011, 2012) propose the detailed explanation.

## State-Event Transformation Knowledge Base

This stores rules for transforming two states and an event mutually. As shown in Figure 5, a transformation rule consists of following three elements: (1) The pattern of the change of states, (2) a set of preconditions for the change, and (3) A set of verb concepts associated with the change. This example means "change of the place where a character exits". Above (2) is the condition to apply a transformation rule and this example means "an agent exits at a place, and the place and another place exists". In above (3), a group of verb concepts produce a same type of state change in common. In the current step of implementation, 138 "transformation rules" and 689 verb concepts are contained.

The transformation rules are hierarchically classified. The highest layer is divided into "the change of location, address, possession, health, durability, and posture" and "generation and disappearance" according to the changing element in each slot in agent, object, and place. Second layer shows the concrete way of changing in a slot and is classified into 27 kinds. For example, in the movement of place, there are the movement among different places, the vertical movement, and the high/low movement in a same place. And, one or more rules according to each movement can be defined. For example, in the movement among different places, an event satisfies both slots of "from" and "to" in common and another event satisfies only "from" or "to". Table 1 lists defined categories of state change. For example, the change of location slot in an agent frame or an object frame is corresponded to 11 types of categories. In this table, "large classification" means it is based on what (or which slot) is changed in a state and "small classification" means it is based on how it changes. For about 4200 kinds of "physical actions that an agent becomes the subject", about 2000 kinds of "other physical actions", and about 4100 kinds of "psychological actions", we are currently proceeding this expansion and revision by focus on what is changed in a state (we need to expand frame as necessary), how a state changes, and what kind of cases a verb concept has.

Type of state changes	
(Change of location: instance moves from X to Y)	
<b>Rule1: agent moves from X to Y</b>	
<b>Pattern of the change of states</b> (agentX's location changes from X to Y)	
<b>Precondition</b> (condition1 (there is agentX in locationX)) (condition2 (there is locationX)) (condition3 (there is locationY))	
<b>Set of verb concepts</b> (歩く(1)[walk(1)] 移動する(1)[move(1)] ...)	

Figure 5: A state-event transformation rule

Table 1: The classification of transformation rules (the details are omitted)

Large classification	Small classification
Change of location	Move, Move[up], Move[down], Move[out], Move[in], Move[near], Move[far], Carry, Go together, Near, Leave.
Change of posture	Stand, Sit, Lie.
Change of possession	Have, Relinquish, Give, Trade, Throw.
Change of health/durability	Death, Break, Damage, Heat.
Change of address	Migrate
Generation disappear	Generation, Disappear, Ingest

## Two Processes of Generation

The flows of transformation are from a story line to a story world (“story world generation”) and from a story world to a story line (“story line generation”). In addition, these transformations can be also repeated continuously or cyclically.

### Story World Generation Process

The process of story world generation is as follows (Figure 6): (1) The user specifies a story line and each value of agents, objects, and places in the story line. (2) The system searches a rule in a state-event transformation knowledge base according to a verb concept from first event in the story line. (3) The system selects a rule which has the verb concept in the group of verb concepts. (4) The system sets a state before the event which is the precondition in the selected rule. If a state already exists, the system simply overwrites by the new state. (5) The system refers the pattern of the change of states in the rule and makes a state after the event by changing the previous state set in above (4). (6) The system refers next event. If it exists, the process returns to above (2). If it does not exist, the process finishes.

### Story Line Generation Process

The flow of story line generation is as follows (Figure 7): (1) The user specifies two or more states in a story world according to the numerical order of ID. (2) The system compares the changed frame(s) and slot(s) in the first two states. (3) In the state-event transformation knowledge base, the system searches a transformation rule in which the first state & the precondition and the change in the second state & the content of change respectively match. (4) The system checks the constraints for each verb concept stored in the rule.

Figure 6: The flow of story world generation

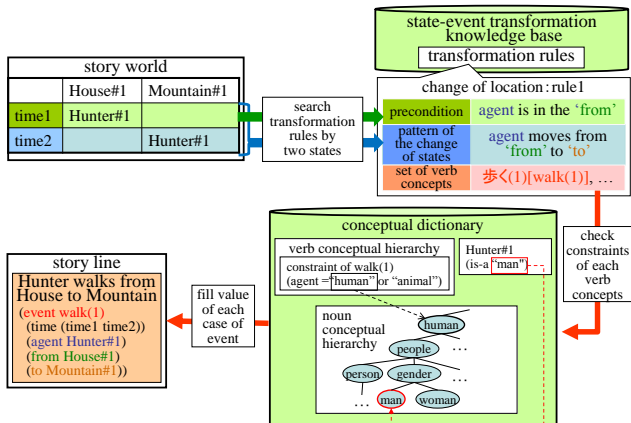

Figure 7: The flow of story line generation process

Specifically, the system checks whether the agents and objects are within the range of each constraint. And, the system allocates agents, objects, and places to the case frame for a verb concept that satisfies all constraints to generate an event. (5) If one or more events remain, the process returns to (2). And if no event, the process finishes.

### Circulative Generation Process

The system can repeat the transformation among story worlds and story lines. For example, an event such as “Taro goes to the park from the house” can be transformed into two states, “Taro is in the house” and “Taro is in the park”. Next, these states can be transformed into an event that is different from the former such as “Taro comes to the park from the house”. The system enables “circulative generation” in which two types of transformations are repeated each other. A verb concept in an event in a story line changes within a given range through such circulative process. However, a story world does not change from the initial story world because it is knowledge to prescribe the story content. Story world and story line have one-to-many relationship in the ordinary mechanism.

Moreover, we introduce a mechanism to produce larger changes in both story line and story world through the circulative generation process. Although we can imagine various methods to actualize it, we implemented a function using a simple mutation mechanism. In story world generation, the function randomly changes a state and the value of an agent or an object in a frame after the generation process. On the other hand, in story line generation, it randomly changes an event and a case’s value in an event concept after the generation process.

## Execution Examples

First, as the input information, we prepare the summary of a part of Mishima’s “The sailor who fell from grace with the sea” (1963) (Figure 8). Table 2 shows a generated story world. In addition, Figure 9 shows the result of a story line based on the story world. In these figures, we show the result by a simple sentence generation program. Figure 8 is a scene that Ryuji, Noboru, and a “don” move from a hill to a dry dock in Yokohama. In Figure 9, some changes occur. For example, Ryuji and Noboru move together in one event and the don moves as if he comes after Noboru.

Second, circulative generation was attempted based on a tale in Yanagita’s “The legends of Tono” (1955) (a story that a hunter forces a big priest to eat burned stones to punish the big priest who ate the hunter’s rice cakes without the permission).

E1: Ryuji#1 takes Sailor cap#1 in Ryuji#1's hand	E17: Ryuji#1 heads to Hill#2
E2: Ryuji#1 goes from Store#1 to Hill#1	E18: Noboru#1 heads to Hill#2
E3: Don#1 goes to Hill#1	E19: Don#1 heads to Hill#2

E9: Ryuji#1 escorts Noboru#1 to Slope#1	E21: Noboru#1 parts with Sailor cap#1
E10: Don#1 advances to Slope#1	E22: Noboru#1 wins Tea#1 in "lottery"
E11: Ryuji#1 moves Noboru#1 from Slope#1 to Tunnel#1	E23: Noboru#1 supplies Tea#1 to Ryuji#1
E12: Noboru#1 posts Don#1 at Tunnel#1	E24: Ryuji#1 drinks Tea#1

Figure 9: A generated story line

In this circulative generation, we implemented a simple mutation function. It randomly changes the generated values for frames of agents and objects or values for case frames of event concepts to other values for agents, objects, and places in the story. In this time, we attempted the mutation probability, 0.1. Figure 10 shows an input story line and two story lines of 4 times and 40 times. As a result, in 4th generation, a scene in which the hunter and the priest bite each other is inserted and various events occur over the rice cakes. In 40th generation, objects in the story are only two rice cakes and a scene in which the big priest dies is omitted. The reason of outstanding reduction of the number of events and the simplification of generated stories are basically by that elements which are introduced in the simple mutation are only ones appeared in the generated stories already. We plan to attempt another circulative experiment by the arbitrary introducing of elements that do not exist in the already generated stories.

### Performance Checks

We show some preliminary checks of the system's basic performance using the result of "The legends of Tono" as mentioned above. First, we analyzed 20 samples which were generated from a same story line to investigate the correctness and the diversity of generated states in the story world. Second, for the story line generation, we analyzed 20 samples which were generated from a same story world to confirm the possibility and the diversity of events. In both experiments, we did not consider the naturalness of context and adopted whether each event simply physically occur as the evaluation criterion. For example, a sample story has a scene in which a big priest eats a burned stone. In spite of actual unnaturalness, this scene is physically possible. In addition, in many stories, physically impossible events and fantastical events also occur. A basic policy of our narrative generation system is the

generation of realistically possible events, and unrealistic and fantastical events are generated on the basis of the advanced rhetorical techniques such as the "defamiliarization" processing by the relaxation and adjustment of conceptual constraints using a conceptual dictionary (Zhang, Ono & Ogata, 2011, 2012). Therefore, the proposed system aims at a mechanism for generating realistic events and to the extent possible. As this preliminary check, we confirmed that the system could generate comparatively adequate and diverse results in both generation mechanisms except that few impossible events are generated in the story line processing. To decrease the impossible events, the elaboration of the conceptual dictionary is required.

Next, for circulative generation, we executed 15 cycles from a story line to analyze the degree of change in the generated story lines. As a result, we observed several types of changes such as the appearance of new event(s) and the disappearance of event(s). Table 3 shows the result of comparison between the 5th story line and the 15th one.

At last, we investigated the naturalness of story lines. The naturalness simply means that a story has not any realistic contradiction. We analyzed 10 story lines by a circulative generation process. As a result, we discovered some types of

Input story line	
E1: Hunter#1 burns Rice cake#1	E12: Hunter#1 burns Rice cake#4
E2: Hunter#1 burns Rice cake#2	E13: Hunter#1 burns Stone#1
E3: Hunter#1 burns Rice cake#3	E14: Hunter#1 acquires Stone#1
E4: Hunter#1 gets Rice cake#1 from Patrol	E15: Hunter#1 abandons Stone#1

E3: Hunter#1 escapes from House#1	E10: Hunter#1 brings Rice cake#1 in House#1
E4: Hunter#1 chews Rice cake#2	E11: Big priest#1 escapes from House#1
E5: Hunter#1 leaves Mountain#1	E12: Big priest#1 runs the whole House#1
E6: Hunter#1 escorts Big priest#1 to Mountain#1	E13: Big priest#1 abandons Rice cake#1
E7: Big priest#1 travels around House#1	

Figure 10: An example of circular generation

Table 3: The change of story lines through circulation

	Input story line	5th story line	15th story line
Appearing agent	Hunter and Big priest are half-and-half	Hunter is two-thirds	Hunter is mostly
Appearing object	Stone and kiln appear once	Stone and kiln appear more than once	Stone is mostly
Location of agent (Hunter)	Stay in the House from beginning to end	Do a round trip to House and Mountain many times	Do a round trip to House and Mountain many times
Location of agent (Big priest)	Do a round trip to House and Mountain two times	Do a round trip to House and Mountain one times	Do a round trip to House and Mountain one times
Contradiction of the story	none	none	Hunter moves to the same location many times
Number of event	23	21	19

contradictions. In an example, an agent moved to the location X from location Y and again moves to a different place from the X. Such contradiction is brought from the random choice of a location by the mutation function. It is necessary to adjust the mutation function so that contradictions do not arise completely or if a contradiction occurs, a kind of complement mechanism rewrites state(s) and event(s) after the story line or the story world were made. We prepared two methods for such ex-post solution. First method is “the rewrite of information” and second one is “the complement of information”. The former is a method that when a contradiction among some events occurs, the description of a state is changed to generate a new story. In the latter, when a contradiction arises, a new state is inserted into the existing states to generate a new story. In the former, an event’s content changes but the story line’s length does not change. On the other hand, in the latter, as a new state and a new event are inserted, the story line’s length gets longer. As another contradiction, a dead agent acts. For such case, we partially alter the mechanism so that a dead man or a disappearing object is not chosen as an agent or an object by changing the category to which the noun concept is belonged. For example, in the event like “Taro (dead-man) walks”, the constraint of agent in verb concept “walk” was originally the category of “human” except for “dead-man”. Accordingly, the system can alter the category to which Taro belongs from “human” to “dead-man”. Of course, for narratives and stories, such contradiction or unreality is certainly necessary and rather very important and essential element. Again, our policy is that we regard the knowledge and mechanism prepared based on the realism or physical possibility in a narrow sense as a standard and basic method, and introduce the processing of rhetorical knowledge and techniques to adjust the reference range in the conceptual dictionary.

## Conclusions

This paper reported the current version of state-event transformation system to transform story lines and story worlds each other using a knowledge base and a conceptual dictionary. Moreover, we extended the basic framework to a circulative generation mechanism with a simple mutation function. Through the preliminary performance checks, we confirmed that the transformation of story worlds and story lines is approximately logically adequate and the circular process produces the diversity of stories. The proposed system is a module in an integrated narrative generation system and the pilot version is already implemented. In the context of the narrative generation system, the proposed system plays roles for expanding the variation of discourse to be generated and limiting possible narrative elements at any given time in a narrative generation process.

## Abstract

We describe an intervention being developed by our research team, Pushing Symbols (PS). This intervention is designed to encourage learners to treat symbol systems as physical objects that move and change over time according to dynamic principles. We provide students with the opportunities to explore algebraic structure by physically manipulating and interacting with concrete and virtual symbolic systems that enforce rules through constraints on physical transformations.

Here we present an instantiation of this approach aimed at helping students learn the structure of algebraic notation in general, and in particular learn to simplify like terms. This instantiation combines colored symbol tiles with a new touchscreen software technology adapted from the commercial *Algebra Touch* software. We present preliminary findings from a study with 70 middle-school students who participated in the PS intervention over a three-hour period.

**Keywords:** Algebra education; learning; perception; mathematical cognition

## Introduction

The core conceptual content of algebra is extraordinarily simple: it is largely exhausted by the properties of addition and multiplication over the real numbers, such as commutativity, associativity, and distributivity, together with basic properties of functions and equivalence relations over the same structure. This formal simplicity belies the great difficulty students have in mastering basic algebra content (NAEP, 2011) — and especially the notation universally used to express algebraic claims (McNeil, 2008; Koedinger & Alibali, 2008).

One way to explain the difficulty of algebra is that unlike number cognition, algebraic reasoning does not seem to fit neatly into a core conceptual domain (Dehaene, 1997; Carey, 2009). Children may then face the challenge of assembling new cognitive tools appropriate to algebraic interactions. This task is made more challenging because typical instruction in basic algebraic notation is often brief and involves an emphasis on memorization of abstract rules.

Algebraic literacy—the fluent construction, interpretation, and manipulation of algebraic notations—involves not just memorizing rules, but also learning appropriate perceptual processes (Goldstone, Landy, & Son, 2010; Kirshner, 1989; Landy & Goldstone, 2007, 2008, 2010; Kellman, Massey, & Son, 2010). Like other formal diagrammatic systems (such as, for example, Venn diagrams) algebraic notation aligns the structure of the content domain with automatic perceptual properties and necessary physical laws (Cheng, 1999; Landy, Allen, and Anderson, 2011; Landy, 2010). In

this way reasoning that is properly cognitive can be accomplished by perceptual-motor systems such as attention (Patsenko & Altmann, 2010) or perceptual organization (Landy & Goldstone, 2007; Novick & Catley, 2008). Although such transformation of cognitive work into perceptual processing may carry distinctive risk of mistaking perceptual properties of representations for content principles (Novick & Catley, 2007; Kirshner & Awtry, 2004), it may also be critical to reducing cognitive load in complex operations (Sweller, 1994).

Successful students often use perceptual and visual patterns available in notations to solve mathematical problems. Like many skills learned from long practices learning algebra involves perceptual training—learning to *see* equations as structured objects (Landy and Goldstone, 2007; Kellman et al., 2008; Kirshner & Awtry, 2004). For instance, people seem to group symbols into perceptual chunks and use these groups, rather than just calculation rules, to perform mathematics. Although in some cases the appropriate perceptual patterns are fairly easy to see (Kirshner & Awtry, 2004), in other cases understanding the visual forms requires that a learner internalize an appropriate way of seeing a piece of notation. Real-world motion, changes, and transformations are naturally memorable and easy to acquire, making these processes natural tools for helping students grapple with algebra (Landy, 2010). Some successful object-centered transformations, however, may not be as immediately obvious as others in traditional instruction. Therefore, training students to *see* the structure of algebra may be a promising approach to teaching algebraic ideas.

While this perceptual-motor understanding of algebraic forms is a potentially rich and powerful source of student understanding, it also stands as a barrier to learning if visual patterning is not taught in a controlled manner. While some students learn easily, others latch on to incorrect perceptions and, consequently, generalizations (Marquis, 1988; Kirshner, 1989; Nogueira de Lima & Tall, 2007). Our goal is to find instructional and pedagogical paths through which students can make use of the strength of perceptual patterns in algebraic notation without falling prey to misleading visual structures or overly procedural, low-level understandings.

## Pushing Symbols: Teaching the Structure of Algebraic Expressions

The purpose of the PS intervention is to explore an alternative method of algebra instruction that focuses

Perceptual Process	Formal Transformation	Illustration
Rigid Motion	Commutation Transposition Rearrangements	$x+a = a+x$
Splitting	Distribution	$a(b+c) = (ab+ac)$
Joining	Factoring, Canceling	$t+2x-2x+q = t+q$
Symmetric Creation/ Destruction	Equation Transformation, Simplifying Fractions	$x-8=3$ $x-8+8=3+8$

Figure 1. Algebraic Transformation Visualizations

student efforts on the visual structure of formalisms, both by directly presenting those visual patterns and by challenging students to maintain and explain them. This method is being instantiated in a pedagogical intervention (PS) consisting of a set of in-class discussions, activities, and a dynamic computer-based visualization method. The intervention allows students to physically and dynamically interact with algebraic expression elements, providing a potentially powerful source of perceptual-motor experiences. Rather than simply rewriting different static expressions, in PS learners directly interact with expression objects and transform them using dynamical laws. Because rigid motion is a powerful perceptual grouping mechanism (Palmer, 1999) it is anticipated that training in which students see correct algebraic structures in dynamic transformations may lead to improved understanding of algebraic concepts.

The PS intervention has several specific aims. First we aim to increase fluency and accuracy by improving the alignment between students' visual-motor processes and proper formal operations and transformations. (Figure 1). Second the PS program is designed to be engaging for students, which is intended to build efficacy in students and develop the attitude that algebra can be intuitive, predictable, and even fun.

### Algebra Structure Tiles

The Pushing Symbols manipulative system uses colored magnets and tiles to decompose the structure of algebraic expressions. There are 4 different colored tiles in a set (see Figure 2), and each color represents a specific mathematical object (number, variable, coefficient, symbol). Yellow tiles represent numbers (from  $\pm 1-9$ ), blue tiles represent symbols or mathematical operations. (+), red tiles represent x variables and coefficients (from  $\pm 1-9$ ), and green tiles represent y variables and coefficients (from  $\pm 1-9$ ). After modeling an expression, the tiles can be rearranged and simplified into equivalent expressions.

Figure 2: Algebra Structure Tiles

### The Algebra Touch Research (ATR) Software

The PS system uses a computer application developed in collaboration with Regular Berry software to teach students basic algebraic principles while richly engaging perceptual-motor systems (Figure 3). We describe software developed by Regular Berry software based on the *Algebra Touch* system, which instantiates the transformations specified by the PS intervention (We will call this *Algebra Touch: Research*, or *ATR*) In ATR students perform arithmetic functions by tapping on a sign and algebraic rearrangements are carried out by touching appropriate symbols and moving them into the desired location. ATR provides dynamical models of basic algebraic properties and transformations such as distributivity of multiplication over addition, commutativity, simplification of like terms through addition, and reduction of fractions to lowest terms.

ATR does not allow students to make mistakes; if they attempt to do something against the laws of mathematics, a brief side-to-side motion (a "shake") provides immediate feedback that their desired action was illegal. As a result, students immediately see how the rules result in legal transformations or manipulations in a way that is impossible with a traditional blackboard or overhead projector lesson.

Problems in ATR can be presented in either an untimed *list* mode or a *game* mode. In both modes the presentation and interaction with individual problems is identical. However, in the *game* mode problems are collected into *level*, and performance on any particular level is scored with a number of stars. Stars are based on the number of mistakes made during problem solution, and the speed with which a particular problem is solved. If too many mistakes are made or time runs out, the level is "failed" and must be restarted. At the end of each problem, the program provides immediate feedback to students about the number of errors they made and the speed to which they simplified the expression.

### Study Details

The PS approach has been instantiated in a single trial lesson covering combination of like terms. This lesson lasts approximately 90 minutes, and involves a large set of symbol tiles for teacher demonstrations on a whiteboard, smaller tiles used by students in pairs, and the ATR software.

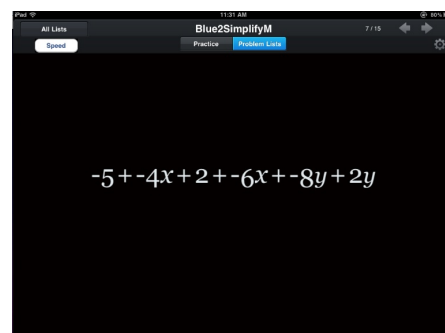

Figure 3: Algebra Touch Research software

We anticipated that the intervention would decrease the amount of structural errors that students made, and improve their overall understanding of simplifying expressions. Since the intervention did not explicitly address solving word problems, we did not anticipate a change in the number of word problems solved successfully. We also hypothesized that pre-test scores, self-efficacy, engagement, and performance on the iPad would positively contribute to post-test scores, while math anxiety would negatively contribute to post-test performance. We also predicted that the intervention would shift participation and engagement.

## Participants

Seventy eighth-grade students from an urban public middle school in the mid-east United States participated in this study during their regular mathematics instruction time. These students had never received instruction on like-terms or simplifying expressions before this intervention. Student assent and parental consent were obtained prior to participation in this study, in accordance with the directions of the University of Richmond Institutional Review Board.

## Study Procedures

The study took approximately 3 hours in total and occurred over three class periods. On the first day (90 minutes), students completed a pre-test on simplifying algebraic expressions and a Mathematics Self-Efficacy and Anxiety questionnaire. Next, students received a whole-group lesson on simplifying expressions. During this lesson, the teacher (the first author) led a series of discussions and used colored tiles to demonstrate algebraic structure. Students were then put into groups of 3 and used colored tiles to identify and combine like terms and simplify expressions. Third, students participated in a 20-minute exploration and training activity that provided students with an opportunity to learn how to use the iPad and *ATR* technology.

On the second day (90 minutes), students were each given an iPad, and were given 40 minutes to solve problems. Practice was divided into two phases. In the first phase, students simplified simple expressions involving no more than about 4 terms; in the second phase, more complex expressions involving up to 8 terms. Each 20 minutes phase was divided between an initial list of 10 untimed problems, followed by a set of 40 game problems.

Any pedagogical approach, especially those based on software interventions, must address the assistance dilemma (Aleven and Koedinger, 2002): how and how much help should be provided to learners, and when? *ATR* makes several fixed commitments: students cannot complete illegal transformations, for instance. In the current study, we also varied the amount of arithmetic support given to students. Participants were randomly assigned into 2 groups. In one group, students manually calculated the simple problems<sup>1</sup>,

<sup>1</sup> An example of manual and automatic calculation modes can be seen at <http://davidlandy.net/PushingSymbols/RPS--12-1-11-Like-Terms-Manual-1.mov> and <http://davidlandy.net/PushingSymbols/RPS--12-1-11-Like-Terms-Automatic-1.mov>

but arithmetic in structurally more complex problems was calculated automatically by the software; in the second condition, assistance pattern was reversed. There were no differences in structural understanding or success in word problems between the two groups, and, this manipulation will not be discussed further.

At the end of the intervention, students completed a questionnaire about their engagement during the intervention and a post-test. We also conducted student focus groups to receive feedback on what aspects of the intervention were most helpful and enjoyable. 2 weeks after the intervention, students completed a retention test.

## Measures

**Simplifying Expressions Assessments.** Each child completed an 18-item pre, post, and retention test on paper involving expression simplification. These tests assessed two major types of expression-related problem-solving skills: procedural facility with simplification (10-items), and expression construction and evaluation (word problems) (6 items). The problems on the pre, post, and retention tests were similar in form and difficulty.

We followed several steps to code the assessments. First, we coded each item on the assessment as incorrect, correct, or did not attempt. Next, to understand the source of the errors, we conducted error analyses on each item. Four error codes were used: 1) no error, 2) structural error; 3) addition or negative error; and 4) did not attempt. Structural errors include combining unlike terms, over-combination (simplifying the expression correctly and then combining un-like terms) or partial structural errors (moving around like terms but not completely simplifying the problem). Since the PS framework is designed to make structure concrete, naturally structural errors are particularly interesting for analysis. Addition and negative errors were coded when students used correct structure, but made an arithmetic error when combining terms. When a problem was left blank, we coded it as “did not attempt”. On average, students did not attempt to solve 25% of the pre-test problems, 16% of the problems on the post-test, and 20% on the retention test.

Figure 4: Proportion of Attempted Problems Solved Correctly (Free of structural errors)

Third, for each assessment (pre, post, and retention), we calculated 2 composite scores. 1) proportion of attempted procedural problems that were free of structural errors. 2) proportion of attempted word problems that were solved correctly. These two scores were used to measure student understanding of algebraic expressions in the analyses.

**ATR Performance.** iPad Performance was measured at 2 different levels, using the *Algebra Speed* game. Level 1 asked students to simplify a series of 36 *simple* expressions (ex.  $5+7+3$ ;  $x+2+6$ ). Level 2 asked students to simplify a series of 40 *complex* expressions (ex.  $7+2x+5x+4y+1+-2y$ ). Students could receive a maximum of 3 points for each problem solved. The points system accounted both the number of errors that they made and the speed to which they simplified the expression. At the end of each level students received a level performance score, which represented the total number of points received on the level. Total points on Level 1 (*simple*) and Level 2 (*complex*) were used as 2 measures of ATR performance.

**Mathematics Self-Efficacy and Anxiety Questionnaire.** Students were administered a set of 10-items pertaining to their self-efficacy and anxiety in mathematics. All 10 items were on a uniform 4-point scale (1=almost never, 2=sometimes, 3=most of the time, 4=almost all of the time). To assess students' math self-efficacy beliefs, 5 items were adapted from the Academic Efficacy subscale of the Patterns of Adaptive Learning Scales (Midgley et al., 2000) (e.g. "I know I can learn the skills taught in math this year") ( $\alpha=.82$ ). To measure students' feelings of math anxiety, 5 items were adapted from the Student Beliefs about Mathematics Survey (Kaya, 2008) (e.g. "I feel nervous when I do math because I think it's too hard") ( $\alpha=.61$ ). Scores for each construct were then averaged to create a mean math self-efficacy and mean mathematics anxiety composite.

**Student Engagement in Mathematics Questionnaire.** Student engagement during the lesson was measured using 18 items that were adapted from the Student Engagement in Mathematics Questionnaire (Kong, Wong, & Lam, 2003): (e.g. "Today I only paid attention in math when it was interesting."). All 18 items were on a 4-point scale (1=no, not at all true, 2=a little true, 3=often true, 4=yes, very true).

## Results

### Analysis 1: Does the Pushing Symbols Intervention improve student understanding of algebraic structure?

**Procedural Problems.** On average the intervention increased students' knowledge of algebraic structure (Figure 4). At pretest only 9.4% of problems were solved without structural errors. At post-test 54% of problems attempted were solved without structural errors (Improvement of 44.6%,  $t=10.48$ ,  $p<0.01$ ). At retention 41.4% of the problems were solved without structural errors (overall improvement of 32%,  $t=6.81$ ,  $p<0.01$ ). After 2 weeks students retained 72% of their structural learning.

**Word Problems.** As expected, the intervention did not appear to improve student understanding of word problems at post-test ( $t=-0.87$ ,  $p>0.05$ ) or retention ( $t=-0.07$ ,  $p>0.05$ ).

### Analysis 2: Relations between structural performance, efficacy, anxiety, engagement, and performance on ATR.

We conducted regression analyses to examine potential predictors of structural performance on the post-test. We included the following variables in the analysis: gender, math self-efficacy, math anxiety, engagement, pre-test performance, and iPad performance.

Correlations and descriptive statistics are reported in Table 1 and the regression results are presented in Table 2. Three main effects were found. First, results indicate that math efficacy was related to higher performance on the post-test (a 1 point increase in efficacy was related to a 1.27 point increase in performance). Second, successfully completing more problems (both simple and complex) on ATR was related to higher scores on the post-test. Further, students who reported being more engaged during the PS intervention performed higher on the post-test (for every 1 point increase in engagement, students performed 1.80 points higher on the post test). Interestingly, students' performance on the pre-test or levels of math anxiety did not predict performance at post-test.

Table 1: Means, Standard Deviations, and Correlations for Measures of Performance, Beliefs, and Engagement

Variable	Mean	SD	1	2	3	4	5	6	7	8	9	10
1. Performance on Post-test	5.40	3.70	-									
2. Gender	0.55	0.51	-0.10	-

Scaffold Group	0.09	1.24	0.50

## Discussion

We have described an approach to algebra instruction that emphasizes perceptual and manual interactions with dynamically realized models of algebraic notation, as a vehicle for helping students become fluent with algebraic structure. Although our current results are quite preliminary and not experimental, they do demonstrate that a short intervention based on this framework may substantially improve student performance at simplifying expressions. Furthermore, this work adds to a small literature suggesting that touchscreen-based learning tools can successfully lead to student learning.

Although our results suggest that, on average, student performance increased substantially after receiving the intervention, not all students mastered the material. Many students still struggled with simplifying expressions or did not attempt many of the problems. It will be important to compare motion-based interventions such as this one with other methods of instruction in algebra notation in the future, to better understand the relative value of the AT system.

The current system contrasts with many popular algebra manipulative systems, such as Algebra Tiles and Hands-on Equations (Foster, 2007), in its emphasis on the structure of mathematical expressions rather than models of the concepts referred to by them. We certainly believe that connecting algebraic structure to relevant and intuitive examples has an important place in the teaching of algebra. However, given the clear demonstrations that students struggle to understand basic algebraic notation (Koedinger, Alibali, & Nathan, 2008), that closely connecting structure to content can impede learning (Kaminski, Sloutsky, and Heckler, 2006), and existing evidence linking teaching algebraic structure to improved student understanding of algebraic expressions (Banerjee & Subramaniam, 2011), we believe that there is good reason to pursue manipulative systems that expressly communicate algebraic structure through engaging perceptual and motor interactions.

The current findings also suggest that a hands-on approach to teaching the structure of algebra may benefit

students. Students reported that physically moving objects (the tiles and ATR) around helped them focus on the steps necessary to simplify expressions. There is also anecdotal evidence that students were applying the ideas of perceptual motion when solving problems on paper. We often observed students gesturing and moving the terms around with their fingers, as well as drawing lines or arrows to represent the legal moves and actions. These observations are consistent with research suggesting that gesturing or alternative ways to represent new ideas may improve student learning (Cook, Mitchell, & Goldin-Meadow, 2008). They also reported that this approach seemed to help them better understand previously taught concepts (such as commutative property, order of operations).

It is also worth noting that the intervention seemed to increase student interest, participation, and interactions. Both observational and student reported engagement during this intervention was high. Virtually all students reported that the intervention was engaging, and fun. In addition, virtually all students reported liking to solve algebra problems more in ATR than in more traditional approaches.

This study has several limitations that limit the conclusions that can be drawn from it. Although beyond the scope of this current study, future work utilizing a control group involving more traditional instruction and practice will better examine the efficacy of this intervention. It is also unclear how the learning from this intervention differs from learning that would occur from typical classroom instruction, and how such differences may impact learning of future topics (Schwartz and Black, 1996). The design of the study also does not allow us to tease apart which components of the intervention (classroom instruction, manipulatives, and/or practice on the iPad) are most useful in building student understanding. Although each of these components implemented the general framework and underlying cognitive principles, given the large current interest in technological interventions, it will be important in future work to distinguish the particular contributions of each of these components and their interaction.

The value of this research at its current stage lies in pointing the direction to a complex of ideas and practices that connect education, cognitive science, and interface design. As designed experiences become more ubiquitous and richly featured, it becomes increasingly possible to construct novel experiences that evoke abstract content in powerful, perceptually specific ways. The limit point of the approach we are pursuing is not just one in which problem solving is fun, game like, and perceptually powerful. Instead, this research represents a starting point toward a conception of formal learning in which the structures of mathematics are directly explorable—in which the abstract is rendered consistently concrete.

## Acknowledgments

This work was funded through a grant awarded by the Institute of Education Sciences, US Department of Education (Grant # R305A1100060).

The *Algebra Touch* software is owned and designed by Regular Berry software, and none of the authors is involved with the production or sale of *AT*. However, features of *AT* have been implemented in collaboration with the second author, with the express purpose of instantiating the *Pushing Symbols* framework.

# Improving Representational Competence in Chemistry with Model-Based Feedback

Shamin Padalkar (shamin.padalkar@psych.ucsb.edu)

Mary Hegarty (mary.hegarty@psych.ucsb.edu)

Department of Psychological & Brain Sciences, University of California, Santa Barbara  
Santa Barbara, CA 93106 USA

## Abstract

Representational competence is an important component of learning Organic Chemistry. However, students are seen to be incompetent in translating from one kind of molecular diagram to another. An instructional method informed by spatial cognition research was designed and administered individually. The instruction involved having students check their solutions by attempting to match concrete models to their solution. The instruction helped students in the experimental group to identify their mistakes, understand the usefulness of concrete models and lead to large improvements in performance for the experimental group.

**Keywords:** concrete models; chemistry education; visualization.

## Introduction

The literature in science education and chemistry education in particular, shows that interconnected cognitive skills, such as visualization, construction of mental models, model based reasoning, and representational competence are essential for acquiring mastery in the discipline (Kozma & Russell, 2005; Coll, 2006; Justi and Gilbert 2006; Treagust & Chittleborough, 2001). Kozma & Russell (2005) define 'representational competence' in the context of chemistry as 'a set of skills and practices that allow a person to reflectively use a variety of representations or visualizations, singly and together, to think about, communicate, and act on chemical phenomena in terms of underlying, a perceptual physical entities and processes'.

Representational competence is particularly important in organic chemistry. Organic chemists use several different representations of molecules, including different kinds of diagrams, models, and equations, for different purposes. For example, three kinds of diagrams are commonly used in organic chemistry and are introduced in the introductory college course on this topic. Mastering these diagrams is challenging, because they use different conventions to represent the three-dimensional (3-D) arrangement of atoms in the molecules in the two-dimensions of the printed page. They are also drawn from different orthogonal perspectives. This paper describes a study in which we examined students' ability to translate between these models, and tested an educational intervention that was designed to improve their representational competence using 3-D molecular models.

Examples of the three types of diagrams are given in Fig. 1 and their conventions and a brief description of each is given below.

## Diagrams Used in this Study

**Dash-Wedge Diagram** (Sometimes referred to, as perspective formula): In a Dash-Wedge diagram (Figure 1a), the molecule is oriented with the backbone carbons<sup>1</sup> at the two 4-way intersections of lines on the left and right of the diagram. Dashed lines represent bonds to atoms that are going into the page (below the plane of the paper). Wedge lines represent atoms that are coming out of the page (above the plane of the paper). Solid lines represent bonds to atoms that are in the plane of the paper.

**Figure 1: 2-Butanol molecule presented in three types of diagrams and concrete models used in this study**

**Newman Projections:** In a Newman projection (Figure 1b), the molecule is oriented with one backbone carbon in front of the other. The front carbon is located at the intersection of the 3 lines (noon, 4 o'clock and 8 o'clock around the circle). The substituents (atoms or groups of atoms) at the ends of these three lines are attached to the front carbon. The rear carbon is behind the circle. The substituents at the ends of the shorter lines connected to the circle (2 o'clock, 6 o'clock, and 10 o'clock around the circle) are attached to the rear carbon.

<sup>1</sup> Carbon backbone: longest series of covalently bonded carbon atoms in an organic compound.

**Fischer Projections:** In the Fischer projection (Figure 1c), the atoms at the right and left of the horizontal lines are coming out of the page (above the plane of the paper) and the atoms at the top and bottom of the vertical line are going into the page (below the plane of the paper). The two backbone carbons are located where the horizontal lines cross the vertical line. These carbons are in the plane of the paper.

The arrangement of atoms is of great importance in Chemistry, because even if the chemical formula is same, different arrangements of atoms result in different chemical properties. Dash-Wedge, Newman and Fischer diagrams serve different functions and hence chemists are often required to translate from one diagram to another. Ability to perform this representation translation task is also a measure of students' understanding of the 3-D structure of a molecule, as well as the conventions of a diagram, and prepares them for further problem solving. Therefore representation translation problems are included in typical assessments in organic chemistry classes.

Since it is difficult to visualize the 3-D structure of molecules from these diagrams, concrete, 3-D models (see Figure 1d) are sometimes used as pedagogic tool. A model represents the 3-D structure of the molecule directly, and therefore does not depend on remembering conventions for how the three dimensions are represented in a 2-D diagram. Furthermore, in translating between diagrams of molecules from different orientations, a student can rotate a physical model and observe the results, rather than having to perform difficult internal spatial transformations (mental rotation or perspective taking). This corresponds to what Kirsh (1997) referred to as a *complementary* action, that is, an action performed in the world that relieves the individual of the need to perform an internal computation. However chemistry instructors differ in their use of models. Some chemistry teachers use models while teaching and encourage their students to use them, but others rarely use models.

In recent studies (Stull, Hegarty, Dixon, & Stieff, submitted), undergraduate students were asked to translate between different kinds of diagrammatic representations of organic molecules and concrete models were made available to them. In different conditions across three experiments, students were encouraged to use the models and the correspondence between the models and diagrams was explicitly pointed out to the students. Students performed poorly on the representation translation task. When models were made available to them, many of the students did not use the models. However, those students who used the models performed significantly better on the diagram translation task. In conclusion, if models are used, they are extremely helpful in the translation task, but many students face a barrier to using them. Thus, just providing models is not enough; research is required to develop an appropriate instructional method for scaffolding the use of models.

## Exploratory study

In order to explore what strategies students use to solve the translation problems and how they interact with models, we first conducted a pilot study. Six undergraduate students were interviewed and asked to think aloud while solving six diagram translation problems. The students were familiar with the diagrams and their conventions. Most of the students used algorithms (rules) and/or internal visualization to solve the translation problems, rather than using models. Interestingly despite making many errors, these students were confident that they were performing the task correctly, which decreased their motivation for exploring the possibility of using models and improvement. That is, students had an illusion of understanding (cf. Rozenblit & Keil, 2002; Dunning, et. al., 2003). Specifically, they did not have clear understanding of the difference between stereoisomers and conformations<sup>2</sup>. Molecules that are stereoisomers have the same bond structure (in terms of which atoms are bonded with which other atoms) but different structures in terms of the relative locations of the substituents (atoms and groups of atoms) in 3-D space. An informal task in which they were asked to match the concrete model to their solution made students realize their mistake and to use the models effectively. From this study it was clear that (1) the participants need to know that they are making errors and what kind of errors they are making, and (2) they need to be guided to pay attention to the 3-D structure of the molecules as shown in the concrete models.

## Experimental Intervention Study

A short instruction, which required the participants use the model to check their solution, was designed and tested in an experiment. This instruction served two purposes: First it provided feedback to the participants. Second, it forced them to structurally align the model, therefore making them pay attention to the 3-D structure of the molecules, and revealed how the model could be used to help translate between the diagrams. We compared the accuracy of solutions of a group given this instruction (experimental group) to that of control group who performed the same representation translation tasks, but without the intervention. In addition to the accuracy of their solutions and demographic facts, we measured their spatial ability and general intelligence. Performance of the diagram translation task has been found to be correlated with spatial ability (Stull et al., submitted) but previous studies did not assess its relation to general intelligence. In addition, given that students are overconfident with their responses and many students do not spontaneously use models, we asked

<sup>2</sup> Stereoisomers have the same bond structure, but the different geometrical positioning of atoms and functional groups in space (e.g. switching the groups around one or more chiral (asymmetric) Carbon atom, which results into different chemical properties. However, rotation around C-C sigma bond results in a different conformation of the same molecules and it has the same chemical properties.

them to judge their levels of confidence and the usefulness of models before and after the interventions. We also videotaped the students while they performed the task and coded whether or not they used the models on each trial.

### Experimental Task

Students solved 18 problems (6 pre-test, 6 post-test and 6 transfer) in which they were provided one kind of diagram of a molecule (e.g., a dash-wedge diagram) and were asked to draw another kind of diagram (e.g. a Newman diagram) for the same molecule. The worksheet (8.5" x 11") included an instruction on the top and a diagram below it. Solution space on the work-sheet for the pre-test was divided into two equal parts by a horizontal line and participants were asked to draw their solution above the line. Post-test worksheets were not divided and participants were allowed to draw their solution wherever they wished.

### Research Design

The experiment followed a pre-test post-test design with control and experimental groups. Both experimental and control groups were first given basic instructions, which included the nature of the task, examples of three kinds of diagrams (see Figure 1) and their conventions (as described earlier). Participants were told that the instruction sheet would be kept, face down on the table and they could refer to it as necessary. They were also given a concrete (Ball & Stick) model<sup>3</sup> and reminded of the color codes for the different atoms in the models. The model was positioned in a clay stand. The experimenter demonstrated that the concrete model could be taken out of the stand and that it could be rotated in space and around the main carbon-carbon bond.

The pre-test consisted of six problems involving 4-Carbon molecules. It was followed by a short questionnaire on participants' level of confidence in their solutions and the usefulness of the concrete models. Then the experimental group went through a training intervention (described below) and the control group participants were given a 5-minute break. The post-test included a second set of six problems with 4-carbon molecules (enantiomers, or, mirror images) of the molecules in the pre-test problems and six 5-carbon problems. We refer to the set of 5-carbon problems as transfer problems, although they were very near transfer. The post-test was followed by a questionnaire which included questions about demographics and the same statements about confidence and usefulness of models as in the pre-test questionnaire. Finally, all participants completed the Vanderberg and Kuse (1978) Mental Rotation Test as a test of spatial ability (20 items administered in two 3 minute blocks) and Abstract Reasoning Test from the Differential

Aptitudes as a test of general reasoning ability (40 items, no time limit).

Participants were videotaped with their consent. The video camera was situated 2 feet above the table, usually on the left side of the participant. The experimenter sat to the left side of the participant, gave relevant instructions, provided relevant models and occasionally monitored the video camera. Participants saw only one model at a time, that is, the model of the molecule in the problem they were solving; the others were kept behind a screen. The assembly is shown in Figure 2.

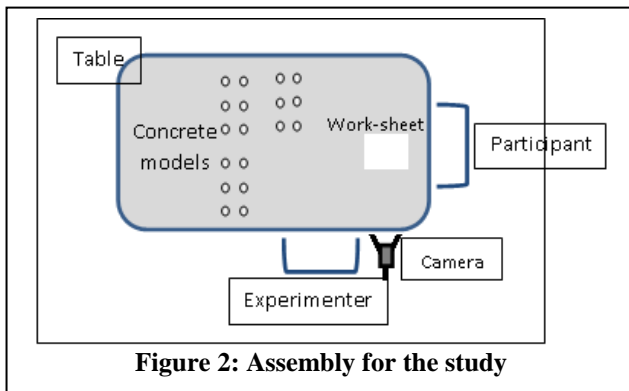

Figure 2: Assembly for the study

The intervention involved directions for participants to use models to check their own solutions and to draw correct solutions, if any of their solutions were found to be incorrect.

In the beginning of the intervention, participants were told "We are going to check the solutions". They were provided the concrete model for each problem and each problem was checked in three steps. Participants were provided help at each step if necessary. As a first step and were asked to match (i.e., structurally align) the model with the *given* diagram (cf., Gentner, 1983). This gave participants an opportunity to confirm that the given model indeed represented the given diagram and also gave practice in seeing the correspondence between model and diagram. In the second step of the intervention, participants were asked to align the model with their *solution* to the problem (which was drawn above the horizontal line). If the participant had drawn a correct solution, once s/he matched aligned the model with the solution, s/he was asked to move to the next problem. If the solution was incorrect, it would not be possible to structurally align the model with the solution. In this case, s/he realized that the model could not be matched and the solution was incorrect. The third step involved drawing a new corrected solution (below the horizontal line).

If the participant again drew an incorrect solution, Steps 2 and 3 were repeated. This was necessary for only 16 participants (on a total of 25 trials, i.e. an average of 1.56 trials per participant). If the participant drew an incorrect solution on the third attempt, he/she was told his/her mistake and was asked to go to the next problem. There was only one participant who could not draw the correct solution even after 3 cycles, and that was only on one trial.

<sup>3</sup> We used a 'Fundamental Organic Chemistry Set' manufactured by HGS Hinomoto Plastic Co., LTD (see Fig. 1d).

## Participants

The experimental group consisted of 30 participants (15 females) and the control group consisted of 24 participants (12 females), all undergraduate students at a research university. These students had completed at least one course in Organic Chemistry, in which they had been introduced to the three types of diagrams of organic molecules. The two groups did not differ in age (average = 20.3 years), spatial ability (average MRT scores = 35.67), general intelligence (average abstract reasoning test scores = 28.94), GPA (average = 3.15) or number of years in college (average = 3). The participants received course credit or \$20 for their participation.

## Coding of Diagrams

The data were coded in 2 ways:

**Number of correct solutions:** A score of '0' or '1' was assigned to each problem. A drawing had to be completely correct to receive a score of 1. The sum of correct solutions served as the total accuracy scores for the pre-test, post-test, and transfer problems.

**Level of accuracy:** Depending upon the type of error a level of 0 to 2.5 was assigned to each problem. In this scoring scheme, level 0 was assigned if a participant drew the wrong type of diagram or drew a diagram with missing or additional substituents. Level 1 was assigned when the diagram drawn was made up of the correct substituents, but these were incorrectly connected to the central carbon atoms. If the substituents were attached to the correct carbon atoms, but their 3-D spatial arrangement was incorrect, level 2 or 2.5 was assigned depending upon whether the mistake was made on both sides of the molecule (level 2) or only on one side (level 2.5). A fully correct diagram was assigned a level of 3. In addition to scoring the level of understanding for each problem, a student was assigned to a level of understanding (ranging from 0 to 3) if two-thirds of their solutions (4 of 6) were at or above this level of understanding for the pre-test, post-test, and transfer problems.

Data for 20 participants were coded independently by two researchers to establish the inter-rater reliability. Cohen's Kappa for the scores of pre-test, post-test and transfer problems together was 0.977.

## Coding of Model Use

Participants' use of the models was coded using the videos. Each trial was coded for whether or not participants moved the model in any way during each trial. Whenever participants moved the model it was coded as a use of the model. Pointing at the model (which happened extremely rarely) was not counted as using the model.

## Results

**Analysis of Correct Solutions:** Performance of the control and experimental groups on the pre-test, post-test and transfer problems is shown in Figure 3. The control group and experimental group had relatively poor performance on the pre-test, consistent with previous studies (Stull et al., submitted) and did not significantly differ on the pre-test,  $t(52) = 1.844$ ,  $p = .07$ . The experimental group performed significantly better after the intervention than before,  $t(29) = 9.344$ ,  $p < .001$ , and scored significantly better than the control group on the post-test,  $t(52) = 4.06$ ,  $p < .001$ . The average score for this group on the transfer problems is almost the same as for the post-test for the experimental group,  $t(29) = .162$ ,  $p = .87$ , indicating that what was learned from the intervention transferred to solving slightly more difficult problems.

Figure 3: Average scores

The control group improved significantly from the pre-test to the post-test,  $t(23) = 2.18$ ,  $p < .05$ , and from the post-test to the transfer problems,  $t(23) = 2.41$ ,  $p < .05$ , thus making the difference between scores of the pre-test and transfer problems significant,  $t(23) = 3.72$ ,  $p = .001$ . Despite this, the experimental group outperformed the control group on the transfer problems,  $t(52) = 3.08$ ,  $p < .01$ .

Figure 4: Percentage of participants at each level in the experimental and the control group

Thus, the intervention was successful and lead to very accurate performance (approximately 5 out of 6 problems solved correctly) on the post-test and transfer problems; although the control group spontaneously improved, they solved less than half of the post-test and transfer problems correctly.

**Analysis of Levels of Accuracy:** In the pre-test, the majority of students' drawings were at level 2.5 indicating that they understand the connectivity between the molecular substituents, but not their relative locations in 3-D space. In the post-test and transfer problems, the majority of students in the experimental group were at level 3, i.e., fully correct solutions. For the control group, the number of students performing at level 3 gradually increased (Figure 4). At the final (transfer) phase of the experiment 83% of participants in the experimental group and 58% of those in the control group were performing at Level 3.

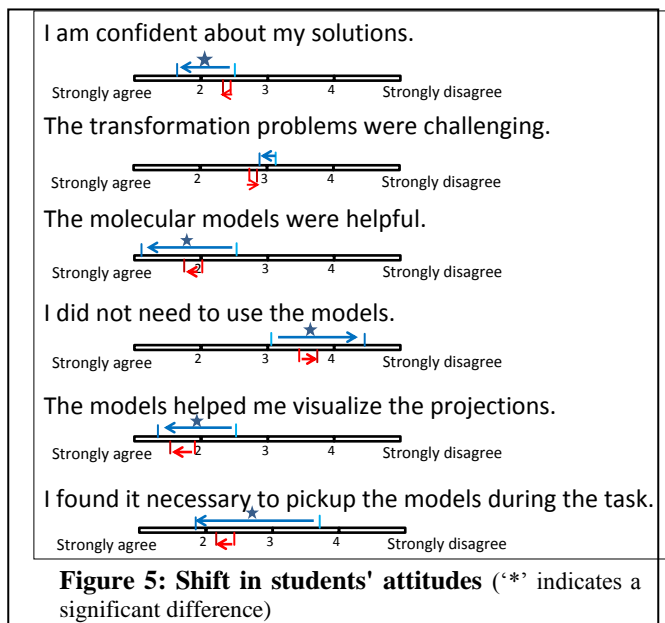

**Correlations:** As Table 1 shows, for the control group, scores on the pre-test, post-test and transfer correlated with each other. However this was not true for the experimental group. Participants in the experimental group performed well in post-test and transfer problems, regardless of their performance in the pre-test, which shows that the intervention was successful, irrespective of students' initial ability to do this task. As expected, scores on the pre-test and post-test correlated with scores on the mental rotation test (MRT) but this test was not significantly correlated with the transfer problems. The abstract reasoning test was correlated with performance only for the control group. Partial correlations of MRT with drawing performance, controlling for abstract reasoning, were significant for the pre-test (0.34\* pooling all participants). However, the correlations of MRT with the post-test and transfer problems were not significant. Thus, spatial ability is an important predictor of performance in the pre- and post-test but as the participants become familiar with the task, spatial ability becomes less important.

**Table 1: Correlations** ('\*' indicates a significant correlation)

Scores		Pre-test	Post-test	Transfer
Post-test	Ctrl	0.832*		
	Expt	0.095	1	
Transfer	Ctrl	0.778*	0.902*	
	Expt	0.079	0.705*	1
MRT	Ctrl	0.480*	0.410*	0.275
	Expt	0.528*	0.361*	0.134
Abstract reasoning	Ctrl	0.519*	0.441*	0.410*
	Expt	0.238	0.311	0.130

**Students' perceptions about models and confidence level:** Students were given six statements (shown in Figure 5) to judge on scale of 1 to 5 after both the pre and post-test.

The arrows indicate the shift in their judgments from pre-test to post-test, with the experimental group shown in blue and the control group shown in red. Although overconfident in the pre-test, after the intervention, participants in the experimental group were significantly more and appropriately confident. They found models to be more helpful, and they recorded that they used the models more after the intervention.

**Participants' use of the models:** Participants in the experimental group moved the model on only 35% of trials during the pre-test but this percentage increased to 86% for the post-test and the transfer problems (Figure 6). On the other hand, participants in the control group moved the model on 62% trials in the pre-test and this percentage increased to 68% for the post-test. Thus the intervention was successful in inducing the experimental group to use the models. The tendency for the control group to use the model more in the pre-test appears to be due to sampling error, however it might also explain why these participants spontaneously improved on the problems, even without an intervention.

**Figure 6: Percentages of trials on which participants moved the models** ('\*' indicates a significant difference)

## Discussion

In summary, the intervention was successful. The accuracy of the experimental group increased from 27% to 83%. Although the control group underperformed the intervention group on the post-test, their accuracy steadily increased from 42% to 55% and their scores for the transfer problems were significantly higher than the pre-test scores. Spatial ability was an important predictor of performance on the pre and post-test, but it did not predict performance on the transfer problems, which suggests that spatial ability becomes less important with practice on the task.

Participants in the experimental group also showed an increase in confidence level, reported that they found models more useful, and reported that they used the models more often after the intervention. The latter result was validated by objective measures of their use of the models.

Analysis of students' levels of understanding (Figure 4) shows that the majority of participants were at level 2.5 in the pre-test which means that they switched the positions of two of the chemical groups around one of the central carbon atoms in the model. This mistake reflects a lack of understanding of the 3-D spatial relations between the chemical groups. There are two possible reasons for this error. First, participants may not realize the importance of the relative 3-D locations and hence draw a different molecule (an isomer of the correct molecule). Second they might understand the importance of the 3-D structure, but not be able to perform the required spatial transformation. The current experiment does not rule out either of these explanations, but it shows that once participants attempted to structurally align the models with the diagrams, they discovered their error and this in turn lead to increased use of the models and better performance in the post-tests.

If students do not understand the importance of the 3-D spatial relations, then giving them constructive feedback, that they drew an isomer, rather than the correct molecule, should be sufficient to improve performance. If they understand the importance of the 3-D relations, but are unable to perform the required spatial transformations, showing them how models map onto the diagrams should help them perform the correct spatial transformations. To identify which of these two reasons played an important role in students' inability to perform the diagram translation task, we are currently conducting a second experiment which compares a 'feedback' condition and 'model match' condition.

In any case, the current paper documents an intervention that was certainly useful. It took a short time (an average of 17 minutes to check the 6 pre-test problems) and could be accommodated in a laboratory or tutorial session in the context of an organic chemistry class. Further studies will be necessary to examine whether this type of intervention can lead to lasting gains in student performance, and whether the intervention leads to an understanding of the structure of molecules that can improve performance in a situation where students do not have access to models. Although experts often use more abstract rule-based

strategies to translate between diagrams (Stieff, 2007) understanding the 3-D structure of molecules is central to organic chemistry knowledge, and models appear to be an important stepping stone to reaching higher levels of understanding. Also, since models, in contrast to diagrams, are powerful representations having the unique quality of three-dimensionality, they have been an important tool in cutting edge research and hence students should be familiar with strengths and weaknesses of models through their own experience. The general approach of the intervention can be adopted and tested in the instructions of other disciplines such as geology, astronomy, architecture etc. in which three-dimensional structure and dynamic properties of the system are very important.

## Acknowledgments

This research was funded by National Science Foundation Grant DRL 1008650. We are thankful to Andrew Stull, Trevor Barrett, David Sanosa, Emily Steiner, Bonnie Dixon, Mike Stieff for their contributions to the research.

## Abstract

An ACT-R model of sensemaking in a geospatial intelligence task was developed based on Instance-Based Learning Theory (IBLT). The model (a) maintains hypotheses about the probability of attacks by insurgent groups, (b) seeks new information based on those hypotheses, and (c) updates hypotheses based on new evidence. The model provides a functional account of how these sensemaking processes are carried out in a cognitive architecture, and model performance can be compared to normative (Bayesian) standards. Simulations exhibit two well-known cognitive biases that are frequently identified as problems in intelligence analysis: (1) anchoring in the weighting of new evidence and (2) confirmation bias in seeking new information.

**Keywords:** ACT-R, cognitive biases, sensemaking

## Introduction

Sensemaking (Klein, Moon, & Hoffman, 2006a, 2006b; Pirolli & Card, 2005; Russell, Stefik, Pirolli, & Card, 1993) is a concept that has been used frequently in studies of intelligence analysis. The term suggests an active seeking and processing of information to achieve understanding. Sensemaking involves a set of processes aimed at seeking and filtering information, plus a set of processes that develop representational schemas (frames) that best fit the available evidence and provide a basis for understanding the data. In this paper we present the cognitive model of basic sensemaking processes for an intelligence analysis task. A major concern in the intelligence community is the impact of cognitive biases on the accuracy of analyses (Heuer, 1999). We present simulation results that exhibit *anchoring bias* in the evaluation of new evidence and *confirmation bias* in seeking evidence.

## The Geospatial Task

The geospatial task (Figure 1) is one of a set of challenge tasks developed as part of the IARPA ICARUS program to drive the development of integrated neurocognitive models of sensemaking. This specific task required reasoning based on a set of rules concerning the relation of observed evidence to the likelihood of attack by four different groups. A layered geospatial map is presented on a computer screen, with different layers presenting different forms of intelligence (INTs). The INTs include HUMINT (human intelligence), IMINT (image intelligence), MOVINT (movement intelligence), SIGINT (signal intelligence),

SOCINT (socio-cultural intelligence), and SIGACT (attack intelligence).

Figure 1: The screen shot of the geospatial task. The letters (A, B, C, D) indicate the center of the group location, and '1' surrounded by a box indicates the attack location.

The task begins with a given attack location (SIGACT) along with group centers (HUMINT), A, B, C, and D representing the center of activity for four possible insurgent groups. The first step is to report probabilities of attack by each group [A%, B%, C%, D%] based on the SIGACT and HUMINT (see Table 1)<sup>1</sup>. After that, the task is to iteratively choose among the four remaining INT layers (Table 1), up to a total of three INTs (layers), one at a time, in any order. Each INT layer provides unique evidence. Specifically, IMINT can reveal whether an attack happened on a government or military building, MOVINT provides evidence whether an attack occurred in dense or sparse traffic, SIGINT indicates electronic “chatter” or “silence” by different groups, and SOCINT indicates the group whose region the attack happened. At each stage, the selection of a particular INT provides evidence that can be used to update the probability distribution over the hypotheses about the responsibility of the four groups in producing the given attack. The rules specifying how evidence ought to update these probabilities is given in the PROBS rules in Table 1. After the last stage of INT selection, the task is to allocate resources (troops) to prevent further attacks.

<sup>1</sup> The new version of the task will provide the initial probabilities based on HUMINT

Table 1: Probabilistic rules provided to user for inferring beliefs about group attack likelihoods.

INTS	PROBS
HUMINT	If a group attacks, then the relative likelihood of attack decreases as the distance from the group center increases.
IMINT	If A or B attack then the attack is four times as likely to occur on a <i>Government</i> versus <i>Military</i> building. If C or D attack then vice versa.
MOVINT	If A or C attack then the attack is four times as likely to occur in <i>dense</i> versus <i>sparse</i> traffic. If B or D attack then vice versa.
SIGINT	If SIGINT on a group reports <i>chatter</i> , then attack by that group is seven times as likely as attack by each other group If SIGINT on a group reports <i>silence</i> , then attack by that group is one-third as likely as attack by each other group.
SOCINT	If a group attacks then that group is twice as likely to attack in its own versus other region.

### Anchoring and Confirmation Biases

Anchoring and confirmation biases have a long history of study in cognitive psychology and the intelligence communities (Heuer Jr, 1999; Klayman, 1995; Klayman & Ha, 1987; Nickerson, 1998; Tversky & Kahneman, 1974; Wason, 1960). Process models of these biases, especially in complex tasks, remain largely unexplored. In this paper we develop cognitively plausible process model of the geospatial task in the ACT-R architecture. We then compare this ACT-R model against a rational Bayesian model of the task to examine evidence of anchoring and confirmation biases.

#### Anchoring Bias and Anchoring and Adjustment Heuristic

Anchoring is a cognitive bias that occurs when individuals establish some belief based on some initial evidence, and then overly rely on this initial decision in their weighting of new evidence (Tversky & Kahneman, 1974). Human beings tend to anchor on some estimate or hypothesis and subsequent estimates tend to be adjustments that are influenced by the initial anchor point—they tend to behave as if they have an *anchoring+adjustment heuristic*. Adjustments tend to be insufficient in the sense that they overweight the initial estimates and underweight new evidence.

#### Confirmation Bias

Confirmation bias is typically defined as (for a survey, see Nickerson, 1998):

- The interpretation of evidence in ways that are partial to existing beliefs, expectations, or a hypothesis in hand (Nickerson, 1998)
- The tendency for people to seek information and cues that confirm the tentatively held hypothesis or belief,

and not seek (or discount) those that support an opposite conclusion or belief (Wickens & Hollands, 2000). The seeking of information considered supportive of favored beliefs (Nickerson, 1998).

Studies (Cheikes, Brown, Lehner, & Adelman, 2004; Convertino, Billman, Pirolli, Massar, & Shrager, 2008; Tolcott, Marvin, & Lehner, 1989) have found evidence of confirmation bias in tasks involving intelligence analysis, and there is a common assumption that many intelligence failures are the result of confirmation bias in particular (Chorev, 1996; Grabo & Goldman, 2004; Heuer Jr, 1999).

#### Biases in the Geospatial Task

The geospatial task might elicit anchoring and confirmation biases at multiple points in the process. Anchoring bias in weighing evidence might be found when participants revise their belief probabilities after selecting and interpreting a particular INT. The estimates of belief probabilities that were set prior to the new INT evidence could act as an anchor, and the revised (posterior) belief probabilities could be insufficiently adjusted to reflect the new INT (i.e., when compared to some normative standard).

Confirmation bias in weighing evidence can also be found in the hypothesis adjustment process. When applying a particular INT, such as IMINT (which supports multiple hypotheses), participants may only apply the adjustment to the preferred hypothesis while neglecting other groups also supported by evidence, or weight the evidence too strongly in favor of the preferred hypothesis.

Finding confirmation bias in seeking evidence in the task is somewhat more difficult since most INTS apply equally to all hypotheses. We used the SIGINT layer to identify this kind of bias because a single hypothesis has to be selected for that layer. SIGINT provides considerable gains to the selected hypothesis when chatter is detected (7 times more likely), so participants could get significant certainty. However, it loses considerable weight (3 times less likely) when silence is detected. Thus, a decision to choose the SIGINT layer too early (before a specific group has dominates the other in terms of relative likelihood) might be interpreted as confirmation bias in evidence seeking.

#### The ACT-R architecture

ACT-R (Anderson et al., 2004; Anderson & Lebiere, 1998) is a cognitive architecture that includes a declarative memory module that stores and retrieves information and a procedural module that coordinates the flow of information. Declarative knowledge in ACT-R is represented formally as *chunks* of information (Miller, 1956; Simon, 1974). Chunks are recalled from long-term declarative memory by an activation based retrieval process. Activation spreads from the current focus of attention, including goals, through *associations* among chunks in declarative memory. The spread of activation from one cognitive structure to another is determined by attentional weights on the associations among chunks. These weights determine the rate of activation flow among chunks. *Partial matching* is a

mechanism that allows for chunks in declarative memory that do not perfectly match a retrieval request to be retrieved. *Blending* is a memory retrieval mechanism that allows all chunks in declarative memory that match or partially match a retrieval request to blend together to create a new chunk representing an aggregate response (Lebiere, 1999).

Production rules are used to represent procedural knowledge in ACT-R. That is, they specify how to apply cognitive skill (know-how) in the current context, and how to retrieve and modify information in other modules. In ACT-R, each production rule has conditions that specify structures that are matched in limited-capacity buffers corresponding to information from the external world or other internal modules. Each production rule has actions that specify changes to be made to the buffers or requested functions in the associated modules.

### The Rational Model versus ACT-R Model

We developed an ACT-R model to perform the geospatial task, as well as a rational (Bayesian) model as a normative benchmark. The ACT-R model implemented a version of instance-based learning theory (Gonzalez, Lerch, & Lebiere, 2003), and the rational model employs a standard Bayesian approach for updating belief and selecting new evidence (INTs) based on an expected information gain metric.

### The Rational Model

From the PROBS rules discussed in table 1, we can extract specifications of the likelihoods of evidence,  $P(e|h)$ , where  $e$  is evidence (e.g., “chatter”) and  $h$  is a hypothesis (“group A attacks”). Bayes rule can be applied to compute the posterior likelihood of  $h$  given specific evidence  $e$  and prior probabilities  $P(h)$

$$P(h|e) = \frac{P(e|h)P(h)}{\sum_i P(e|i)P(i)}$$

where  $i$  iterates over all hypotheses.

For instance, in Figure 2, we assume some HUMINT data has been processed, a probability has been assigned to each of the hypotheses, and the goal is to evaluate the choice of an IMINT layer. The outcomes represent the estimates of government and military building attacks given the current hypotheses strengths. The posteriors are the updated probability distributions according to the outcomes.

The choice of INT layers can be evaluated by their effects on *expected information gain* (Austerweil & Griffiths, 2011). Information gain is defined as the reduction in entropy measured over the hypothesis probabilities that occur by acquiring additional evidence. Information gain is specified as

$$IG(D, e) = H(D) - H(D|e)$$

where  $H(D)$  is the entropy of the distribution of probabilities over hypotheses, and  $H(D|e)$  is the entropy of the distribution of posterior probabilities after some evidence  $e$  has been discovered.

$$H(D|e) = - \sum_i P(D|e) \log_2 P(D|e)$$

In Figure 2, the information gain for seeing an attack on a government building is .4 and an attack on a military building is .09. The *expected information gain* is calculated by weighting each of the possible outcomes of information gain by the probability of obtaining that outcome. Thus, the expected information gain for selecting the IMINT layer is  $(.56)(.4) + (.44)(.09) = .26$

Our rational model computed the expected information gain for all layers at each stage. The rational choices were compared to the selections made by ACT-R to identify biases.

Figure 2: An example of the rational Bayesian hypothesis estimates for an IMINT layer selection.

### The ACT-R Model

We assume that an average person is not able to compute the expected information gain of all possible layers, because it involves substantial amounts of computation. We considered two cognitively plausible alternatives to develop an ACT-R model.

- *Difference reduction heuristics.* One cognitively plausible way to reduce complexity is to assume that people use a heuristic such as hill climbing to evaluate moves. Rather than focus on maximizing expected information gain, hill-climbing analysis could focus on achieving states that are closer to an ideal goal state (i.e., in this case, a state in which the attacks are unambiguously caused by Group A, or Group B, etc.). This would require some heuristic for evaluating differences (distances) from the goal state.
- *Memory-based move evaluation.* It is well known in the field of naturalistic decision making that experts invariably rely on vast amounts of declarative memory experience and well-practiced cognitive skill (Klein, 1998). We assume that participants store move outcomes in declarative memory, and that blended retrievals based on current states and possible moves can produce a blended retrieval of outcomes to those moves. This would be a weighted smoothing of gains that had been made by similar moves in the past. Although not precisely equivalent to the computation of rational expected information gains (a weighting over the gains achieved by possible layer selection outcomes), blending over memory of past INT outcomes and gains should produce similar effects.

Our ACT-R model of the geospatial task explored some plausible difference reduction heuristics in a memory-based move evaluation framework. The following weighted distance function assumes that the goal is to achieve certainty on one of the hypotheses (i.e.,  $p_i = 1$ ).

$$\sum_{i \in \text{hypotheses}} p_i(1 - p_i)$$

We assume that the model relies on the use of declarative chunks that represent hypothetical past experiences of selecting INT layers. This is intended to capture a hypothesized learning process whereby participants have attended to a current probability distribution, chosen a layer, revised their estimates of the hypotheses, and assessed the utility of the layer selection they just made. For instance, if a participant had experienced two situations in which they had assessed a probability distribution [.4 .2 .2 .2] and selected an IMINT layer, and had experienced a “government building” attack one time and a “military building” attack a second time (See figure 2). The model assumes the two chunks in its declarative memory.

(exp1	(exp2
isa layer-choice	isa layer-choice
prior-a 0.4	prior-a 0.4
prior-b 0.2	prior-b 0.2
prior-c 0.2	prior-c 0.2
prior-d 0.2	prior-d 0.2
layer IMINT	layer IMINT
outcomes government	outcomes military
utility 0.58)	utility 0.69)

where the utilities are computed by the weighted distance metric.

At a future layer selection point, a production rule will request a blended/partial matching retrieval from declarative memory like below:

```
+blending>
  isa layer-choice
  prior-a 0.45
  prior-b 0.15
  prior-c 0.15
  prior-d 0.25
  layer IMINT
  utility =utility
```

This retrieval will partially match against the experience chunks above, and will blend across the stored utilities for all experienced IMINT outcomes (i.e., both government and military building experiences in the past) to produce a kind of “expected” utility to match the =utility request.

### Hypothesis Probability Updating

Lebiere (1999) proposed a model of cognitive arithmetic that used retrieval of arithmetic facts to generate estimates of answers without explicit computations. The cognitive arithmetic model uses partial matching to retrieve facts related to the problem, and uses the blending mechanism to merge them together to issue an aggregate estimated answer. The model reproduced a number of characteristics of the distribution of errors in elementary school children, including both table and non-table errors, error gradients around the correct answer, higher correct percentage for tie

problems, and, most relevant here, a skew toward underestimating answers, as is common in anchoring and adjustment processes.

This approach was leveraged in the current model to account for how the PROBS rules (from table 1) are interpreted and applied to estimate the effects of the rules on the relative probabilities that the groups are responsible for the attack under examination. The ACT-R model’s memory was populated with a range of facts consisting of triplets: an initial probability, an adjustment factor, and the resulting probability. These chunks are derived from the PROBS rules shown in Table 1. For example, if the attack is found to occur on of road with dense traffic, the MOVINT rule specifies that groups A and C are 4 times as likely to have been responsible. When a layer of information is made available to the model, it adjusts the current set of probabilities by retrieving the relevant chunks and replacing the prior probabilities with the posteriors representing in the retrieved chunks. The results of this chunk based rule interpretation were then averaged over a thousand runs, given the variations in answers resulting from activation noise in the retrieval process. When provided with ratio similarities between probabilities (and factors), the primary effect is an underestimation of the adjusted probability for much of the probability range.

### Assessment

Biases can be defined as deviations from some norm (Jonathan D. Nelson, 2005; J.D. Nelson, McKenzie, Cottrell, & Sejnowski, 2010). In conjunction with producing the geospatial challenge tasks, the IARPA ICaRUS program has developed metrics for assessing cognitive biases. Anchoring bias or confirmation bias in weighing evidence is assessed by a *negative entropy* metric,  $N$  and confirmation bias in seeking information is assessed using a task-specific *confirmation metric*,  $C$ .

### Anchoring bias metric

Negative entropy is defined as

$$N = (H_{max} - H)/H_{max}$$

where  $H$  is the entropy of the distribution of probabilities over hypotheses and  $H_{max}$  is the maximum possible entropy.  $N$  increases with the certainty in a hypothesis (i.e., the “peakiness” of the distribution). At a given stage of updating belief probabilities [A%, B%, C%, D%] given some new INT evidence, we may assess the negative entropy,  $N_{ACT-R}$ , of the belief probabilities in ACT-R, and the negative entropy of the rational model,  $N_{Rational}$ . If  $N_{ACT-R} > N_{Rational}$  then the ACT-R model is exhibiting a confirmation bias in weighing evidence – i.e., over-weighting evidence that confirms the most likely hypothesis. Conversely, if  $N_{ACT-R} < N_{Rational}$  then the ACT-R model is exhibiting the anchoring bias.

### Confirmation bias metric

Confirmation bias in seeking evidence, is assessed by the fraction,  $C$ , of SIGINT choices requested about the

insurgent group that has been assigned highest probability of being the attackers.

$$C = \frac{\text{No. of SIGINT choices on the highest Prob. group}}{\text{Total no. of SIGINT choices}}$$

SIGINT provides considerable weight when “chatter” is detected, so selection of SIGINT for the highest probability group is interpreted as being confirmatory. It is assumed that if  $C > .5$  then the model exhibits confirmation bias in seeking evidence (random choice strategy be  $C = .25$ ).

## Results and Discussion

Each model was used to simulate 30,000 layer selections in 10,000 tasks. By using metrics that we explained in the previous section, we could identify that the ACT-R model exhibits anchoring and confirmation biases while conducting the task.

### Anchoring bias in weighing evidence

In the geospatial task, the ACT-R model revises its probability distribution over hypotheses after each layer selection, and this can be compared against the probability distribution of the rational model. As can be seen in figure 3, the ACT-R model is most often showing lower negative entropy than the rational model ( $N_{\text{ACT-R}} < N_{\text{Rational}}$ ). In other words, rather than showing a confirmation bias it is exhibiting a form of anchoring bias.

Figure 3: Difference negative entropy between the ACT-R model and rational model after each layer selections.

### Confirmation bias in seeking evidence

We analyzed the fraction of SIGINT choices for which the model requests SIGINT on the group with the highest probability. The result of the fraction for the ACT-R model is presented in table 2. The fraction of the model is greater than .5, so the ACT-R model is exhibiting confirmation bias in seeking evidence according to the  $C$  metric.

We also analyzed how the INT layers selected by the ACT-R model compared to the rational choice based on the expected information gain. The result is presented in figure

4. Note that the number of alternative choices varies within a task: The task begins with seven alternatives (IMINT, MOVINT, SOCINT, and four SIGINTs) available, and depending on the selection of the layer, the alternatives decrease within each trial.

Table 2: The results of the confirmation bias in seeking evidence for both models.

	SIGINT on the highest prob. group	Total No. of SIGINT	Fraction
ACT-R Model	6,191	9,044	.68

Figure 4: Frequency of the ACT-R model selecting the rational choice of Rank  $n$  (Rank 1 is the optimal choice).

Table 3 shows a confusion matrix that indicates the proportion of times the ACT-R model makes the same choice as the rational model. Although the ACT-R model agrees with the rational model at a level well above chance, it often differs from the rational. The rational model scarcely selects SOCINT layer (3 times among 30000), because the expected information gain for SOCINT is relatively low.

Table 3: Confusion matrix of the ACT-R model and rational model for layer selection.

		Rational Choice			
		IMINT	MOVINT	SIGINT	SOCINT
ACT-R Choice	IMINT	75%	15%	4%	0%
	MOVINT	18%	79%	4%	66%
	SIGINT	4%	3%	91%	0%
	SOCINT	3%	3%	1%	33%

Note that there is some interaction between the anchoring bias in evidence weighing and any biases that might emerge in choosing layers. If the ACT-R models (or participants) under-weight evidence and believe in a “less peaky”

probability distribution over hypotheses, then that can affect how far they believe that the current state or next state is from the goal, or how much more uncertainty can be reduced by a given layer choice. Biases in beliefs about the current situation will impact evidence-gathering choices.

The ACT-R model exhibits confirmation bias when evaluated against the ICArUS task-specific norm, *C*, which measures the propensity to use SIGINT to confirm the strongest current hypothesis. However, the selection of INT layers is generally highly consistent with the rational norm of seeking evidence that will produce the highest expected information gain. This illustrates how the notion of “bias” is dependent on the choice of norm, and how such norms do not always agree, especially in the case of “confirmation bias” (Jonathan D. Nelson, 2005). It has been shown (Austerweil & Griffiths, 2011) that confirmatory strategies are rational for a large class of tasks and people appear to approximate choices based on expected information gain.

# Can native-language perceptual bias facilitate learning words in a new language?

Bożena Pajak<sup>1</sup> (bpajak@ucsd.edu), Sarah C. Creel<sup>2</sup> (creel@cogsci.ucsd.edu), Roger Levy<sup>1</sup> (rlevy@ucsd.edu)

## Abstract

Acquiring a language relies on distinguishing the sounds and learning mappings between meaning and phonetic forms. Yet, as shown in previous research on child language acquisition, the ability to discriminate between similar sounds does not guarantee success at learning words contrasted by those sounds. We investigated whether adults, in contrast to young infants, are able to attend to phonetic detail when learning similar words in a new language. We tested speakers of Korean and Mandarin to see whether they could use their native-language-specific perceptual biases in a word-learning task. Results revealed that participants were not able to fully capitalize on their perceptual abilities: only faster learners – as independently assessed by baseline trials – showed enhanced learning involving contrasts in phonetic dimensions informative in their native language. This suggests that attention to phonetic detail when learning words might only be possible for adults with better learning skills or higher motivation.

**Keywords:** word learning; non-native speech perception; second language acquisition

## Introduction

Humans are able to take advantage of many different resources available to them in the course of learning. For example, when learning a new language – whether in infancy or adulthood – humans actively search for regularities by analyzing the input in several alternative ways (e.g., examining either adjacent or non-adjacent dependencies; Gómez, 2002), and are able to simultaneously entertain multiple implicit theories about the input's underlying structure (e.g., Gerken, 2010). One of the complex features of learning a language is that listeners must perform concurrent analyses of the input at different levels of processing and integrate these multiple pieces of information at once. If, for example, we zoom in to the level of processing single words, one needs to encode phonetic cues and, at the same time, map the phonetic form onto meaning. This task may be particularly hard for beginner second language (L2) learners who are not yet familiar with the L2 sound system, especially when they are processing words with novel sounds that do not exist in their native language (L1). However, there is evidence that learners capitalize on whatever pieces of information are available to them to achieve this task: they might use lexical cues to make inferences about sound categorization (Feldman, Myers, White, Griffiths, & Morgan, 2011), and – conversely – take advantage of perceptual learning on sound categorization to help them make inferences about the lexicon (Perfors & Dunbar, 2010). The question we are addressing in this paper is another piece of this puzzle.

Specifically, we know that prior language knowledge is one of the starting points when learning a new language: L1-based perceptual biases can facilitate perception of novel sound contrasts that differ along phonetic dimensions informative in L1 (Pajak, 2010a, 2010b; Pajak & Levy, in prep.), and can

affect interpretation of distributional information from novel language input (Pajak & Levy, to appear). How efficiently, then, do adults capitalize on their L1-based phonetic generalizations when learning the lexicon in a new language?

Intuitively, it might seem that whatever perceptual abilities adults have, they should be able to use them both when distinguishing sounds and when learning novel words. That is, if they hear a distinction between sounds *b* and *p*, they should be able to easily distinguish between words like *ban* and *pan*. However, the picture emerging from prior research is far less clear. In fact, research with young infants suggests that the ability to discriminate perceptually between similar sounds does not in general guarantee immediately successful learning of words that are contrasted by those sounds. At 14 months, infants can easily discriminate the sounds *b* and *d*. However, when taught that a novel object is called a *bih*, but later on is referred to as a *dih*, infants do not notice this mispronunciation (Stager & Werker, 1997). The initial explanation proposed for this result was the limited resource hypothesis (Stager & Werker, 1997; Werker, Fennell, Corcoran, & Stager, 2002): since attending to fine phonetic detail while learning new words is computationally very demanding, young infants – who have limited attentional and cognitive resources – might have difficulty accessing all phonetic detail when focusing their attention on learning meaning. Subsequent research showed that 14-month-old infants succeed only with additional contextual information or under less demanding learning conditions (Fennell & Werker, 2003; Fennell, Waxman, & Weisleder, 2007; Rost & McMurray, 2009; Swingley & Aslin, 2002; Thiessen, 2007; Yoshida, Fennell, Swingley, & Werker, 2009).

Some evidence suggests that adults might have similar difficulties when learning words in a new language. In a study by Perfors and Dunbar (2010), native speakers of English were first trained on discriminating a non-native contrast between a prevoiced and a voiceless unaspirated stop ([gipur] vs. [kipur]), and then taught word-picture mappings using minimal-pair words distinguished by this non-native contrast. The results showed that while participants performed better than chance at learning similar words with the exact contrast they had been trained on ([gipur]-[kipur]), they were at chance at learning words contrasted by sounds with an analogous contrast ([bipur]-[pipur]). This was despite the fact that, after perceptual training on [g]-[k], participants were able to distinguish [b] and [p] perceptually. Thus, just like 14-month-old infants, adults had difficulty differentiating between similar words in a word-learning task, even though they could tell these words apart in a pure perceptual task.<sup>1</sup>

<sup>1</sup>Better performance on [gipur] and [kipur]) might have been due

However, the difficulty in learning similar-sounding words found by Perfors and Dunbar (2010) might have a purely perceptual basis. That is, learners' ability to discriminate a pre-voiced [b] vs. a voiceless unaspirated [p] might not have been sufficiently robust to be of any use in a word-learning task. This is similar to the intuition of Perfors and Dunbar, who point out that learners' representations of [b] and [p] categories might have been too fragile to see any advantage in word learning. If this reasoning is correct, then the comparison between 14-month-olds and adults in Perfors and Dunbar's (2010) study is less warranted because, at 14 months, infants have difficulty learning the words *bih* and *dih* despite easily discriminating between the sounds *b* and *d*.

In the study reported here we achieve a more direct comparison with the situation of 14-month-old infants by investigating how adults learn similar-sounding words that they can distinguish perceptually due to their L1-based phonetic generalizations. Specifically, we used two distinctions: *length* (e.g., [taja]-[tajja]) and *place* of articulation between alveolo-palatal and retroflex sounds (e.g., [gotɕa]-[gotɕa]). Our participants were native speakers of Korean and of Mandarin, who were previously shown to have differential perceptual sensitivity to these two distinctions, as illustrated in Figure 1 (Pajak, 2010a, 2010b; Pajak & Levy, in prep.). In particular, Korean speakers were shown to be better than Mandarin speakers at discriminating consonant length contrasts ([m]-[mm], [n]-[nn], [l]-[ll], [s]-[ss], [f]-[ff], [j]-[jj], [w]-[ww]), but the reverse was true for the alveolo-palatal vs. retroflex place contrasts ([ɕ]-[ʂ], [tɕ]-[ʈ], [ʑ]-[ʑ], [dʑ]-[dʑ]). This result was likely due to the fact that Korean has length distinctions, and Mandarin does not, but Mandarin has alveolo-palatal and retroflex sounds, while Korean does not (Lin, 2001; Sohn, 2001). Crucially, however, these perceptual sensitivities cannot be attributed to direct L1-to-L2 phonetic category transfer alone (as has been generally proposed for these types of perceptual patterns; Major, 2008) because not all of the tested speech sounds exist in Korean or Mandarin.<sup>2</sup> Consequently, Pajak hypothesized that perceptual advantages in non-native speech processing can arise from sensitivity to phonetic *dimensions* that are informative in L1, and not just sensitivity to specific L1 categories. In this study we test whether these perceptual advantages are exploited during word learning.

## Experiment

Participants learned novel word-picture mappings, where each word was in a minimal pair with either a *length* dis-

to the familiarity with these lexical items from perceptual training, which is consistent with infants also performing better on familiar words (Swingley & Aslin, 2002).

<sup>2</sup>Korean mostly uses length distinctions on vowels (e.g., [pu:l] 'fire' vs. [pu:l] 'blow'), but some long consonants ([ll], [nn], [mm]) arise from phonological assimilation processes (Sohn, 2001), and Korean tense obstruents ([p̚], [t̚], [k̚], [s̚], [t̚ɕ]) have sometimes been analyzed as long (Choi, 1995). As for Mandarin, alveolo-palatals and retroflexes exist as allophones of the same phonemic category, and voiced obstruents ([ʑ], [dʑ], [dʑ]) are entirely absent (except [ʑ]) since Mandarin has obstruent distinctions in aspiration, not voicing (Lin, 2001).

Figure 1: Perceptual discrimination results (Pajak, 2010a, 2010b; Pajak & Levy, in prep.).

inction or an alveolo-palatal vs. retroflex *place* distinction. We predicted that if adult L2 learners are able to attend to phonetic detail by using their L1-based resources when learning a new lexicon, then we should observe the same pattern in both the perceptual discrimination and the word-learning tasks: that is, Korean speakers should be better at learning *length* minimal pairs, and Mandarin speakers better at learning *place* minimal pairs.

## Method

**Participants** 54 undergraduate students at UC San Diego participated in the experiment for course credit or payment. Half were speakers of Korean, and the other half were speakers of Mandarin. Participants varied in terms of their length of residence in the US: some were born in the US, while others immigrated at some point after birth or were international students who arrived very recently. Consequently, they varied in English proficiency. Importantly, however, they all learned Korean or Mandarin from birth, reported high proficiency in those languages, and still used them regularly, predominantly with family. In most cases they had some high school and/or college exposure to Spanish or French. Some Mandarin speakers were also familiar with Taiwanese, mostly through family exposure. All participants reported no history of speech or hearing problems.

**Materials** The materials consisted of 16 nonce words of the form CVC(:)V, where each was in a minimal pair differing only in the middle consonant (a subset of contrasts tested by Pajak, 2010a, 2010b; Pajak & Levy, in prep.). There were 12 *length* words, with either a short or a long middle consonant, and 4 *place* words, with either an alveolo-palatal or a retroflex consonant (both pronounced as in Polish, which has a distinction similar to Mandarin), as illustrated in Table 1.

The materials were recorded in a soundproof booth by a phonetically-trained native speaker of Polish. There were 10 tokens recorded for each word. For *length* words, two tokens of each word with long consonants were chosen for the experiment. Subsequently, words with short consonants were created by shortening the tokens with long consonants in a way that, for each word and each recording, the naturally-recorded long consonant was reduced to half its duration so as

Table 1: Stimuli (in IPA).

LENGTH WORDS		PLACE WORDS	
<i>short</i>	<i>long</i>	<i>alveolo-palatal</i>	<i>retroflex</i>
taja	tajja		
tala	talla		
diwa	diwwa	gotça	gotṣa
difa	diffa	goṣa	goṣa
kema	kemma		
kena	kenna		

to maintain a constant 2:1 duration ratio (cross-linguistically, the long-to-short consonant ratio varies between 1.5 to 3; Ladefoged & Maddieson, 1996). For *place* words, two tokens each were chosen for the experiment with the goal of maximizing the similarity between the words in minimal pairs with regards to how vowels were pronounced, but at the same time choosing tokens with clearly enunciated middle consonants.

Each word was paired with a picture of a different kind of mushroom (see two examples in Fig. 2), which were chosen in order to include objects that were unfamiliar to our participants, but not so unfamiliar that participants would find them bizarre and hard to remember. We selected pictures that varied in shape and color so as to maximize visual differences between them. We created four different one-to-one word-to-picture mappings that were counterbalanced between participants in order to make sure that the results were not driven by any peculiarities in the mappings we chose.

**Procedure** Participants sat in front of a computer, and responded by using a mouse. They were instructed that in this experiment they would be learning a novel language, and, specifically, the language’s words for mushrooms. The experiment was completed in a single session. There were 4 training blocks (each with 128 trials, about 10-15min long) and 4 testing blocks (each with 64 trials, about 5min long), interleaved. Blocks were separated by self-terminated breaks. In each trial, two pictures were presented on a computer screen (see Fig. 2), and a word was played through headphones with a delay of 500ms. Participants were asked to click on the picture that they thought went with the word. In training, feedback was provided following the response in the form of the correct picture staying on the screen. A mouse click triggered the start of the next trial. Presenting feedback after participant’s response meant that the early responses were necessarily random. Participants were told to guess at first, and that through feedback they would eventually learn the correct word-to-picture mappings. In testing, no feedback was provided.

The training trial types consisted of picture pairs that were always associated with dissimilar word pairs (e.g., *taja-diwa*, *gotça-kemma*) so that participants were not directly alerted to the distinctions of interest. The testing trial types were always different from the training trials. There were four types of tri-

Figure 2: Example of a screen shot that participants saw throughout the experiment.

als in testing depending on the minimal-pair contrast that corresponded to the pictures, as illustrated in Table 2: (i) *length* (24 trials per block), (ii) *place* (8 trials), (iii) filler-dissimilar (16 trials), and (iv) filler-similar (16 trials). The critical trials consisted of the critical minimal-pair picture pairings (i.e., pairs of pictures whose corresponding words were a minimal pair): *length* pairs and *place* pairs. The filler trials consisted of *dissimilar* pairs, always differing in the first CV sequence, and *similar* pairs that shared the initial CV sequence. The picture position was counterbalanced. The trial order was pseudo-randomized: we created four randomized lists, and then altered them manually so that the same word was never repeated in two consecutive trials. Furthermore, the minimal-pair trials were always separated by at least two other trials. Each participant heard each list once, with a different list for each block. The block order was counterbalanced across participants.

Table 2: Trial types in testing.

<b>Place</b>	gotça-gotṣa	<b>Similar</b>	tala-taja

## Results

We analyzed accuracy scores from testing with mixed-effects logit models (Jaeger, 2008). We included random intercepts for participants and items, and random slopes for participants and items for all effects of interest that were manipulated within participants or within items. We controlled for participants’ nonverbal IQ, self-reported L1 proficiency, and current L1 exposure and use by adding them as fixed effects to the models. Although we present data for the four test blocks separately for purposes of visualization, in statistical analyses we collapse across test block.

As a sanity check, we expected that all participants, regardless of language background, should perform best on *filler-dissimilar* trials, slightly worse on *filler-similar* trials, and worst on *critical* trials. These overall results were borne out, as illustrated in Figure 3. In a model with fixed effects of TRIAL TYPE (*filler-dissimilar*, *filler-similar*, *critical*)

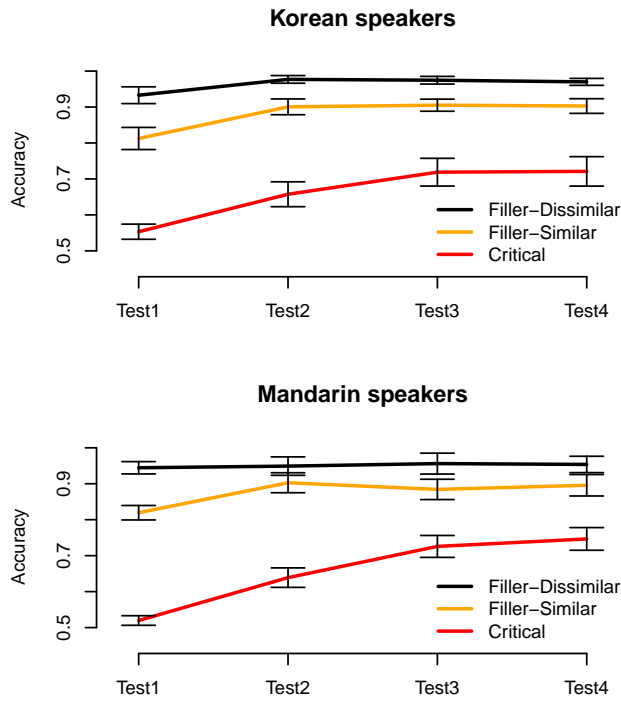

Figure 3: Proportion of correct responses on critical and filler trials (in all figures, error bars are standard errors).

and LANGUAGE (*Korean, Mandarin*), we found that the responses in the *filler-dissimilar* condition were significantly higher than in the *filler-similar* condition ( $p < .001$ ), which in turn were higher than in the *critical* condition ( $p < .001$ ). Neither LANGUAGE nor its interactions were significant in the model. Furthermore, a log-likelihood ratio test comparing the full model to a reduced version which did not contain LANGUAGE revealed no evidence that language background significantly contributed to the model ( $\chi(5) = 2.20; p = .82$ ), thus suggesting that there were no significant differences between the two language groups in overall response patterns.

Next, we compared Korean and Mandarin speakers on critical trials in a model with fixed effects of CRITICAL TRIAL TYPE (*length, place*) and LANGUAGE (*Korean, Mandarin*). If learners are able to capitalize on their L1-based perceptual generalization when beginning to learn new words, we should observe a difference in performance between the two language groups in line with their perceptual biases: Korean speakers should be more accurate on *length* pairs, and Mandarin speakers more accurate on *place* pairs. However, there was no significant interaction between CRITICAL TRIAL TYPE and LANGUAGE ( $p=.21$ ), indicating that Korean and Mandarin speakers did not differ in their accuracy when learning similar-sounding words that differed in either length or place. These results are illustrated in Figure 4. This is in striking contrast to perceptual discrimination results (Fig. 1; Pajak, 2010b, 2010a; Pajak & Levy, in prep.), where – using similarly constructed stimuli – Korean speakers clearly outperformed Mandarin speakers on perception of length con-

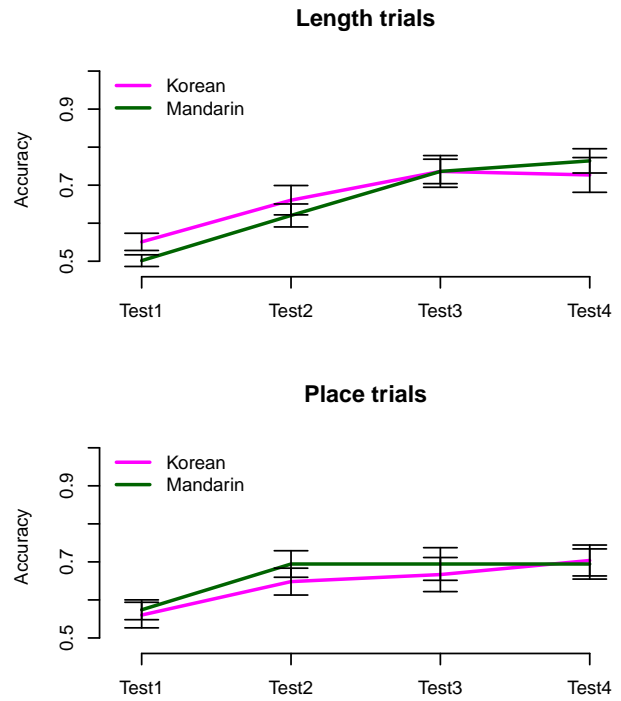

Figure 4: Proportion of correct responses on critical trials.

trasts, and the reverse was true for place contrasts.

However, we know that learners vary in their attention, motivation and learning skills. Thus, we asked whether only better learners are able to use their L1 resources and attend to fine phonetic detail in word learning. To answer that question we split the participants into two halves, top- and bottom-scoring on filler trials. We chose this way of doing the median split due to the fact that performance on fillers was a dimension independent from the variables of interest. The median score on all fillers combined was 94.5% accuracy. There were 7 participants who scored right at 94.5%, who were then split based on their performance on *dissimilar* fillers alone. The distribution of participants in terms of their language background was fairly equal in both groups: Korean=13 and Mandarin=14 in the top half, and Korean=14 and Mandarin=13 in the bottom half. The filler scores for both top-scoring and bottom-scoring participants are provided in Table 3 (next page). Both groups were highly accurate on filler pairs (at least 80% accuracy), but there was much more variability in the bottom-scoring group.

The results split by top-scoring vs. bottom-scoring participants are illustrated in Figures 5 and 6. Even by visual inspection alone, the results on critical trials look strikingly different in the top vs. bottom-scoring group: in the top half, participants were clearly improving in the course of the experiment (with the biggest jump from Test1 to Test2), while in the bottom half, participants' responses were close to chance throughout the experiment, with only minimal signs of learning (namely, Mandarin speakers seemed to improve on *length* trials toward the end of the experiment). We analyzed these

Figure 5: Faster learners: proportion of correct responses on critical trials.

Table 3: Proportion of correct responses on filler trials (standard errors in parentheses).

FILLER TYPE	TOP HALF		BOTTOM HALF	
	<i>Korean</i>	<i>Mandarin</i>	<i>Korean</i>	<i>Mandarin</i>
Test 1	.95 (.01)	.92 (.01)	.80 (.04)	.84 (.02)
Test 2	.98 (.01)	.98 (.01)	.90 (.02)	.87 (.05)
Test 3	.98 (.01)	.97 (.01)	.90 (.01)	.86 (.05)
Test 4	.99 (.00)	.99 (.01)	.89 (.02)	.86 (.05)

results with a model with fixed effects of CRITICAL TRIAL TYPE (*length*, *place*) and LANGUAGE (*Korean*, *Mandarin*), and an additional fixed effect of FILLER PERFORMANCE (*top*, *bottom*). We found a significant three-way interaction between CRITICAL TRIAL TYPE, LANGUAGE, and FILLER PERFORMANCE ( $p < .01$ ), indicating distinct response patterns for Korean vs. Mandarin speakers on *length* and *place* trials depending on their overall success rate in learning, as measured by their accuracy on filler trials. (A regression analysis treating filler performance as a continuous covariate yielded similar results).

For the top-scoring group, we found the pattern indicating that participants were taking advantage of their perceptual biases: Korean speakers more accurate on *length* trials than Mandarin speakers, but not on *place* trials, as indicated by a significant interaction between CRITICAL TRIAL TYPE and LANGUAGE ( $p < .01$ ). Furthermore, a model examining *length* trials only revealed a significant main effect of

Figure 6: Slower learners: proportion of correct responses on critical trials.

LANGUAGE ( $p < .05$ ). On *place* trials, Korean and Mandarin speakers were not significantly different, but the numerical tendency was the opposite of that seen in the *length* trials: Mandarin speakers were slightly more accurate than Korean speakers.

For bottom-scoring participants, on the other hand, we found no significant interaction between CRITICAL TRIAL TYPE and LANGUAGE. There were also no significant differences between Korean and Mandarin speakers when only *length* ( $p = .21$ ) or only *place* trials ( $p = .99$ ) were examined. However, Mandarin speakers did seem to improve on *length* – but not *place* – trials toward the end of the experiment. It is unclear why Mandarin, but not Korean speakers showed this improvement, especially since – if anything – it was Korean speakers who seemed to perform slightly better on filler trials in the bottom-scoring group. As for the learning asymmetry – improvement on *length*, but not on *place* – it could be that *length* was simply easier to learn, perhaps due to it being a more salient cue (note that in the perception study, Fig. 1, *length* contrasts were obviously easier than *place*) and due to the fact that the stimuli included significantly more *length* words compared to *place* words, thus allowing more opportunity for perceptual learning of the *length* contrast.

Why did some learners succeed at using their perceptual abilities while others did not? The individual measures we collected indicate that the top-scoring and the bottom-scoring groups did not differ in nonverbal IQ nor L1 proficiency. However, the bottom-scoring participants did, on average, immigrate to the US later in life, and, consequently, had lower

English proficiency. This suggests that there might be an advantage for more balanced bilinguals (consistent with findings by Kaushanskaya & Marian, 2009), or perhaps students less accustomed to the US educational system have more overall difficulty performing these kinds of tasks in a laboratory setting.

## Discussion

Previous work (Pajak, 2010a, 2010b; Pajak & Levy, in prep.) has shown beneficial effects of L1 properties on L2 discrimination, but what about learning? For the populations as a whole there was no clear effect indicating that participants made effective use of their native-language resources, but there is evidence that the faster learners (as independently assessed by filler performance) were able to do so. This is in contrast to the discrimination results we cited, where L1-based perceptual advantages were observed for all participants. This result suggests that there is something inherently hard about the early stage of word learning that precludes attention to fine phonetic detail that is otherwise available during phonetic processing. This is even more surprising given that adults have well-developed attentional and cognitive capacities, but nevertheless fail to use them in this task. It is still an open question as to what exactly made the faster group of learners succeed at using their L1 resources and attending to fine phonetic detail. Perhaps they were more attentive throughout the experiment, more motivated, or had better learning skills.

Overall, the results reported here shed some more light on the interaction between sound perception and word learning in adults. In particular, they suggest that perceptual resources are not easily used when learning minimal-pair words. An intriguing possibility – consistent with results from infant studies (Thiessen, 2007; see also Feldman, Griffiths, & Morgan, 2009) – is that learners' initial strategy is to assume that similar sounding minimal pairs are homophones, and only phonetic evidence from non-minimal pairs (or explicit information about the number of categories) pushes them to revise that assumption. This kind of parsimony might benefit learning when there is uncertainty about phonetic category boundaries – a possibility that we plan to pursue in future research.

# Seeing who sees: Contrastive access helps children reason about other minds

Kathie Pham, Elizabeth Bonawitz, & Alison Gopnik

## Abstract

Does contrastive access help preschoolers succeed on traditional false-belief tasks? Three- and four-year-olds were presented with a modified version of the change-of-location story in which *two* characters are the focus of interest. In the contrastive access condition preschoolers observe that one character leaves the room while the other stays and witnesses the moving event; in the non-contrastive condition both characters leave the room and fail to observe the moving event. Despite having to track two different characters and their different knowledge states about the location of the toy, preschoolers were more likely to succeed on the task when the characters had contrasting access to the moving event. This result supports a previously unexplored qualitative prediction of the Goodman et al (2006) computational model of the false-belief task and also provides tentative support for the theory theory view of the false-belief transition.

**Keywords:** Cognitive development; theory of mind; False-belief task; Contrastive learning.

## Theory theory of mind

The ability to reason about other people's mental states, such as their beliefs and desires, their fears and aspirations, is often referred to as theory of mind. Having a theory of mind allows us to construct others as mental beings: entities much grander than their physical attributes or their observable actions. One result of this understanding is that as adults, we are able to not only consider our own beliefs, but the beliefs of countless others—diverging beliefs about a single reality, beliefs that may be mistaken.

Decades of research have suggested that three-year-olds tend to struggle with false-belief reasoning in a very specific way. Studies have shown that three-year-olds misinterpret minds systematically—when an agent's beliefs and reality diverge, they predict actions of that agent to be consistent with the reality, rather than the false-belief (Wimmer & Perner, 1983; Perner et al., 1987). One classic example that tests a child's false-belief understanding is the change-of-location task (Wimmer & Perner, 1983). A child is read a story about a character (e.g.) Sally, who stores her toy and then leaves the room. While she is away, a mischievous character moves the toy. Sally then returns to look for her toy and the child is asked, "Where will Sally first go look for her toy?" Three-year-olds often say that Sally will look where the toy actually is, consistent with the true state of the world, rather than the location consistent with the agent's false-belief. In contrast, older four-year-olds more often correctly answer that Sally will look in the place that the toy was initially left, successfully considering an agent's beliefs

(e.g. Baron-Cohen et al., 1985; Perner, Leekam, & Wimmer, 1987; Wimmer & Perner, 1983).

Despite decades of research replicating this finding, there is much debate about how and when knowledge about other's mental states develops, and in particular when children develop an understanding of false-belief. Some studies suggest that children go through a conceptual change around ages three to five—from systematically failing false-belief tasks to performing above chance (Wellman, Cross, & Watson, 2001). However, there have been compelling arguments for earlier developing theory of mind competence suggesting that as early as 10 to 15 months infants already have an awareness that actors act on the basis of their beliefs and false-beliefs (e.g., see Baillargeon, Scott, and He, 2010 for a review).

It is not yet clear how to best interpret these infant "false-belief" findings nor how to reconcile or integrate them with the preschool ones. Regardless, something definite and important is happening in children's theory-of-mind understandings in the preschool years, beyond earlier developments in infancy. There are likely to be contrasts between implicit predictive and explicit causal-explanatory knowledge. Furthermore, differences in false-belief understanding as measured in the preschool years predict several key childhood competences, such as how and how much children talk about people in everyday conversation, their engagement in pretense, their social interactional skills and consequently their interactions with and popularity with peers (Astington & Jenkins 1995; Lalonde & Chandler 1995; Watson et al. 1999). Furthermore, variability in preschool performance on theory of mind tasks overlaps with but is distinctively different from executive function and IQ (e.g., Carlson & Moses 2001). These findings are important for confirming theory of mind's significance and relevance during the preschool years as indexed by preschool theory of mind tasks (especially as researched thus far for false-belief tasks).

Though it is unclear what factors support success on looking-time measures in young infants, the research that will be presented here assumes a theory-like competence that, in particular, supports explanation (e.g. Gopnik & Wellman, 1992; Wellman & Liu, 2007). We take the idea that theory of mind is analogous to scientific theories, resulting in children's distinctive patterns of predictions and interpretations of evidence, which is often referred to as the theory theory account of theory of mind development (e.g. Gopnik, 1993; Gopnik & Wellman, 1992; Perner, 1991). What a theory-like understanding of mind permits is conceptual change—theory revision in the face of new

evidence, and beliefs that support verbal predictions, explanations, and counterfactual reasoning.

The explanatory value of the theory theory is limited in that current accounts do not define the specific mechanisms for change. However, advances in computational accounts of theory change and probabilistic models in particular naturally integrate with qualitative predictions of the theory theory (e.g. Schulz, Bonawitz, & Griffiths, 2007). In what follows we will briefly describe one such account of the false-belief transition and discuss a prediction about the role of contrast that falls out of this model. We then present a new empirical study designed to test this prediction. We conclude with a discussion of how these findings support a theory theory account of false-belief.

### Rational account of the false-belief transition

There have been a few computational accounts of false-belief transition (Berthiaume, Schultz, & Onishi, in review; Goodman et al, 2006; O’Loughlin & Thagard, 2000; Triona, Masnick, & Morris, 2002; Van Overwalle, 2010). Consistent with the idea that children’s changing proficiency on false-belief tasks are guided only by changes in executive function, O’Loughlin and Thagard (2000) have produced a connectionist model where the false-belief transition is driven by an increase in inhibition of the true belief location. We consider a different proposal consistent with the theory theory (Goodman et al. 2006, Figure 1). The model makes explicit the variables (concepts) that children before and after false-belief transition represent and provides an account of why the explanatory variables appealed to by passers and failers are different. Specifically, the model proposes that children incorporate a visual access variable (seeing the final location of the toy) into their theory of mind models. This is a critical variable in the change-of-location story; passers seem to understand that visual access influences an agent’s belief states and her subsequent actions: because Sally did not see the toy moved, she does not know that it is in the new location.

In support of the claim that an understanding of visual access is changing in a young false-belief reasoner, children’s explanations also reflect a shift in understanding the causal relation between an agent’s access and beliefs. In the failer’s model of theory of mind, explanatory power is reduced because of fewer variables available in the model. Goodman et al. (2006) found that children who successfully predicted an agent’s action in a false-belief task generate more belief and access explanations, whereas failers of the task appeal more to desires. For example, a passer of the task may explain why an agent went to a surprising location (where the toy is not): “Because she did not see it moved” (appealing to access), whereas a failer may explain why an agent went to a surprising location: “Because she wanted to go there” (appealing to desire). This is consistent with the proposed models in figure one—only in the passers’ model do children have access as a causally connected variable. In contrast, the failers’ model only has alternate desire available as an explanation of surprising behavior.

In this paper we explore one previously untested implication of the Goodman et al. (2006) model. If access is made more salient to children at the cusp of false-belief understanding, then success (correct predictions and explanations that appeal to “belief”) on the false-belief task should increase. Critically, our modification of the classic false-belief task makes the task more complicated for children to follow; if children’s success on these tasks is only dependent on development of executive function, then such a modification should *decrease* success. If instead children have a theory-like representation of mental states as sketched by the Goodman et al. (2006) model, then we should observe an increase in correct predictions (where Sally and Billy will look for their toy) and an increase in explanations that appeal to belief state.

### Learning by contrast

How might we make the access variable more salient to our young learners? One factor that might facilitate learning is contrast (for review, see Gentner, 2010). Comparisons help learners identify differences and similarities between concepts, making salient the relevant variables and causal connections between them (Gentner, Loewenstein, & Hung, 2007; Ming, 2009). For example, learning by contrast has helped adults discriminate between mathematical problem types, identify the deep underlying structure of the problem as well as the critical structural features required to solve it (Ming, 2009), and it has helped children learn quickly from small amounts of data (Gentner et al., 2009).

Contrastive learning has been largely unexplored in the theory of mind domain. To our knowledge, no task has looked at children’s understanding of false-belief and whether contrast can help children reason about other minds (though see Gershon & Woodward, 2012 for an example of how comparisons help children learn goals of tool use actions). If contrastive learning is robust, theory of mind understanding may be facilitated by presenting a situation in which agents have contrasting access (one agent sees the object moved, whereas one agent does not see the object moved). This may help children identify visual access as a critical variable mediating beliefs, and may tip the scales in favor of the passers’ model, thus increasing predictions characteristic of that theory<sup>1</sup>. Favoring the passers’ model will also lead to an increase in explanations that appeal to belief and access, rather than simply desire (as seen in Goodman et al., 2006 when comparing failers’ explanations to passers’ explanations).

### Extension to the “false-belief” task

While false-belief understanding is a hallmark of theory of mind, as it seems to indicate a critical appreciation of the distinction between mind and world, it may over-simplify

---

<sup>1</sup> The potential “boost” from contrast in recognizing the importance of visual access may only help children at the cusp of theory of mind understanding, who may already be (implicitly) weighing between both theories.

(and thus obscure) developmental change. Wellman and Liu (2004) designed a more nuanced conceptual scale that captures preschooler's developmental progression of theory of mind understanding. Thus, besides using age as a general marker, one way to gauge where a child lies on the spectrum of theory of mind understanding is to adopt Wellman and Liu's (2004) false-belief battery, and see where each participant scores on the developmental progression.

We adopt the full battery and use an element of the battery that tests false-belief understanding, the change-of-contents task, to control for false-belief ability when assigning participants to our experimental conditions and so we do not give children training on the change-of-location task used as our test. According to the Wellman, Cross, and Watson's (2001) meta-analysis, children who lack a coherent theory of mind have just as much trouble reasoning about their own false-beliefs as they do reasoning about others' false-beliefs. In the "self" change-of-contents tasks, a child is shown (e.g.) a band-aid box and then asked what they think is inside. Most children reply band-aids, as that is what it appears to contain. The box is then opened, revealing (e.g.) a key, rather than band-aids inside. The box is closed, and the child is asked "What did you think was inside the box before we opened it?" Three-year-olds often say key, rather than their true initial guess (band-aids), unsuccessfully ascribing false-beliefs to themselves. In the "others" version of this task, they also incorrectly ascribe the correct belief about the box contents to a new individual that should be naïve of the contents. This false-belief task, according to Wellman, Cross, and Watson's (2001) meta-analysis, is comparable to the change-of-location task—children who succeed in one will succeed in the other. The change-of-contents false-belief task (self and others) will provide an initial measure, independent of our modified test books, that we can use to classify children's starting false-belief understanding.

### Contrasting access in false-belief experiment

In this experiment, children at the cusp of the false-belief transition (three-and-a-half- to -five-year-olds) are first given a diagnostic assessment using Wellman and Liu's (2004) false-belief tasks, sans the change-of-location task. We then present children with one of two modified false-belief stories. In one version of the story, there are two characters (Sally and Billy) that together put their toy in a basket; one character leaves the room while the other stays and observes the toy being moved by a third character (Alex). The question posed to the children is where will Sally and Billy each look for the toy. After generating a prediction, children see that Sally goes to the original location and Billy goes to the new location and children are asked why each character looked there. The control task is nearly identical except both Sally and Billy leave the room and do not observe Alex moving the toy, and after the prediction phase both characters go to the original location and children are asked why Sally and Billy went there.

**Figure 1:** Goodman et al. (2006) model of (a) failers and (b) passers. Belief (B) & desire (D) determine action, but only in (b) is belief influenced by visual access (V). The parameter  $\gamma$  represents all the reasons, outside of the story, that an agent might change her mind.

If the models proposed by Goodman et al. (2006) accurately capture a relevant change (the addition of access in the passers' model) in children's theory of mind, then the contrasting access in the first book may make this variable more salient to children and may improve their performance on the task. Another possibility is that children's shifting ability in false-belief tasks is best explained by changes in executive functioning. If so, then increasing the task demands as with the contrasting access book (children have to track the multiple and different knowledge states of two characters) should make the task more difficult and lead to more incorrect predictions and explanations.

## Methods

### Participants

62 children (mean: 50 months, range: 38 to 65 months) were recruited from preschools and museums in the Berkeley area. Children were assigned to a *Contrast* or *Non-contrastive Control* condition based on their performance on the change-of-contents tasks, such that there were equal numbers of passers, failers, and children who answered 1 of 2 parts of the task correctly, assigned to each test condition.

### Procedure

Children were first given the diagnostic tests and then assigned to one of the two test conditions.

**Diagnostic tests.** We adapted the Wellman and Liu (2004) scaling of theory of mind tasks to include the following six tasks (in the order listed): Diverse Desires (i.e. can George like this even if you don't); Diverse Beliefs (i.e. if Linda thinks it is there but you think it's here, where will Linda look?); Knowledge Access (i.e. given this opaque box that Molly can't see inside, will she know what's inside?); change-of-contents self (i.e. what did you think was in the Band-Aid box when you first saw it?); change-of-contents other (i.e. what will this new person think is inside the Band-Aid box?); Belief-Emotion (i.e. will Sam be disappointed when he looks in the box?). Children were then assigned to one of the test conditions based on their performance on the change-of-contents self and change-of-contents other task such that equal numbers of passing and failing children were assigned to each condition.

**Test books.** The test books were the modified change-of-location story previously described. In the story, Billy and Sally have a stuffed bear. They hide their stuffed bear

underneath the lid of a basket. In the *Contrast* condition Sally has to leave the room. When Sally leaves the room, and Billy is in the room, a new character – Alex – is introduced. The experimenter says to the child, “Uh, oh. Here comes Alex. Alex is a troublemaker. Look, while Sally is away, Alex moves their toy from the basket to the box, and Billy sees Alex move their toy. See! When Alex moves the toy, Sally is not in the room, but Billy is in the room and sees!” There is a memory check: “Where is the toy now?” (box). Then the child is asked to predict where Sally will first go to look for her toy (if she went to look before Billy), and where Billy will first go to look for his toy (if he went to look before Sally); the order of questions was counterbalanced. Children were prompted to provide an answer or point to the location. The child is then shown where Sally and Billy actually go: in the *Contrast* condition Sally goes to the basket and Billy goes to the box, and then the child is asked to explain freely why Billy and Sally went to their respective locations, despite the true location of the toy. Once the child explains why Sally and Billy acted in the way that they did, the child must pass the final memory check in order to be included in the study: “Can you point to who was in the room, if anyone, when Alex moved the toy?” No child was excluded.

In the *Non-contrast* condition, Sally and Billy both leave the room. The experimenter then says, “Oh, oh. Here comes Alex. Alex is a troublemaker. Look, while Sally and Billy are away, Alex moves their toy from the basket to the box, and Billy and Sally don’t see Alex move their toy. See? When Alex moves the toy, Sally is not in the room, and Billy is not in the room, and they both do not see!”<sup>2</sup> Like the *Contrast* condition, there is a memory check, and then the child is asked to predict where Sally and Billy will first go to look for their toy. However, in the *Non-contrast* condition, the child is shown that both Sally and Billy go to the basket and then asked to explain freely why “they both went there.” In both conditions, if the child only provided an explanation for one character, he or she was asked to explain the behavior, in isolation, of the other character.

## Results

Children were divided into conditions such that there were 31 children in the *Contrast* condition ( $M = 50$  months,  $SD = 7.52$  months) and 31 children in the *Non-contrast* condition ( $M = 51$  months,  $SD = 8.15$  months) with no significant difference in ages between conditions  $t(61) = -0.34$ ,  $p = 0.73$ . Children were divided into a condition in order to control for false-belief ability: in each condition, there were three groups of children based on their change-of-contents performance—12 children who passed (passers) by correctly ascribing a false-belief to themselves and to another agent, 13 children who failed (failers) who were unable to ascribe a false-belief to either themselves or

another agent, and 6 children who we deem “liminal” because they were able to ascribe a false-belief in one case, but not in another case.

### Predictions by change-of-contents performance

In order to pass the predictions portion of the task, the child needed to correctly predict both where Sally will go to look for her toy and where Billy will go to look for his toy. Any other kind of prediction (e.g. correctly predicting where Billy goes, but incorrectly predicting where Sally goes) was scored as failing the task.

The children in the *Contrast* condition did significantly better in predicting both Sally and Billy’s actions than in the *Non-contrast* condition, Fisher exact  $p = .04$ , (see Figure 2a). In the *Non-contrast* condition: 13% incorrectly predicted where both Sally and Billy will go, 39% correctly predicted where both Sally and Billy will go, and 48% made one correct prediction about Sally or Billy (7 of 15 correctly predicting Sally). In the *Contrast* condition: 16% incorrectly predicted where both Sally and Billy will go, 65% correctly predicted where both Sally and Billy will go, and 19% made one correct prediction about Sally or Billy (half correctly predicting Sally).

### Predictions by complete diagnostic score

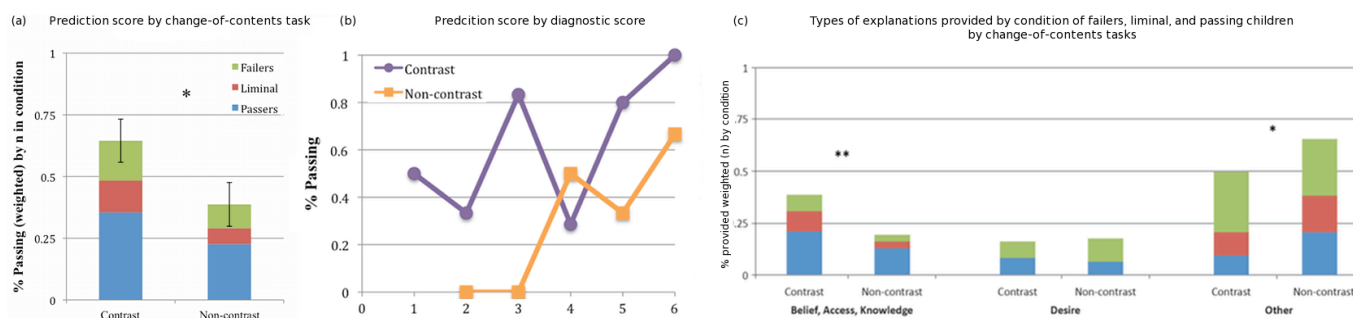

Participant responses were also analyzed as a factor of the number of tasks children initially passed on the six-task, diagnostic battery. In the *Contrast* condition, participant scores ranged from one to six, and in the *Non-contrast* condition participant scores ranged from two to six. Children in the *Non-contrast* condition had a marginally significant higher diagnostic score than the children in the *Contrast* condition,  $t(60) = -2.61$ ,  $p = .11$ , but this works against our hypothesis since children with higher scores on other theory of mind tasks should have higher false-belief performance.

There was an overall interaction between diagnostic score, condition, and passing,  $G^2(13) = 25.28$ ,  $p < .05$ , (see Figure 2b). Consistent with the predictions by change-of-contents performance, there was an interaction between condition and whether or not the child passed the predictions such that children in the *Contrast* condition were significantly more likely to correctly predict the agents’ actions,  $G^2(1) = 4.58$ ,  $p < .05$  (see Figure 3), even when the influence of the diagnostic score was removed  $G^2(5) = 15.58$ ,  $p < .05$ . There was also an effect of diagnostic score and passing; not surprisingly, children with higher diagnostic scores were significantly more likely to correctly predict where the agents would go in the false-belief tasks  $G^2(4) = 8.72$ ,  $p = .07$ .

### Explanations

Explanations were collapsed into three categories: “Belief, Access, Knowledge explanations” (which contained any explanation that appealed belief, access, or knowledge), “Desire explanations” (any explanation that appealed to desires), and “Other” (all non-mental explanations: an

<sup>2</sup> In both conditions, the Change-of-location story was modified to explicitly mention visual access (seeing) two times in order to emphasize who sees and who does not see the character move the toy.

**Figure 2.** Preschoolers' performance by condition based on (a) change-of-contents task (% predicting correctly), (b) diagnostic score (% predicting correctly), and (c) types of explanations generated by children based on change-of-contents task. So as not to conflate within group proportions, the percentages reported in (a) and (c) are the product of the percent responding in a particular group (e.g. 4/6 liminal Contrast children passed) weighted by the number of children in that group (e.g. 6/31).

explanation that appealed to the initial world, the final world, external information, or was unclassifiable). The first author coded all explanations and a research assistant reliability coded 82% of explanations. Coding was compared using a maximally conservative approach (using the 8 classification subdivisions) and both coders were blind to condition; reliability was high ( $\kappa = 0.79$ ). Analysis revealed an overall interaction between condition, explanation type, and initial false-belief performance,  $G^2(12) = 38.6$ ,  $p < .001$ . Consistent with Goodman et al.'s (2006) results, we also saw an interaction between explanation type and false-belief performance such that the better children performed on the diagnostic tasks, the more likely they were to appeal to belief, access, and knowledge in their explanations  $G^2(4) = 29.5$ ,  $p < .0001$ . Follow-up comparisons revealed that participants in the *Contrast* condition significantly more often appealed to beliefs, access, and knowledge than participants in the *Non-contrast* condition, Fisher exact  $p = .02$ . Furthermore, participants in the *Non-contrast* condition were more likely to appeal to "other" non-mental explanations, Fisher exact  $p = .05$ , (see Figure 2c).

## Discussion

Consistent with our predictions, results suggest that children are better able to predict and explain human behavior when observing agents who have contrastive visual access. Our modified false-belief tasks were more difficult in that they involved more characters, predictions, and explanations as compared to original change-of-location tasks. The *Contrast* condition was in a sense more complex than the *Non-contrast* condition because the child had to entertain two different perspectives, make two distinct predictions based on those perspectives, and then generate an explanation that accounts for these different perspectives and resulting behaviors; the *Non-contrast control* condition effectively required something much simpler: reason about Billy in the same way you reasoned about Sally. Nonetheless, predictive success in the *Contrast* condition was significantly higher than in the *Non-contrast* condition.

Explanatory success (where success in explanation requires appealing to higher level mental states such as beliefs and access) was also higher in the *Contrast* condition. These findings further support the claim that highlighting the access variable by contrast facilitates the child's ability to incorporate it into his or her model of other minds, and in turn, use it to explain behavior.

There are numerous alternative accounts for three-year-olds failures to pass false-belief tasks. Executive functioning involves planning, response inhibition, and cognitive flexibility (Zelazo, Carter, Reznik, & Frye, 1997). Thus, the ways in which executive functioning may potentially interact or interfere with theory of mind performance is vast (e.g. premature inhibitory control see Carlson, Moses, and Hix, 1998; for theory of mind Mechanism/Selection Processing see Scholl and Leslie, 2001). This kind of account is inconsistent with our findings. Because age and initial false-belief performance are controlled, executive functioning (such as inhibitory selection abilities) in the children should also be comparable between conditions. There is no reason to assume that the children in the *Contrast* condition developed greater inhibitory control than their *Non-contrast* counterparts. The *Non-contrast* condition did require the child inhibit the real world contents twice in order to pass the task – they must ascribe a false-belief to both Billy and Sally in the story. However, according to Wellman, Cross, and Watson's (2004) meta-analysis children given consecutive and equivalent false-belief tasks, which varied only in character and object, responded in highly consistent ways, giving identical responses 84% of the time. This finding suggests that asking a child to ascribe a false-belief twice, given equivalent situations, but differing in character, does not encourage switching answers. A child who is able to inhibit the real world contents once should be able to inhibit the real world contents a second time.

The study illustrates the helpfulness of presenting multiple and contrasting perspectives to a young learner with a developing theory of mind. Contrast has been shown to facilitate learning. However, until now, it has not been applied to the social domain. How contrast is helping may be, as Gentner (2010) proposes, a matter of highlighting a

variable and making it available for learning. Children appear to be incorporating the access variable into their working theory of mind, and contrast may be a means to facilitate this understanding. More generally, the results are consistent with a theory theory account of theory of mind: children seem to theorize others' inner workings, others' ambiguous actions and other's intangible beliefs, adjusting their theories in light of more information. The results support the theory that understanding other minds is learned just as any other theory is learned, and contrast can be applied to help interpret the ambiguous actions of others in the complex context of reality.

## Abstract

The pragmatic tolerance hypothesis (Katsos & Smith, 2010) was originated to explain the difference between children and adults concerning scalar implicatures. They introduced the use of a Likert-scale to test this hypothesis. We conducted a study with a within subjects design in which we compare children's binary and scalar responses to the same underinformative sentences. We also used two separate tasks to look at the effects of task difficulty on performance. The results show that the more difficult task, Euler circles, lead to less pragmatic responses compared to the easier task, drawings. Confirming the study by Katsos and Smith (2010; see also Katsos & Bishop, 2011) children choose the middle options on the scale more when they are confronted with underinformative sentences and they choose more extreme options for the control sentences. The comparison with the binary responses however, reveal that the link between the two measuring methods is not as straight forward as we would think.

**Keywords:** Scalar Implicatures; underinformative sentences; children; scalar responses pragmatic tolerance.

## Introduction

Communication is not always as straightforward as one might think. In 1989 Grice published his work on the cooperative principle that was meant to explain how our human interaction can be described. The cooperative principle expects a person to interact in a way that furthers the purpose of the conversation and indicates that a second person expects the first person to do so. The cooperative principle allows for implicatures to be used. When a person uses an implicature, the meaning of what that person says is not explicitly communicated, but can nonetheless be derived from what he says. The utterance is under-informative, more information could have been given but has not. For example when a wife asks her husband whether he'll be home for supper, and the husband answers that he has a meeting that will run late that day, then the husband is using an implicature. His wife will not expect him for dinner. One can assume that she accepts the meeting running late will be the reason, or at least a possible reason, that the husband will not be present at dinner. Nevertheless it is still possible that the husband will appear for dinner, for the implicature is cancellable. It is possible that the husband just meant he would be a little late for dinner, still he would not have lied in his earlier utterance.

One specific form of implicatures are scalar implicatures, which we will focus on in this paper. As the name implies, scalar implicatures consist of words that can be situated on a scale, known as Horn scales (see Horn, 1984). These words range from less informative to more informative, for example a scale containing words like <none>, <some> and <all>. Each word further on the scale contains more elements of a group. When a speaker uses a certain less informative word in an utterance, it is implicated that the more informative word is not applicable. When a person uses the word 'some', the word 'all' would not be appropriate. It is considered a mutual understanding between speaker and recipient that the speaker would have used the more informative word if it were suitable. Nevertheless he deliberately chose to use the less informative word on the scale therefore the more informative is not suitable. For example when the prime minister says 'Some banks are collapsing due to the financial crisis', a citizen can assume that 'not all' banks are collapsing due to this crisis, for the expression of 'some' implicates 'not all'. The citizen presumes that the prime minister would have said 'All banks are collapsing due to the financial crisis' if this were the case. If a few months later the prime minister makes the announcement 'All the banks have collapsed due to the financial crisis', this would not be a withdrawal of his earlier statement. Specific to implicatures is that they are cancellable in only one direction. When a speaker uses the weaker term 'some', it can later be easily corrected to 'all'. Yet when a speaker initially uses the stronger term 'all', it is not possible to change it to 'some' later on. At least not without admitting one was erroneous the first time. The stronger term 'all' entails the weaker term 'some' but not vice versa.

When a speaker uses the word 'some' in an utterance, there are two different ways to interpret this weak scalar term. The first way is the pragmatic way that was described above. A recipient might produce a scalar implicature and assume that the speaker meant 'some and not all' with the statement. Yet another way of interpreting the word 'some' is a purely explicit logical interpretation. The explicit meaning of the word 'some' is 'at least one and possibly all'. Both interpretation of the word are equally correct and it is the choice of the recipient on how he will interpret it.

Further in this article, we will refer to scalar implicatures as underinformative items or sentences.

We already know from different studies that children and adults interpret underinformative sentences in alternative ways. Noveck (2001) argues that a weak scalar term is understood in its explicit meaning first and will appear first in human development. Only later on the more complex pragmatic meaning will be incorporated. This argument is clearly demonstrated by the results of Noveck's study (2001). He found how children of 7-8 years old and 10-11 years old have acceptance rates of 89% and 85% for sentences that are logically true but pragmatically infelicitous. Adults on the other hand, accept these sentences in only 41% of the cases. This clearly demonstrated how for children the pragmatic meaning of these sentences is not incorporated. While for adults these pragmatic meanings are fully incorporated and are used as the principal criteria to accept or reject sentences.

The results also show how these differences between children and adults cannot be explained by the children's limited understanding of words like 'some' and 'all'. For all the different utterances that do not hold a conflict between the logical and the pragmatic meaning, the answering patterns of children and adults are very alike. The reason for the discrepancy between children and adults is not entirely clear. Noveck explains this by the posterior development of the pragmatic understanding of underinformative sentences. The processing of the pragmatic meaning of underinformative sentences is also cognitively much more demanding than the processing of the logical meaning (De Neys & Schaeken, 2007). Because of this, the pragmatic interpretation is harder to incorporate for children. Another factor that contributes to this is the nature of the task.

Pouscoulous et al. (2007) reported experiments in which they changed the nature of the task from verbal judgments to action-based judgments. Using small boxes that contained tokens, participants were asked to alter the setting of the tokens to match a statement. They were also allowed to leave a setting as it was. Within the experimental design, children's performance on producing implicatures was much higher than in experiments with verbal judgments. This increased implicature production was found for all ages (4-, 5-, and 7-year-olds as well as adults). Still, the developmental effect was present. These experiments show how the understanding of implicatures can be facilitated in young children by changing task features. Other studies have also showed how changing task features can facilitate children's performance (Guasti et al., 2005; Papafragou & Musolino, 2003; Papafragou & Tantalou, 2004).

Katsos and Smith (2010) did research on underinformative sentences in children and adults. They raised the pragmatic tolerance hypothesis to explain for differences between children and adults as well as differences between adults. The starting point of this hypotheses is that there are different degrees of violations. Several violations can lie within an utterance yet not every violation is equally grave. Participants can and will reject

utterances that are a grave violation of the logical truth. Yet they might accept or reject an utterance that only holds a violation of informativeness and thus is an infringement of the cooperative principle. There is no implicit rule on how to deal with pragmatically infelicitous utterances. The threshold of what is and what is not acceptable is individual for each person and is called pragmatic tolerance by Katsos and Smith (2010).

An obvious way to test this hypothesis was adopted by Katsos and Smith (2011, also see Katsos and Bishop (2011) and Katsos et al (2011)). Katsos and Smith (2010) introduced the use of a Likert scale to the research on underinformative sentences. A Likert scale is a bipolar psychometric scale on which a participant can indicate to what extent he agrees or disagrees with a certain statement. Katsos and Bishop (2011) made their participants indicate how much they agreed with utterances containing the words 'some' and 'all'. Both children and adults clearly rejected utterances that were inherently false and accepted utterances that had an optimal use of the words 'some' and 'all'. Interestingly, for the underinformative utterances, the answering patterns for children and adults were also very similar, as both groups chose the middle option on a 3-point Likert scale. This is in strong contrast with Noveck (2001) where the answering patterns for children and adults were much more distinct, notwithstanding the children in this study were older. Katsos and Smith (2011) explain this with the pragmatic tolerance principle. Children appear to be competent pragmatic comprehenders. They do sense the pragmatic violation when underinformative sentences are used. Yet due to their different tolerance levels, they do not experience this violation to be grave enough to be rejected. Therefore, when they are confronted with a two alternatives forced choice, they will not reject the violation while adults will.

In this paper, we want to explore these results more thoroughly and make three hypotheses. First of all, we will vary the task method. Pouscoulous et al. (2007) and others taught us that the nature of the task is of great importance. We expect that when we use different tasks, we will be able to make children reason more or less pragmatic, depending on the task difficulty. We will apply different methods than those used in Katsos and Bishop (2011) and Katsos and Smith (2010). Earlier research on underinformative sentences used different methods than the current ones. For example Newstead (1989, 1995) used Euler circles in his research. This abstract testing method should be difficult for children and thus induce more logical reasoning. We also developed a more child-friendly method using drawings which should induce more pragmatic reasoning in children.

Our second hypothesis concerns pragmatic tolerance. It seems obvious that this theory should be examined with a within subjects design in which children are confronted with a Likert scale as well as with the two alternative forced choice paradigm. We expand the testing method used in Katsos and Bishop (2011). Participants will be confronted with each underinformative sentence twice, once with the

option of responding on a Likert scale or once with a two alternative forced choice. With this research we expect to replicate Katsos and Bishops (2011) findings, namely that children do seem to detect a conflict when they are confronted with underinformative sentences. We expect that this conflict detection will be hidden when confronted with a two alternative forced choice but will become clear when they are confronted with the Likert scale. We will use children around the age of eleven, congruent with Noveck (2001). According to this study we expect children of this age to be still much more logical than adults.

Finally, we will look at consistency in children's answers. We expect that children that answer logically or pragmatically with the scalar measuring method, will answer in the same direction with the two alternative forced choice measuring method.

## Method

Twenty-two Dutch speaking children participated in this research (mean age 11,3 range 11-13).

The children received a pen and paper test. The test started with a cover-up story about a boy named Thomas. The children were told that Thomas was new in class and came from a foreign country. They were told he was still learning the Dutch language and the children were to indicate how precise his answers were. Children had to indicate their answers either by indicating right or wrong, or on a 5-point Likert scale. The ends of the Likert scale were illustrated with a happy smiley and a frowning smiley. On the scale, the children were to indicate how well they thought that the boy's answer was, going from completely wrong to completely right. They were also allowed to use the middle options when the answer was only a little right or wrong or evenly right and wrong.

Two different tests were used. Both tests had the same basic structure. We started each trial with a given situation. This situation was presented either by a figure or a drawing. Then the participants were given a statement about the situation. They were instructed to indicate how well the statement described the situation given above.

First was the Euler circles task. The circles for each figure were either completely overlapping, partially overlapping or completely disconnected. Each circle represented a group of blocks, for example 'red blocks', 'square blocks', which was written inside each circle. The participants received a statement about the blocks and had to judge how precise the statement described the circles setting. For an example of this, see Figure 1.

For the second task, we used a method which was more adapted to children, Drawings. For the given situation, the children were now shown a drawing of a real life setting, for example a few kids playing with a bow and arrows. Again the children had to judge a statement about the setting, e.g. 'Some arrows are shot in the bull's-eye'. Due to the more authentic stimuli, the task became much easier for children.

Figure 1: Example of Euler circles, drawings, scalar response option and binary response option.

## Results

We inverted all scores of the logically false items. This way, high scores on the control items, for both logically false items and optimal items, indicate competent reasoning. We also inverted answers on the underinformative items. Because of this, the maximal score of five points is an extreme pragmatic answer and the minimal score of one is an extreme logical answer. Finally we converted the binary zero and one scores to one and five scores to make them comparable with the scalar responses.

For the control items we found very high average scores, 4.72 (.20) for binary responses and 4.56(.34) for scalar responses. This means that the children understand the words 'some', 'all' and 'none' adequately. For the underinformative items, we found average scores of 3.93(.89) for the binary responses and 3.16(.98) for the scalar responses. For more detailed results, see Table 1.

Table 1: Mean ratings and standard error of the mean for Euler circles (EC) and Drawings (D)

	Binary	Scalar
EC – Control items	4.60 (.36)	4.46 (.36)
D – Control items	4.92 (.18)	4.65 (.41)
EC – Underinformative items	3.18 (1.51)	2.65 (1.05)
D – Underinformative items	4.70 (.57)	3.71 (1.11)

We ran a repeated measures design with three within factors with two levels each, namely measuring method, task and item type. We found three main effects. The two measuring methods levels, binary answers versus scalar answers, are significantly different from each other ( $F(1,21) = 9.46$ ,  $p < .01$ ). Binary responses are higher than scalar responses, as expected because binary responses only allow extreme answers. For the two tasks, Euler Circles seem to

be more difficult and lead to more logical answers than Drawings,  $F(1,21) = 54.07$ ,  $p < .00$ . For the item types, control items versus underinformative items, children answer more extreme for control items and more varied for underinformative items,  $F(1,21) = 54.72$ ,  $p < .00$ . We found two interaction effects. The interaction between measuring method and task was not significant but the other two interaction effects were, measuring method versus item ( $F(1,21) = 4.63$ ,  $p < .04$ ; see Figure 2) and task versus item ( $F(1,21) = 21.62$ ,  $p < .00$ ; see Figure 3). The three-way interaction was not significant.

Figure 2: Interaction between measuring method and item type.

We calculated the difference between the control items and the underinformative items for each measuring method. A paired-samples t-test on these values was significant ( $t(21) = 2.21$ ,  $p < .04$ ). This means that the interaction between measuring method and item type is explained by a difference in size of the effect of measuring method on item type.

The main effect of task and its interaction with item, mean that the Euler Circles were more difficult, especially for the underinformative items and thus lead to more logical answers. To confirm this, we calculated the difference between the control items and underinformative items for each task and analyzed with a paired t-test,  $t(21) = 4.65$ ,  $p < .00$ .

For the control items, 84% of the items were answered with an extreme answer of one or five on the scale. For the underinformative items, only 47% were answered with an extreme one or five. These two percentages were significantly different from each other ( $t(21) = 5.22$ ,  $p < .00$ ).

Finally we look at consistency of answers. We interpret being consistent between the two methods when a child gives an extreme answer of one or five on the scale and gives the equal binary response for the same item. For the control items, the children were fairly consistent between the two measuring methods. 80% of the children can be considered consistent under this rule. For the

underinformative sentences, children were much less consistent, only 33 % of them was consistent in their answers between the two methods. When we adopt a more flexible rule including also the two and four answers on the scale, which would also be acceptable, 87% and 57% of children can be considered consistent. For the underinformative items, 16% of the time the middle option of the scale was chosen.

Figure 3: Interaction between task and item type.

## Discussion

In this study we examined three hypotheses. First of all, we expected that children's performance will depend on the task difficulty. More precisely, we expected the Euler circles to be more difficult than the Drawings task and to lead towards less pragmatic answers for the underinformative items. Next we expected to replicate Katsos and Bishops (2011) findings, namely that children answer extremely pragmatic or logical when confronted with control items but more doubtful when confronted with underinformative items and a scale. Finally we expected children to be consistent in their answers on the two different measuring methods.

For the first hypothesis, we can find confirmation in the main effects of task and the interaction between task and item type. The Euler Circles task is clearly more difficult than the Drawings task. For the control items this difference is small but significant. For the underinformative items, this difference becomes even larger. For the more difficult task, the Euler circles, this leads to more logical answers. For the easier task, the Drawings, children become more pragmatic. There still remains a significant difference with the control items though. We hereby can confirm what Pouscoulous et al. and others made us expect. Task features can influence children's pragmatic reasoning on underinformative sentences. We noted earlier that we expect task difficulty to be the determining factor here. Yet we acknowledge that another factor may be at work as well. The Euler Circles task is believed to rely on logical reasoning skills. It might

be possible that the logical interpretation is triggered by the general logical characteristics of the task. In this case, not task difficulty but the logical nature of the task would be the determining factor. More in depth research on the matter seems necessary. The tasks used in this study were also very adapted to usage with children. More grammatical approaches to the material might lead to different conclusions. If the grammatical view of scalar implicatures (e.g. Chierchia, 2006; Fox, 2007) is correct, then in principle the implicature-computing operator could also be inserted in embedded positions, thus giving rise to embedded scalar implicatures. Chierchia, Fox and Spector (de twee papers) argue that an implicature-computing operator can indeed be inserted in embedded positions. It would be interesting to see how our conclusions and those of Katsos and Smith (2010) and Katsos and Bishop (2011) could be incorporated into this grammatical approach.

Secondly, we found a significant effect of measuring method and an interaction with item type. The difference between binary answers and scalar answers for the control items is significant. But the difference between the methods becomes much larger for the underinformative items. This confirms our hypothesis and replicates Katsos and Bishop (2011). When confronted with a scale, children do feel that there is a conflict between the pragmatic and the logical interpretation of underinformative sentences. They tend to choose the middle options of the scale more often (53%) than when confronted with control items (16%). This rules out the possibility that children are just unfamiliar with the use of scales. They are adequate in using scales and it is a deliberate action to choose the middle options for the underinformative items and the more extreme options for the control items. This confirms the pragmatic tolerance hypothesis in that children use the scale to express that they feel the conflict between the logical and the pragmatic interpretation.

We do however find a difference with common literature. The children in this study seem to be much more pragmatic than reports from other studies, especially with the binary responses. One explanation for this is probably the children's ages. Much research on this topic used younger children than the ones used in this study. It is self-evident that the slightly older children used in this study would perform more pragmatically and adult-like. Moreover, the current study was conducted in Dutch. Previous unpublished research on underinformative sentences with Dutch speaking children, revealed that these children are more pragmatic than their English-speaking (Katsos and Bishop, 2011) or French-speaking (Noveck, 2001) counterparts. Dutch speaking children seem to be more comparable to Spanish speaking children for example. In a study by Katsos et al. (2011), Spanish-speaking children rejected pragmatically false underinformative statements in 87% of the cases. It seems that the Dutch word 'sommige' is not the exact equal of the English word 'some'. This will probably contribute to the high rate of pragmatic answers in Dutch-speaking children.

Finally we examined consistency. These results seem to differentiate from the earlier found results. The children were not very consistent in their answers. Especially for the underinformative items, children were consistent in only 57% of the cases and 16% they chose the middle option. This still leaves 27% of the cases where children were not consistent. This percentage seems rather high to us and it interferes with the pragmatic tolerance theory. In roughly one fourth of the times, children's binary responses and their responses on the scale are not related. On top of that and in contrast to the study by Katsos and Smith (2010), we found much larger variances for both the control items and the underinformative items. This all suggests that the link between binary answers and scalar answers is not a direct link. For control items and underinformative items, up to 19% of the answers were cases in which the children gave an exact opposite to answer the binary items and the scalar items. We can hypothesize that in these cases children just made a simple error and that this wasn't intentional or due to a lack of understanding. But there is no way to be sure of this and it is in contrast with high overall levels of performance.

In conclusion, our study mainly confirms the pragmatic tolerance hypothesis but it also questions some aspects of it. It is clear to us that the pragmatic tolerance hypothesis and the relationship between binary and scalar answers on underinformative sentences is not as straightforward and that more thorough research on the matter is necessary.

## Abstract

It is not surprising to find that the quantity picked out by terms like *a few* and *a lot* is context dependent. We can easily accept that *a few* books might be 10 books, yet *a lot* of smartphones might only be 4 smartphones. The current paper posits that there are two hypotheses that can explain this context dependency: the Definite Number Hypothesis (DNH), and the Gradable Quantifier Hypothesis (GQH). The DNH suggests that the term *a few* corresponds to a definite range of values, and may pick out a larger quantity only if the range seems implausible for the given context. The GQH suggests that context-dependency is actually built into the meaning of *a few*. Experiment 1 supports the intuition that there is variability in the quantity that *a few* picks out based on context. The findings of Experiments 2 and 3 support the Gradable Quantifier Hypothesis.

## Introduction

When we consider terms such as *a few* and *a lot*, we intuitively know that relative to each other *a few* will always be smaller than *a lot*; however, what does this tell us about how we should evaluate the quantity that they represent across different sets in the world? One potential strategy is to assume that *a few* is always a small quantity and that *a lot* is always a large quantity. However, this strategy may lead us astray. For example, in Experiment 1 we find that 19 English-speaking adults suggest that *a few* friends on Facebook® is about 76 friends, whereas *a lot* of houses owned by a single individual is approximately 4.3 houses. Given this finding, it seems highly unlikely that the aforementioned strategy is the best for describing how we evaluate these terms in the wild. How then might we be dealing with these terms?

There is no doubt that we must be using some sort of contextual information to guide our interpretations. But how do we do this? We constructed and consider two hypotheses. On the Definite Number Hypothesis, the meaning of *a few* corresponds to a definite range of values – namely, small subitizable quantities (2 to 4 or 5). It was predicted that this range might be determined by comparison to other similar quantity terms using pragmatics (see: Grice, 1989; Barner, Brooks, & Bale, 2011). Given

that adults could easily select other terms such as *a couple* or *a pair* to represent 2 items, and terms such as *several* or *a handful* to represent slightly larger quantities, it was predicted that people could interpret the term *a few* with relation to these quantity terms, and therefore give *a few* a definite range of 3 to approximately 5. However, when speakers use *a few* Xs in contexts where 3 to 5 Xs is an extremely atypical quantity of Xs (say, Facebook friends), hearers interpret what the speakers have said by making a post-hoc adjustment from the definite meaning of *a few* (i.e., 3 to 5) to the smallest plausible quantity, say about 70 for Facebook friends. On the Gradable Quantifier Hypothesis, the meaning of *a few* is inherently context-sensitive, much like the meaning of gradable adjectives like *small*, or *tall*. In other words, the range of quantities corresponding to *a few* cannot be fully specified in the abstract; it can only be specified given some particular context. For example, there is no sense in asking what degree of height corresponds to *small* in general. Rather, one must know what type of individual is being measured, and what is the typical height for that type of individual (see: Kennedy, 2007; Syrett, Kennedy, & Lidz, 2010). The same may be true for the range of quantities that correspond to *a few* (i.e., one may have to know what type of individual is being quantified, and what is the typical quantity in which such individuals are found).

Both hypotheses are consistent with the fact that the numerical value associated with *a few* varies with context. Therefore, that fact alone cannot adjudicate between them. However, they attribute this variability to different factors. According to the Definite Number Hypothesis, the variability of *a few* is a function of whether the quantities in the range of its meaning (i.e., 3 to 5) are plausible; if they are not, then one adjusts to the smallest plausible value for the context at hand. In contrast, according to the Gradable Quantifier Hypothesis, the likelihood of finding 3 to 5 individuals of a given type matters not at all. Rather, all that matters is the typical quantity in which these individuals cluster. In the current paper, we test these hypotheses in two ways. First, in Experiment 1 we confirm the intuition that there is variability in the quantities associated with *a few*. In Experiment 2, we ask whether one observes variability in the quantities associated with *a few*, even in contexts where

3 to 5 are highly plausible quantities. Finally, in Experiment 3, we ask whether speakers associate *a few* with various quantities when they have information about typical quantities, but no information concerning whether 3 to 5 are plausible quantities. Whereas the Definite Number Hypothesis predicts that there should be no variability in the quantities associated with *a few* in Experiments 2 and 3, the Gradable Quantifier Hypothesis predicts the opposite pattern of results.

## Experiment 1

In Experiment 1 we aimed to look at what quantities English-speaking adults attribute to the terms *a few* and *a lot* with regards to common every day scenarios. Participants were asked to estimate values of *a few* and *a lot* when they were used in context of various common real world situations. It was expected that participants' responses would be affected by context (the estimated average for each situation), such that the overall averages given for both *a few* and *a lot* would vary for each scenario based on the average.

### Methods

**Participants** Nineteen fluent English-speaking adults ( $M = 20.7$  years old, 15 females) were recruited from the University of Waterloo. Participants received partial course credit for participating in the study.

**Materials and Procedure** Participants were asked to fill out a questionnaire where they were required to estimate the values associated with a series of one-sentence scenarios. Twenty different scenarios were constructed. Fourteen of the scenarios were about types of things individuals might own / have (dogs, cats, cars, computers, bicycles, books, children, guitars, smartphones, houses, DVDs, shirts, pennies, and TVs), and the remaining 6 items were about things and events in the world (trees in a park, apples picked in an outing, goals scored in a season, emails received over a week, friends on Facebook, and photos tagged online). Half of the items were expected *a priori* to have very small averages (Small Quantity Items), and the other half were expected to have relatively higher reported averages (Large Quantity Items). Each of the scenarios were described by one sentence containing the target term *a few* (1), or *a lot* (2), and were paired with a question asking the participant to evaluate how many items were described in each scenario. Additionally, the questionnaire included items asking participants to evaluate what the average might be for each scenario (3).

- (1) Dan has a few friends on Facebook. How many friends do you think he has on Facebook?
- (2) Dan has a lot of friends on Facebook. How many friends do you think he has on Facebook?
- (3) What is the average number of friends that people might have on Facebook?

The questionnaire contained all 60 test items. Each of the terms (*a few*, *a lot*, and *average*) were presented in separate blocks. The order of the scenarios was counterbalanced across blocks, and the order of the blocks was counterbalanced across participants. Each block appeared on a separate page.

### Results

Participants were elicited to pick a number to answer each of the test items. Since they were not given specific numbers to choose from their responses were fairly variable. As a result, before conducting any analyses we ran a recursive outlier detector on the responses made by each participant per test item, and removed any data points that were deemed to be outliers by the PJ Outlier program (Van Selst & Jolicoeur, 1994). Using this measure we deleted 3.6% of the responses. We then conducted a 2x2 repeated measures ANOVA with Quantifier (*a few*, *a lot*, and *average*) and Test Item as the repeated measures, and Subject Gender and Order as the between subjects measures. The results indicated an effect of Test Item ( $F(19,19) = 3.055$ ,  $p < .001$ ), and an interaction of Test Item and Quantifier ( $F(38,38) = 2.655$ ,  $p < .03$ ). Indicating that the results differ based on the individual test items, and that the quantifier used plays a role in the results for each test item. There was no effect of Quantifier, Subject Gender, or Order, nor any other significant interactions ( $ps > .1$ ).

We conducted several planned comparisons to investigate the interaction. As predicted there was a significant difference between the Small Quantity Items ( $M = 1.48$ ), and the Large Quantity Items ( $M = 73.57$ ) when the participants were asked to estimate the means for the items ( $t(18) = 9.89$ ,  $p < .001$ ). Similarly, we found a difference between the Small Quantity Items ( $M = 2.26$ ), and the Large Quantity Items ( $M = 20.63$ ) when the participants were asked to estimate what was meant by *a few* ( $t(18) = 6.4$ ,  $p < .001$ ), and a difference between the Small Quantity Items ( $M = 4.96$ ), and the Large Quantity Items ( $M = 264.34$ ) when the participants were asked to estimate what was meant by *a lot* ( $t(18) = 6.69$ ,  $p < .001$ ).

## Experiment 2

Both the Definite Number Hypothesis and the Gradable Quantifier Hypothesis can explain the variability found in Experiment 1. In Experiment 2 we ask if we can find contexts where having 3 to 5 items is highly plausible, but where people interpret *a few* as picking out quantities larger than 5.

Experiment 2 provided participants with contexts where the use of *a few* could plausibly be used felicitously to describe 3 to 5 items, or could also be used to describe a potentially larger quantity based on the participants' world knowledge. Participants were also asked to give a plausibility rating for scenarios such as in (4) which incorporated the numbers 3 to 5 rather than using the terms *a few* or *a lot*. The Definite Number Hypothesis predicts a very low plausibility rating for all contexts where *a few*

picks out a quantity greater than 5. Alternatively, the Gradable Number Hypothesis is more agnostic about the role of plausibility, but might predict that the all of the contexts where *a few* picks out quantities larger than 5 should be considered plausible.

(4) Martha has four friends on Facebook.

## Methods

**Participants** Forty-four fluent English-speaking adults ( $M = 20.4$  years old, 25 females) were recruited from the University of Waterloo. Participants received partial course credit for participating in the study.

**Materials and Procedure** Participants were asked to fill out a questionnaire where they were required to estimate the values associated with a series of one-sentence scenarios (Estimation Survey). Seven new scenarios were constructed. These scenarios included: silver cars in a parking lot, trips to the mall / gym / library in a semester, upper year students in a first year class, movies watched in a semester, and instances of eating pizza in a year. These items were chosen because it was predicted by the authors that they were contexts where *a few* could pick out a quantity larger than 5, but that they could plausibly be used in scenarios with quantities between 3 to 5. Unlike in Experiment 1, each of the scenarios was used in just a single trial that used the target term *a few*. The order of the scenarios was counterbalanced across participants.

Each participant completed a second survey following the Estimation Survey. The second survey (Plausibility Survey) included the 7 new scenarios introduced in Experiment 2, and 9 of the items from Experiment 1 (specifically items where *a few* picked out larger quantities). Each context was turned into a one sentence scenario which incorporated a number between 3 to 5 (e.g., “There are three silver cars parked in the UW parking lot today.”). Participants were asked to rate the plausibility for each of these sentences on a scale of 1 to 5, where 1 is highly implausible, and 5 is very plausible. The Plausibility Survey was always completed after the Estimation Survey, and was always presented on a separate page. The order of the scenarios was randomized between old and new items, and was counterbalanced across participants.

## Results

Table 1 reports the average plausibility ratings for all the test items rated in Experiment 2, and the average quantity associated with *a few* for each of these items.<sup>1</sup> The items are listed in decreasing order of plausibility. Table 1 shows that subjects associated quantities larger than 5 with several of

the items that were rated as having at least medium plausibility (3 out of 5 or higher). Of the items analyzed, the number of friends on Facebook was the only one where subjects associated a large quantity with *a few*, but where quantities between 3 and 5 were judged as having low plausibility. This provides evidence that *a few* is genuinely gradable.

Table 1: Mean responses given for “a few X” in Experiment 1 (noted by\*) and Experiment 2, and the mean plausibility rating for each corresponding trial in Experiment 2

Test Item	Plausibility of 3-5	A Few
E-mails in a week	4.42	8.39*
Trips to the mall in a semester	4.42	4.02
Trips to the gym in a year	4.28	8.18
Trips to the library in a semester	4.28	5.73
Upper year students in a first year class	4.19	10.61
Movies watched in a semester	4.19	6
Apples picked in an outing	3.94	8.28*
Books	3.89	10.16*
Photos tagged online	3.78	27.16*
Pennies in a jar	3.78	25*
Shirts	3.75	10.89*
Pizzas eaten in a years	3.75	9.85
DVDs	3.67	8.28*
Silver cars in the parking lot	3.19	8.1
Trees in a park	3.08	18.5*
Friends on Facebook	2.5	76.26*

## Experiment 3

Experiments 1 and 2 provide evidence that adults use context to adjust their interpretations of *a few* and *a lot*. Experiment 2 further showed that it is unlikely that this effect is as a result of the participants interpreting the use of the term *a few* as being infelicitous.

Experiment 3 provides further evidence that *a few* must be gradable, as predicted by the Gradable Quantifier Hypothesis. In Experiment 3 participants are told about novel objects that people from Southern Mexico like to collect. It was assumed that the participants had little to no experience with people from Southern Mexico or the things that they like to collect, thus, the participants could not use any of their prior knowledge to make inferences. Instead, we provided the participants with information about the average number of each of the objects owned by individuals, and then asked them to estimate how many items are picked out by *a few* or *a lot* for each of the novel items. Since the participants have no prior experience with the objects, and since we did not provide them with any information about the plausibility of individuals only owning 3 to 5 of the items, participants must rely on the information provided to them.

<sup>1</sup> Note: Similar to Experiment 1 participants were asked to make personal judgments and the responses varied greatly. A test for outliers (Van Selst & Jolicoeur, 1994) suggested that 6.82% of responses be removed due to being significant outliers. The data reported in Table 1 excludes the outliers in Experiment 1 and Experiment 2.

The Definite Number Hypothesis predicts that in Experiment 3, all participants would say that *a few* is 3 to 5 items regardless of the provided average information. Conversely, the Gradable Quantifier Hypothesis predicts that the number that *a few* picks out in Experiment 3 should vary depending on the context.

## Methods

**Participants** Sixteen fluent English-speaking adults ( $M = 21.6$  years old, 10 females) were recruited from the University of Waterloo. Participants received partial course credit for participating in the study.

**Materials and Procedure** Participants were seated at a computer table beside an experimenter. The study was composed of three parts: two training tasks, and the main task. First, the participants were introduced to the format of the task. They were instructed that they would be told some short stories. Accompanying these stories would be pictures displayed on the computer screen. They were instructed that when the stories were completed that they would be asked questions about the stories. In order to respond to these questions the participants were asked to make a selection between three cards visible on the screen. Participants would indicate the answer they thought was correct. Additionally, they were told that only two of the cards would have visible answers, and if they did not think that the correct answer was on the visible cards that they should choose the blank card.

In the first training task participants were given three trials where they were asked to locate specific items (e.g., toy car, teddy bear, 2 monkeys) using the three card response system, and received feedback on their choices.

In the second training task participants were introduced to a picture of a novel object, and were told that it was a kind of object that people in Southern Mexico like to collect. They were then shown a slide that looked like the top left box in Figure 1, and told (5). For the second training task the number of items shown on the screen was either 2 or 3. They heard three stories with three different individuals, each with the same number of items. Participants were then asked to guess how many of the novel objects a fourth individual might own, and were given the choice between the same number of items from the previous slides (2 or 3), and another amount (1 or 5). The purpose of this training trial was to determine if the participants could abstract average information from three short stories. There were two trials in the second training task. No feedback was given on these trials.

(5) This is Sarah, and she has this many Xs.

The test trials were identical to the second training task, except the design of the question response slide. On each trial participants were told stories about a novel object that people in Southern Mexico like to collect. They were told about three individuals, and were shown how many objects

each of those individuals owned. Each participant heard 4 stories, of which half of the stories were about characters who owned an average of 5 of the novel stimulus item (Small Quantity Context), and the other half were about characters that owned an average 40 of the novel stimulus item (Large Quantity Context). The novel stimuli items were always presented inside of a box shaped like a rotated card. The size of the box, and the size of the items remained constant throughout the story slides, and in the question response slide. It was assumed that visual cues such as the density of the items should provide evidence to indicate a difference between the quantities presented in the story slides, and those on the question response slides.

Figure 1: Example of Experiment 3 design. Row 1: an example of the slides that correspond with each of the three stories in the Small Quantity Context. Row 2: example of the slides that correspond with each of the stories in the Large Quantity Context. Row 3: the 4th character, the test question, and question response slide.

After hearing about how many items three characters had, participants were introduced to a fourth character and were told that the character “has *<a few / a lot>* of Xs.” After hearing this statement, participants were shown the question response slide with the three cards, and were asked to estimate how many of the novel objects they thought that the fourth character had. Participants had the option to pick between three cards: 10, 20, and blank, for each of the stories. If the participant chose the blank card they were asked to estimate how many items should be on the card. Each term was used once per context, and the order of the terms and contexts were counterbalanced across participants.

## Results

Figure 2 reports the percentage of response by card choice for each of the conditions in the task. As predicted by the Definite Number Hypothesis 93.75% of the participants chose the blank card in the Small Quantity Condition in the

*a few* trial, and reported that the quantity picked out for *a few* in this trial should be ~3.9. However, contrary to the Definite Number Hypothesis only 25% of the participants picked the blank card in the Large Quantity Condition, reporting that the quantity picked out for *a few* in this trial should be ~3.3. The remaining 6.25% and 75% respectively chose the small quantity card indicating that the quantity picked out for *a few* for these trials should be 10. Participants were significantly more likely to pick the blank card in the Small Quantity Condition for *a few* than in the Large Quantity Condition ( $\chi^2(1, N = 16) = 9.091, p < .01$ ). Additionally, participants were significantly more likely to pick the blank card in the Large Quantity Condition for *a lot* than in the Small Quantity Condition ( $\chi^2(1, N = 16) = 4.900, p < .03$ ).

Figure 2: Percent per response type for each trial in Experiment 3.

## General Discussion

The results of the experiments presented in this paper provide direct evidence that there is variability in the quantities picked out by the term *a few*, and that this variability can be explained by context. This finding is highly unsurprising – no one would argue that context plays a role in the interpretation of all quantifiers. However, we set out to investigate more than just the effect that context has on the quantities picked out by *a few*, and endeavored to figure out how context is having this effect. We speculated that there are two hypotheses that could explain the role that context is playing for *a few*: 1) the Definite Number Hypothesis, and 2) the Gradable Quantifier Hypothesis.

According to the Definite Number Hypothesis, the variability of *a few* is a dependent on whether the quantities in the range of its meaning (i.e., 3 to 5) are plausible. If the quantities are not within the range of its meaning (like in the case of Facebook friends), then they must be adjusted to the smallest plausible value for the context at hand. Alternatively, according to the Gradable Quantifier Hypothesis, the likelihood of finding 3 to 5 individuals of a given type is not what matters, but rather the typical quantity in which these individuals cluster. These two

hypotheses made separate predictions regarding the outcomes of Experiments 2 and 3 in this paper.

In Experiment 2, the Definite Number Hypothesis predicted that participants would rate all of the contexts that for which quantities plausibly fall within its range as being highly plausible, and those for which quantities do not plausibly fall within its range as being implausible. The Gradable Quantifier Hypothesis makes no such prediction, and is not constrained in its meaning. Thus, it should have predicted that the plausibility ratings given by participants should not depend on the plausibility of the quantities falling within a specific range. The findings of Experiment 2 go against the predictions of Definite Number Hypothesis, as there was evidence for several items that do not fall within the range of *a few*'s definite meaning, yet were rated as being plausible scenarios. Though the prediction made by the Definite Number Hypothesis did hold true for the context involving friends on Facebook, but only for that one context. The results of Experiment 2 consequently seem to imply that people do not expect *a few* to have a definite range that requires post-hoc adjustments for larger contexts.

In order to further test these hypotheses, in Experiment 3 the only context information made available to participants was average information. Participants could not rely on their prior knowledge with the novel items to determine whether the definite range of quantities picked out by *a few* in the Definite Number Hypothesis is plausible for the novel contexts. Thus, the Definite Number Hypothesis predicted that participants should indicate that the quantity picked out by *a few* in all contexts should fall within the range of meaning (i.e., 3 to 5). On the other hand, the Gradable Quantifier Hypothesis predicted that *a few* would pick out a quantity relative to the typical quantity (i.e., average) for each context. Consequently, it would predict that the responses for the Small Quantity Condition would be different from the responses for the Large Quantity Condition. The results of Experiment 3 support the hypothesis predicted by the Gradable Quantifier Hypothesis, in that there was a significant difference in the responses given for the different context scenarios. Conversely the Definite Number Hypothesis only correctly predicted the responses for the Small Quantity Condition.

One potential limitation of Experiment 3 is that it is possible that while participants were not explicitly supplied with information that confirmed or denied the probability of 3 to 5 items being plausible quantities in the novel contexts, the participants may have inferred that the 3 to 5 would be implausible in the Large Context Condition. While this may be the case, when the results of Experiment 3 are considered with respect to the results of Experiment 2, which suggested that that we still see variability in the quantities picked out by *a few* despite 3 to 5 being plausible quantities for the given contexts, the Gradable Quantifier Hypothesis still provides a better explanation for the data.

The future direction of this research aims to investigate several questions left open by the findings in this paper. First, if the Gradable Quantifier Hypothesis is true, how

does context tell us what quantity is picked out by *a few*? The answer to this question can perhaps be found by determining the semantic form of *a few* and other gradable quantifiers with respect to the form of gradable adjectives. Secondly, it would be interesting to investigate whether all quantifiers are gradable like *a few*, or if it is the case that only some quantifiers are gradable in this way; it would be interesting to study what makes a specific quantifier gradable. Finally, the structure of gradable quantifiers seems like it would be very difficult to acquire. Given that both *a few* and *a lot* can be used in variable contexts to mean either a small quantity, or a relatively large quantity, how do children learn that what is important about gradable quantifiers is the context in which they are used, and not a definite number range?

The results of the present study support the Gradable Quantifier Hypothesis, suggesting that context-dependency is built into the meaning of terms such as *a few*, and rejects the Definite Number Hypothesis. This finding opens up a host of interesting questions about the gradability of other terms, and the acquisition of gradable quantifiers. Current research in the authors' lab aims to answer these questions with future and ongoing studies.

### Acknowledgments

Thanks to the members of the Developmental Science Lab and the members of the Developmental division in the Department of Psychology at the University of Waterloo for the useful feedback. A.P. would also like to thank Christie Haskell, Jonathan Fugelsang, and Hugh Rabagliati for the statistics advice. ## Abstract

With the increasing dependence on autonomous operating agents and robots the need for ethical machine behavior rises. This paper presents a moral reasoner that combines connectionism, utilitarianism and ethical theory about moral duties. The moral decision-making matches the analysis of expert ethicists in the health domain. This may be useful in many applications, especially where machines interact with humans in a medical context. Additionally, when connected to a cognitive model of emotional intelligence and affective decision making, it can be explored how moral decision making impacts affective behavior.

**Keywords:** Cognitive modeling, Machine ethics, Medical ethics

## Introduction

In view of increasing intelligence and decreasing costs of artificial agents and robots, organizations increasingly use such systems for more complex tasks. With this development, we increasingly rely on the intelligence of agent systems. Because of market pressures to perform faster, better, cheaper and more reliably, this reliance on machine intelligence will continue to increase (Anderson, Anderson & Armen, 2005).

As the intelligence of machines increases, the amount of human supervision decreases and machines increasingly operate autonomously. These developments request that we should be able to rely on a certain level of ethical behavior from machines. As Rosalind Picard (1997) nicely puts it: “the greater the freedom of a machine, the more it will need moral standards”. Especially when machines interact with humans, which they increasingly do, we need to ensure that these machines do not harm us or threaten our autonomy. This need for ethical machine behavior has given rise to a field that is variously known as Machine Morality, Machine Ethics, or Friendly AI (Wallach, Franklin & Allen, 2010).

There are many domains where machines could play a significant role in improving our quality of life as long as ethical concerns about their behaviors can be overcome (Anderson & Anderson, 2008). This may seem difficult, and incorporating ethical behavior into machines is indeed far from trivial. Moral decision making is arguably even one of the most challenging tasks for computational approaches to higher-order cognition (Wallach, Franklin & Allen, 2010).

Moreover, with the increasing complexity of autonomous agents and robots, it becomes harder to predict their behavior, and to conduct it along ethical guidelines. Some may argue that this is a good reason not to let machines be responsible for making ethical decisions. However, the behavior of machines is still far easier to predict than the behavior of humans. Moreover, human behavior is typically far from being morally ideal (Allen, Varner & Zinser, 2000). One of the reasons for this is that humans are not very good at making impartial decisions. We can expect machines to

outperform us in this capability (Anderson & Anderson, 2010). Looking at it from this side, it seems that machines capable of sufficient moral reasoning would even behave ethically better than most human beings would. Perhaps interacting with ethical robots may someday even inspire us to behave ethically better ourselves.

There have been various approaches in giving machines moral standards, using various methods. One of them, called casuistry, looks at previous cases in which there is agreement about the correct response. Using the similarities with these previous cases and the correct responses to them, the machine attempts to determine the correct response to a new ethical dilemma.

Rzepka and Araki (2005) demonstrate an approach, in which their system learns to make ethical decisions based on web-based knowledge, to be ‘independent from the programmer’. They argue it may be safer to imitate millions of people, instead of a few ethicists and programmers. This seems useful for imitating human ethical behavior, but it does not seem plausible that machines using this method will be able to behave ethically better than humans. After all, the system bases its decision on the average behavior of humans in general, misbehavior included.

Guarini (2006) offers another approach that could be classified as casuistry. The presented system learns from training examples of ethical dilemmas with a known correct response using a neural network. After the learning process, it is capable of providing plausible responses to new ethical dilemmas. However, reclassification of cases remains problematic in his approach due to a lack of reflection and explicit representation. Therefore, Guarini concludes that casuistry alone is not sufficient.

Anderson and Anderson (2007) agree with this conclusion, and address the need for top-down processes. The two most dominant top-down mechanisms are (1) utilitarianism and (2) ethics about duties. Utilitarians claim that ultimately morality is about maximizing the total amount of ‘utility’ (a measure of happiness or well being) in the world. The competing ‘big picture’ view of moral principles is that ethics is about duties and, on the flip side of duties, the rights of individuals (Wallach, Allen & Smit, 2008).

The two competitors described above may not differ as much as it seems. Ethics about duties can be seen as a useful model to maximize the total amount of utility. Thinking about maximizing the total amount of utility in a too direct manner may lead to a sub-optimal amount of utility. For example, in the case of the decision to kill one person to save five, killing the one person seems to maximize the total amount of utility. After all, compared to the decision of inaction, it leads to a situation with four more survivors (Anderson, Anderson & Armen, 2006). However, for humans it may be impossible to favor the decision of killing

a person in this case over the decision of inaction, without also making it more acceptable in other cases to kill human beings. Therefore, not having the intuition that it is wrong to kill one person to save more people would probably lead to a smaller total amount of utility in the world.

Anderson, Anderson and Armen (2006) use Ross's *prima facie* duties (Ross, 1930). Here, *prima facie* means a moral duty may be overruled by a more pressing one. They argue that the ideal ethical theory incorporates multiple *prima facie* duties with some sort of a decision procedure to determine the ethically correct action in cases where the duties give conflicting advice. Their system learns rules from examples using a machine learning technique. After learning, the system can produce correct responses to unlearned cases.

However, according to Wallach, Franklin and Allen (2010), the model of Anderson, Anderson and Armen (2006) is rudimentary and cannot accommodate the complexity of human decision making. In their work, Wallach et al. make a distinction between top-down and bottom-up moral-decision faculties and present an approach that combines both directions. They argue that the capacity for moral judgment in humans is a hybrid of both bottom-up mechanisms shaped by evolution and learning, and top-down mechanisms capable of theory-driven reasoning. Morally intelligent robots will eventually need a similar fusion, which maintains the dynamic and flexible morality of bottom-up systems, which accommodate diverse inputs, while subjecting the evaluation of choices and actions to top-down principles that represent ideals we strive to meet. Wallach, Franklin & Allen (2010) explore the possibility to implement moral reasoning in LIDA, a model of human cognition. This system combines a bottom-up collection of sensory data, such as in the neural network approach of Guarini (2006), with top-down processes for making sense of its current situation, to predict the results of actions. However, the proposed model is not fully implemented yet.

The current paper can be seen as a first attempt in combining a bottom-up and top-down approach. It combines a bottom-up structure with top-down knowledge in the form of moral duties. It balances between these duties and computes a level of morality, which could be seen as an estimation of the influence on the total amount of utility in the world.

Wallach, Franklin and Allen (2010) argue that even agents who adhere to a deontological ethic or are utilitarians may require emotional intelligence as well as other "supra-rational" faculties, such as a sense of self and a theory of mind (ToM). Therefore, we represented the system in such a way that it is easy to connect to Silicon Coppélia (Hoorn, Pontier and Siddiqui, 2011), a cognitive model of emotional intelligence and affective decision making. Silicon Coppélia contains a feedback loop, by which it can learn about the preferences of an individual patient, and personalize its behavior. Silicon Coppélia estimates an Expected Satisfaction of possible actions, based on bottom-up data combined with top-down knowledge. This compares to the predicted results of actions in Wallach, Franklin and Allen (2010).

For simulation purposes, we focus on biomedical ethics, because in this domain relatively much consensus exists about ethically correct behavior. There is an ethically defensible goal (health), whereas in other areas (such as business and law) the goal may not be ethically defensible (money, helping a 'bad guy') (Anderson & Anderson, 2007). Moreover, due to a foreseen lack of resources and healthcare personnel to provide a high standard of care in the near future (WHO, 2010), robots are increasingly being used in healthcare.

Healthcare is a valid case where robots genuinely contribute to treatment. For example, previous research showed that animal-shaped robots can be useful as a tool for occupational therapy. Robins et al. (2005) used mobile robots to treat autistic children. Further, Wada and Shibata (2007) developed Paro, a robot shaped like a baby-seal that interacts with users to encourage positive mental effects. Interaction with Paro has been shown to improve users' moods, making them more active and communicative with each other and caregivers. Research groups have used Paro for therapy at eldercare facilities and with those having Alzheimer's disease (Kidd, Taggart & Turkle, 2006; Marti et al., 2006). Banks, Willoughby and Banks (2008) showed that animal-assisted therapy with an AIBO dog helped just as good for reducing loneliness as therapy with a living dog.

By providing assistance during care tasks, or fulfilling them, robots can relieve time for the many duties of care workers. However, care robots require rigorous ethical reflection to ensure that their design and introduction do not impede the promotion of values and the dignity of patients at such a vulnerable and sensitive time in their lives (Van Wynsberghe, 2012)

According to Gillon (1994), beneficence, non-maleficence, autonomy and justice are the four basic *prima facie* moral commitments. Here, confidentiality and truthfulness can be seen as a part of autonomy. Because we aim to match the expert data given from Buchanan and Brock (1989), who focus on dilemmas between autonomy, beneficence and non-maleficence, we focus on these three moral duties in the remainder of this paper.

### **The moral reasoner and its relation to Silicon Coppélia**

Silicon Coppélia (Hoorn et al., 2011) is a model of emotional intelligence and affective decision making. In this model, the agent perceives the user on several dimensions, which leads to (simulated) feelings of involvement and distance. These feelings represent the affective component in the decision making process. The rational component consists of the expected utility of an action for the agent itself (i.e., the belief that an action leads to achieving desired goals).

The system contains a library of goals and each agent has a level of ambition for each goal. There are desired and undesired goals, all with several levels of importance. The levels of ambition the agent attaches to the goals are represented by a real value between [-1, 1], where a negative value means that the goal is undesired and a positive value means that the goal is desired. A higher value means that the goal is more important to the agent.

The system contains a library of actions from which the agents can perform. The agent has beliefs about actions inhibiting or facilitating goals, represented by a real value between  $[-1, 1]$ ,  $-1$  being full inhibition,  $1$  being full facilitation.

The expected utilities of possible actions are calculated by looking at the goal-states it influences. If an action or a feature is believed to facilitate a desired goal or inhibits an undesired goal, this will increase its expected utility and vice versa. The following formula is used to calculate the expected utility for the agent itself.

$$\text{ExpectedUtility}(\text{Action}, \text{Goal}) = \text{Belief}(\text{facilitates}(\text{Action}, \text{Goal})) * \text{Ambition}(\text{Goal})$$

Given the level of ambition for a goal and the believed facilitation of that goal by an action, the agent calculates the expected utility for itself of performing that action regarding that goal by multiplying the believed facilitation of the goal with the level of ambition for the goal.

In the current moral reasoner, the agent tries to maximize the total amount of utility for everyone. In complex situations, it would take too much computational load to calculate all possible consequences of an action for everyone, and extract this into a single value of ‘morality’ of the action. Therefore, the agent tries to estimate the morality of actions by following three moral duties. These three duties consist of seeking to attain three moral values: (1) Autonomy, (2) Non-Maleficence and (3) Beneficence. In the moral reasoner, the three duties are seen as ‘moral goals’ to satisfy everyone’s needs as much as possible. This corresponds with Super’s conceptualization of the relationship between needs and values: “values are objectives that one seeks to attain to satisfy a need” (Super, 1973). The moral reasoner aims to pick actions that serve these moral goals best.

What priorities should be given to these three moral goals? According to Anderson and Anderson (2008), the following consensus exists in medical ethics. A healthcare worker should challenge a patient’s decision only if the patient is not capable of fully autonomous decision making (e.g., the patient has irrational fears about an operation) and there is either a violation of the duty of non-maleficence (e.g., the patient is hurt) or a *severe* violation of the duty of beneficence (e.g., the patient rejects an operation that will strongly improve his or her quality of life). In other words, Autonomy is the most important duty. Only when a patient is not fully autonomous, the other moral goals come into play. Further, Non-maleficence is a more important duty than Beneficence, because only a severe violation of Beneficence requires challenging a patient’s decision, while *any* violation of Non-maleficence does. Therefore, the ambition level for the moral goal ‘Autonomy’ was set to the highest value and ‘Non-maleficence’, which was set to a higher value than the ambition level for ‘Beneficence’. The ambition levels that were given to the moral goals in the moral reasoner can be found in Table 1.

The agent calculates estimated level of Morality of an action by taking the sum of the ambition levels of the three moral goals multiplied with the beliefs that the particular actions facilitate the corresponding moral goals. When

Table 1: Ambition levels for moral goals

Moral Goal	Ambition level
Non-Maleficence	0.74
Beneficence	0.52
Autonomy	1

moral goals are believed to be better facilitated by a moral action, the estimated level of Morality will be higher. . The following formula is used to calculate the estimated Morality of an action:

$$\text{Morality}(\text{Action}) = \sum_{\text{Goal}} (\text{Belief}(\text{facilitates}(\text{Action}, \text{Goal})) * \text{Ambition}(\text{Goal}))$$

Note that this is similar to calculating the Expected Utility in Silicon Coppélia. To ensure that the decision of a fully autonomous patient is never questioned, we added the following rule to the moral reasoner:

IF belief(facilitates(Action, autonomy) = max\_value  
THEN Morality(Action) = Morality(Action) + 2

As can be seen Figure 1, this can be represented as a weighted association network, where moral goals are associated with the possible actions via the belief strengths that these actions facilitate the three moral goals. A decision function F adds the rule and picks the action with the highest activation as output.

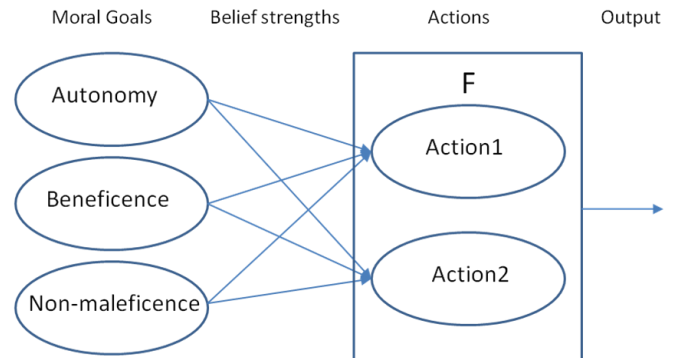

Figure 1: Moral reasoner shown in graphical format

## Simulation Results

To see whether the moral reasoner could simulate the moral decision making of experts in medical ethics, the analysis of ethical dilemmas by expert ethicists was taken from Buchanan and Brock (1989). The following simulation experiments examine whether the moral reasoner reaches the same conclusions as these expert ethicists.

### Experiment 1

Table 2: Simulation results of Experiment 1.

	Autonomy	Non-Malef	Benef	Morality
Try Again	-0.5	1	1	0.76
Accept	0.5	-1	-1	-0.8

In the simulated situation, the patient refuses to take an antibiotic that is almost certain to cure an infection that would otherwise likely lead to his death. The decision is the

result of an irrational fear the patient has of taking medications. (For instance, perhaps a relative happened to die shortly after taking medication and this patient now believes that taking any medication will lead to death.)

According to Buchanan and Brock (1989), the correct answer is that the health care worker should try again to change the patient's mind because if she accepts his decision as final, the harm done to the patient is likely to be severe (his death) and his decision can be considered as being less than fully autonomous.

As can be seen in Table 2, the moral reasoner also classifies the action 'Try again' as having a higher level of morality than accepting the decision of the patient. In this and the following tables, the fields under the three moral goals represent the believed facilitation of the corresponding moral goal by an action, as taken from Buchanan and Brock (1989). 'Non-Malef' stands for Non-maleficence, and 'Benef' stands for Beneficence.

## Experiment 2

Table 3: Simulation results of Experiment 2.

	Autonomy	Non-Malef	Benef	Morality
Try Again	-0.5	1	1	0.76
Accept	1	-1	-1	1.70

Once again, the patient refuses to take an antibiotic that is almost certain to cure an infection that would otherwise likely lead to his death, but this time the decision is made on the grounds of long-standing religious beliefs that do not allow him to take medications.

The correct answer in this case, state Buchanan and Brock (1989), is that the health care worker should accept the patient's decision as final because, although the harm that will likely result is severe (his death), his decision can be seen as being fully autonomous. The health care worker must respect a fully autonomous decision made by a competent adult patient, even if she disagrees with it, since the decision concerns his body and a patient has the right to decide what shall be done to his or her body.

As can be seen in Table 3, the moral reasoner comes to the correct conclusion. Here, the rule to ensure the decision of a fully autonomous patient is never questioned made a difference. If the rule would not have existed, the morality of 'Accept' would have been -0.3, and the moral reasoner would have concluded that it was more moral to try again.

## Experiment 3

Table 4: Simulation results of Experiment 3.

	Autonomy	Non-Malef	Benef	Morality
Try Again	-0.5	0.5	0.5	0.13
Accept	1	-0.5	-0.5	2.37

The patient refuses to take an antibiotic that is likely to prevent complications from his illness, complications that are not likely to be severe, because of long-standing religious beliefs that do not allow him to take medications.

The correct answer is that the health care worker should accept his decision, since once again the decision appears to be fully autonomous and there is even less possible harm at

stake than in Experiment 2. The moral reasoner comes to the correct conclusion and estimates the Morality of 'Accept' higher than 'Try Again', as can be seen in Table 4

## Experiment 4

Table 5: Simulation results of Experiment 4.

	Autonomy	Non-Malef	Benef	Morality
Try Again	-0.5	0	0.5	-0.26
Accept	0.5	0	-0.5	0.26

A patient will not consider taking medication that could only help to alleviate some symptoms of a virus that must run its course. He refuses the medication because he has heard untrue rumors that the medication is unsafe.

Even though the decision is less than fully autonomous, because it is based on false information, the little good that could come from taking the medication does not justify trying to change his mind. Thus, the doctor should accept his decision. The moral reasoner also comes to this conclusion, as can be seen in the last column of Table 5.

## Experiment 5

Table 6: Simulation results of Experiment 5.

	Autonomy	Non-Malef	Benef	Morality
Try Again	-0.5	0.5	0.5	0.13
Accept	0.5	-0.5	-0.5	-0.13

A patient with incurable cancer refuses chemotherapy that will let him live a few months longer, relatively pain free. He refuses the treatment because, ignoring the clear evidence to the contrary, he is convinced himself that he is cancer-free and does not need chemotherapy.

According to Buchanan and Brock (1989), the ethically preferable answer is to try again. The patient's less than fully autonomous decision will lead to harm (dying sooner) and denies him the chance of a longer life (a violation of the duty of beneficence), which he might later regret. The moral reasoner comes to the same conclusion, as can be seen in Table 6.

## Experiment 6

Table 7: Simulation results of Experiment 6.

	Autonomy	Non-Malef	Benef	Morality
Try Again	-0.5	0	1	0.04
Accept	0.5	0	-1	-0.04

A patient, who has suffered repeated rejection from others due to a very large noncancerous abnormal growth on his face, refuses to have simple and safe cosmetic surgery to remove the growth. Even though this has negatively affected his career and social life, he is resigned himself to being an outcast, convinced that this is his fate in life. The doctor is convinced that his rejection of the surgery stems from depression due to his abnormality and that having the surgery could vastly improve his entire life and outlook.

The doctor should try again to convince him because so much of an improvement is at stake and his decision is less than fully autonomous. Also here, the moral reasoner comes to the same conclusion, as can be seen in Table 7.

## Discussion

The paper described a moral reasoner that combines a bottom-up structure with top-down knowledge in the form of moral duties. The reasoner estimates the influence of an action on the total amount of utility in the world by the believed contribution of the action to the following three duties: Autonomy, Non-maleficence and Beneficence. Following these three duties is represented as having three moral goals. The moral reasoner is capable of balancing between conflicting moral goals. In simulation experiments, the reasoner reached the same conclusions as expert ethicists (Buchanan & Brock, 1989).

Because the representation of goals and beliefs in the moral reasoner is very similar to the representation of beliefs and goals in the affective decision making process of Silicon Coppélia (Hoorn, Pontier & Siddiqui, 2011), the moral reasoner could easily be connected to the system. Thereby, the moral reasoning could be combined with human-like affective decision making, and the behavior of the system could be personalized for individuals.

According to Anderson, Anderson and Armen (2006), simply assigning linear weights to the moral duties is not sufficiently expressive to capture their relationships. Indeed, an extra rule had to be added to satisfy the expert data in Experiment 2. However, for all other experiments, this rule turned out not to be necessary.

Also without this rule, it would have been arguable that the moral reasoner simulates human-like moral reasoning. The analysis of the expert ethicists may not reflect the public opinion, however. Perhaps the majority of laymen would decide to question the patient's refusal to take life-saving medication. Arguably, it would not be seen as inhuman if someone did.

Even between doctors, there is no consensus about the interpretation of values and their ranking and meaning. In the work of Van Wynsberghe (2012) this differed depending on: the type of care (i.e., social vs. physical care), the task (e.g., bathing vs. lifting vs. socializing), the care-giver and their style, as well as the care-receiver and their specific needs. The same robot used in one hospital can be accepted differently depending on the ward. Workers in the post-natal ward loved the TUG-robot, while workers in the oncology ward found the robot to be rude, socially inappropriate and annoying. These workers even kicked the robot when they reached maximum frustration (Barras, 2009).

There may be doctors that feel the urge to pursue a patient to take the life-saving medication, but only choose not to do so because of ethical guidelines. It could be argued that, when health care professionals are making decisions on a strict ethical code, they are restricting their regular way of decision-making.

Further, it can be questioned whether a patient can ever be fully autonomous. According to Mappes and DeGrazia (2001), for a decision by a patient concerning his or her care to be considered fully autonomous, it must be intentional, based on sufficient understanding of his or her medical situation and the likely consequences of foregoing treatment. Further, the patient must be sufficiently free of external constraints (e.g., pressure by others or external circumstances, such as a lack of funds) and internal

constraints (e.g., pain/discomfort, the effects of medication, irrational fears or values that are likely to change over time). Using this definition, it could be questioned whether the patient in Experiment 2 is not under the influence of external constraints (i.e., pressure from a religious leader).

Moreover, it seems that medical ethics are contradictory with the law. A fully autonomous decision of a patient wanting to commit euthanasia would be represented by the same believed contributions to following moral duties as those given in experiment 2. In the case of euthanasia, the patient also makes a fully autonomous decision that will lead to his death. However, in many countries, committing active euthanasia is illegal. In countries where euthanasia is permitted, it is usually only allowed when the patient is in hopeless suffering. By the definition of Anderson and Anderson, being in hopeless suffering would mean the patient is not free of internal constraints (i.e., pain and suffering) and therefore not capable of making fully autonomous decisions. On the other hand, in the case of hopeless suffering, it could be questioned whether one could speak of maleficence when the patient is allowed to commit euthanasia.

However, we would not like to argue against strict ethical codes in professional fields such as health care. It is important to act based on a consensus to prevent conflicts and unnecessary harm. Just as doctors restrict their 'natural' behavior by maintaining a strict ethical code, we can also let a robot restrict its behavior by acting through the same strict ethical code.

Moreover, we may well want to aim for machines that behave ethically better than human beings. Human behavior is typically far from being morally ideal, and a machine should probably have higher ethical standards (Allen et al., 2000). By matching the ethical decision-making of expert ethicists, the presented moral reasoner serves as a nice starting point in doing so.

From a cognitive science perspective, an important product of work on "machine ethics" is that new insights in ethical theory are likely to result (Anderson & Anderson, 2008). As Daniel Dennett (2006) stated, AI "makes philosophy honest". Ethics must be made computable in order to make it clear exactly how agents ought to behave in ethical dilemmas. Without a platform for testing the adequacy of a particular model of moral decision making, it can be quite easy to overlook hidden mechanisms" (Wallach, 2010).

According to Tronto (1993), care is only thought of as good care when it is personalized. Therefore, we intend to integrate the moral reasoner with Silicon Coppélia in future research. This could be done in various manners. Different applications might benefit from different ways of implementation.

When developing a decision-support system in the medical domain such as (Anderson, Anderson & Armen, 2006), it should have a strict ethical code. When there are conflicting moral goals, the outcome of the moral reasoning should always give the final answer on how to act. Additionally, in consult with medical ethicists and experts from the field in which the moral reasoner will be applied, it may be necessary to add more rules to the system.

However, when developing a companion robot or virtual character that interacts with the patient, it may be more beneficial to give a bit less weight to moral reasoning. Moral goals could perhaps be treated the same as other goals that motivate the robot's behavior. In entertainment settings, we often like characters that are naughty (Konijn & Hoorn, 2005). In entertainment, morally perfect characters may even be perceived as boring. In Silicon Coppélia (Hoorn, Pontier & Siddiqui, 2011), this could be implemented by updating the affective decision making module. Morality would be added to the other influences that determine the Expected Satisfaction of an action in the decision making process. By doing so, human affective decision-making behavior could be further explored.

# Modeling the Influence of Cognitive Fluency and Stereotype Threat on the Processing of Implicit Attitudes

Boon-Kiat Quek (boonkiat.quek@northwestern.edu)

Andrew Ortony (ortony@northwestern.edu)

Department of Psychology, Northwestern University, Evanston, IL 60208, USA, and  
Institute of High Performance Computing, Agency for Science, Technology and Research, Singapore

## Abstract

Studies reveal that the processing of implicit attitudes could be affected by individual differences in cognitive fluency, as well as by the presence of stereotype threat induced when subjects were primed with negative prejudices about their own social group. Using a previously proposed computational model of human performance on the Implicit Association Test, we examine possible processing mechanisms in which cognitive fluency and stereotype threat could influence the processing of implicit attitudes. Our goal is to extend the model to provide a cohesive and computationally plausible account for these effects; this is achieved by manipulating several model parameters that are analogous to human cognitive ability (in terms of processing speed and information retention ability) and shifts in confidence criteria for decision-making.

**Keywords:** Implicit attitudes; cognitive ability; simulation; localist-connectionist networks.

## Introduction

Implicit attitudes are generally assumed to underlie people's thoughts, actions, choices and behavior (Greenwald & Banaji, 1995). Understanding how such attitudes are processed might therefore provide some insight about why people behave in the way they do. Some ways in which such processes could be investigated include affective priming (Fazio, Sanbonmatsu, Powell & Kardes, 1986) and the Implicit Association Test (IAT; Greenwald, McGhee & Schwartz, 1998). The IAT was designed to assess automatic associations between concepts in memory. It relies on a simple two-choice response time paradigm which measures the time taken by subjects to classify sequentially presented input stimuli (words or images) into one of two composite categories, each comprising a target concept (e.g., *flower*, *insect*) paired with an attribute concept (e.g., *pleasant*, *unpleasant*). Response latencies are expectedly shorter when targets are paired with *compatible* attributes (e.g., "*flower* or *pleasant*", "*insect* or *unpleasant*"), and longer when paired with *incompatible* attributes (e.g., "*flower* or *unpleasant*", "*insect* or *pleasant*"). The difference in mean response times between *compatible* and *incompatible* categories is known as the *IAT effect*, and is taken as the relative preference for one target over another.

Despite its wide application, many issues concerning the construct validity of the IAT have been raised (e.g., De Houwer, Teige-Mocigemba, Spruyt & Moors, 2009; Mierke & Klauer, 2003). Apart from automatic associations, performance on the IAT seems to also depend on various other factors, such as stimulus familiarity (Ottaway, Hayden & Oakes, 2001), concept saliency (Rothermund & Wentura,

2004), and extra-personal knowledge about prevailing cultural or societal norms (Karpinski & Hilton, 2001). Furthermore, several anomalous effects have also been observed. In a recent review, De Houwer, Teige-Mocigemba, Spruyt and Moors (2009) suggested that the processing of implicit attitudes could be influenced by differences in cognitive ability, citing McFarland and Crouch (2002) who observed significant correlations between response latencies and magnitudes of IAT effects, and Hummert, Garstka, O'Brien, Greenwald and Mellott (2002) who observed that IAT effects tended to increase with age. Given that processing speed is an important aspect of cognitive ability (Hunt, 1983) and declines with age (Salthouse, 1996), we will expect subjects with lower cognitive abilities (especially with age-induced decline) to exhibit longer response latencies across all tasks on the IAT. Why this is associated with larger IAT effects, however, remains to be determined.

Another intriguing aspect of performance on the IAT is the possible role of stereotype threat. In a number of Race-IATs, Frantz, Cuddy, Burnett, Ray & Hart (2004) consistently observed that White subjects exhibited stronger pro-White IAT effects on the Race-IAT when they were instructed beforehand that the test might expose their racial prejudices, as compared to other White subjects in control groups who were not similarly informed. Frantz et al. suggested that being told beforehand of the actual purpose of the Race-IAT would present a stereotype threat experience (Steele & Aronson, 1995) to the informed subjects, where knowledge of the test's purpose might induce anxiety over the risk of confirming negative stereotypes about the racial attitudes that people in their social group are often presumed to endorse (e.g., being pro-White or anti-Black). Thus, we would expect subjects informed of the test's purpose to have a greater interest in positive self-presentation and hence stronger motivation to respond in a more egalitarian manner (Frantz et al., 2004). Ironically, attempts to avoid the negative stereotype appeared to interfere with performance on the Race-IAT, producing a stronger pro-White IAT effect instead of reducing it. However, no suggestions were provided to explain how such task interference might have taken place, nor the manner in which strategies for coping with the stereotype threat experience might have backfired.

Both the *cognitive fluency effect* and the *stereotype threat effect* are noteworthy because they have important implications for our understanding of the nature of information processing that underlie performance on the IAT. In this paper, we examine some of these implications, and propose

Figure 1. Network model for simulating IAT performance (Quek & Ortony, 2011)

a cohesive information processing account of these two effects, by means of a previously proposed computational model of implicit task performance on the IAT (Quek & Ortony, 2011). Our approach is to replicate the observed effects in simulations by manipulating model parameters that provide analogs for human cognitive ability and confidence criteria for decision-making. The first simulation allows us to explore how differences in cognitive fluency affect response latencies, as well as allowing us to explain the causes of the larger IAT effects. In the second simulations we examine plausible mechanisms behind how certain actions taken by subjects to cope with the stereotype threat would ironically exacerbate IAT effects instead of reducing them. This, as we discuss, has implications for the effortful control or influence over performance on the IAT.

## Model Overview

In this section, we provide a brief overview of the proposed computational model; more details can be found in Quek & Ortony (2011). The model employs a spreading activation algorithm over a localist-connectionist network (e.g., Page, 2000) to emulate multiple processing pathways from the visual perception of a stimulus (i.e., a word or image) to the automatic activation of associated concepts in memory and motor responses. Nodes in the network represent concepts while edges or connections represent associations between them. Propagation of activation through the network is governed by the following rule:

$$x_i(k+1) = (1-\delta)x_i(k) + \alpha \sum_{j \in E} x_j(k) \cdot w_{j,i}(k), \quad (1)$$

where  $x_i$  is the activation level of a node  $v_i$ ,  $w_{j,i}$  is the weight of the connection  $e_{j,i}$  from a node  $v_j$  to  $v_i$ ,  $E$  is the set of all edges,  $\alpha$  is the propagation gain and  $\delta$  is a decay parameter that reduces activation over time. In each time step  $k$ , activation spreads to  $v_i$  from each neighbor  $v_j$  at a rate proportional to the weight  $w_{j,i}$  of the connection  $e_{j,i}$  between them.

Virtual subjects are each represented by a network of the topology described in Figure 1. The *Associative Network* contains nodes representing the target concepts AFRICAN-AMERICAN (AA) and EUROPEAN-AMERICAN (EA), generalized

concepts for positivity (POS) and negativity (NEG), input stimuli such as words belonging to the semantic fields *pleasant* and *unpleasant* (e.g., *happy*, *wonderful*, *joy*, *evil*, *horrible*, *hurt*), and pictures of *European-American* and *African-American* individuals. Connections between these concepts, for instance,  $EA \leftrightarrow POS$ ,  $EA \leftrightarrow NEG$ ,  $AA \leftrightarrow POS$ , and  $AA \leftrightarrow NEG$  represent implicit associations between them. As an example, positive attitudes towards AA can be represented as excitatory  $AA \leftrightarrow POS$  or inhibitory  $AA \leftrightarrow NEG$  associations, or both, such that activation of AA will excite POS but inhibit NEG.

The *Task Mapper* dynamically transmits activation accumulated from target concepts and evaluative attributes to nodes  $cue_L$  and  $cue_R$  indicating that a left or right key-press is required. If the current task requires a right response for “*European-American* or *pleasant*”, the *Task Mapper* routes both POS and EA to  $cue_R$ . These connections remain active throughout the task block but are reconfigured prior to each subsequent task block (see Quek & Ortony, 2011, Figure 2).

The *Response Generator* is a network-based instantiation of the cue-tendency-action model (CTA; Revelle, 1986) of the dynamic interactions between conflicting tendencies and competing actions. Using CTA as a template, two response-generating pathways (for the left and right key-presses) are instantiated. Activated cues stimulate tendency nodes that in turn excite the left and right motor response nodes. When either  $action_L$  or  $action_R$  exceeds a response threshold  $x_{thres}$  (set to 1.0 by default), it is taken as the winning action.

The interactions between the above representations occur in the form of excitations and inhibitions between all input stimuli to motor response propagation pathways. For example, in a task block requiring a left key-press for “*European-American* or *pleasant*” stimuli and a right response for “*African-American* or *unpleasant*” stimuli, a picture of a European-American individual would activate EA, and activation will be transmitted to  $cue_L$ . However, if the network is configured with a strong  $EA \leftrightarrow NEG$  connection, activation will also be transmitted to  $cue_R$ , competing with  $cue_L$ . This reduces the rate that activation accumulates in the left response node, and thus a longer time is required for it to reach the response threshold.

Figure 2. Distributions of response latencies on compatible and incompatible task blocks and corresponding IAT effects with variations in propagation gain  $\alpha$  for 250 virtual subjects configured with a relative preference for one target concept over the other.

### Simulating the IAT

When simulating the IAT, each virtual subject's network is initialized with a set of associative strength configurations, and put through all task blocks. On each trial, the virtual subject is presented with a verbal or pictorial stimulus and the input node corresponding to the stimulus is set with an activation of 1.0. The number of iterations taken to produce a response (i.e., when the activation level of either the left or right response node reaches its threshold) is recorded. This quantity is transformed by a scaling factor into mean response times (in milliseconds) of approximately the same magnitudes as those observed in human subjects (e.g., Greenwald et al., 1998; Klauer, Voss, Schmitz & Teige-Mocigemba, 2007). The IAT effect is then taken to be the difference between mean response times in the two combined task blocks.

### Modeling Cognitive Fluency Effects

Cognitive ability and intelligence are often considered to be closely related to information processing speed (e.g., Lansman, Donalson, Hunt & Yantis, 1982; Hunt, 1983). In addition, the ability to retain information during the execution of cognitive operations is another important aspect (Salthouse, 1996). An inability to retain products from earlier processing operations due to information decay or displacement would impair problem solving performance especially when processing speed is slow. Thus, information needed for later processing stages might be partially lost by the time it is needed, in which case additional time would be required to reprocess it.

To the extent that our computational model could emulate information processing on the IAT, it should be capable of replicating both the increase in response latency and the corresponding increase in IAT effect that arises with a reduction in cognitive ability. This can be achieved by manipulating both the parameters for propagation gain  $\alpha$  and propagation decay  $\delta$  in Equation (1), which governs the rate at which activation is propagated through the network, and

the rate at which activation is reduced or lost in the absence of excitatory inputs, respectively. Both of these parameters can be considered as the model's analog for the aforementioned aspects of general cognitive ability that relate to information processing and retention.

To examine the effect of variations in the propagation gain  $\alpha$  on response latencies and IAT scores, we generated instances of the network model for a population ( $N = 250$ ) of virtual subjects using the associative strength configuration in which  $EA \leftrightarrow POS$  and  $AA \leftrightarrow NEG$  were set to 0.5 (i.e., excitatory), while  $AA \leftrightarrow POS$  and  $EA \leftrightarrow NEG$  were set to -0.5 (i.e., inhibitory), representing individuals with positive attitudes towards EA and negative attitudes towards AA. As shown in Quek & Ortony (2011), this configuration produces an IAT effect in favor of EA. As in earlier simulations, weights in the network were randomly perturbed with Gaussian noise of  $\sim \mathcal{N}(0, 0.1^2)$ , to ensure inter- and intra-subject variability. Each virtual subject's network was then configured with a random value of  $\alpha$  (within a reasonable range), and put through all five standard IAT tasks.

The distributions of response latencies on both compatible and incompatible task blocks and the corresponding IAT effects in Figure 2 reveal a distinct inverse relationship between the propagation gain  $\alpha$  and the response latencies, as well as the magnitude of the simulated IAT effects. While smaller values of  $\alpha$  resulted in longer response latencies on both the compatible and incompatible task blocks, and stronger IAT effects, the converse is true for larger values of  $\alpha$ . From the different coefficients of curve-fitting indicated in the figure, we can infer that the increase in magnitude of the IAT effect with a reduction in  $\alpha$  is due to a divergence between the response latencies of the two task blocks.

We repeated the above simulation by varying the propagation decay parameter  $\delta$  while keeping the propagation gain  $\alpha$  at its default value. Plots of response latencies and IAT effects with respect to the decay parameter  $\delta$  are shown in Figure 3. The scatter plots reveal a direct relationship between  $\delta$  and the response latencies, and magnitudes of the IAT effects. Faster rates of information decay, as implied by higher values of  $\delta$  not only resulted in longer response times

Figure 3. Distributions of response latencies on compatible and incompatible task blocks and corresponding IAT effects with variations in the propagation decay  $\delta$  for 250 virtual subjects configured with a relative preference for one target concept over the other.

on both the compatible and incompatible task blocks, but also produced stronger IAT effects. The converse is true for smaller values of  $\delta$  which, if taken to imply better information retention ability, results in better overall performance on the IAT. As in the case of propagation gain, the larger IAT effects with reduction in information retention is due to a divergence between the response latencies of the two task blocks, as inferred from their curve-fitted coefficients.

The above simulations demonstrate the efficacy of the network model in replicating cognitive fluency effects on the IAT, namely that a lower propagation gain or higher decay rate (both indicative of lower cognitive ability) in the model would lead to higher response latencies on both compatible and incompatible tasks, and stronger IAT effects. Since both response latencies and IAT effect magnitudes vary inversely with propagation gain, the first simulation shows consistency with the observed correlation between response latencies and IAT effect magnitudes reported in McFarland and Crouch (2002). Higher values of the decay parameter  $\delta$ , corresponding to a higher rate at which activation in nodes are leaked or lost over time, appear to impair virtual subjects' efficiency and performance on the tests—an observation consistent with Salthouse (1996).

### Modeling Stereotype Threat Effects

The anxiety resulting from stereotype threat could potentially interfere with performance in various ways, for instance, via both automatic and strategic processes (Beck & Clark, 1997), and causing a diversion of resources from the task, heightened self-consciousness, or over-cautiousness (Steele & Aronson, 1995). Diversion of resources from task-relevant to threat-relevant information processing translates to a reduction in the overall information processing throughput on the task. A slowdown in information processing might even be effortful (Gazzaley, Cooney, McEvoy, Knight & D'Esposito, 2005). Using our model as an exploratory framework, this would be analogous to a reduction in the propagation gain  $\alpha$  of the network model, or suppression (i.e., negative bias) of activation on all nodes in the

network, or both. In the case of the former, a reduction in propagation gain would lead to an increase in the amount of time required for every unit increase in a node's activation. In the latter, the negative bias due to the suppression would need to be countered before activation can be accumulated to a level that approaches the threshold for a key-press response. The effect is the same as directly increasing the response activation threshold itself.

This brings us to the second possible coping mechanism, namely the deliberate act of exercising greater caution in the completion of the tasks, wherein subjects might require of themselves a higher degree of confidence before committing to a response. This explanation is similar in spirit to Brendl, Markman, and Messner's (2001) suggestion that subjects might increase their response activation thresholds in response to an increase in the perceived difficulty of the task (i.e., with tasks in the incompatible task blocks being more difficult or demanding than those in other task blocks). In addition, the increase in confidence criteria is consistent with Beck and Clark's (1997) proposal that anxiety activates reflective modes of thinking. In our terms, the process of exercising additional caution or adopting more stringent response criteria is analogous to an upward shift in  $x_{thres}$ , which is the level of activation that  $action_L$  or  $action_R$  must reach before a motor action is performed.

We have already shown in the previous section that a decrease in propagation gain would be accompanied by longer response latencies as well as more pronounced IAT effects (see Figure 2). Without having to repeat this simulation, the same reasoning in explaining the relationship between cognitive fluency and performance on the IAT can be applied here to account for the increase in IAT effects due to slowdowns in information processing (as a result of task interference). Such reductions in the rate of information processing (or propagation gain, as shown in Figure 2) would have resulted in stronger IAT effects, confirming the observations in Frantz et al. (2004).

Our next and remaining task is to examine the impact that increasing the response threshold  $x_{thres}$  would have on IAT performance. So far,  $x_{thres}$  has been set to the maximum pos-

Figure 4. Distributions of response latencies on compatible and incompatible task blocks and corresponding IAT effects with variations in response threshold  $x_{thres}$  for 250 virtual subjects configured with a relative preference for one target concept over the other.

sible activation level of 1.0, but in this simulation, its value is varied within a reasonable range to determine how it affects response latencies on the combined tasks and the corresponding IAT scores. We begin by generating a population of 250 virtual subjects and initializing them with the same associative strengths as in the previous simulation, namely with  $EA \leftrightarrow POS$  and  $AA \leftrightarrow NEG$  set to 0.5 while  $AA \leftrightarrow POS$  and  $EA \leftrightarrow NEG$  were set to -0.5. Connections in each virtual subject's network were then randomly perturbed with Gaussian noise, before being put through all five standard tasks on the simulated Race-IAT.

Simulated response latencies on both the compatible and incompatible task blocks, and corresponding IAT effects are shown in Figure 4. We observe that higher response thresholds resulted in longer response latencies on both combined task blocks, as well as more pronounced IAT effects. In addition, the increase in response threshold is accompanied by higher variance in both response latencies and IAT effect. Thus, to the extent that an increase in the response activation threshold can be interpreted as the coping strategy of exercising caution or raising the confidence criterion, such a strategy could be responsible for a portion of the increase in IAT effect, as predicted by the simulation.

## Discussion

The fact that cognitive ability has a moderating effect on IAT performance has important implications for the validity of the IAT as a measure of the automatic associations and not some other construct. Suppose two subjects have IAT effect scores in the same direction but with different magnitudes. The fact that one of them has an IAT effect with a larger magnitude than the other would not necessarily imply that he or she definitely endorses a stronger positive implicit attitude towards the favored target concept, or a stronger negative implicit attitude towards the less preferred target concept, since the larger IAT effect could be due to differences (e.g., a reduction) in cognitive ability. In the case of this simulation, the associative strength configurations in all

250 subjects were the same (apart from their superposed random perturbations), yet they had a wide distribution of response latencies and IAT effects through just the manipulation of the processing gain and decay rate. For this reason, other means of calculating IAT effects, such as standardizing IAT scores with the “improved scoring algorithm” (Greenwald, Nosek & Banaji, 2003) should be utilized if a reasonable between-subject comparison is desired, although there is continued debate on this matter (cf. Blanton, Jaccard, Gonzales & Christie, 2006; Nosek & Sriram, 2006).

The computational model that we have employed provides some insight about reactions or strategies that might be adopted by subjects during the IAT to cope with stereotype threat. The idea that subjects actually engage in the effortful control of information processing (through either enhancement or suppression) is supported by empirical evidence from fMRI and EEG studies (Gazzaley, Cooney, McEvoy, Knight & D’Esposito, 2005). Furthermore, the ability to exercise greater caution in terms of focusing attentional resources and raising the response threshold or confidence criterion (Treisman & Faulkner, 1984; Petrusic & Baranski, 2009) is equally plausible, especially if the presence of stereotype threat increases the perceived difficulty of the tasks (cf. Brendl, Markman & Messner, 2001). The remaining research question lies in clarifying the nature of these mechanisms through experiment involving human subjects, especially with the advent of neuro-imaging techniques (e.g., Gazzaley et al., 2005; Stanley, Phelps & Banaji, 2008).

## Conclusion

Using a computational model of performance on the IAT, we examined the influence that cognitive fluency, and strategies for coping with stereotype threat could have on the processing of implicit attitudes. By varying several critical model parameters that are analogous to human cognitive ability (such as processing speed and information retention ability), the model accounts for the correlation between

longer response latencies and IAT effects that arises with lower cognitive ability. Furthermore, a reduction in information processing, and the adoption of a more conservative response criterion (which was modeled as shifts in response thresholds) was found capable of reproducing the exacerbated IAT effects that were empirically observed when stereotype threat was present.

## Abstract

Using a previously proposed computational model of human performance on the Implicit Associations Test (IAT), we explore how evaluative conditioning could inform attitude acquisition and formation of automatic associations in memory, and demonstrate the effects of such learning on implicit task performance on the test. This is achieved by augmenting the model with a learning mechanism based on a modified Hebbian learning rule that adapts associative strengths between concepts depending on the temporal proximity of their activation. By manipulating the frequencies at which different stimuli are paired and presented as input to the network, we demonstrate how virtual subjects could acquire associative strengths that were subsequently reflected in simulated IATs as stronger relative preferences in favor of targets that were more frequently presented with positively-valenced stimuli. The model predicts that associations that are already strong have limited prospects for continued reinforcement.

**Keywords:** Hebbian learning; implicit attitudes; simulation; localist-connectionist networks.

## Introduction

Much discussion over the emergence of automatic associations between concepts and their evaluations in memory has taken place within the context of evaluative and classical conditioning (e.g., De Houwer, 2007; De Houwer, Baeyens & Field, 2005; Olson & Fazio, 2001; 2002). Evaluative conditioning is defined as a change in the extent of liking or disliking towards a stimulus that is caused by the frequent pairing of that stimulus with other liked or disliked stimuli (De Houwer, Baeyens & Field, 2005).

The interest in evaluative conditioning research is fueled by the fact that it has the potential to explain the emergence of attitudes and account for the ways in which people's attitudes and beliefs, and consequently their behavior, could be influenced. Thus, it has wide implications especially with regards to consumers' preferences, tastes, and purchasing habits. For instance, Gibson (2008) recently demonstrated the effect of evaluative conditioning in influencing implicit attitudes towards mature brands (e.g., Coke and Pepsi). It was shown that the consistent pairing of positive stimuli with a particular brand could help create and strengthen positive attitudes towards that brand, although the effect was observed only for subjects who had relatively neutral attitudes towards both brands to begin with. Olson and Fazio (2001; 2002) reported similar conditioning effects in which frequent pairings between novel conditioned stimuli (CS) and valenced unconditioned stimuli (US) could result in the acquisition of implicit attitudes towards novel target con-

cepts that were created *a propos* for the experiments, and consequently influence subjects' behaviors and responses on Implicit Association Tests (IAT; Greenwald, McGhee & Schwartz, 1998) involving those novel targets, even though subjects reported no explicit memory of the CS-US pairings.

However, the causal mechanisms by which the evaluative conditioning effect could emerge have yet to be satisfactorily uncovered, owing in part to conflicting empirical data about the conditions under which such effects might occur (De Houwer, Baeyens & Field, 2005). Many controversies revolve around whether associations were learnt as a result of automatic as opposed to conscious controlled processes, whether evaluative conditioning effects were due to a repertoire of processes (as opposed to a single mechanism) or contingent on subjects' awareness of stimuli pairing, and whether the learning is resistant to extinction (De Houwer, 2007; Walther, Weil & Dusing, 2011).

This paper represents our attempts at providing a computational account of the effect of evaluative conditioning on the acquisition of automatic associations between concepts in memory. Through simulations, we examine the impact that frequent pairing of target stimuli with various positively or negatively valenced stimuli would have on implicit task performance, such as on the Implicit Association Test. This is done with a number of goals in mind. First, to provide additional support for the cognitive plausibility of a previously proposed computational model of implicit task performance on the IAT (Quek & Ortony, 2011). Our approach is to augment the localist-connectionist model with a cohesive explanatory account of how automatic associations between concepts in memory could be formed or acquired through experience, a process analogous to how various attitudes are acquired throughout an individual's lifetime.

A second goal is to determine if we could make use of the computational model to address some of the research gaps identified by De Houwer, Baeyens and Field (2005), especially in view of what they see as a lack in the availability of detailed accounts for the processes and mechanisms that underlie evaluative conditioning, and the conditions under which it could occur. More generally, and as pointed out by Van Overwalle and Sieber, (2005), there appears to be limited theoretical advancement in the "understanding of the storage or strengthening of attitude-object associations in human memory." Before more empirical insights are made available, computational approaches such as modeling and simulation could provide an interim but effective means for understanding various candidate processes underlying attitude acquisition or formation (e.g., Eiser, Fazio, Stafford &

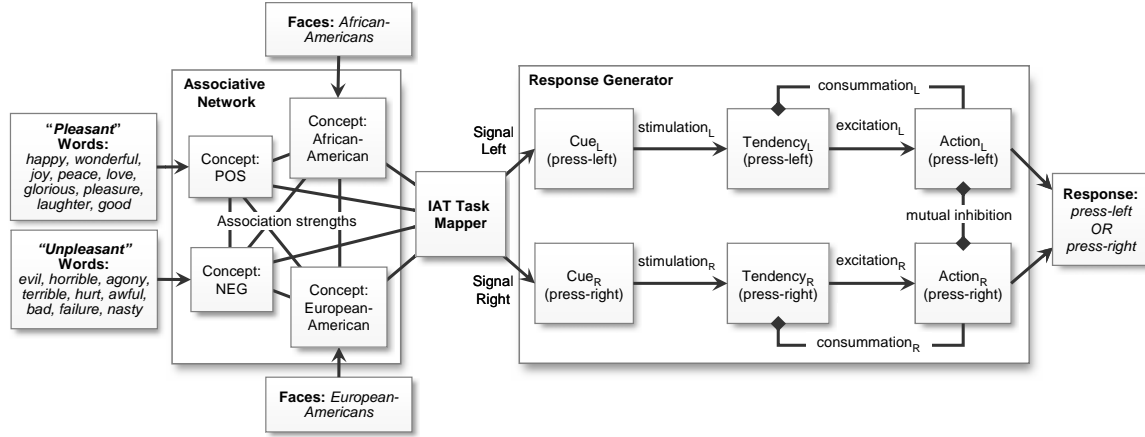

Figure 1. Network model for simulating performance on the IAT (Quek & Ortony, 2011)

Prescott, 2003; Van Overwalle & Sieber, 2005). In our case, a computational model that is demonstrably capable of replicating IAT effects on the basis of different associative strengths between concepts could serve as a platform on which various candidate learning mechanisms could be evaluated, by examining their impact on performance on the IAT. Doing so would also provide an example to demonstrate how learning mechanisms could be incorporated into localist-connectionist models, to fulfill a gap pointed out by some theorists that current associative models of attitudes lack mechanisms that could learn or update internal states and representations in response to information obtained externally from the world, as compared to connectionist models (Van Overwalle & Sieber, 2005). Finally, providing a psychologically plausible mechanism for how associative strengths in the network could be learnt would help allay potential criticisms and modeling concerns over the seemingly arbitrary manner in which associative weights in the earlier model were configured or initialized.

### Model Overview

In this section, we provide a brief overview of the computational model used (for more details, see Quek & Ortony, 2011). The model is a localist-connectionist network (e.g., Page, 2000) that emulates the multiple processing pathways from visual perception (i.e., a word or image) to the automatic activation of associated concepts in memory and motor responses. In general, nodes in the network represent concepts while connections represent associations between them. Information is processed in the network through the flow of activation from one node to another, a process governed by the following propagation rule:

$$x_i(k+1) = (1-\delta)x_i(k) + \alpha \sum_{j,i \in E} x_j(k) \cdot w_{j,i}(k), \quad (1)$$

where  $x_i$  is the activation level of a node  $v_i$ ,  $w_{j,i}$  is the weight of the connection  $e_{j,i}$  from a node  $v_j$  which is a neighbor of  $v_i$ ,  $E$  is the set of all edges,  $\alpha$  is the propagation gain (set to 0.2) and  $\delta$  is a decay parameter (set to 0.001) that reduces activation over time. In each time step  $k$ , activation spreads to  $v_i$  from each of its neighbors  $v_j$  at a rate proportional to the

weight  $w_{j,i}$  of the connection between them. Positive values of  $w_{j,i}$  are excitatory while negative values are inhibitory, while a value of zero implies a neutral or null connection.

### Model Components

The network comprises a few components (see Figure 1). The *Associative Network* contains nodes representing the target concepts AFRICAN-AMERICAN (AA) and EUROPEAN-AMERICAN (EA), attribute concepts for positivity (POS) and negativity (NEG), input stimuli such as a list of *pleasant* and *unpleasant* words (e.g., *happy*, *wonderful*, *joy*, *evil*, *horrible*, *hurt*), and pictures of *European-American* and *African-American* individuals. Connections between target-attribute concept node pairs (i.e.,  $EA \leftrightarrow POS$ ,  $EA \leftrightarrow NEG$ ,  $AA \leftrightarrow POS$ , and  $AA \leftrightarrow NEG$ ) are taken to represent implicit attitudes. For example, a positive attitude towards EA can be represented as excitatory  $EA \leftrightarrow POS$  or inhibitory  $EA \leftrightarrow NEG$  associations, or both, such that when EA is activated, POS will be similarly activated while NEG would be inhibited. Similarly, negative attitudes towards EA can be represented by excitatory  $EA \leftrightarrow NEG$  or inhibitory  $EA \leftrightarrow POS$  associations, or both, such that activation of EA would excite NEG but inhibit POS.

The *Task Mapper* is responsible for transmitting activation from target and attribute concepts to  $cue_L$  and  $cue_R$  which are nodes indicating that a left or right key-press is required. If the present task requires a right response for “*European-American* or *pleasant*”, both POS and EA would be routed to  $cue_R$ . These connections are reconfigured at the beginning of each task block, and during which they remain active (see Quek & Ortony, 2011, Figure 2).

The *Response Generator* implements Revelle’s (1986) cue-tendency-action model (CTA), which in turn is based on Atkinson and Birch’s (1970) dynamics of action theory. CTA describes the dynamic interactions between conflicting tendencies and competing actions. Using CTA as a template, we construct two response-generating pathways (for the left and right key-presses). When activated, response cue nodes will stimulate action-tendency nodes, which will activate response nodes representing the left and right motor responses. When either of the response nodes exceeds a certain activation threshold, it is taken as the winner.

The interactions between the above representations take place as excitations and inhibitions along different propagation pathways. For example, in a task block requiring a left key for “*African-American* or *unpleasant*” and a right key for “*European-American* or *pleasant*”, an African-American picture would activate  $AA$ , and activation will be transmitted to  $cue_L$ . However, if the network is configured with a strong  $AA \leftrightarrow POS$  connection, activation will also be transmitted to  $cue_R$ , competing with  $cue_L$ . This reduces the rate that activation will accumulate in the left response node, and thus a longer time is required for it to reach the response threshold.

### Simulating the Implicit Association Test

Each virtual subject’s network is first initialized with a set of associative strengths that represents its implicit attitudes, and put through the standard IAT task blocks. The network is provided with a simulated verbal or pictorial input in each trial. The number of iterations taken to produce a response is recorded, and then transformed by a scaling factor into a simulated response time (in milliseconds) of the same order of magnitude as those observed in human subjects (e.g., Greenwald et al., 1998; Klauer, Voss, Schmitz & Teige-Mocigemba, 2007). To compute the IAT effect, we take the raw difference between the simulated mean response times in the two combined task blocks.

### Simulating Evaluative Conditioning

To examine the effect that learning processes might have on IAT performance, it would be necessary to extend the localist-connectionist model with mechanisms that could modify its internal features in response to environmental input. While the use of learning is a mainstay of connectionist and parallel distributed processing models (e.g., Cohen, Dunbar & McClelland, 1990; McClelland & Rumelhart, 1986; Read et al., 2010), it is relatively uncommon in localist-connectionist models (Page, 2000).

A number of connectionist models for simulating the automatic acquisition of associations in memory have been proposed (e.g., Eiser, Fazio, Stafford & Prescott, 2003); these typically employ some form of error-correction learning (such as the ubiquitous *delta rule*) that adjusts weights to learn particular stimulus-to-response mappings such that the actual and expected outcomes will eventually converge over time. It is unclear if this is a realistic portrayal of the manner in which associations between concepts are learnt or formed, since the notion of what an *expected outcome* or *reward* ought to be, is ill-defined, or at best, arbitrary. For instance, frequent exposure to a pair of conditioned and unconditioned stimuli need not necessarily involve a motor response or behavioral outcome, though it can be accompanied by a change in state—which in this case would be an increase or decrease in the associative strength between concepts in memory, which can be taken as a change in the degree of liking or disliking for the said stimuli. Work by Herz, Sulzer, Kühn and van Hemmen (1989), and more recently Verguts and Notebaert (2008) employed Hebbian learning rules to learn such state changes.

Hebbian learning (or *plasticity*, Hebb, 1949) can be construed as a form of reinforcement learning in which connections between nodes that *fire* (in the context of neural networks) or are jointly activated within a temporally proximate timeframe would be strengthened over time, such that future joint activation of the associated nodes would co-occur with greater ease. Mathematically speaking, the Hebbian learning rule can be characterized as:

$$\Delta w_{i,j} = \lambda \cdot (x_i \cdot x_j) \quad (2)$$

where  $\lambda$  is a learning rate parameter,  $x_i$  and  $x_j$  are the activation levels of two nodes  $v_i$  and  $v_j$ , while  $w_{i,j}$  is the weight of the edge  $\varepsilon_{i,j}$  originating from node  $v_i$  and terminating at  $v_j$ . In neural networks,  $x_i$  and  $x_j$  are known as the pre- and post-synaptic activation levels of the connection between  $v_i$  and  $v_j$ , respectively. The product  $x_i x_j$  can be conceived as a measure of similarity between the activation levels of both nodes. The learning rule causes the connection weight between these two nodes to increase proportionately with respect to the degree in which both nodes are temporally activated together. However, this rule is known to be unstable in that connection weights will tend to increase without bounds over time if repeatedly reinforced, or saturate at their maximum and minimum boundaries. To enhance stability, we add a discounting term representing the portion of activation in  $v_j$  that is not due to  $v_i$ :

$$\Delta w_{i,j} = \lambda \cdot (x_i \cdot x_j) \cdot (x_j - x_i w_{i,j}). \quad (3)$$

Doing so ensures that  $w_{i,j}$  will be adapted in relation to only that portion of the activation in  $v_j$  that is not due to  $v_i$ , which prevents  $w_{i,j}$  from over-learning the joint activation between  $v_i$  and  $v_j$ . Thus, associations that are already strong to begin with will cease to increase without bounds. Our formulation of the Hebbian learning rule is similar to the simple but provably stable form proposed by Oja (1982):

$$\Delta w_{i,j} = \lambda \cdot x_j \cdot (x_i - x_j w_{i,j}). \quad (4)$$

The difference between the two formulations is that we have swapped the roles of  $x_i$  and  $x_j$  within the parentheses, and kept  $x_i$  in the product to preserve the role of the similarity term  $x_i x_j$ . Furthermore, we inserted a decay term to allow weights to gradually decay over time, in the absence of activation, to arrive at the following:

$$\Delta w_{i,j} = -\gamma \cdot w_{i,j} + \lambda \cdot (x_i \cdot x_j) \cdot (x_j - x_i w_{i,j}), \quad (5)$$

where  $\gamma$  is the weight decay rate. For implementation purposes, the learning rule is rewritten as an update function:

$$w_{i,j}(k+1) = (1-\gamma) \cdot w_{i,j}(k) + \lambda \cdot x_i(k) \cdot x_j(k) \cdot [x_j(k) - x_i(k) w_{i,j}(k)] \quad (6)$$

We further constrained the model to learn only the weights of associations between positively-activated concept nodes, while allowing associative weights between non-activated or negatively-activated (i.e., inhibited) node pairs to decay and eventually become extinct over time.

Prior to performing the simulation,  $\lambda$  and  $\gamma$  were set to 0.05 and 0.0005 respectively after an initial process of iterative search through parameter space to yield post-learning weights that had a large but unsaturated range.

## Simulations

To perform the simulations, we begin with a network configuration in which the weights of the associations  $EA \leftrightarrow POS$ ,  $EA \leftrightarrow NEG$ ,  $AA \leftrightarrow POS$ , and  $AA \leftrightarrow NEG$  are all initialized to zero. In each epoch, 100 pairs of input stimuli, each comprising an attribute concept exemplar (e.g., the word *wonderful*) and a target concept exemplar (e.g., a picture of a White or Black individual) were selected at random. Input nodes corresponding to both exemplars in each stimulus pair were set with an activation of 1.0. The learning rule in Equation (6) was then applied in tandem with the propagation rule defined in Equation (1). Propagation of activation through the network would activate the concept nodes corresponding to these input stimuli. At the same time, the learning rule is expected to enhance the connection weights between pairs of activated concept nodes, for instance, between EA and POS, or AA and POS, using the above example of the word *wonderful* and a picture of a White or Black individual.

By manipulating the frequency at which input exemplars are selected from each attribute and target concept pair, we can simulate situations in which the exemplars of specific target-attribute concept pairs co-occur more frequently than others. As an example, to produce the condition that EA and *pleasant* exemplars co-occur twice as often as EA and *unpleasant*, the frequency for the latter is set to half of the former's. We expect the learning rule to adapt association weights in a manner that will eventually reflect the patterns of distributions across the frequencies at which each target-attribute concept pair is presented.

In this first simulation, two learning conditions were defined, as shown in Table 1. In the first condition (a), the frequency distribution across the target-attribute concept pairs  $AA+POS$ ,  $AA+NEG$ ,  $EA+POS$ , and  $EA+NEG$  were set to 40%, 10%, 10%, and 40%, respectively. The second condition (b) was defined by the distribution 10%, 40%, 40%, and 10%, for target-attribute pairs in the same order. These represent the probability in which paired-stimuli are sampled from the respective concept pair, thus the absolute proportions themselves may vary. Virtual subjects in each condition were put through a pre-learning IAT, followed by the above learning phase during which 100 pairs of stimuli were presented for 100 epochs each. Finally, a post-learning IAT was administered to the virtual subjects. More details concerning the procedures in which the simulated IATs were conducted are found in Quek & Ortony (2011).

Figure 2 shows the evolution of target-attribute associative strengths over the course of learning for 25 virtual subjects in each condition, while the post-learning associative strengths are shown in Table 2. In condition (a), stronger  $AA \leftrightarrow POS$  and  $EA \leftrightarrow NEG$  associations emerged after learning, while  $AA \leftrightarrow NEG$  and  $EA \leftrightarrow POS$  increased but at a much slower rate. In (b), stronger associations were found for  $EA \leftrightarrow POS$  and  $AA \leftrightarrow NEG$ , while the remaining two increased but at a much slower rate. When put through both the pre-learning and post-learning IATs, condition (a) had a non-significant mean IAT effect of -0.03ms prior to learning,  $t(24) = -0.132$ ,  $p = 0.896$ , but a significant post-learning mean IAT effect of

Table 1: Presentation frequency of paired stimuli in two experimental conditions during the learning phase

Stimulus Pair	Prototypical exemplars	Presentation Frequency	
		Condition (a)	Condition (b)
$AA+POS$	 + “happy”	40%	10%
$AA+NEG$	 + “sorrow”	10%	40%
$EA+POS$	 + “laughter”	10%	40%
$EA+NEG$	 + “horrible”	40%	10%

Note: EA: European-American; AA: African-American; POS: Positivity; NEG: Negativity.

Table 2: Post-learning target-attribute associative strengths

Association	Condition (a)		Condition (b)	
	<i>M</i>	<i>SD</i>	<i>M</i>	<i>SD</i>
$AA \leftrightarrow POS$	.865	.083	.287	.148
$AA \leftrightarrow NEG$	.289	.084	.862	.093
$EA \leftrightarrow POS$	.256	.120	.862	.091
$EA \leftrightarrow NEG$	.874	.061	.292	.117

Note: EA: European-American; AA: African-American; POS: Positivity; NEG: Negativity.

-124.8ms,  $t(24) = -19.0$ ,  $p < .001$ , which is indicative of an implicit preference for AA over EA. Similarly, condition (b) exhibited a non-significant pre-learning mean IAT effect of 0.24ms,  $t(24) = 0.771$ ,  $p = 0.448$ , but a significant post-learning mean IAT effect of 120.6ms,  $t(24) = 22.3$ ,  $p < .001$ , indicative of an implicit preference for EA over AA. Considering that each network began with non-significant pre-learning IAT test scores but expressed significant post-learning IAT effects, and since no other modifications were made to the network, we may conclude that the increase in IAT effect is due to the associations that were acquired over the course of learning. As expected, the emerging associative strengths in each condition (Table 2) showed a similar pattern to the distributions of presentation frequencies of the corresponding target-attribute pairs (Table 1).

To investigate the impact of different co-occurrence frequencies on the post-learning IAT effect, we repeated the above simulation for 250 virtual subjects, only this time varying the frequency distribution for each subject by interpolating randomly between 50%, 0%, 0%, 50%, and 0%, 50%, 50%, 0% for the respective target-attribute concept pairs  $AA+POS$ ,  $AA+NEG$ ,  $EA+POS$ , and  $EA+NEG$  that were presented during learning. When the proportions of both  $AA+POS$  and  $EA+NEG$  stimuli were reduced from 50% to 0%, the proportions of  $AA+NEG$  and  $EA+POS$  stimuli were increased from 0% to 50%, in a complementary manner, while ensuring that all four proportions add up to 100%.

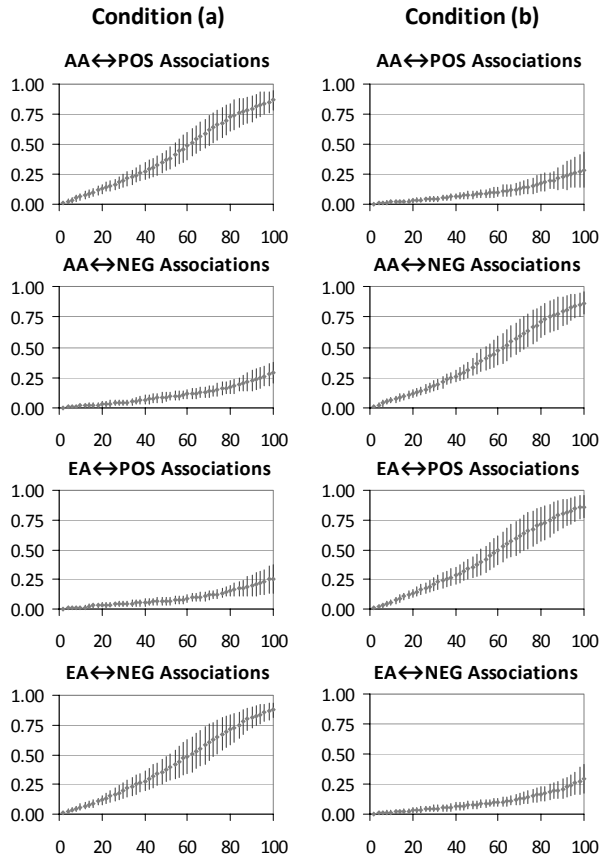

Figure 2. Evolution of associative strengths over the course of learning, for virtual subjects in two conditions. EA: European-American; AA: African-American; POS: Positivity; NEG: Negativity. Y-axis: associative strengths. X-axis: learning epochs. Error bars: standard deviations.

Plotting the post-learning IAT effect against the presentation frequencies for the four target-attribute concept pairs in Figure 3, we found that when a larger proportion of EA+POS and AA+NEG paired stimuli were presented to the model during the learning phase, the post-learning IAT subsequently produced larger IAT effects that were in favor of EA. Conversely, when more input stimulus pairs were selected from AA+POS and EA+NEG and presented to the model during learning, the post-learning IAT had larger IAT effects in favor of AA. When all input stimulus pairs were presented with about the same probability (i.e., keeping the proportions to 25% for each target-attribute concept pair), the post-learning IAT effect was close to zero.

## Discussion

With the computational model, we have demonstrated how automatic associations between target and attribute concepts could be acquired by repeated exposure to pairs of input exemplars—as similarly achieved in human subjects via evaluative or classical conditioning (De Houwer, 2007; Olson & Fazio, 2001). Stronger associations were acquired for target-attribute concept pairs whose input exemplars were presented together more frequently, and weaker associations

were learnt for other target-attribute concept pairs whose input exemplars were presented together less frequently.

These simulations have some important implications especially with regards to the malleability of implicit attitudes. First, the ability to influence or generate novel associations through consistent pairing of target and attribute stimuli supports the findings of Olson and Fazio (2001) and of Gibson (2008), particularly the latter's discovery that the effects of evaluative conditioning were observed only for subjects who initially had relatively neutral attitudes towards the targets, and not those who already possess a significantly stronger preference for one target over the other. In our terms, this could be explained by the longer amount of time required for stronger associative strengths to decay or weaken over time when the corresponding paired stimuli were no longer presented as frequently.

Second, the evolution of associative strengths over learning epochs in Figure 2 showed a gradual slowdown as they approached 1.0, suggesting that, as these associations increase in strength over the course of learning, the extent to which they can be further increased is limited. Thus, there is limited room for the continued positive reinforcement of associations whose strengths are already high, such that they become less susceptible to learning. Consistent with empirical observations (Gibson 2008; Joy-Gaba & Nosek, 2010), the model thus predicts that this would limit the impact that evaluative conditioning might have on attitudes that have already been firmly ingrained, and thus the continued malleability of attitudes through such means could be reduced. While it could be argued that this effect is largely a result of the modified Hebbian learning rule we devised in Equation (6) that limits the extent to which already-strong associations could continue to be increased, the weights will nonetheless be subject to the finite upper boundary even when the standard unconstrained Hebbian rule in Equation (2) were used instead, and give rise to the same observations.

Third, the simulation results so far are in agreement with Mitchell, Anderson and Lovibond's (2007) proposal that the IAT itself could be used as a means for detecting the occur-

Figure 3. Post-learning IAT effects in virtual subjects (N=250) across presentation frequencies of input stimuli from each of the target-attribute concept pairs during the learning phase.

rence of evaluative conditioning, which, to be consistent with Gibson (2008), is to be expected only for target concepts that have yet to be strongly associated with any particular attributes. Finally, considering that the simulated mechanisms of learning are not specific to valenced attributes, they could be relevant not just for evaluative conditioning, but for explaining other more generic forms of conditioning or learning, such as the effectiveness of re-affirmations to enhance self-concept and self-esteem.

## Conclusion

In summary, we have augmented the cognitive plausibility of our computational model (whose purpose was to account for the emergence of IAT effects) by providing a cohesive and cognitively-plausible account of the manner in which implicit attitudes could be acquired through evaluative conditioning, as well as their subsequent effects on implicit task performance on a simulated IAT. This is achieved via a modified Hebbian learning rule that adapts associations between concept representations in memory relative to the different frequencies at which target stimuli are paired with other positively or negatively valenced stimuli. An additional contribution of the model is in demonstrating how localist connectionist models too are amenable to learning mechanisms, just like their connectionist counterparts (Van Overwalle & Sieber, 2005). Extending the simulations beyond the permitted scope of this paper to include additional learning conditions and a more comprehensive analysis of the viability of the learning algorithms presented (in comparison to possibly other candidates) would be a logical continuation of this work in future.

## Abstract

How do we reason about incomplete spatio-temporal descriptions? How might a map influence formerly constructed preferred mental models? Little research so far focused on a combination of two central fields important for successful route planning: the way humans deal with constraint based reasoning (especially with some sort of spatio-temporal constraints) and the way in which humans plan with a given map (especially with problems inspired by typical Traveling Salesman Problems). This, however, becomes even more interesting in cases in which the spatio-temporal constraints allow for several solutions. Do the predictions of the preferred mental model theory still hold true in such situations? This article investigates the influence of maps on the generation of preferred models. The goal is to bring together the theory of (preferred) mental models and route planning.

**Keywords:** Spatial reasoning; preference effects

## Introduction

In everyday life we often reason with incomplete information or have to take constraints into account during reasoning. Cognitive processes involved in such reasoning about spatial relations and the construction of according mental models have recently been the subjects of interest in studies about spatial relations (Knauff, Rauh, Schlieder, & Strube, 1998; Rauh et al., 2005). However, the question of how external representations of space such as maps, or map-relevant knowledge influences and interacts with reasoning processes is widely unknown. The research communities concerned with how people use maps to solve spatial or navigational problems and how people solve reasoning problems are mostly distinct. There are, however, many situations in which people reason with maps or with map-like knowledge. In this paper we present and investigate two classes of problems.

**Path planning from maps.** Imagine planning a sightseeing trip through the downtown area of an unfamiliar city: you do have a map and you want to visit multiple sites of interest. Of course, you are interested in minimizing the distance you have to traverse along your tour. Problems of this kind are typically referred to as Traveling Salesperson

Problems (TSP): A salesman has to visit a number of cities and start from a specific location to which he will also return after visiting each city. The traveling salesman will aim for the shortest possible route and avoid any detours (Wiener & Tenbrink, 2008). Formally, TSP-Problems are NP-complete (Garey & Johnson, 1979).

Human performance and the cognitive strategies employed when solving TSPs have been investigated in real environments involving movement through space (e.g., Gärling & Gärling, 1988) as well as in more abstract visual or map-like versions of the TSP in which a number of dots are displayed on a computer screen which have to be connected such that the resulting tour is as short as possible (e.g., MacGregor & Ormerod, 1996). When planning actual site seeing trips, however, we often face additional constraints besides minimizing distances: some sites of interest may close before others and therefore have to be visited earlier. Or, you may want to be at a specific site at a particular time, for example, to have lunch. In addition, you are still striving to minimize path length. Similar challenges arise when planning shopping trips during which multiple stores have to be visited. Here, we also often face additional constraints besides minimizing distances: Frozen food or ice-cream, for example, is best be bought towards the end of the shopping tour to avoid defrosting before returning home. Moreover, in order to minimize the effort of carrying purchased goods, heavy items should be bought towards the end of the trip. Again, path length should be minimized. All these factors impose constraints on the path-planning problem and have to be taken into account when planning a trip. Below is an example of combined spatial optimization and reasoning problem:

- (1) Buy bread before ice-cream.  
Buy eggs after ice-cream  
Buy a gallon of water after eggs.  
Buy a chair after a gallon of water.

Problems (1) belongs to a class of problems that are referred to as *determinate problems*, as they allow only for a single solution:

bread ice-cream eggs water chair

Problem (2) belongs to a class of problems that are referred to as *indeterminate problems*, as they allow for multiple – three – solutions.

- (2) Buy bread before ice-cream.  
Buy eggs after ice-cream.  
Buy a gallon of water after ice-cream.  
Buy a chair after a gallon of water

Which is consistent with the following three models:

bread ice-cream eggs water chair  
bread ice-cream water eggs chair  
bread ice-cream water chair eggs

The key idea of the *mental model theory* is that reasoners translate these constraints into a mental model – an abstraction or analogical reflection – of the state of affairs and use this representation to solve the reasoning problem. An important finding is that when faced with indeterminate problems featuring multiple solutions, humans tend to construct only one initial model – the so-called *preferred mental model* (Rauh et al., 2005; Ragni, Fangmeier, Webber, & Knauff, 2007), which is easier to maintain in working memory than any other mental model (Ragni et al., 2007; Knauff, 2006). Preferred mental models have been initially identified for Allen's interval calculus (Knauff, Rauh, & Schlieder, 1995), a more detailed introduction of preferred mental models is given in the next section. What happens when reasoning about a problem – as the one described above – when the shortest path does not correspond to the preferred mental model? Is any influence measurable? Although this question is of high ecological validity, to the authors' knowledge, it has not yet been approached. In this paper we will present a first experiment to analyze from the perspective of a mental model theorist whether – and if so, how – preferred mental models can be “overridden” by external stimuli.

## Background

### The theory of preferred mental models

A central question in the context of incomplete information is: How are indeterminate problems such as Problem (2) processed? Are there preferred interpretations? The mental model theory (MMT), introduced by Johnson-Laird and Byrne (1991), suggests that people draw conclusions by constructing and inspecting a spatial array that represents the state of affairs described in the premises. It is a three-stage process consisting of a comprehension, description, and validation phase. In the comprehension phase, reasoners construct a mental model that reflects the information from the premises. If new information is encountered during the reading of the premises it is immediately used in the construction of the model. During

the description phase, this model is inspected to find new information that is not explicitly given in the premises. Finally, in the validation phase alternative models are searched that refute this putative conclusion. However, some questions remain open with regards to how people deal with multi-model problems. For example, which model is constructed first, and does this model construction adhere to certain principles? And, why do reasoners neglect some models? None of these questions are answered by the classical mental model theory. In contrast the preferred mental model theory (PMMT) has been developed to explain why humans in general tend to construct a preferred mental model (PMM). The PMM is the starting point for deriving a putative conclusion. In the model variation phase the participants tend to make local and continuous transformations starting from the PMM to search counter-examples (Rauh et al., 2005).

Several predictions of the PMMT about insertion principles as well as transformation strategies in spatial relational reasoning can be shown (Ragni et al., 2007). Assume we have two premises of the form

- (1) A is to the left of B and
- (2) A is to the left of C.

Humans tend to process these premises sequentially, i.e. first a model A B is generated and then object C is inserted into the model. There are two possibilities where C can be inserted, in-between A and B (first-fit principle) and to the right of B (first-free-fit principle). The latter principle has been empirically confirmed in small-scale descriptions (e.g., Ragni et al., 2007; Jahn et al., 2005). An interesting aspect, however, is how this might influence reasoning if a map is given?

**Path planning and Distance Optimzation.** Path planning and optimization with maps has primarily been investigated by means of visual versions of the TSP (e.g., Graham, Joshi, & Pizlo, 2000; Vickers, Butavicius, Lee, & Medvedev, 2001). In these experiment, participants are presented with a number of target locations on a computer screen – usually presented as identical black dots on a white background – and are asked to connect these locations with straight lines such that the resulting path is as short as possible. Results from these studies demonstrate that humans reach very good performance levels even with as many as a few dozen target locations. The strategies and heuristics applied are a matter of ongoing debate. The convex hull has been suggested to be part of the problem solving strategy (MacGregor & Ormerod, 1996), the crossing avoidance hypothesis states that participants avoid crossing tours, as they know that crossings lead to sub-optimal solutions (Van Rooij, Stege, & Schactman, 2003), and the hierarchical nearest neighbor strategy assumes that in a first step clusters of several neighboring dots are established, which are then sequentially linked into a tour, using the nearest neighbor algorithm (Vickers, Bovet, Lee, & Hughes, 2003).

Only few studies investigating TSPs with maps used richer environments in which different target locations could be visually distinguished requiring some form of memory. In a recent study, Tenbrink and Wiener (2009) presented participants with maps depicting a regular 5x5 grid of locations each of which could be identified by a unique symbol. Participants were given so-called shopping lists depicting the symbols of a start location and four to nine target locations. Their task was to identify the locations in the grid and then mark the shortest possible round trip from the start that visits all target locations in the map. By analyzing participants' planning performance, their chosen paths, as well as retrospective linguistic representations, a number of cognitive strategies applied when solving the TSPs could be identified. Most importantly, participants flexibly employed and connected a repertory of multifaceted strategies allowing them to simplify and structure the problem space across subtasks involved in solving the TSPs (for a navigational version of this paradigm, see Wiener, Ehbauer, & Mallot, 2009).

As mentioned before, path planning in every-day life often requires taking into account additional constraints besides minimizing distances. Hayes-Roth and Hayes-Roth (1988) presented one of the view studies investigating complex planning from maps with additional constraints (but see also the related Plan-A-Day paradigm, Nellen & Funke, 2002). Participants were given a map of a town depicting multiple shops and other locations along with a list of errands. These errands included buying vegetables at the grocery, buying a toy for a dog at the pet store (both purely spatial constraints), but also picking up a car at a certain time in a certain location (spatio-temporal constraint). Moreover, more errands were specified than the subject could possibly accomplish in the time available, which required him/her to sort out (less important) errands to formulate a realistic plan. Hayes-Roth & Hayes-Roth developed a general model of complex planning, assuming that the planning process comprises many distinct *specialists* contributing decisions to a tentative plan that is refined incrementally.

## Experiment – Reasoning, Route Planning, and Maps

In this experiment we investigated the connection between the construction of (preferred) mental models from a set of premises and the subsequent task of planning a trip consistent with the premises. In order to do so, participants were presented with determinate and indeterminate reasoning problems describing spatio-temporal relations between sets of destinations. After processing the premises and (possibly) constructing a (preferred) mental model, they were asked to draw a round trip into a map visiting the destinations in an order that is consistent with the premises. If the planning task in fact interfered with the constructed mental model, we expected performance differences depending on whether or not the round trips defined by the

premises were optimal or clearly sub-optimal with respect to path length.

### Participants.

Nineteen students from the University of Freiburg took part in this experiment (9 females,  $M = 23.3/22.1$ ,  $SD = 2.2/2.1$ ). They were paid for their participation or received course credits.

### Materials.

To investigate the impact of map like presentation of target locations on reasoning performance and the selection of preferred mental models, we generated four types of reasoning problems (see Fig. 1).

1. **Optimal determinate problem (D-optimal):** The correct solution to these reasoning problems always matches the shortest possible – optimal – route to visit all target destinations.
2. **Suboptimal determinate problem (D-sub-optimal):** The correct solutions to these reasoning problems were clearly suboptimal with respect to their length.
3. **Preferred optimal indeterminate problems (IP-optimal):** The preferred mental model to these reasoning problems matched the shortest possible – optimal – route. Two alternative correct solutions existed that were not identical with the preferred mental model and that were sub-optimal with respect to their length.
4. **Preferred suboptimal indeterminate problems (IP-suboptimal):** The preferred mental models to these reasoning problems were clearly suboptimal with respect to their length. Two alternative correct solutions existed, one of which was optimal with respect to metric length.

### Methods.

Each participant was presented with 16 reasoning problems, four of each type described above. To control for the influence of the specific configuration of start and target places, we used four different configurations and balanced the types of reasoning problems across the configurations. Each reasoning problem was presented on three pages: The first page contained the first two premises; the second page contained the third and fourth premises, and the third page contained a regular  $5 \times 5$  grid in which the 5 positions mentioned in the premises were marked (see Figure 1). Participants were instructed to read premises 1 and 2, to turn the page over, read premises 3 and 4, turn the page over, and

to connect the positions in the layout in order to mark a round trip that was consistent with the premises. They were instructed not to scroll back after having turned a page or to take any notes.

## Hypotheses & Predictions.

Given the specific procedures of the experiment, two competing hypotheses are conceivable: **First**, the external representation and the task of sketching the corresponding route do not influence the reasoning process. This is based on the assumption that the mental model is generated while reading and processing the premises. Hence, the external representation that is provided only after the last premises was processed does not influence the mental model. Participants would then simply sketch the tour that corresponds to their mental model. In case of determinate problems this would lead to identical performance (with respect to error rate) between the types of reasoning problems (D-optimal/D-suboptimal). In case of indeterminate reasoning problems, we expect that participants will select the preferred mental model, regardless of whether or not the according path was optimal or suboptimal (IP-optimal/IP-suboptimal). **Second**, the external representation influences the mental model, as the task of sketching a round trip for the shopping route implicitly requires choosing a short solution. In this case, we expect interferences between finding the correct solution to the reasoning problem and planning the shortest path. Such an interference would have a selective impact on performance for determinate reasoning problems of type *D-suboptimal*, for which the shortest (optimal) path and the correct solution to the reasoning problem were different, but not for determinate reasoning problems of type *D-optimal*, for which the optimal path and the correct solution to the reasoning problem were identical. The predictions for indeterminate problems are not as straight forward, as each indeterminate problem features three different solutions.

## Results.

Three out of the 19 participants were removed from the final data as their performance on finding the correct solution for determinate problems was clearly below 50% (12.5%, 12.5%, 37.5%). In addition, thirteen trials were removed from the final data set, as these solutions featured branching points – participants had drawn two arrows from one location.

The different spatial configurations had no influence on participants' performance ( $F(3, 46.35) = .27, p = .85$ ). For the remaining analyses we therefore pooled the four different configurations. On average, participants found a correct solution to 89.1% of the reasoning problems. A 2x2 ANOVA with the factors of *type of reasoning problem*

(determinate, indeterminate) and *solution* (optimal, suboptimal) was carried out. We did not observe a main effects for type of reasoning problem [ $F(1, 17.99) = 0.12, p = .91$ ] or for solution [ $F(1, 18.28) = .06, p = .81$ ]. However, the interaction type of reasoning problem x solution was significant [ $F(1, 16.72) = 8.96, p < .01$ ].

To further investigate the nature of this interaction, we performed post hoc *t* tests revealing that performance for determinate problems of type *D-optimal* was better than for determinate problems of type *D-suboptimal* (93.2% vs. 82.8%; *t*-test:  $t(15) = 2.24, p = .04$ , see Figure 2). For indeterminate reasoning problems, the pattern was different: surprisingly, participants performance was better for problems of type *IP-suboptimal* than for those of type *IP-optimal* (97.8% vs. 82.8%; *t*-test:  $t(14) = 2.38, p = .03$ , see Figure 2).

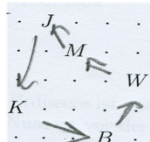

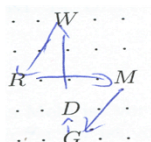

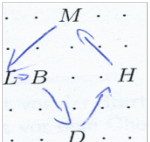

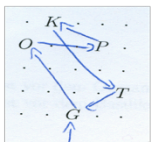

Determinate optimal	Determinate suboptimal
Premises 1. K is before B 2. B is before W 3. W is before M 4. M is before J 	Premises 1. G is before D 2. D is before W 3. W is before R 4. R is before M 
Indeterminate preferred = optimal	Indeterminate preferred = suboptimal
Premises 1. L is before B 2. B is before D 3. B is before H 4. H is before M 	Premises 1. G is before O 2. O is before P 3. O is before K 4. K is before T 

Figure 1: The four different types of reasoning problems along with exemplary data by participants. All participants received the premises (in German) with full names, e.g. der Trevibrunnen vor dem Kolosseum (the Fountain of Trevi before the Colosseum) instead of initials.

For correct solutions to indeterminate problems, we evaluated whether or not participants chose the preferred mental model. In 87.8% of the cases, they did choose the preferred mental model (*t*-test against chance level [with three possible solutions, chance level was 33.33%]:  $t(15) = 15.79, p < .001$ ).

Figure 2: Results of the Experiment: **left:** the determinate problem description – allowing for one path solution only; **right:** the indeterminate problem description, allowing for three solutions.

Preference for the preferred mental model did not differ between types of indeterminate problems (IP-optimal: 87.2% versus IP-suboptimal: 85.0%;  $t$ -test:  $t(14)=0.29$ ;  $p=.78$ ).

## Discussion.

The findings for the determinate problems to which only a single correct solution exists, revealed a clear difference in performance. Specifically, participants showed better performances for problems in which the correct solution to the reasoning problem was identical to the shortest possible path (D-optimal) as compared to reasoning problems in which the correct solution and the optimal path were different (D-suboptimal). This finding suggests interference between the reasoning process and the task of planning a round trip. In other words, the map influenced the reasoning process.

Contrary to classical deduction tasks, indeterminate reasoning problems do not appear to be more difficult than determinate ones. A possible explanation for the lack of a systematic difference in the current paradigm comes from the fact that the higher number of possible solutions in indeterminate problems in the specific task allows for a higher error tolerance (in all cases the objects 3, 4, and 5 in the premises).

Some of the participants had drawn routes with branching points, i.e., they had drawn two arrows from one object. Such branching solutions were mostly found in indeterminate problem cases (14 out of the 17 cases in total). We had to remove these cases from the final data set as we were not able to extract a single unambiguous solution. However, these branching solutions clearly reflect a special type of errors, as they usually reflected the indeterminate nature of the problems. Note, however, that by removing these trials from the analysis, we artificially increased performance primarily for indeterminate problems, which might explain the surprisingly high performance in these problems.

An analysis of the chosen solutions for indeterminate problems clearly demonstrated that participants did not choose randomly between the three possible solutions, but preferred one over the others. The preferred solution was identical to the one generated by the first-free fit strategy, a preferred mental model generation strategy identified in previous experiments (Ragni et al., 2007) on small-scale scenarios. Then again, the constraints in this experiment were clearly spatio-temporal in their nature – the premises “the fountain of Trevi before the colosseum” refers to the sequence of the events. In that sense, it is not surprising that the identified preferences were similar to those identified in small-scale scenarios (Schaeken, Johnson Laird, & d’Ydewalle, 1996).

## General Discussion

In dealing with maps there is one important and new question: What is the influence of the (implicit) task of planning a short path using maps while taking into account spatio-temporal constraints? The way reasoners typically construct preferred mental models when reasoning about indeterminate problems has been identified in several experiments (cp. Ragni et al., 2007). The most prominent encoding strategy applied in such cases is the first-free-fit strategy. This strategy, however, does not allow for predicting how external constraints such as the length of the routes resulting from reasoning problems influence the reasoning process itself. In this study we combined reasoning about spatio-temporal constraints with the task of planning short paths with a map (without explicitly stating that the shortest path must be found). The planning task influenced the reasoning task: In determinate problems – in which only a single solution existed – participants showed better performance if that solution was identical to the shortest possible path. Furthermore, for indeterminate cases, we found strong preferences for the solution that corresponded to the first-free-fit strategy. Participants’ performance in finding a possible solution for IP-suboptimal problems was greater than for IP-optimal problems. This result is surprising and was not predicted, as the optimal solution to the route-planning problem – i.e., the shortest possible route – was identical to the preferred mental model for IP-optimal problems but not for IP-suboptimal problems. Future research will address this interesting effect.

## Abstract

Problem solving requires the use of higher mental functions, functions that can be improved with training (Brown, Ryan, & Creswell, 2007). The current study examines the effects of *meditation* on creative problem solving. Participants were undergraduate students ( $n = 81$ ) who were randomly assigned to meditate or rest. Next, Pp were asked to solve a problem: fishing out a small object from inside a box using one of four available tools. Two of the available tools were potentially useful, but the other two were intentionally designed to be useless (i.e., they were incapable of retrieving the object). There were no differences between meditators and non-meditators with respect to solution rates, tool switching behavior, or overall persistence. However, meditators spent more time with their first tool that they selected, and more time attempting to solve the task with the useful tools. Brief meditation training may promote certain cognitive strategies that are conducive to successful problem solving; implications are discussed.

**Keywords:** problem solving; cognitive training; meditation.

## Introduction

Recently, investigations have demonstrated that *cognitive training*, activities designed to improve performance, self-control, and brain physiology, provides an effective method for improving a variety of higher order mental functions including reasoning, decision-making, and task-set switching (Basak, Boot, Voss, & Kramer, 2008; Mestre, Dufresne, Gerace, & Hardiman, 1993; Willis et al., 2006). Research suggests that a broad range of cognitive training techniques is effective. Manger, Eikenland, and Asbjornsen (2002) were able to improve the social-cognitive functioning of female schoolchildren with a 9-month long social-cognitive training program. Basak et al. (2008) utilized 23.5 hours of training using a real-time strategy video game, and found that the training improved task switching, working memory, and reasoning. Smith et al.

(2009) found that a computerized cognitive training program improved attention and memory of aged adults. Indeed, these and many other studies demonstrate that cognitive training can improve cognitive performance in a variety of areas when used over the long term.

The study described here investigated a very specific form of cognitive training called focused *meditation*, a process where a person attempts to sustain attention on a selected thought, detect mind wandering, and return to focused attention. Meditation is a form of cognitive training, and studies have demonstrated the benefits of meditation on cognitive functions (Ramsburg & Youmans, 2011; Tang et al., 2007; Zeidan, Johnson, Diamond, David, & Goolkasian, 2010). Meditation techniques are also relatively simple to teach, and some research has demonstrated measurable improvements in cognitive function even with very little meditation experience. Ramsburg and Youmans (2011) found that initial periods of meditation that lasted only six minutes at the start of a class lecture improved academic performance amongst lower division college students. Tang et al. (2007) found that five 20-minute sessions of meditation reliably improved attentional functioning, while Zeidan et al. (2010) found improvements in attentional functioning, working memory, and visuo-spatial processing with only four sessions of meditation training.

## Problem solving and meditation?

General problem solving skills involve an ability to understand a problem, devise a plan of action, execute the plan, and examine the results (Newell & Simon, 1972). An important question in the problem solving literature is whether the individual steps within the problem solving process can be enhanced, and the answer it would seem is 'maybe.' For example, we know that experts in a given domain are often superior to novices at both understanding a problem and devising a plan of action. However, we also know that when the rules of a domain are compromised

(e.g., impossible chess positions) or when an expert in one domain is asked to perform a task in a different domain, so-called ‘experts’ often fail to *transfer* their expertise between the two domains (Ohlsson, 2011).

Although meditation has been shown to improve a variety of cognitive functions, relatively few studies have directly examined the influences of meditation training on problem solving (Dillbeck, 1982; Kindler, 1979; Raingruber & Robinson, 2007). Kindler (1979) found that group problem solving could be improved with meditation training, specifically, improving speed to solution and promoting effective teamwork. Raingruber and Robinson (2007) found using a qualitative approach that nurses engaged in meditation training reported improvements in their problem solving abilities, attention, and calm. These findings suggest that meditation *might* be an effective method for improving problem solving, but more study is clearly required.

If meditation were to enhance problem solving, we hypothesize here that its influence might be most pronounced on the actual execution of any given problem solving strategy. Whereas expertise is likely to act on the stages of problem solving that require accurate problem framing (i.e., understanding problems and devising solutions), meditation and other types of cognitive training might have positive effects on some of the key cognitive processes utilized while trying to execute a plan of action during problem solving (Lutz et al., 2009; Mayer, 1992; Tang et al., 2007; Zeidan et al., 2010). Ly and Spezio (2009) found via fMRI that meditation could improve decision-making by influencing neural circuits in an enduring manner for recruitment during the self-regulation of social cognitive processes. Other studies have demonstrated that mediators appear to display more conscientious decision making (Kirk, Downar, & Read Montague, 2011), or cognitive flexibility, a mental ability important in problem solving (Dillbeck, 1982; So & Orme-Johnson, 2001). These and other studies suggest a link between meditation and other forms of cognitive training, and the cognitive functions used during problem solving itself.

In this study, we examined the effect of meditation, a form of cognitive training, on a real-world, creative problem-solving task. Participants received either brief meditation training or rest, and then attempted to solve a novel creative problem. Although past studies have shown only moderate training benefits on problem solving tasks (e.g., Kershaw & Ohlsson, 2004), we hypothesized that meditation, which has been shown to improve cognitive functioning (So & Orme-Johnson, 2001; Tang et al., 2007) may be an effective method for promoting creative problem solving in general.

## Method

### Participants

Eighty-one California State University, Northridge students participated for course credit. Participants had an average age of 18.73 with a standard deviation of 1.32. There were

61 females and 20 males. Participants identified themselves as Latino/Hispanic (45.7%), Black/African-American (19.8%), Caucasian (19.8%), more than one race/other (6.2%), Asian or Pacific Islander (4.9%), and Middle Eastern (2.5%).

### Problem-solving task

The researchers developed a novel creative problem-solving task. The task was a physical problem that required the use of unique experimenter designed tools to solve the task. Specifically, the objective was to get a bolt out of a box and across a red line (six and a half feet away from the box) using the four experimenter designed tools.

### Materials

**Box and Bolt.** The box (see Figure 1) was made using 5 ½ by ¾ inch wood, a 16 inch in length, 3 inch high, and 1/16 inch thick piece of clear flexible plastic, and a 23 by 18 inch plywood base. The back face of the box measured 17 ¼ inches. The two wooded sides measured 23 inches in length. The clear plastic front piece with red tape lining its top was 3 inches high and was glued into place 16 ½ inches from the back side of the box, which left two 6 ¾ inch in length non encased walls. A modified 5/8<sup>th</sup> inch lag bolt was the target that participants were trying to retrieve. The bolt was placed standing upright inside the box at the beginning of each experiment. The bolt was 3 inches in length had seven 1 ¾ inch washers secured by two 5/8<sup>th</sup> inch nuts.

Figure 1. The Box with the Bolt in the Starting Position.

**Claw.** The claw was one of the two tools that were capable of retrieving the bolt (see Figure 3). It consisted of a modified metal grabber extension tool. The claw was 53 ¾ inches long. A piece of thin rope connected the “trigger” at the handle, and the grasping claw. The grasp of the claw was weak, making the straightforward method of using the tool to retrieve the bolt difficult, but not impossible.

Figure 2. The Claw.

**Magnet.** The magnet was the second tool that was capable of retrieving the bolt (see Figure 4). It consisted of a 35 ½ inch long PVC pipe that was 1 ¼ inches in diameter that was connected to another PVC pipe that was 12 inches in length. The two pieces of PVC pipe were joined by a spring that was 5/6 inch diameter and 8 inches long. A rope was laced through the top that hung 34 ½ inches. At the end of the rope was a 2-inch diameter magnet. The magnet was too weak to lift the bolt outright, but it could be used to drag the bolt. Using the magnet and loose string in combination, it was difficult, but possible, to retrieve the bolt.

Figure 4. The Magnet.

**Spatula.** The spatula was one of two tools that were not capable of retrieving the bolt. It consisted of a 49-inch long piece of flexible PVC pipe that was 5/8 inches in diameter had a plastic paint scrapper fastened to one end by three screws (see Figure 5). The other end had a less flexible PVC pipe that was 11 ½ inches long and 5/8 inch in diameter attached. At each of these ends was a 23 ½ inch long PVC pipe that would serve as the handles for the tool. The flexibility of the tool made the tool useless.

Figure 5. The Spatula.

**Ring.** The ring was the second tool that was not capable of retrieving the bolt. It consisted of a 48-inch long fiberglass rod that was 1/8 inches in diameter where at one end of the rod a thin rope was attached that was 44 inches in length (see Figure 6). At the end of the rope a 4 ½ inch long heavy-duty carabineer was tied; this carabineer served as the 'ring' that participants would use for 'hooking' the bolt. The shape of the ring made the tool useless.

Figure 6. The Ring.

**Self Report Measures.** Six items administered pre and post examined feelings of tension, ease, anxiety, self-confidence, nervousness, and overexcitement measured on five-point likert scales (1 = Not at all to 4 = Very Much So). Additionally post measures for 'how difficult was the task?' (1 = very difficult to 5 = very easy) and 'how frustrating was the task?' (1 = very frustrating to 5 = not frustrating) were recorded.

**Video Camera.** A handheld digital-video camera on a stationary platform was used to record tool switch behavior and allow for an objective measure of time.

## Design & Procedure

The study was an experimental design. Participants entered the laboratory individually and were given consent forms to review, after which, they were given a brief mood questionnaire. This was followed with a 10-minute audio recording of eyes closed guided meditation or eyes closed rest.

Following the 10-minute training participants received instructions for the creative problem-solving task. Participants were informed that they would be participating in a creative problem-solving task with the objective to remove a bolt from a box and bringing it across a red line using four experimenter-designed tools. Importantly, participants had to obey the following four rules: 1) you must stay within the red box when using a tool 2) you can only touch the red and black parts of the tool when in use 3) you can only use one tool at a time 4) you can switch tools back and forth at your own discretion. Any participant that had questions or needed clarification was given further instruction if necessary for understanding the task and rules.

The participants were informed that the camera would be recording tool usage. When a participant either solved the task or quit the camera was turned off and the participant then filled out questionnaires assessing mood, perceived frustration of the task, perceived difficulty of the task, and demographics information. Finally, participants were debriefed and thanked for their time.

## Results

The hypothesis was that meditation training would result in successful completion of the task. For those that failed to solve the task meditation would result in greater initial persistence, overall persistence, and fewer tool switches. Tool use behavior was also examined in order to determine favoritism in tool usage. No significant differences were found for mood,  $F < 1$ , frustration,  $F(1, 78) = 1.17, ns.$ , or task difficulty,  $F(1, 79) = 1.3, ns.$  The results revealed no significant difference in success rates between meditation (36.59%) and rest (35%),  $\chi^2(81) = .02, ns.$  Overall tool success rates were as follows: claw (20.99%), magnet (13.58%), spatula (0%), and ring (0%; see Figure 7 for results by condition).

Figure 7. Success rates by tools, split by condition.

Of the remaining 52 participants that failed to solve the task, 51 were used in the other analyses. One was removed due to lost data. The meditation condition ( $M = 60.44$  seconds,  $SD = 29.21$ ) compared to the rest condition ( $M = 43.62$  seconds,  $SD = 20.79$ ) spent significantly more time with the first tool,  $F(1, 49) = 5.65$ ,  $p < .05$ . No reliable differences were found between the meditation condition ( $M = 722.64$  seconds,  $SD = 534.2$ ) and the rest condition ( $M = 790.69$  seconds,  $SD = 539.06$ ) for total time spent,  $F < 1$ . No reliable differences were found between the meditation condition ( $M = 7.52$ ,  $SD = 3.72$ ) and the rest condition ( $M = 7.73$ ,  $SD = 3.52$ ) for tool switch behavior,  $F < 1$ .

In a series of follow-up analyses, we examined tool use behavior. Specifically, the time participants spent with the useful tools (i.e., tools that were successfully used to solve the task, the magnet and claw) and the useless tools (i.e., tools that no one could solve the task with, the spatula and ring), in order to, determine whether participants favored the useful over the useless tools. Post-hoc Tukey's HSD tests showed that meditators spent more time with the useful tools ( $M = 436.88$  seconds,  $SD = 420.07$ ) than the useless ones ( $M = 227.13$  seconds,  $SD = 227.62$ ),  $p < .05$ , and that resters had no reliable differences between time with the useful tools ( $M = 372.82$  seconds,  $SD = 310.02$ ) compared to the useless ones ( $M = 276$  seconds,  $SD = 303.56$ ),  $p > .05$ ; see Figure 8). In sum, success rates did not differ between groups, nor did overall persistence, or tool switch behavior, but those that meditated had a greater initial persistence, and spent more time with the useful tools than the useless tools, where resters did not differ in tool use preference.

Figure 8. Time spent with tool types by condition.

## Discussion

Although our hypotheses were not fully supported, the findings suggest that meditation training might promote some important behaviors useful in problem solving. One could view the enhancement in initial persistence as taking the time to get to know the problem, and spending more time with the useful tools might suggest that meditators were recognizing what tools appeared to be getting them closer to the goal. Nonetheless, problem-solving success did not differ between the groups, but was higher than anticipated with  $1/3^{\text{rd}}$  of both conditions completing the task. However, the  $1/3^{\text{rd}}$  success rate may be low enough to demonstrate the difficulty of the task, where ratings of task difficulty did not differ between groups. One might expect that the meditation training might improve mood or reduce frustration with the task since meditation is often associated with better mood and less anxiety (Brown et al., 2007), but the brevity of the training as seen in other studies using limited training measures does not consistently result in improvements in mood (Ramsburg & Youmans, 2011).

In order to gage persistence we had to eliminate those that had solved the task because their times would reflect time to solution, and not persistence. When we examined persistence among those that failed to solve the task, we found no differences between the groups, which might suggest that brief meditation training does not enhance persistence. However, when examining initial persistence we found that those receiving the meditation training spent significantly more time with their initial chosen tool, perhaps, suggesting a need to become more familiar with the problem before attempting the task with other tools.

Notably, of the four tools available to the participants, two of the tools could be used to solve the task (claw and magnet) and two were useless (spatula and ring). We found that participants in both conditions did not differ in the number of switches they made, suggesting similar levels of flexibility. However, a closer inspection of the amount of time with the various tools revealed that meditators spent more time with the useful tools, whereas, the resters had no reliable difference in how they spent their time attempting to solve the task. The increase in time for useful tools among meditators may have resulted from recognition of their value for solving the task, perhaps as a result of improvements in cognitive functioning. Conceivably, attentiveness for usability of one tool over another might lead those with meditation training to use the tools that appear to be more effective given that meditation training is associated with improved attentional functioning (Tang et al., 2007). Nonetheless, more research is needed to determine what aspects of cognitive functioning might most benefit from meditation training when faced with a problem-solving task and whether success rates might increase with extensive training.

A problem with the present study that makes further interpretation of the results difficult stems from the finding that meditators did not improve in overall problem success.

One admittedly post-hoc explanation might be related to the observation that succeeding in this particular problem solving task actually required that participants not only select the tools that made the task possible, but use them in non-traditional ways to retrieve the bolt. Research suggests that chunk decomposition and constraint relaxation can account for success with creative or insight problems when faced with an impasse (see Knoblich, Ohlsson, Haider, & Rhenius, 1999). Chunk decomposition relates to the ability to unpack chunks of information to where detailed approaches can be vested. Constraint relaxation involves the ability to reduce the severity of constraints that may occur when faced with a problem. These processes appear to be activated via successive failures that elicit further decomposition and greater constraint relaxation. To be a successful problem solver in the present study, a participant would need to relax the constraints associated with how the tool can be used because solutions require participants to use the useful tools in a non-normal fashion in order to achieve the goal (e.g., the claw's grasp is ineffectual, but with some maneuvering the claw could be used like a shovel). Additionally, problem solving success may depend on decomposition of chunks associated with the possible strategies that when chunked are unsuccessful, but when decomposed may provide novel strategies (i.e., a chunked strategy can involve many steps that are thought of as one process, but when the steps are isolated novel divergent approaches could be adopted by combining different steps from different strategies). More broadly, a participant would need to think divergently, which is not a process influenced by meditation training, although thinking divergently is a process associated with some eastern philosophies that utilize meditation training (see Dogen, 2007). Our participants were only exposed to a brief 10-minute meditation exercise absent eastern philosophical approaches that expound divergent thinking. As such, in the absence of an enhancement in divergent thinking, neither group could be expected to think more creatively.

## Future Research

The present study presented findings that may suggest cognitive improvements with some aspects of problem solving. However, the present study did not adequately determine what underlying mechanisms cognitive training via meditation influenced. Future research might investigate what components of cognitive functioning, influenced by meditation, are responsible for enhancing problem solving. For instance, past research has shown that meditation can enhance creativity (Jedrczak, Beresford, & Clements, 1985; Travis, 1979), attention (Lutz et al., 2009), memory (Kozhevnikov, Louchakova, Josipovic, & Motes, 2009), and self-regulatory functioning (Brown, Ryan, & Creswell, 2007), but less is known about the applicability of these benefits to problem solving. Understanding how the training influences performance will help in determining how the training might be used and whether certain aspects of the training should be emphasized over other options.

The present study utilized a unique physical problem-solving task, with the objective of determining whether meditation training could improve creative problem solving performance. The results of the experiment left more questions than answers, demonstrating the breadth of studies that could follow, which might better clarify the processes responsible for the benefits seen in the present study. For instance, a brief ten-minute training exercise may have produced some benefits to problem solving; one might infer that more extensive training might further enhance performance, where deliberate practice has been known to enhance performance amongst novices and experts (Ericsson et al., 1993).

## Abstract

Unlike peer nations' residents, Americans are less accepting of, and concerned by, (especially anthropogenic) climate change. Reinforced Theistic Manifest Destiny theory (RTMD; e.g., Ranney, 2012) explains many such "U.S.-exceptionalist" phenomena by combining geopolitical history with six belief constructs: afterlife, deity, nationalism, creation, evolution, and global warming. We assess predictions that climate change acceptance is increased by mechanism-explaining interventions. A 270-participant survey established widespread mechanistic ignorance, and an experiment with 149 other Americans (Californians and Texans) showed that a 400-word description of climate change's mechanism dramatically reduced ignorance and increased climate change acceptance. The mechanism, briefly, is: (a) Earth's surface absorbs (mostly visible) sunlight and subsequently emits *infrared* light, which (b) greenhouse gases selectively absorb and retain (because these molecules can become asymmetrical), so (c) heat energy leaves more slowly, warming Earth. Our intervention yielded desirable conceptual changes and science-coherent attitude changes. RTMD-predicted between-construct relationships were obtained and/or again replicated.

**Keywords:** Climate Change; Global Warming; Conceptual Change; Society; Science Education; Belief Revision.

In contrast to our exploding human population, many species are dwindling—often due to people's actions (e.g., hunting, degrading environments, and introducing non-native species). Still, many past effects pale compared to the threat of global climate change. (Nb. We will henceforth largely use the colloquial term, "global warming," although of course not *all* locations may exhibit warming due to human-enhanced greenhouse conditions.) In geologic time—on the order of 10,000 years or more—warming periods have consistently resulted in high levels of extinction (Mayhew, Jenkins, & Benton, 2008). Now, though, comparable warming is occurring over hundreds of years or less—posing a unique threat to many species' futures (cf. Harte & Harte, 2008), and direct threats to humans (particularly the poor)—such as increased risks of floods, droughts, and low crop yields (Kerr, 2007). Nothing, then, seems to exceed the importance of researchers finding ways to help people accept that anthropogenic global warming is (1) occurring, and (2) crucial to quickly address (Harte & Harte, 2008).

This urgent state is due to dramatic, human-caused atmospheric greenhouse gas increases from pre-industrial levels (about 260 years ago); for instance, methane is up by 150% and carbon dioxide is up by 40%. These levels are

*accelerating*, and may easily cause rapid mass extinctions (Malcolm et al., 2006), as with prior fast warmings. Fortunately, if humans act quickly, we may be able to conserve much of the current biosphere (Harte & Harte, 2008).

Sadly, U.S. attitudes clash with the 97% of actively publishing climate scientists who accept global warming's tenets (Anderegg, Prall, Harold, & Schneider, 2010). Leiserowitz, Maibach, and Roser-Renouf (2010) report that only 57% of the U.S. accepts global warming as occurring, and only 47% accepts it being "caused mostly by human activities." The U.S. accepts *both* less than do similarly developed "peer" nations. Indeed, among 33 peers *and* non-peers, only Indonesia, South Africa, and Nigeria rated global warming as less "serious" than the U.S. (Leiserowitz, 2007). Given global warming's potentially disastrous, irreversible effects, increasing Americans' global warming acceptance seems a worthy goal (Ranney, 2012). In the next subsection, we highlight a theory (RTMD) designed to explain U.S. exceptionalism regarding scientific, religious, and nationalistic affinities—especially the marked divergence in climate beliefs noted above. We then describe two empirical studies that test the RTMD-inspired notion that science instruction may powerfully rectify false beliefs about climate change.

## Theory: Reinforced Theistic Manifest Destiny

As Ranney (2012; Ranney & Thanukos, 2011) and other researchers have discussed, Americans are clearly outliers compared to peer nations' residents. Beyond global warming acceptance, Ranney describes other dimensions of American exceptionalism (e.g., regarding guns, murders, prisoners, military costs, executive salaries, income variability, teen pregnancies, infant deaths, health inefficiency, evolution acceptance, biblical literalism, piety, and beliefs in God and an afterlife). He also proposed the Reinforced Theistic Manifest Destiny (RTMD) theory to explain how a nation's collective theistic (and related) beliefs are reinforced—militarily, economically, etc. (Ranney, 2012; Ranney & Thanukos, 2011). RTMD focuses on beliefs and attitudes regarding the six inter-related constructs shown in Figure 1. The theory predicts that (1) acceptances of *creation*, *nationalism*, a *deity/dieties*, and an *afterlife* positively correlate, (2) acceptances of *evolution* and *global warming* positively correlate, and (3) constructs in (1) negatively correlate with those in (2)—partly because creation and evolution incohere. Among other offered explanations, RTMD explains the U.S.'s low acceptance of both evolution (Mil-

ler, Scott, & Okamoto, 2006) and global warming, compared to peer nations. At its heart, RTMD posits that unparalleled U.S. military and economic success—especially in WWI and WWII—has bolstered U.S. nationalism and theism, inhibiting American acceptance of evolution and global warming (Ranney, 2012). (In brief, Americans feel most reinforced for thinking “God is on our side.”)

Figure 1. RTMD theory extends an often implicit “received view” (the three bold ovals; Ranney, 2012) of modest U.S. evolution acceptance with three extra constructs (non-bold ovals), such as global warming. Solid/dashed lines respectively represent coherent/conflicting conceptual links.

To date, RTMD has been assessed with seven data sets from the U.S. and one from Canada. RTMD predicts the directions of the 15 possible correlations among Figure 1’s six constructs; only the five main theoretical links are shown. Empirically, the 15 correlations virtually always exhibit the directions RTMD predicts (Ranney, 2012). RTMD theory also predicts that a change in one’s global warming acceptance may affect the other five variables—especially evolution acceptance. Analyses of such correlation-change predictions, though, exceed this piece’s space and scope.

## Mechanistic Knowledge and Climate Attitudes

RTMD notes the negative correlations between science-based and more faith-based constructs, and suggests that increased scientific knowledge may enhance positive attitudes towards evolution and climate change. Acceptance beliefs largely follow understanding, given variation in both. Thus, while evolutionary acceptance might be uniformly high or low in a certain classroom or campus, evolutionary biologists largely accept evolution more than do “Intro to Bio” students (Shtulman & Calabi, 2012). Therefore, low global warming acceptance may well be related to a lack of understanding. Consider humanity’s adoption of a heliocentric model of our solar system over geocentrism. Although geocentrism had (or has) its appeal, an understanding of gravity and orbits renders geocentric arguments hard to accept—or even “silly.” Similarly, we might expect that increasing individuals’ knowledge of the mechanism of global warming may help them accept the “less desirable” model of the world in which global warming is occurring (Ranney & Thanukos, 2011; cf. just world theory, e.g., Feinberg & Willer, 2011). Our approach to environmental conceptual and belief changes thus differs from most other efforts, which don’t focus as heavily on understanding the mechanism of the greenhouse effect (e.g., Al Gore’s Climate Project). Ours appears to be the first work to examine the extent to which one’s mechanistic global warming understanding affects relevant attitudes and support for climate policies.

Our research group is carrying out experiments and surveys that assess the hypotheses that (1) a proper understanding of global warming is rare, but (2) enhancing such understanding has desirable effects, such as increased global warming acceptance. There are many global warming education efforts, yet it is difficult to find an explanation of the basic physical/chemical mechanisms involved that is appropriately complete (see below) and yet not filled with too much extra detail (Ranney, Clark, Reinholz, & Cohen, 2012). We are not sure why this mechanistic pedagogical lack exists, but suggest that many would-be climate educators (1) do not adequately understand the mechanism themselves, and/or (2) fear that Americans are incapable of learning the basic scientific principles behind the greenhouse effect; others may (3) doubt that a scientific understanding would make much difference in our attitudes and policies towards global warming, and still others may (4) despair about the political, financial, or even agnotological (e.g., deceptive) elements of the quandary, suggesting that “the masses just can’t learn this.” But the aforementioned survey data suggest that peer nations’ residents accept (and fear—e.g., anthropogenic) global warming more than Americans do, and humanity has accepted other difficult ideas that were heavily suppressed by political or economic powers—such as heliocentrism and the links between tobacco smoke and severe illnesses. Likewise, we predict that a mechanistic warming explanation *may* help many people appreciate the soundness of climate change’s science—driving greater acceptance, concern, and imperative action.

Unless you read (and recall) this piece’s abstract, it is not likely that you can explain (even quite basically) the physical mechanism by which global warming occurs—as was true of most of our research team prior to our studies. Indeed, part of the present piece’s motivation stems from dozens of interviews the first author carried out with colleagues and acquaintances. Responses were often embarrassing and rarely accurate. So, imagine that you were chatting with a physicist/chemist, and she eyeballs you and asks, “How would *you* explain global warming’s mechanism?” Please take 30 seconds to answer this query before reading on.

Now that you’ve pondered global warming’s mechanism, please visit the abstract’s points (a) through (c). Did your explanation include these fundamental mechanistic aspects? In contrast to our abstract’s directly *mechanistic* explication (which is much abbreviated), many people articulate global warming’s *temporal precursors*, such as over-industrialization, rather than the fundamental mechanism that greenhouse gases are transparent to the sun’s incoming visible (i.e., “colors of the rainbow”) light, yet largely opaque to the infrared light that the Earth radiates. Other people often articulate global warming’s *effects*—such as increasing mean global temperatures, sea level increases, extinctions, or melting icecaps—but draw a blank mechanism-wise. Yet others focus on atmospheric features that don’t, or negligibly, explain global warming (e.g., ozone layer depletion). Many people who are familiar with both global warming’s potential precursors (e.g., more CO<sub>2</sub> emis-

sions) and effects cannot describe the *causal mechanism* between them. (Nb. Only one of the many dozens of interviewees knew that greenhouse gas molecules exhibit at least a transient electric dipole moment—e.g., via vibrations, bending, etc., to become asymmetrical—as CO<sub>2</sub> and CH<sub>4</sub> can, but O<sub>2</sub> cannot.)

Given the relations that RTMD theory coordinates, we infer that many Americans who *accept* global warming do so with sub-scientific rationales, and many who *reject* it do so by repressing the science due to religiously or nationalistically motivated reasoning. Thus, if Americans could grasp global warming's science, that might offer a better basis for shifting or strengthening their attitudes. Given that our dozens of informal interviews suggest the widespread lack of a mechanistic global warming understanding among U.S. residents, we predicted that this lack undermines U.S. global warming acceptance. Unfortunately, surveys about global warming knowledge (e.g., Leiserowitz, Maibach, & Roser-Renouf, 2010) rarely ask for mechanistic knowledge and often focus on recognition (thus likely overpredicting what is known by non-climatologists). Therefore, Study 1 below assessed our hypothesis that a broader, more representative sample than those in the informal interviews might also show a modest understanding of global warming's mechanism. Then, in Study 2, we assessed whether a brief explication of the mechanism might be successful in markedly enhancing both global warming knowledge and acceptance regarding anthropogenic climate change.

### Study 1: Gauging Global Warming Knowledge

Prior studies have documented numerous difficulties in understanding global warming (e.g., Shepardson, Niyogi, Choi, & Charusombat, 2011; Bord, Fisher, & O'Connor, 1998). Herein, though, we focus on less-studied difficulties in *mechanistic* understanding, three of which we believed were most critical to understanding the greenhouse effect (as highlighted in the abstract): (a) differentiating types of light/radiation, (b) understanding how the greenhouse effect depends on infrared light's selective absorption by greenhouse gases, and (c) understanding how that consequently warms the troposphere, water, and ground. To test the hypothesis that an understanding of global warming is indeed related to acceptance, we needed to determine whether the above conceptual difficulties were prevalent in a general adult population. Thus, we designed and administered a survey of global warming attitudes *and* understandings.

### Method: Participants, Design, Procedure, Materials

We collected 270 anonymous surveys from park visitors ( $n = 201$ ) and community college students ( $n = 69$ ) in San Diego. Random intercept sampling techniques were used for the park visitors; the community college students agreed to fill out the survey during a scheduled class break. A \$5 gift card compensated each participant. We refrain from offering contrived hypothesis tests below, simply reporting percentages—as is common with survey data. The full survey took 10-15 minutes to complete. We report here on a subset of

items: (1) 20 policy preference Likert items (e.g., “How much effort do you want the federal government to put into X?”), (2) two global warming belief items, (3) six short-answer global warming knowledge questions, (4) 13 items on possible causes of global warming (e.g., participants were to label Y as a major/minor/non- cause of global warming), and (5) four items gauging respondents' willingness to make personal sacrifices for specific climate policies. Short answers were coded and scored with a rubric that showed high inter-rater reliability (mean Cohen's  $\kappa = 0.74$ ).

### Results and Discussion

The data support our hypothesis that Americans rarely understand global warming's mechanism. When asked to explain “the basic physical, chemical, or biological mechanism of global warming,” only 32 participants (12%) referenced gases in the atmosphere (e.g., emissions, CO<sub>2</sub>, or pollution) trapping heat—which is merely a partial understanding. Of these 32, only four (1%) attempted to differentiate types of energy (or light). Not a single participant (0%) mentioned either correct absorption(s) or the difference (input/output asymmetry) between visible and infrared light, which is the crux of understanding the greenhouse effect. Notably, only eight participants (3%) even named the greenhouse effect. Many responses included possible *causes*, yet few included possible mechanisms—and the item's median score was 0.

Problematic conceptions were also prevalent. For instance, in answering our question about global warming's mechanism, 42 participants (16%) claimed that the destruction of the atmosphere or ozone layer was letting in more heat, thus causing global warming. This finding echoes the results of previous work (e.g., Bord, Fisher, & O'Connor, 1998). Indeed, on a subsequent “possible cause” item, 201 participants (74%) incorrectly believed that ozone depletion was a major cause of global warming, but only 81 (30%) knew that livestock are a major cause of global warming.

Despite this poor showing regarding global warming knowledge, many people were willing to accept global warming and its anthropogenic origins. In particular, when the responses “mildly agree” and “strongly agree” are combined, 217 people (80%) agreed with the statement, “I am certain that global warming (i.e., climate change) is actually occurring,” and 208 participants (77%) agreed that “human activities are a significant cause of global warming.” Although this willingness to accept global warming is higher than the averages found on most national surveys, there appears not to have been a prohibitive ceiling effect.

Crucially, experimenter-scored knowledge of the mechanism significantly correlated with peoples' willingness to accept global warming as both real ( $r = .22, p = .0002$ ) and anthropogenic ( $r = .17, p = .005$ ). Also importantly, anthropogenic climate change acceptance significantly predicted (via ordinal models) *all four* survey items about willingness to sacrifice ( $\chi^2(4) > 32, p < 0.001$ )—and one's knowledge score significantly predicted two of these ( $\chi^2(1) > 3.8, p < 0.05$ ). In addition, all 15 correlations among the six RTMD

constructs fell in the predicted directions—replicating previous findings—and 13 of the 15 were significantly different from zero at  $p < .01$ ; likewise, evolution/creation acceptance strongly predicted global warming knowledge and acceptance (as occurring *and* anthropogenic)—notably, even more strongly than political party.

In sum, these U.S. respondents clearly knew little about the mechanism of the greenhouse effect—the anthropogenic increase of which is the basis for global warming. This is true even of individuals who accept the reality of global warming, which ought give us pause. The mere acceptance of global warming, even absent knowledge of its basic science, appears to yield warranted climate policy attitudes. We predict, though, that skeptically evaluated knowledge of a basic mechanistic account should enhance that precursory global warming acceptance. (Consider someone who might accept evolution without even having a rudimentary understanding of how organisms procreate!) Scientific literacy ought to mean that people seek out causal explanations, just as those who deny global warming—should they be believed—ought to explain the mechanism by which our planet would be unaffected by massive additions of greenhouse gas emissions. More directly, Study 1 shows that, in crucial cases, veridical knowledge has a clear relationship to one’s willingness to sacrifice. It seemed incumbent upon us, then, to begin developing interventions meant to improve Americans’ understandings of the basic physical-chemical global warming mechanism—as described in Study 2.

## Study 2: Learning and Increased Acceptance

Drawing on past research on both physics cognition and the Numerically Driven Inferencing paradigm (NDI; e.g., Garcia de Osuna, Ranney, & Nelson, 2004), we hypothesized that a small amount of targeted information could yield dramatic conceptual changes—ultimately including changes in attitude and acceptance. In the NDI paradigm, people are asked to estimate the value of a quantity, and they are later told its true value. By having individuals “put their cards on the table” before receiving the true value, we inhibit hindsight bias and post-hoc rationalization, and the impact of the information is thus increased (Rinne, Ranney, & Lurie, 2006). Here we report on a similarly compact and empirically grounded intervention with a 400-word text that highlights the three key conceptual pieces noted in Study 1’s introduction (labeled a-c). See Ranney et al. (2012) for the full text. Our most recent work combines NDI and RTMD, utilizing misleading “anti-climate change acceptance” numeric quantities—yielding notable shifts in attitudes and self-rated knowledge—but this is outside the scope of this paper.

### Method: Participants, Design, Procedure, Materials

For Study 2, 103 University of California, Berkeley, and 46 University of Texas, Brownsville, undergraduates were randomly assigned to one of two groups: “sandwich” or “no-pretest.” Sandwich group participants: (1) both provided an explanation of the greenhouse effect (effectively “putting their cards on the table”) and filled out knowledge and atti-

tude surveys, (2) read a 400-word explanation of the mechanism of the greenhouse effect and gave a rating of experienced surprise, and (3) were re-tested on their knowledge and attitudes (with a posttest identical to the pretest). No-pretest (or “open-faced”) group participants completed only (2) and (3) above. Thus, (1) and (3) can be thought of as “bread” and (2)—the explanation—is the “jam” of our design. The no-pretest group offers a between-subjects contrast via their posttest, obviating test/re-test concerns about experimenter demand regarding the sandwich group. Just before leaving the experiment, all participants also filled out a demographic questionnaire. Surveys were again anonymous, as in Study 1.

Below, we report data from the 85 Berkeley and 41 Brownsville students who completed the survey as intended and had been U.S. residents for ten years or more (because we expressly consider *U.S.* exceptionalism/nationalism). Of the Berkeley data, we analyzed 43 no-pretest (open-faced) surveys and the pretest part of 42 sandwich surveys—but due to anticipated time constraints, only 30 sandwich post-tests could be completed/obtained. Of the Brownsville data, we analyzed 22 no-pretest and 19 sandwich surveys. To be conservative, all between-group t-tests were Welch-method adjusted for unequal variance and sample size. All hypotheses below were clearly stated as *a priori* ones and were replicated across our two samples except where noted.

The attitude survey used 12 items (on 9-point Likert scales) to assess the six RTMD constructs. True knowledge of global warming was assessed based on (1) three written responses by participants and (2) (on the posttest only:) two fill-in-the-blank items about the types of light (visible, infrared, etc.) involved in the greenhouse effect. *Self*-reports of knowledge were also reported on a 9-point Likert scale.

## Results and Discussion

### The Crucial Global Warming Mechanism Was Learned

Even our rather sophisticated samples initially exhibited incorrect or non-normative understandings of the greenhouse effect’s mechanism (e.g., on the roles of ultraviolet light, the ozone layer’s depletion, non-greenhouse-gas pollution, and the reflection of incoming light). Most notably, not a *single* pre-test explanation mentioned different light/radiation types or atmospheric retention time, despite an explicit prompt to explain any differences between the energy traveling toward and away from Earth. However, after reading the 400-word description, 61% of the Berkeley participants across both groups correctly answered that “infrared” light was emitted from Earth (in its fill-in-the-blank space), as did 55% of the Brownsville students who responded.

Beyond the blank-filling items, we statistically analyzed individuals’ *qualitative* explanations—creating scoring rubrics for three central concepts: (a) differentiating between the types of light entering and exiting the atmosphere, (b) atmospheric greenhouse gases’ interactions with radiation, and (c) the increased atmospheric retention time of energy. Inter-rater reliability was again high (weighted  $\kappa = 0.71$  based on about one-third of the Berkeley data;  $\kappa = 0.67$

across the full Brownsville dataset). Table 1 shows the percentages of all possible points: overall, we found dramatic knowledge increases (doublings, triplings, or more), which were significant for all subscales—both within-subjects for the sandwich condition, and between-subjects from the sandwich pretest to the no-pretest condition's posttest, ( $p < .05$  for all six improvement possibilities).

Table 1. The mean percentage scores for each of the three assessed global-warming constructs (with greenhouse gases = GHGs), for each test and sample (for California;Texas). All improved from pretest (\*:  $p < .05$ ; \*\*:  $p < .005$ ).

Group & Test (& means)	Light	GHGs	Energy
Sandwich Pretest (means <sub>CA;TX</sub> = 33%;11%)	33%; 7%	39%;16%	28%;11%
Sandwich Posttest (means <sub>CA;TX</sub> = 69%;37%)	78%;36% **,*	83%;39% **,**	47%;35% *,*
No-pretest Posttest (means <sub>CA;TX</sub> = 66%;49%)	66%;43% **,**	74%;54% **,**	57%;51% **,**

### Global Warming Acceptance Via Mechanistic Learning

It may seem quite remarkable, but participants' global warming acceptance increased dramatically after our brief intervention, as predicted. To assess this, we used all of the 73 Berkeley posttest ratings in a paired t-test, and used imputation for pretest scores for the no-pretest group. (In particular, the full set of 42 pretest ratings was used to avoid sampling bias.) We found a significant change in global warming acceptance on the posttests, as compared to pretest measures ( $t(72) = 2.28, p = .01$ ). This result was replicated with the Brownsville surveys ( $t(39) = 4.24, p < .0001$ ). In addition, although Study 2's statistical power was rather limited, the correlation matrices for the RTMD variables again largely supported RTMD theory—as was certainly found in Study 1 and all prior studies. The relationship between knowledge and attitudes was also reflected in Berkeley students' naïve pre-test data, in which participants' *self-perceived* ratings of their own global warming knowledge correlated significantly with their global warming attitudes ( $r = .39, p = .01$ ). This was not the case with Brownsville students ( $r = .15, p = .55$ ), which may be reflective of their overall lower self-perceived knowledge.

Please recall that we had also predicted a between-conditions difference in surprise ratings due to reduced hindsight biases among the sandwich participants. The difference for Berkeley students was at the significance borderline ( $t(42.08) = 1.65, p = .05$ ); the surprise ratings only reached "6" in the no-pretest condition (out of 9, with "5" being "somewhat surprising"), but were as high as "9" (i.e., "extremely surprising") in the sandwich condition. Among Brownsville students, surprise was uniformly higher, with a numerically similar difference between conditions, although this result was not significant ( $t(38.1) = 0.92, p = .18$ ).

### Conclusions from Study 2

This experiment replicates and extends the findings noted earlier (from prior interviews and Study 1), such that even

rather well-educated people initially held mostly non-normative understandings of global warming's mechanism. Only 400 words later, though (roughly the duration of a TV commercial break), dramatic increases were observed in (1) mechanistic knowledge and (2) global warming acceptance. (Further, the increases were found in divergent U.S. states and colleges.) Differences in surprise ratings between the sandwich and "no-pretest" ("open-faced") groups further support the notion that eliciting an explanation or theory prior to offering information *increases* surprise and *reduces* post-hoc rationalization and hindsight bias. (On surprise, see Clark & Ranney, 2010; Munnich, Ranney, & Song, 2007.)

## General Discussion

Of Study 1's 270 participants, none could fully explain that (a) visible light makes its way to Earth's surface where it is (mostly) absorbed and emitted later as infrared light, (b) this infrared light is largely (actually, 90%) absorbed by greenhouse gases before reaching outer space, and (c) this slows energy loss and warms Earth. (Ranney calls the unimpeded 10% the "Goldilocks tithe.") While others (e.g., Leiserowitz, 2007) have shown aspects of U.S. ignorance, we extend these results to mechanistic understandings of the greenhouse effect. If our sample even vaguely represents the U.S. public, then they rarely understand global warming's mechanism. Further, such knowledge *does* relate to policy preferences, willingness to sacrifice due to legislation, and beliefs about (anthropogenic) climate change's reality. We suggest that prior works' inattention to this mechanism may be because it is scientifically uncontroversial relative to the effects, mitigation strategies, and other causes re: climate change. However, it seems that mechanistic knowledge may play a key role in successful climate policy ventures.

Just as knowing "how reproduction works" supports evolutionary acceptance (cf. Shtulman & Calbi, 2012), our studies show that a mechanistic global warming understanding (e.g., a-c above) supports *its* acceptance. Study 2 showed that we increased students' acceptance by increasing global warming knowledge. Space prohibits a full treatment of this, but a new study further shows that, after providing people with misleading, cherry-picked facts, we caused them to discount climate change (dropping from 6.5 to 5.9 on a 9-point scale) with a dramatic, concurrent drop in their confidence in their knowledge (plummeting from 5.0 to 2.9, on a 9-point scale). Thus, as the nefarious are well aware, empirical data *do not always* increase acceptance, global coherence, and self-confidence in one's understanding.

In short, work spawned by the Reinforced Theistic Manifest Destiny theory (Ranney, 2012; Ranney & Thanukos, 2011) regarding concerns about U.S. exceptionalism led us to find a successful way to enhance wisdom about the greenhouse effect's mechanism. That is, we found that instruction focused on a mere 400 words of text dramatically increases undergraduates' global warming understandings *and* increases their mean acceptance of anthropogenic global warming. We suspect that our instruction is effective in that it addresses head-on the implicit mystery of how ener-

gy—as visible light—can easily get close to Earth’s surface and troposphere, yet has difficulty leaving that surface/troposphere (as absorbed, intercepted infrared light). Future research will determine our intervention’s longevity, among other attempts to better comprehend the landscape of the cognitions and emotions regarding global warming. As the studies above demonstrate, insights from cognitive science show much promise for tackling the challenges for climate-relevant education in the U.S. and abroad.

## Abstract

We tested the hypothesis that threatening situations enhance creativity. 60 participants viewed a series of photographs and rated them on level of threat. They then wrote two short stories: one based on the photograph they rated as most threatening, and the other based on the photograph they rated as least threatening. The stories were rated for level of creativity. Paired samples t-tests revealed that stories based on threatening pictures produced a higher degree of creativity than those based on non-threatening pictures. Theoretical frameworks consistent with these findings are discussed.

**Keywords:** Cognitive tuning, creativity, existential anxiety, inspiration, mood, narrative, story telling, threat.

## Introduction

Creativity can be defined as the ability to generate ideas, interpretations, or solutions that are both novel, and meaningful or appropriate (Sternberg *et al.*, 2010). Creativity is widely associated with personal fulfillment (May, 1975; Rogers, 1959), self-actualization (Maslow, 1959), and with maintaining a competitive edge in the marketplace. Creative therapies are useful in clinical contexts, including the assessment and resolution of conflict (Goldblatt *et al.*, 2011), dementia (Hannemann, 2006), self-esteem (Anzules, Haennl & Golay, 2007), and stress reduction (Curl, 2008). In addition, creative individuals tend to have higher levels of life satisfaction (Tan, Ho, Ho, & Ow, 2008), emotional intelligence (Noferesti & Alghorabaie, 2011), and intelligence in general (Batey & Furnham, 2009). These findings suggest that creativity is, generally speaking, a positive attribute with numerous constructive byproducts.

However, there are significant drawbacks to creativity (Cropley, Cropley, Kaufman, & Runco, 2010; Ludwig, 1995). Generating creative ideas is time consuming, and a creative solution to one problem often generates other problems, or has unexpected negative side effects that may only become apparent after much effort has been invested. Creative people often reinvent the wheel, and may be more likely to bend rules, break laws, and provoke social unrest (Cropley, Kaufman, & Cropley, 2003; Sternberg & Lubart, 1995; Sulloway, 1996). They tend to be more emotionally unstable and prone to affective disorders such as depression and bipolar disorder, and have a higher incidence of schizophrenic tendencies than other segments of the population (Andreason, 1987; Flaherty, 2005; F. Goodwin

& Jamison, 1990). Computational models suggest that there is a detrimental impact on society if either the ratio of creative to relatively uncreative individuals is too high, or if the creative individuals are *too* creative (Gabora & Firouzi, 2012; Gabora & Leijnen, 2009; Leijnen & Gabora, 2009).

There is also preliminary evidence that situations that are demanding, threatening, or involve conflict, put one in a more creative state of mind. For example, it has been shown that individuals who are in the midst of conflict set broader and more inclusive cognitive categories (De Dru, Carsten & Nijstad, 2008). Creativity is positively correlated with aggression (Tacher & Readdick, 2006), group conflict (Troyer & Younggreen, 2009) anxiety (Carlsson, 2002), and dishonesty (Gino & Ariely, 2011). Finally it has been found that negative affect leads to greater creative output (Akinola, Mendes, 2008).

This study further investigates the hypothesis that threatening situations put one in a more creative state of mind. Specifically, it assesses whether stories written in response to threatening stimuli are more creative than stories written in response to non-threatening stimuli.

## The Study

### Participants

Participants ( $n = 60$ ; 19 M, 41 F) were recruited for this study through the University of British Columbia (Okanagan campus) course credit for research participation program used in introductory psychology classes. Participants received 1% added to their overall course grade.

### Stimuli

Participants were shown 15 photographs depicting situations that had been independently classified as either threatening or nonthreatening by both experimenters. Classification was determined by assessing whether a normal individual would feel significantly at risk of harm or death if they were in the scenario depicted by the photograph. The photographs classified as 'threatening' were deemed to be threatening not directly, but indirectly, in the same sense that one feels threatened by a war movie or horror film.

Examples of the threatening and non-threatening photographs used to generate stories in this study are given in Figures 1 and 2.

Figure 1. Example of non-threatening photograph.

Figure 2. Two examples of threatening photographs.

## Procedure

The participants were asked to rate each photograph according to how threatening they believed it to be on a 7-point Likert scale. Each participant was then given 30 minutes to write two short stories: one about the photograph that was rated by that participant as most threatening, and one about the photograph that was rated by that participant as least threatening. If two photographs were rated as

equally threatening, the photograph that was presented first in the sequence was used. To guard against order effects, both story order and picture order were counterbalanced.

## Raters

Four raters were University of British Columbia undergraduates who were enrolled in an advanced psychology research methods and statistics course. They are referred to as *student raters*. They consisted of three females and one male.

The fifth rater was a well-known and extensively published fiction author who was not reimbursed for his participation. He is referred to as the *expert rater*. He was male.

## Rating

Raters were trained to evaluate participant responses using a previously developed rubric for assessing story creativity, the 'Creativity' portion of the Wisdom Intelligence Creativity Synthesized (WICS) rubric (Sternberg, 2005; Sternberg *et al.*, 2010, 2012), and a set of stories that had previously established creativity ratings. The WICS rubric assesses story creativity on the basis of evidence of the respondent's ability to provide novel yet meaningful ideas, narratives or interpretations of situations, or solutions to problems, or to view situations and events in a new and meaningful way.

Raters practiced on the sample stories until their ratings on these sample stories correlated significantly with these stories' previously established creativity ratings.

## Results

The creativity ratings provided by the expert rater were significantly positively correlated with the creativity ratings provided by the student raters, as shown in Table 1.

Table 1: Bivariate correlation between expert rater and each of the four student raters.

	Rater One	Rater Two	Rater Three	Rater Four
Non-threatening	.289*	.454**	.286*	.313*
Threatening	.376**	.156	.368**	.477**

\*Significant at < .05; \*\*Significant at < .01.

Intraclass correlation was used to assess the level of agreement amongst all five raters. They were significantly in agreement, as shown in Table 2.

Table 2. Inter-class correlation between all raters.

	ICC	Value	Sig.
Single Measures	.430	8.542	.001
Average Measures	.883	8.542	.001

We created two rater groups: the average of all the raters' scores, as well as the average of the two most central raters,

for each of the stories. The central raters were selected by dropping the raters with the highest and lowest means, and then selecting from the remaining three raters the two whose mean ratings were closest to one another. We conducted a paired samples t-test between stories based on threatening pictures, and stories based on non-threatening pictures, for both rater groups. The mean creativity scores for stories generated in response to non-threatening and threatening stimuli are shown in Figure 4.

Figure 4. Mean creativity scores for stories generated in response to non-threatening and threatening stimuli.

The results indicate a high level of agreement between raters ( $p = .001$ ) and support for our hypothesis. As shown in Table 3, using both the average of all raters, as well as the two central raters, paired sample t-tests revealed that stories based on threatening pictures were rated as significantly more creative than those based on non-threatening pictures ( $p < .05$ ).

Table 3. Paired samples t-tests.

	t-value	SE	Cohen's <i>d</i>	Sig.
All Raters	2.08	.077	.269	.041
Central Raters	2.29	.101	.296	.026

## Discussion

These results support our hypothesis that stories written in response to threatening photographs elicit a higher degree of creativity than those written in response to non-threatening photographs. Several theoretical frameworks are consistent with and could help explain these findings.

One kind of explanatory framework comes from creativity research. It is widely assumed that the creative process involves *searching* through memory and/or *selecting* amongst a set of predefined candidate ideas. For example, computer scientists have modeled the creative process as a heuristic search (e.g., Simon, 1973, 1986). In psychology, there is much evidence for, and discussion of, the role of *divergent thinking* in creativity (Guilford, 1968; for a review see Runco, 2010). Divergent thinking is presumed to involve the generation of multiple, often unconventional, possibilities. When construed from this perspective, the creative process often goes hand-in-hand with the notion of selection, since if you come up with

multiple alternatives you eventually weed some of them out. Indeed, many well-known theories of creativity, such as the Geneplore model (Finke, Ward, & Smith, 1992), and the Darwinian theory of creativity (Simonton, 1999) involve two stages: the generation of possibilities, followed by the exploration and ultimately selective retention of the most promising of them.

However, there are strong neurobiological (Gabora, 2010a), experimental (Gabora, 2010b; Gabora, O'Connor & Ranjan, in press), and theoretical (Gabora, 2005, 2007), reasons to believe that the generation stage of creative thinking may be *divergent* not in that it moves in multiple directions or generates multiple possibilities, but in the sense that it produces a raw idea that is vague or unfocused, and that requires further processing to become viable. Similarly, the exploration stage of creative thinking may be *convergent*, not in ordinary sense that it entails selecting from amongst alternatives, but in the sense that it entails considering a vague idea from different perspectives until it comes into newly defined focus. In other words, the terms 'divergent' and 'convergent' may be applicable to creative thought in the sense of going from well-defined to ill-defined, and *vice versa*. Although a particular creative thinking process *may* involve search or selection amongst multiple well-defined possibilities, it *need* not, and moreover, that *selection* need not figure prominently in a general theory of creativity.

According to this alternative view of creativity, creative individuals wrestle with those issues or ideas that are, for them, in a state of *potentiality*. An artist might wrestle with how to capture the feeling of a particular landscape, and a writer might wrestle with depicting how events in an imaginary world would unfold. Over time, creative ideas come to assume a form that is more fully *actualized*, or well-defined, as they are considered from different perspectives in accordance with the constraints of the domain in which they are expressed. By giving form to that which exists in a state of potentiality, the individual gains a richer understanding and appreciation of it, as well as a sense of control or mastery over it.

Central to this view of creativity is the notion of a *worldview*. The term worldview is used to refer to one's internal model of the world, as well as one's values, predispositions, and habitual patterns of response (Gabora, 2000, 2008; Gabora & Aerts, 2009). Each idea the creator comes up with is construed as a different expression of the same underlying core network of understandings, beliefs, and attitudes. Thus an individual's outputs are inter-related, and potentially pave the way for one another. By adopting the notion of a worldview, our account places equal emphasis on external creative outcomes and the internal cognitive and emotional restructuring brought about by the creative process. The cognitive reorganization and personality dynamics (e.g., involving wellbeing, self-discipline, or self-discovery) are viewed as the internal, less readily measurable, but equally important, counterpart to external manifestations of the creative process. The

transformation that occurs on canvas or on the written page is mirrored by a sense of personal, cognitive transformation and self-discovery from within.

In the case of our study, this alternative theory suggests that the threatening stimuli created a dichotomy in terms of one's understanding of the world. On the one hand, we believe that the world is a just and fair world, and that we, as individuals, are deserving of just and fair treatment. However, the threatening stimulus confronts this conception by imposing upon us a negative reality that threatens our internal model of how the world operates. In response to this, we tap into our creative potential and hone in on a suitable explanation for the threat's existence. This is done in an attempt to reconcile the worldview dichotomy, and impose a sense of meaning and understanding as to why this negative reality exists, ultimately forging a new and cohesive worldview structure.

These findings are consistent with the previously mentioned literature on the dark side of creativity. The positive correlation between negative affect and creativity (Akinola & Mendes, 2008) gives credence to the notion that creativity can arise from worldview disequilibrium, that is, from a schism between one's reality and one's internal conception of reality. In the case of negative affect, one's reality is that one is experiencing unpleasant and unsettling emotions; however, the internal conception of reality is predicated on the notion that one should be happy. In response to this dichotomy, the creative process helps to create a new, cohesive worldview structure that reduces negative affect (e.g., Curl, 2008).

These findings can also be interpreted in terms of the cognitive-tuning hypothesis (Schwarz, 2002). This theory posits that our mood mirrors our surroundings, and mood-states in turn, affect how information from the environment gets processed. In the case of a negative mood-state, one narrows attention and focuses on the negative environment. One then becomes more motivated to appropriately cope with the negative mood, and engage in bottom-up processing of the environment to understand the factors underpinning the negative environment. Conversely, a positive-mood state does not require an in-depth assessment of the underpinning factors; thus, one engages in top-down processing, and uses heuristics to understand the environment. In terms of creative output, the bottom-up processing used in negative mood-states allows for a more in-depth analysis of the environment, which can lead to more novel interpretations of its underpinning factors. The positive-mood state does not necessitate this in-depth analysis; thus a common, less novel narrative is developed. In the study reported here, the threatening photographs may have induced a negative mood-state, and the non-threatening photographs may have induced a neutral or positive mood-state, with the ensuing impact on information processing and creative output.

To best of our knowledge, this paper is the first study to directly assess the role of threatening stimuli on creative output. However, the study has some weaknesses and

limitations. First, the photographs used were not drawn from the International Affective Picture System. Although the photographs used in the study did, on a qualitative level, hold a high degree of consistency in terms of arousal and valence, future studies should consider using standardized photographs. Furthermore, due to time constraints, participants were limited to 15 minutes of writing time per story. It is possible that, given adequate time, we could see a convergence of creative output. Despite these limitations, we believe the study yielded some highly intriguing preliminary findings concerning the role of threat on creative output, which pave the way for further research into this phenomenon.

## Appendices

Appendices A, B, C, and D provide examples of stories that scored high or low with respect to creativity, generated in response to non-threatening or threatening photographs. (The stories may end abruptly because they were asked to stop at the end of the allotted writing time.)

### Appendix A

The following is an example of a high scoring story produced in response to the non-threatening stimulus shown in Figure 1.

In Jaredsville, Fourth of July parade was something everyone in town looked forward to. The sleepy town in Missouri came together once a year to provide food, movies, festivities, and friendship to their fellow townsman. The streets are filled with people, some searing food on the grill while others paint children's faces into tigers and clowns.

But everyone came, of course, to see the Jaredsville professional dance exhibition. A few of the ladies in town had once been professional dancers, traveling across the world displaying their beauty and raw skills. They all began to slowly get in position with the start of the drums. The seguin on their clothes danced in the sunlight to the movement of their bodies. The drums began beating faster and faster and the women expertly kept with the beat, dancing faster and more radically until their bodies looked like surges of light. The effect was almost hypnotizing as the crowd had quieted down; became fixated by the dancing flashes of light.

And just as quickly as they had started, they finished. As they left the middle of the street, the crowd applauded them fiercely. Yet, something had changed; the crowd was no longer the large bustling rabble it once was. It had now been neutralized, as if soother by the dancers.

### Appendix B

The following is an example of a low scoring story produced in response to the non-threatening stimulus shown in Figure 1.

The town had a celebration today, an annual celebration that celebrated the culture and music of the country. The women were the center of the attention, they dressed in black or white like the men did, but they were skirts. The women danced to the music and paraded around the whole town. Some knew exactly what was going on and the moves to perform such a dance. Others had their eyes towards the 'leader', who perhaps was the one who made the routine.

The bright sunny day made it all the more amazing to watch the show, as old men were wearing matching hats and marching around with drums. There were people everywhere along the sides of the road, up in the balcony, just to get a glimpse of the festivities that were happening. Some cheered and waved around, and some took pictures. All of the stores in that main road seemed to be closed, probably because of how hectic and wild the place was getting!

It probably was a great success; the warm weather, the loud music, and cheering of people made the day so great! This celebration will most likely continue with similar events every year. After all, it is a celebration of culture and music to the country!

### Appendix C

The following is an example of a high scoring story produced in response to the threatening stimulus shown in Figure 3.

The man pushed Cheryl under the truck, "Where is he?" he was screaming at her. Cheryl could only sob more, trying to control the

emotion was impossible, an endless waterfall of emotions falling over her was all she could feel. "I said, where is he!" The unknown man yelling once again, for the first time in days she felt something, the clasp of his hand over her face. Only days earlier someone she loved had placed his hands in the same place, but this time there was no tenderness, no caress to show they cared. "I will put your body under the tire and back over you slowly, crushing one bone at a time 'till you tell me where the man I am looking for is!" She looked down still focusing on the hand on her face, how she missed him! A few days ago, her lover had left. Where, she had no idea, "Business to take care of" he had said, but what business would leave her alone so this man, the one with the strangling hold on her face, could find her. She had tried to run, but with everyone here who only cared for themselves (all they could care for really with so much sickness and death around), no one answered her screams, her frantic running and trying to escape this man. She ripped her shirt on one of the branches she hit and had the sensation of a bruise forming. She paid no heed to it, only a small discomfort when she compared it to the gaping hole she felt in her chest. Suddenly the man's coat began vibrating, he answered the phone with his hand still around her neck. "Mmmm ok, yes, dead? Good." Without warning he dropped her to the ground and stood looking over her. "Turns out we don't need you" he said leering, "but I do know some of the boys may want you". He picked her up by the hair and began dragging her to the truck "And who knows? Maybe we will let you see your man's body before we lay you down for us" Cheryl tried to force herself once more, with less gusto than before as a part of her heart was crying out what the bald man said to be true was not! She would believe he was alive until she laid her head on his still, dead chest and felt him one last time.

### Appendix D

The following is an example of a low scoring story produced in response to the threatening stimulus shown in Figure 3.

His hands were cold and gritty upon my face they began to turn white as he squeezed harder and threatened me for the money. All I wanted to do was run away, run away from this life in general. He looked at me with such disdain. I wonder how I even got to this point in my life. My heart raced while tears poured down my face, he was a vile man with the intent to kill. "Please" I repeated over and over, "give me one more chance. I'll get you your money." He spat on the ground under the bridge at my feet like I was a piece of scum. I wanted a different life but this grease bag was what I had to deal with every day. Constantly abusing every inch of me. The only thing that scared me more than staying with him was leaving him. He'd find me, he always did. I didn't just need to break away physically, but emotionally and for my own safety. The numbness of the drug he provided was my only gateway out of this hell hole. This could have been the last time I ever saw daylight. Daylight and his eyes, burning with power over every meek creature that would obey him.

# Automatic selection of eye tracking variables in visual categorization for adults and infants

## Abstract

Visual categorization and learning of visual categories exhibit early onset, however the underlying mechanisms of early categorization are not well understood. The main limiting factor for examining these mechanisms is the limited duration of infant cooperation (10-15 minutes), which leaves little room for multiple test trials. With its tight link to visual attention, eye tracking is a promising method for getting access to the mechanisms of category learning. But how should researchers decide which aspects of the rich eye tracking data to focus on? To date, eye tracking variables are generally handpicked, often resulting in biases of the eye tracking data. Here, we propose an automated method for selecting eye tracking variables based on their usefulness to discriminate learners from non-learners of visual categories. We presented infants and adults with a category learning task and tracked their eye movements. We then extracted an over-complete set of eye tracking variables encompassing durations, probabilities, latencies, and the order of fixations and saccadic eye movements. We applied the statistical technique of ANOVA ranking to identifying those variables among this large set that covaried with the learner/non-learner label. We were able to identify learners and non-learners above chance level using linear SVM and the top eye tracking variables.

**Keywords:** eye tracking; category learning.

## Introduction

Categorization is the process of forming an equivalence class, such that discriminable entities elicit a common representation and/or a common response. This task has two components (a) category learning (i.e., forming a common representation for a set of items and/or learning a common response) and (b) categorization or classification (i.e., partitioning a stimulus set using this common representation). While category learning exhibits an early onset (Quinn, Eimas, & Rosenkrantz, 1993), relatively little is known about the underlying mechanism and the development of early categorization. One of the reasons is the limited duration of typical experimental paradigms with infants, yielding only a small number of data points per participant. These limitations have restricted researchers ability to answer fundamental questions about categorization in infants: How do infants learn a category? And what changes in the course of development?

Given that eye movements are tightly linked to visual attention (see Rayner, 1998, for a review), eye movements can provide critical information of how attention allocation changes during category learning. However, eye tracking yields a large amount of data, and it is usually not clear from the outset how to make sense of these data. These data could be converted into numerous variables, and there is no principled way of deciding which of these variables should be selected and why. The *key idea* of our approach is to develop algo-

(a) Category object

(b) Identical category pair

Figure 1: Image (a) is an example category object used in the eye tracking study, with the Areas of interest (AOI)s enumerated. Image (b) defines the AOIs for a pair of objects. The numbers were not shown to participants.

rithms that *automatically* select the eye tracking variables that are systematically linked to category learning.

Our approach was as follows. We extracted a large set of possible variables from the adult or infant gaze sequence during a categorization task (e.g. fixations, saccades, gaze sequences, etc). Some of the variables have been used in analyzing categorization experiments, whereas others are new. We used ANOVA to identify the eye tracking variables that best predict category learning in adults and subsequently in infants, and validated the variables using linear SVM. The significant contribution of this work is that it provides a methodology for identifying eye-tracking variables that are linked to category learning, thus allowing researchers to better understand categorization.

## Method

### Category Object

The category members were flower-like objects with six petals. An example category object is shown in Fig. 1(a), with the petals enumerated for clarity. The four different categories used were defined by a single petal having a distinguishing color and shape. Specifically, the category defining features were A (pink triangle at AOI 4), B (blue semi-circle at AOI 4), C (orange square at AOI 6), and D (yellow pentagon at AOI 6).

### Adult Experiment

To validate the efficacy of the approach before applying it to infants, adult participants were tested. Adult participants from an introductory psychology course at The Ohio State University underwent a series of category learning tasks while their eye gaze was tracked by a Tobii T60 eye tracker at 60Hz. Adults had normal or corrected-to-normal vision, and sat approximately 60 cm away from the display.

Adult participants were assigned to either a supervised or an unsupervised condition. In the supervised condition participant were advised to look for a single distinguishing fea-

ture prior to the start of the experiment. In the unsupervised condition, no hint was given. Previous research suggests that this hint has large consequences with respect to how quickly participants learn to classify the objects, especially when there are few overlapping features (Kloos & Sloutsky, 2008).

The experiment had 8 blocks, with each block consisting of a learning phase and a testing phase. The learning phase had 8 trials, and during each trial a category member was displayed on the center of the screen one at a time for 1.5 seconds each. The testing phase immediately followed the learning phase. There were 4 testing blocks, and on each testing block a category member of the to-be-learned category and a member of a new category were presented side by side. The images were displayed until the participant identified the learned category object by pressing a key. The position of the learned category member (left or right) was counter-balanced. In addition, in-between trials a randomly located fixation point (cross-hair) directed the participants gaze to a position on the monitor.

The to-be-learned category remained the same for the first 4 blocks. A second to-be-learned category was introduced in the final 4 blocks. If the experiment started with category A or B, the second category was either the C or D, and vice-versa. That is because while the A and B categories were defined by a relevant feature at AOI 4, categories C and D were defined by a relevant feature at AOI 6. This provided a mechanism to verify the reproducibility of the variables determined most important.

### Infant Experiment

The infant experiment was similar to the adult experiment, but was adapted for infants by using a familiarization paradigm. To aid infant learning, category exemplars were shown in pairs on each trial. This was also done so that the images in the learning and testing phases had an identical layout. Furthermore, there was only a supervised condition, in which the infants were presented with a pre-trial fixation video of synchronized sound and motion (e.g., looming with whistle sound) to draw the infants attention to the single category-relevant feature. Once the infant looked at the fixation video, the learning trial commenced. Infants had to accumulate 3 seconds of looking to the category exemplar pairs. Whenever an infant looked away, an attention-grabbing fixation was presented until the infant reconnected with the images on the screen. After accumulating 3 seconds of looking to the stimulus pair, the supervisory fixation video was again presented followed by another learning image pair. This procedure was repeated with 8 learning pairs per block.

The testing phase of the infant experiment used a paired preference test with one category member paired with one non-category member. The standard assumption is that the infant can discriminate between the category and non-category object if he or she consistently looks at one object significantly more than the other object (i.e., whether the infant displays a novelty or familiarity preference). There were two test trials per block, where an exemplar from the learned cat-

egory was paired with an exemplar from a novel category. Test trials were presented for a fixed duration of 6 seconds, and left/right position of familiar or novel category objects was counterbalanced.

### Filtering eye tracking data

The gaze data obtained with the Tobii eye tracker contains noise, missing data, and micro-saccades, which makes identifying true fixations and saccades difficult. Therefore, raw eye tracking data exported from every experimental block was filtered using a Kalman filter (Murphy, 2004) before extracting the variables of interest. The eye gaze data from both the left and right eye were filtered separately. The average of the filtered data from left and right eyes yielded the mean eye gaze data, which were used in the current analyses.

### Labeling the Data

The eye movement sequences during the *learning phase* of the experiment aid in understanding category learning, while the sequences during the *testing phase* aid our understanding of category use. Before applying our methodology to understand these processes, however, the eye tracking data from both the learning and testing phases of the experiments were labeled as *learner* (class 1), *non-learner* (class 0), or *indeterminate* (class 2). Indeterminate samples were not used.

**Adult Labels:** Intuitively, labels for adult data are readily identified based on the accuracy of the responses during the testing phase. An uninterrupted string of correct responses during the testing phase suggests that the participant has learned the category. Each adult experimental block yielded 12 eye movement sequences. These correspond to eye movements during the presentation of 8 exemplar images during the learning phase and 4 test images during the testing phase. Adult participants had 4 blocks of learning and discriminating the same category before switching to a new category. This amounted to 32 samples of the learning phase, and 16 samples of the testing phase for each category per participant. The 16 samples from the testing phase were associated with a 16 digit binary string, called the *response string*. This data structure shows performance over the first and last 4 blocks of the experiment. A one identifies a correct response, while a zero denotes an incorrect response on the associated test trial.

We expect a learner's response string to contain a series of ones beginning within the string and terminating at the end of the response string. This pattern indicates that at some point the participant learned the category and correctly discriminated the category from that point on. A participant who has not learned the category (non-learner) would select one of the two stimuli by chance in each trial. A non-learner could get lucky and achieve a series of correct guesses. In order to determine if a participant is a learner or a non-learner we need to establish a criterion that allows us to reject chance as the cause for a series of ones. The question that we need to answer is how many ones we should expect for a learner. We address this problem by assessing how likely it is that we see a sequence of  $M$  consecutive ones in a binary response string

of length  $R = 16$ . Under the null hypothesis, the participant does not know the category label and selects one of the stimuli by chance, giving her a 50% chance of correctly guessing the category member. Each sequence is equally likely given this assumption, so the probability of guessing at least  $M$  right in a row is the total number of sequences having  $M$  ones in a row ( $(R - M + 1) \times 2^{(R-M)}$ ) divided by the total number of binary sequences of length  $R$  ( $2^R$ ). This yields the probability  $p = (R - M + 1)/(2^M)$ . For  $R = 16$ ,  $M = 10$  is the minimum number that achieves a significance level of  $p < 0.01$  ( $p = 0.0068$ ). Therefore, we rejected the null hypothesis that a participant was guessing randomly when we identified a consecutive string of 10 correct responses.

We call the position of the first correct response in this string of correct responses the point of learning (POL). The *test phase* and *learning phase* samples before the POL were labeled as non-learner, while the samples after the POL were labeled as learner. The learning phase samples from the block associated with the POL were labeled as indeterminate, because it was unclear at exactly which trial during the block the category was learned.

If the learning criterion was not achieved, we then identified the remaining non-learning and indeterminate samples. We first labeled correct responses at the end of the respond string as indeterminate. Those samples did not meet the learning criterion, but might be attributed to learning late in the experiment. The remaining samples were labeled as non-learner. Approximately 8% of the adult eye track samples were labeled indeterminate.

**Infant Labels:** Obviously, infants are not able to respond by keyboard to identify a category object. Instead, we used a variant of the preferential looking paradigm to determine if an infant could discriminate between novel exemplars of a familiar category object and a novel category object. Recall that the preferential looking paradigm assumes that infants who consistently look more to one class of stimuli when shown two classes of stimuli are able to discriminate between the two classes. This means that if the infant consistently looks longer at the learned category object (or novel category object), then he or she is assumed to be discriminating between the familiar and novel categories.

Given this paradigm, we labeled each infant's gaze data by blocks. Each block consisted of two test phase samples. We determined novelty preference as the ratio of total looking time to the novel category object compared to the total looking time to the novel category plus the familiar category object. We sorted the mean of the novelty preference for each block according to the absolute difference from 0.5. A third of the blocks with mean novelty preference closest to 0.5 were labeled as non-learner. The third of the blocks with novelty preference furthest from 0.5 in absolute value were labeled learner. Otherwise, the samples were labeled indeterminate. Approximately 33% of the infant eye track samples were labeled indeterminate.

## Variables List

We compiled an over-complete list of eye tracking variables. We began with the fundamental variables, fixations and saccades. Fixations occur when eye gaze is maintained at a single position for at least 100ms. They were identified using the dispersion threshold algorithm of (Salvucci & Goldberg, 2000). Saccades are rapid eye movements that move the eye gaze between points of fixation. To be considered a saccade, the eye movement needed to exceed smooth pursuit velocity of  $30^\circ$  per second or  $0.5^\circ$  per sample at 60Hz (Stampe, 1993). The fixations and saccades were determined with respect to a specific Area of Interest (AOI) within an object. AOIs are regions of an object image or scene that can be grouped in some meaningful way, such as color uniformity, and are relevant or non-relevant based on their role in determining the object category.

These fundamental eye tracking variables were combined in various ways to derive a larger set of variables. Our variables list is defined as follows:

1. *AOI fixation percentage* describes the percentage of time fixated at the different AOIs during a trial. All non-AOI fixations were discarded in this and all of the variables defined. The fixation percentages were normalized so that they sum to 1, unless there were no fixations at AOIs. In that case, all percentages were set to 0.
2. *Relevant AOI fixation density* describes the percentage of time fixated at the relevant AOI(s).
3. *AOI fixation sequence* describes the sequence of AOI fixations during one trial. We limited this sequence to a fixed number of fixations, starting with trial onset (not counting fixations to the fixation mark). The number of fixations to consider as well as the start position were determined using cross validation (CV). In addition, the fixation sequence was represented as a sequence of relevant and non-relevant AOI fixations. The analysis showed that the latter representation was more informative in some cases.
4. *Duration of fixations in sequence* describes the duration of each fixation in the sequence described by variable 3.
5. *Total distance traveled by eye* is a scalar describing the total distance traveled by the eye gaze during a trial.
6. *Histogram of fixation distances to relevant AOI* describes how much time is spent fixated near or far from the relevant AOI(s). The number of bins was determined using CV.
7. *Number of unique AOIs visited* is a scalar describing the total number of unique AOIs fixated during a trial.
8. *Saccade sequence* is similar to variable 3, but describes the sequence of AOI saccades during one trial. All saccades whose targets were not to AOIs were discarded in this and all of the variables defined. The sequence was limited to a fixed number of saccades, starting at the first saccade. The

number of saccades to consider as well as the start saccade were determined using CV. In addition, the saccade sequence was represented as a sequence of saccades to relevant and non-relevant AOIs.

9. *Relative number of saccades to an AOI* is the saccade analogue of variable 1, and describes the relative number of saccades to the AOIs during eye movement.
10. *Fixation latency to relevant AOI* describes the delay before fixating at a relevant AOI during an eye movement. It is a scalar between 0 and 1, where 0 corresponds to fixating to a relevant AOI immediately and 1 describes a sequence where a relevant AOI is never fixated.
11. *Saccade latency to relevant AOI* is a scalar between 0 and 1 defining the delay before saccading to a relevant AOI.

Thus, eye movement was represented by a *feature vector*  $\mathbf{x} = (x_1, x_2, \dots, x_d)^T$  whose  $d$  entries correspond to the variables described. For clarity, *features* denote the entries of the feature vector which encodes the eye tracking variables, while *variables* correspond to the measures of the eye tracking enumerated above. Therefore,  $d$  is much larger than 11, because encoding certain variables requires multiple feature values. In addition, the information encoded by several of these features overlaps. This over-complete representation allows us to find the encoding that is best suited to describe the categorization task. To this end we performed variable selection on this over-complete set.

### Variable Selection

Our goal is to identify the subset of variables from the set defined above that can best separate the classes: category learners and non-learners. This was achieved using ANOVA feature selection by ranking. ANOVA feature selection relies on a standard hypothesis test on each feature of  $\mathbf{x}$ . Specifically, let  $x_i$  denote the  $i^{th}$  feature of  $\mathbf{x}$ . Using a dataset of eye tracking feature vectors and the associated class labels, we performed a two tailed  $t$ -test of the null hypothesis which states that samples of  $x_i$  coming from classes 1 and 0 are independent random samples from normal distributions with equal means,  $\mu_{i1}$  and  $\mu_{i0}$ , respectively. The alternative says that the class means are different. We calculated the test statistic and the corresponding  $p$ -value. A low  $p$ -value means the null hypothesis is rejected with confidence. Since the goal is to find the variables which best separate the classes, the feature with lowest  $p$ -value is ranked as best. The  $p$ -values were calculated for all features  $x_i, i = 1 \dots d$ , and they were ranked from best to worst according to increasing  $p$ -values. If we vectorize the indices of the  $t$  top ranked features as  $\mathbf{k} = (k_1, k_2, \dots, k_t)^T$ , then after feature selection  $\mathbf{x} = (x_{k_1}, x_{k_2}, \dots, x_{k_t})^T$ .

### Linear Classification

Once the important variables were identified, we used them to classify the gaze data as having originated from a learner

Figure 2: Illustration of a linear classifier.  $\mathbf{w}$  is the normal vector of the hyperplane which separates the feature space into two decision regions, and  $b$  is the distance from the origin to the hyperplane. The blue circles represent samples from class 1, while the green squares represent samples from class 0. All but one of the blue circles exists on the positive side of hyperplane, and are classified correctly.

or non-learner. This required that we train a classifier to distinguish between two classes of data. Recall that each eye movement results in a feature vector, or *sample*  $\mathbf{x}$ . A classifier defines a decision rule for predicting whether a sample is from class 0 or 1. A linear classifier was used because of its ease of interpretation (Martinez & Zhu, 2005) – the absolute model weights give the relative importance of the eye tracking variables. We illustrate in Fig. 2 with a 2-dimensional linear classifier model specified by  $\mathbf{w}$  and  $b$ .  $\mathbf{w}$  is the normal vector of the hyperplane which separates the feature space into two decision regions, and  $b$  is the distance from the origin to the hyperplane (i.e., the offset).

All samples  $\mathbf{x}$  above the hyperplane are assigned to class 1 while the samples below are assigned to class 0. Data samples  $\mathbf{x}$  existing on the boundary satisfy  $\mathbf{w}^T \mathbf{x} - b = 0$ . Therefore, samples are classified according to the sign of  $\mathbf{w}^T \mathbf{x} - b$ . In this example  $\mathbf{w} = (-.55, .83)^T$ , so the second dimension,  $x_2$ , is more informative for classification because it has a larger absolute value. Note that in our case the feature space has not two but up to 334 dimensions, depending on the cut-off for variable selection.

In this work we used the Support Vector Machine (SVM) classifier. SVM is a linear classifier which maximizes the margin between two classes of data (Burgess, 1998). In the case that the training samples are perfectly separable by a hyperplane, we can find  $\mathbf{w}$  and  $b$  such that the data satisfies the following constraints,

$$\mathbf{x}_i^T \mathbf{w} - b \geq 1 \text{ for } y_i = 1, \quad (1)$$

$$\mathbf{x}_i^T \mathbf{w} - b \leq -1 \text{ for } y_i = 0. \quad (2)$$

Essentially, these constraints specify that the samples from the different classes reside on opposite sides of the decision boundary. The margin between the classes, defined by  $\frac{2}{\|\mathbf{w}\|_2}$  where  $\|\cdot\|_2$  defines the L2-norm, is then maximized subject to the above constraints. The dual formulation of the constrained optimization problem results in a quadratic program for  $\mathbf{w}$  and  $b$ . In the case that samples from each class are not linearly separable, a penalty is introduced to penalize the amount that a sample is on the wrong side of the hyperplane. Again, the dual formulation results in a quadratic program for  $\mathbf{w}$  and  $b$ . We used the implementation of (Chang & Lin, 2001).

The classification accuracy used for adults was the leave-

Figure 3: Leave-one-subject-out cross-validation accuracy for adult participants as a function of the number of top ranked variables used for classification. Classification was done with SVM while ANOVA was used for feature selection. AB and CD correspond to category object A or B and C or D respectively. In almost all cases, the classification accuracy was near the maximum after including very few features.

one-subject-out cross-validation (LOSO-CV) accuracy. In LOSO-CV, the samples belonging to one participant are sequestered, and the remaining samples are used to train the classifier. The sequestered samples are then classified with the learned classifier, and the procedure is repeated for every participant in the database. The total number of correctly classified samples divided by the total number of samples is the LOSO-CV accuracy. The classification accuracy used for infants was the leave-one-experiment-block-out cross-validation (LOBO-CV) accuracy. This alternative accuracy measure makes more effective use of the eye movement data when the sample size is very small. In LOBO-CV, the samples belonging to one experiment block are sequestered, and the remaining samples are used to train the classifier. The sequestered samples are then classified with the learned classifier, and the procedure is repeated for every block in the database. The total number of correctly classified samples over the total number of samples is the LOBO-CV accuracy.

## Results

### Adult Experiment

A total of 24 adults were tested in the supervised experiment while 46 adults were tested in the unsupervised adult experiment. This resulted in 728 learning class samples and 1256 non-learning class samples for the learning phase, and 473 learning class samples and 601 non-learning class samples for the testing phase in the A or B category learning condition. There were 496 learning class samples and 1568 non-learning class samples for the learning phase, and 323 learning class samples and 717 non-learning class samples for the testing phase in the C or D category learning condition. The indeterminate samples were not used in any of the experiments. After labeling the data, the eye tracking variables were extracted from each gaze sequence. Each labeled data sample resulted in a 182-dimensional feature vector for the learning phase samples, and a 334-dimensional feature vector for the testing phase samples.

SVM was applied to determine the LOSO-CV error as a function of the number of top features selected by ANOVA feature selection. The results are summarized in Fig. 3, and show that a very small set of variables yields a high classification rate. Adding more variables does not improve the accuracy.

The stable performance beyond just a few variables suggests that a small number of variables is sufficient for dis-

Table 1: The following variables were determined most relevant during the adult category learning and testing phases. The results suggest that looking at the relevant AOI is important during the learning phase. In addition, the first few fixations are very important during testing. The bold face entries show variables that were consistently determined most relevant across category conditions. We used shorthand notation for a few words: fixation (fix), saccade (sac), relevant (rel).

A or B Learning Condition	C or D Learning Condition
<b>1. Latency to relevant AOI fix</b>	<b>1. Latency to relevant AOI fix</b>
<b>2. Density of fix at AOI 4</b>	<b>2. Density of fix at AOI 6</b>
3. Distance to AOI 4, hist bin 2 of 30	3. Distance to AOI 6, hist bin 5 of 30
4. Look at AOI 4 on fix 2	<b>4. Look at AOI 6 on fix 1</b>
<b>5. Look at AOI 4 on fix 1</b>	5. Look at non-rel AOI on fix 1
A or B Testing Condition	C or D Testing Condition
<b>1. Look at non-relevant AOI on fix 3</b>	1. Look at non-relevant AOI on fix 4
2. Look at non-relevant AOI on fix 2	<b>2. Look at non-relevant AOI on fix 3</b>
<b>3. Look at non-relevant AOI on sac 2</b>	<b>3. Look at non-relevant AOI on sac 2</b>
4. Look at non-relevant AOI on fix 1	<b>4. number of unique AOIs fixated</b>
<b>5. number of unique AOIs fixated</b>	5. Look at non-relevant AOI on sac 3

criminating learners and non-learners. The top five variables are listed in Table 1. The bolded entries are present in the top five variables across both the A or B and C or D conditions. Note that AOI 4 for the A or B condition is equivalent to AOI 6 in the C or D test condition.

### Infant Experiment

A total of 16 infants ranging from 6 to 8 months of age were tested in the supervised infant experiment. One participant's data were discarded because the infant would not cooperate. This resulted in 135 learning class samples and 137 non-learning class samples for the learning phase, and 40 learning class samples and 40 non-learning class samples for the testing phase in the A or B category learning condition. For the C or D category learning condition this resulted in 139 learning class samples and 127 non-learning class samples for the learning phase, and 40 learning class samples and 40 non-learning class samples for the testing phase. The indeterminate samples were not used in any of the experiments. After labeling the data, the eye tracking variables were extracted from each gaze sequence. Each labeled data sample resulted in a 334-dimensional feature vector for the learning and testing phase samples.

SVM was applied to determine the LOBO-CV error as a function of the number of top features selected by ANOVA feature selection. The results are shown in Fig. 4, where we see that the accuracy varies when considering different features. Thus, while classification of learners and non-learners is still possible with infants, it is not as clear-cut as with adults. This is to be expected because of the amount of random movements typical of babies. The top five infant variables are shown in Table 2. There are no bold entries because no variables were consistently selected across the A or B and C or D conditions.

Figure 4: Leave-one-block-out cross-validation accuracy for infant participants as a function of the number of top ranked variables used for classification. Classification was done with SVM while ANOVA was used for feature selection. AB and CD correspond to category object A or B and C or D respectively. Chance level was at 0.5.

Table 2: The following variables were determined most relevant during the infant category learning and testing phases. There were no consistently relevant features across category conditions. We used shorthand notation for a few words: fix-ation (fix), saccade (sac), relevant (rel).

A or B Learning Condition	C or D Learning Condition
1. Den of fix at AOI 10	1. Distance to AOI 13, hist bin 5 of 35
2. Look at AOI 10 on fix 3	2. Distance to AOI 6, hist bin 21 of 35
3. Distance to AOI 11, hist bin 5 of 35	3. Density of fix at AOI 13
4. Density of saccade to AOI 10	4. Distance to AOI 13, hist bin 2 of 35
5. Distance to AOI 4, hist bin 20 of 35	5. Look at non-rel AOI on sac 3
A or B Testing Condition	C or D Testing Condition
1. Look at non-relevant AOI on fix 6	1. Density of fix at AOI 7
2. Distance to AOI 4, hist bin 20 of 35	2. Look at AOI 3 on sac 3

## Comparing Infants to Adults

The above results raise a new question. How similar are the attention models of adults and infants? Specifically, since the infant data is so noisy, can we use the adult model to improve on the infant one? To test this, we used the adult classifier model trained with the top five variables to predict if infants were learners or non-learners. This was done only for the testing phase, because the testing phase images for adults and infants are similar so that the extracted variables correspond. Infants were classified with 49% accuracy in the A or B condition, and with 50% accuracy in the C or D condition with chance level at 50%. These findings suggest that infant category learners do not direct their attention like adult learners.

## Discussion and Conclusion

We have developed a methodology for automatically determining eye tracking variables that are relevant to understanding category learning and discrimination processes. Previous research has relied on ad-hoc techniques to determine which variables should be analyzed. Instead, we used statistical methods to find the important variables in an over-complete set of variables.

The efficacy of the approach was verified with an adult categorization study. The variables determined most relevant for adults emphasize looking at the relevant AOI(s) longer, and earlier during the categorization tasks. This result is satisfying for two reasons: 1) It is expected that category learners quickly focus their efforts on the relevant AOI(s), and 2) These variables coincide with the variables *proportion fixation time* and *relative priority* of previous eye-tracking category learning studies such as (Rehder & Hoffman, 2005). Finally, we demonstrated that the adult model does not predict

infant categorization. This is evidence of different attention processes for infants and adults during categorization.

Note that the important variables were verified by the *task* and *stimuli* described. Altering these parameters may result in different important variables. By comparing the important variables among different tasks and stimuli, we can further dissociate which eye tracking variables are linked to specific processes during categorization.

## Acknowledgments

This research was partially supported by NIH grant R01 EY-020834 to AM, NSF grant BCS-0720135 and NIH grant R01 HD-056105 to VS, and a Seed Grant by the Center for Cognitive Science (CCS) at OSU to DBW, VS, and AM. SR was partially supported by a fellowship from the CCS.

## Abstract

Disorders provide an important source of information in developing theories of normal categorisation. Disruption in categorisation in individuals diagnosed with schizophrenia has been widely evidenced. However, findings are often contradictory and subject to significant confounds. In the present study 35 high schizotypes and 35 low scorers completed a semantic categorisation task and a borderline categorisation task, with measures of category membership judgment, similarity and response time being taken. Results revealed that high schizotypes made significantly fewer positive category membership judgments than low schizotypes ( $p = .003$ ) and suggest that different theoretical explanations may be required to explain the categorisation of high and low schizotypes. Explanations in terms of theories of normal categorisation are developed.

**Keywords:** Concepts; Categorisation; Schizotypy; Essentialism; Semantic Processing.

## Introduction

Disorders of categorisation are an important source of information in developing theories of normal categorisation. Work on category-specific impairment, for example, has led to the proposal that functional and appearance attributes are represented in concepts in different ways (cf. Strnad, Anzellotti & Caramazza, 2011).

Categorisation is known to be disrupted in other disorders, most notably dementia (Doughty et al., 2009), autism (Church et al., 2010), and schizophrenia (Doughty & Done, 2009), as well as in neuropsychological cases (Cohen, Johnston & Plunkett, 2000).

Schizophrenia has long been associated with the suggestion that categorisation is subject to over-inclusion, that category boundaries are shifted outward, incorporating into the category items that would normally be regarded as non-members (Lawrence, Doughty, Al-Mousawi, Clegg & Done, 2007). However, disorders also present difficulties for experimental investigations of categorisation. In the case of schizophrenia, for example, significant confounds are often present, such as hospitalisation, medication, psychosis, and attentional dysfunction. Perhaps unsurprisingly, and in spite of the prominence the suggestion of over-inclusion has received, relatively little is actually known of categorisation in schizophrenia. Moreover, the sparse evidence is often inconsistent or contradictory.

However, schizophrenia has been linked theoretically to schizotypy, a multidimensional construct that assumes healthy individuals may manifest subclinical presentations of schizophrenic symptoms. Schizotypy varies in degree

along a continuum from such psychologically healthy individuals to those diagnosed with schizophrenia (Claridge, 1985). Those high in schizotypy are described as psychosis-prone, and may experience oddities of belief, behaviour, eccentricities, idiosyncratic speech, peculiar ideas, and social awkwardness or aversion at a subclinical level (Siever, Kalus & Keefe, 1993). High schizotypes have been studied in order to gain understanding of vulnerabilities to schizophrenia (Peters, Pickering & Hemsley, 1994). Indeed, in the presence of sufficient environmental stressors, the contention is that high schizotypes may develop schizophrenia, and present with appropriate clinical symptoms.

High schizotypes therefore provide the researcher with a compelling opportunity to examine 'disordered' cognition in an otherwise healthy population. However, there have been relatively few studies of categorisation in high and low schizotypes, and what data there are appear inconsistent.

## Semantic Processing in Schizophrenia

Abnormalities in semantic processing are thought to be central to cognitive abnormalities in schizophrenia, with deficits reported on a wide variety of semantic processing tasks (Chen, Wilkins & McKenna, 1994). Further, semantic deficits are suggested to underlie disturbances in thought and language in schizophrenia, which might not only explain deficits observed in other cognitive domains, but also provide a cognitive explanation for common symptoms in schizophrenia, such as delusions (Rossell, Rabe-Hesketh, Shapleske & David, 1999) and thought disorder (Gouzoulis-Mayfrank et al., 2003).

## Semantic Processing in Schizotypy

Although impairments in attention (Lenzenweger, Cornblatt & Putnick, 1991) and executive functioning (Suhr, 1997; Tallent & Gooding, 1999) have been found in schizotypy, few studies have addressed the relationship between schizotypy and semantic processing. Those that have done so have used semantic priming tasks (Beech, McManus, Bayliss, Tipper & Agar, 1991; Morgan, Bedford & Rossell, 2006) and revealed differences between high and low schizotypes (Morgan et al., 2006).

However, there has been little research on other areas of semantic processing in schizotypy, Morgan, Bedford, O'Reagan & Rossell (2009) being a notable exception. Very few studies of schizotypy have included categorisation tasks and none have made categorisation a primary focus.

## Categorisation in Schizotypy

The majority of studies on categorisation in schizotypy have used fluency tasks whereby participants are asked to generate exemplars given a category label (Barrantes-Vidal et al., 2003; Duchene, Graves & Brugger, 1998; Kiang & Kutas, 2005). Fluency tasks are typically used to make estimates of the semantic distance between pairs of concepts. Although these provide a measure of the organisation of semantic information, they do not address the process of categorisation directly. Categorisation tasks, which require participants to make category membership judgments, have been used in only two studies (Kiang & Kutas, 2005; Morgan et al., 2009).

Kiang & Kutas (2005) presented their participants with a category definition followed by exemplars of varying typicality and required them to judge whether or not each was a category member. In their EEG study, no group differences were found in the N400 component, although they did report a negative correlation between schizotypy score and ERP amplitude differences between category members and non-members.

Morgan et al. (2009) asked participants to rate the category membership of exemplars of varying degrees of relatedness. Group differences were found only for low frequency items, with high schizotypes regarding low frequency exemplars as belonging less to the category than did low schizotypes. Differences in the same direction were reported as nearing significance for high frequency category members and borderline exemplars.

Surprisingly, the authors did not comment on the contrast between this apparent ‘under-inclusion’ and the over-inclusion reported in schizophrenia. Indeed, despite the suggestion that in schizophrenia categories are over-included, there has been very little focus on this question in relation to schizotypy. It is unclear whether differences in categorisation between high and low schizotypes are generally not reliable, or whether previous studies have not been sufficiently sensitive to detect them.

## Categorising Borderlines

Previous investigations of schizotypy have not examined the relative contribution of different attributes to categorisation. Yet characteristic and necessary features (cf. Rips, Shoben & Smith, 1973) allow for the creation of two borderline cases: exemplars with characteristic but not necessary features and exemplars with necessary but not characteristic features. Similar cases have been used in previous research, for example, in debates as to whether categorisation is similarity- or theory-based (e.g. Rips, 1989).

This study therefore consists of two tasks: a replication of the semantic categorisation task reported by Morgan et al. (2009) with the additional measures of response times, and similarity ratings to better gauge whether categorisation in schizotypy is characterised by over- or under-inclusion; and a borderline categorisation task using two types of borderline exemplars, as above, for artefact and natural kind categories, with measures of categorisation and similarity

judgments, and response times, in order to shed light on the ways in which category boundaries might be shifted.

## Experiment

### Method

#### Design

The study employed two tasks. In both, dependent variables were categorisation (member, non-member), similarity rating (1-7), and response time (ms).

**Semantic categorisation** This employed a 2 x 5 design with one between-participants factor (Group [low, high]) and one within-participants factor (Relatedness [high frequency, low frequency, borderline, related but outside of the category, unrelated]).

**Borderline categorisation** This employed a 2 x 2 x 2 x 3 design with one between-participants factor (Group [low, high]) and three within-participants factors (Appearance [+,-], Essence [+,-] and Category [artefact, food natural kinds, non-food natural kinds]).

#### Participants

Two hundred and seventy eight participants were screened using an online questionnaire, the Oxford-Liverpool Inventory of Feelings and Experiences (O-LIFE: Mason, Claridge & Jackson, 1995). Scores from the questionnaire were used to determine high and low groups: high group ( $n = 35$ ), above the 70th percentile ( $\geq 44$ ) and the low group ( $n = 35$ ), below the 30th percentile ( $\leq 29$ ). The high group consisted of 6 males and 29 females with a mean age of 25.83 ( $SD = 9.39$ ) and the low group consisted of 9 males and 26 females with a mean age of 27.54 ( $SD = 11.37$ ).

#### Materials

**O-LIFE** The O-LIFE is a 159-item questionnaire based on the Combined Schizotypal Traits Questionnaire (Bentall et al., 1989) and is used to measure schizotypy. The O-LIFE yields 4 factors: unusual experiences (e.g. ‘Do you think that you could learn to read other’s minds if you wanted to?’), cognitive disorganisation (e.g. ‘Are you easily confused if too much happens at the same time?’), introverted anhedonia (e.g. ‘Are there very few things that you have ever enjoyed doing?’), and impulsive nonconformity (e.g. ‘Do you at times have an urge to do something harmful or shocking?’).

**Semantic categorisation** The semantic categorisation task replicates and extends the task reported by Morgan et al. (2009). They had selected eighteen categories from the norms of Battig and Montague (1969) and of Hampton and Gardiner (1983): body parts, clothing, drinks, flowers, food flavouring, furniture, insects, instruments, mammal, metal, part of building, professions, reading material, sport, tools, type of cloth, vehicle, and weapon. For each category,

Morgan et al. (2009) identified 5 different exemplars of differing degrees of relatedness, resulting in 90 trials, as follows: (1) high frequency (e.g. leg for the category ‘body part’), (2) low frequency (e.g. thumb), (3) borderline (e.g. joint), (4) related but outside the category (e.g. wig), and unrelated (e.g. cricket). To extend the replication, response times (ms) and similarity ratings were also measured.

**Borderline categorisation** Based on Braisby (2004), this task employed three types of category (food natural kinds, non-food natural kinds and artefacts), with 4 different categories for each: apple, chicken, potato and salmon for food natural kinds; canary, dog, oak tree and rose for non-food natural kinds; and car, fork, piano and sailboat for artefacts. For each category, 4 different exemplars were described, defined by the presence or absence of appearance and essence properties, resulting in 48 trials. Exemplars were presented in scenarios and were defined by having: (1) appearance properties absent, essence properties absent (A-E-), (2) appearance properties absent, essence properties present (A-E+), (3) appearance properties present, essence properties absent (A+E-), and (4) appearance properties present, essence properties present (A+E+). The following is an example of how stimuli were presented in scenario form for the category ‘apple’, for the exemplar type (A+E-).

‘You have just acquired an apple. You discover that it has been genetically modified so that it has NONE of the genetic properties specific to apples. Upon examination, you find that it looks, feels, smells and even tastes JUST like an apple.’

For natural kind categories, essential properties were expressed in terms of possession of the genetic properties specific to the category; for artefacts, these were expressed in terms of the original intended function (cf. Bloom, 1996).

## Procedure

Participants completed both tasks and stimuli were presented and responses recorded using E-Prime (Schneider, Eschman & Zuccolotto, 2002). The order of tasks was counterbalanced.

**Semantic categorisation** Participants were required to read the exemplar and category names and make a similarity judgment, and then a category membership judgment (Yes or No). Practice examples were used.

**Borderline categorisation** The scenario appeared on screen and participants were required to make a similarity judgment, and then a category membership judgment (Yes or No). Practice examples were used.

## Results

For both semantic categorisation and the borderline categorisation task, category membership judgments were scored 1 for a ‘yes’ response and 0 for a ‘no’ response. For

the borderline categorisation task, category membership judgments, category membership judgment response times, similarity ratings and similarity rating response times were all averaged over the four categories belonging to each superordinate category.

A series of 2 x 5 ANOVAs were conducted to examine category membership judgments, category membership judgment response times, similarity ratings and similarity rating response times.

## Semantic Categorisation

Critically, no group differences were found for measures of category membership judgment, similarity judgment or response times, nor did any approach significance (all  $p > .3$ ). Thus Morgan et al.’s (2009) key finding of group differences for low frequency items was not supported.

Consistent with their findings, however, the main effect of relatedness was significant for category membership judgments [ $F(2.82, 191.80) = 1613.00, p < .001$ , partial  $\eta^2 = .96$ ] and similarity ratings [ $F(2.52, 171.27) = 1558.00, p < .001$ , partial  $\eta^2 = .96$ ], with both ratings increasing with semantic relatedness (see Figure 1).

Figure 1. Mean proportion of positive category judgments (left axis) and mean similarity ratings (right axis) for each level of relatedness.

Examining response times, as expected, the main effect of relatedness was also significant for category membership judgments [ $F(2.74, 186.32) = 17.22, p < .001$ , partial  $\eta^2 = .20$ ] and similarity ratings [ $F(3.37, 229.10) = 43.91, p < .001$ , partial  $\eta^2 = .39$ ]. These results support previous findings with categorisation response times following an inverted V-shaped function: response times increase as the semantic distance between the category and the exemplar increases to the boundary, and decrease with increasing semantic distance (Rips et al., 1973).

Figure 2. Mean category judgment (left axis) and similarity rating (right axis) response times (ms) for each level of relatedness.

### Borderline Categorisation

A series of  $2 \times 2 \times 2 \times 3$  ANOVAs were conducted to examine category membership judgments, category membership judgment response times, similarity ratings and similarity rating response times.

**Category membership judgments** Critically, the main effect of group was significant [ $F(1, 68) = 9.52, p = .003$ , partial  $\eta^2 = .12$ ], with high schizotypes providing significantly fewer positive category membership judgments ( $M = .43$ ) than low schizotypes ( $M = .52$ ).

The category by appearance interaction was significant [ $F(1.70, 115.31) = 12.03, p < .001$ , partial  $\eta^2 = .15$ , Huynh-Feldt corrected here and elsewhere] and contrasts revealed significant interactions when comparing artefacts to food natural kinds [ $F(1, 68) = 15.48, p < .001$ , partial  $\eta^2 = .19$ ] and artefacts to non-food natural kinds [ $F(1, 68) = 13.80, p < .001$ , partial  $\eta^2 = .17$ ]. The effect of appearance properties was greater for food (0.44) and non-food (0.43) natural kinds than it was artefact categories (0.29).

The category by essence interaction was also significant [ $F(1.68, 113.98) = 30.04, p < .001$ , partial  $\eta^2 = .31$ ]. Contrasts revealed significant interactions when comparing artefacts to food natural kinds [ $F(1, 68) = 41.50, p < .001$ , partial  $\eta^2 = .38$ ], and artefacts to non-food natural kinds [ $F(1, 68) = 31.31, p < .001$ , partial  $\eta^2 = .32$ ]. The effect of essence properties was greater for artefact categories (0.68) than both food (0.43) and non-food (0.46) natural kinds.

Similar effects were obtained for similarity ratings. Taken together, these results imply that overall participants essentialised artefact categories more strongly than they did the food or non-food natural kinds, for which the influence of appearance properties was equally strong.

There was a significant three-way interaction between appearance, essence and group [ $F(1, 68) = 8.02, p = .006$ , partial  $\eta^2 = .11$ ]. Pairwise comparisons revealed differences nearing significance between the high group ( $M = .895, SE = .038$ ) and low group ( $M = .974, SE = .015$ ) for [A+E+] exemplars [ $t(68) = 1.94, p = .059, r = .23$ ] and between the high group ( $M = .462, SE = .062$ ) and the low group ( $M =$

.621,  $SE = .059$ ) for [A-E+] exemplars [ $t(68) = 1.88, p = .064, r = .22$ ]. Pairwise comparisons between the high group ( $M = .352, SE = .056$ ) and low group ( $M = .462, SE = .062$ ) for [A+E-] exemplars were not significant [ $t(68) = 1.31, p = .196, r = .16$ ]. Thus, the low schizotypes tended to give a higher proportion of positive categorisation judgments than high schizotypes when essence properties were present. However, these conclusions must be tempered due to the possibility of a floor effect (i.e. in the [A-E-] condition).

Figure 3. Three-way interaction between appearance, essence and group. Mean proportion of positive category judgments are shown for each exemplar type.

The three-way interaction between category, appearance and group was also significant [ $F(1.70, 115.31) = 3.84, p = .031$ , partial  $\eta^2 = .05$ ]. Contrasts revealed a significant difference between the high and low group when comparing artefacts to food natural kinds [ $F(1, 68) = 6.31, p = .014$ , partial  $\eta^2 = .09$ ]. High schizotypes (0.34) were more influenced by appearance properties than low schizotypes (0.24) when categorising artefacts. However, low schizotypes (0.49) were more influenced by appearance properties than high schizotypes (0.39) in categorising food natural kinds.

Figure 4. Effect of appearance properties (A+ minus A- category membership judgments) for high and low group, artefact, food natural kind and non-food natural kind categories.

**Category judgment response times** Importantly, the main effect of group was not significant [ $F(1, 68) = .54, p = .465$ , partial  $\eta^2 = .008$ ] suggesting that the difference in categorisation judgments does not stem from a speed-accuracy trade-off. The category by group interaction was significant [ $F(1.91, 129.53) = 3.40, p = .039$ , partial  $\eta^2 = .048$ ]. Contrasts revealed a significant interaction when comparing the high schizotypy group and low group response times for the artefact and the non-food natural kind categories [ $F(1, 68) = 5.27, p = .025$ , partial  $\eta^2 = .072$ ]. For the artefact category, response times were similar for the low group and the high group, however for the non-food natural kinds category response times decreased for the high group and increased for the low group. Pairwise comparisons revealed differences nearing significance between artefact categories ( $M = 1508, SE = 126.3$ ) and non-food categories ( $M = 1895, SE = 215.6$ ) for the low group [ $t(34) = -1.98, p = .056, r = .32$ ], while those between artefact categories ( $M = 1612, SE = 203.5$ ) and non-food categories ( $M = 1492, SE = 178.5$ ) for the high group were not significant [ $t(68) = 1.18, p = .247, r = .20$ ].

**Similarity ratings** The main effect of group was not significant [ $F(1, 68) = .008, p = .928$ , partial  $\eta^2 = .000$ ] nor were there any significant interactions involving group.

## Discussion

The current research aimed to explore over- or under-inclusion in categorisation in schizotypy by (a) utilising more sensitive measures of categorisation (i.e. similarity ratings and response times) than in previous studies and (b) utilising borderline exemplars.

### Semantic Categorisation

Kiang and Kutas (2005) used only high and low frequency, and unrelated exemplars, and found no group differences. Morgan et al. (2009) used similar stimuli, taken from similar norms (Battig & Montague, 1969; Hampton & Gardiner, 1983), as well as borderline and related exemplars, and found group differences. The present study found no group differences, and so it remains unclear where the locus of any group difference, if such exists, might lie.

### Borderline Categorisation

In contrast, the borderline categorisation task provides some limited support for the findings by Morgan et al. (2009). Consistent with their findings, high schizotypes provided significantly fewer positive category judgments than the low group – that is high schizotypes show evidence of under-inclusion. It is possible that the semantic categorisation task is too insensitive to reliably reveal group differences, and that the borderlines task, which focuses attention on cases whose categorisation is uncertain, is more sensitive.

That the group difference appears localised to exemplars possessing essential properties suggests that low schizotypes may be more essentialist, making positive category judgments more readily when essential properties are

present. For both groups, the effect of appearance properties was greater for natural kinds than it was for artefact categories, and the effect of essence properties was greater for artefact categories than for natural kinds. At least for these participants and these stimuli, the artefact categories appear to be more strongly essentialised.

Finally, it is interesting that no group differences emerged in response times on the semantic categorisation task. Morgan et al. (2009) reported that they may have revealed group differences as they used shorter SOAs than Kiang and Kutas (2005), thus increasing task demands. It is possible that increasing the demands of the semantic categorisation task would render it more sensitive to group differences.

The data support previous findings that have shown an inverted V-shaped function in categorisation times (Chen et al., 1994; Rips et al., 1973). Again, no group differences were noted, suggesting that group differences in categorisation in the Morgan et al. (2009) study were not due to high schizotypes requiring more time to categorise.

## Explaining Group Differences

As indicated, one possible explanation for the fact that high schizotypes provided fewer positive category judgments than the low group, and fewer positive category judgments for both types of borderline exemplar, is that they weighed less heavily the presence of essential properties. Alternatively, they may have operated with a stricter definition or higher threshold for category membership than low schizotypes, with the categorisation of high schizotypes being more similarity-based.

Essence properties were only present in the [A-E+] borderline exemplars and on this basis these exemplars should have received more positive category membership judgments if participants were essentialist. As noted above, it appears as though artefact categories were more strongly essentialised. It also appears as though the low group were more essentialist, as [A-E+] borderlines were categorised more positively by the low than by the high group.

Of course, as this is one of the few studies to directly examine the relationship between schizotypy and categorisation, these data are unlikely to be decisive as regards extant theories of concepts. Further work is needed to confirm these findings, possibly including meta-analytic studies that offer the prospect of considerably greater statistical power. Nevertheless, it is possible that the categorisation of high and low schizotypes may require somewhat different theories, with those of high schizotypes being more similarity-based, and those of low schizotypes being more essentialist. Although the current study is not able to adjudicate between different theoretical frameworks, it does suggest the promise of further studies of schizotypy and categorisation in helping to do so.

## Acknowledgements

Our thanks go to the many participants who gave their time to take part in this research, and to Mercè Prat-Sala for helpful comments on earlier versions of this research.

## Abstract

Drawing from a large corpus (17,000+ articles) of financial news, we perform a Bayesian sparse model analysis of the argument-distributions of the UP and DOWN-verbs, used to describe movements in indices, stocks and shares. Previous work, by Gerow and Keane (2011a, 2011b, 2011c), has shown, using measures of overlap and k-means clustering, that metaphor hierarchies and antonymic relations can be found in this data; for instance, UP verbs have *rise* as a superordinate organizing a distinct set of subordinate verbs (*soar, jump, climb, surge, rebound, advance*). This work empirically realizes theories about the structuring of our conceptual systems with metaphors (Lakoff, 1992; Lakoff & Johnson, 1980) but does so using a distributional approach to meaning; namely, that words that occur in similar contexts have similar meanings (see Wittgenstein, 1953). However, Gerow and Keane's analysis does not show the overall structure of how these metaphors semantically relate to one another. In the present paper, we re-analyzed their data using a Bayesian sparse model (Lake & Tenenbaum, 2010) in order to infer this metaphor space as a uniform representation, based on the argument distributions. Therefore, we treated arguments as features of metaphors. Our model learned three dimensional graphs in an unsupervised manner as sparse representations of the metaphoric structure over all argument distributions, in parallel. Doing so, it also successfully indicates the metaphoric hierarchies and antonymy relations, that were found by the previous models. In conclusion, we discuss the benefits of this approach.

**Keywords:** Argument features; analogy; Bayesian inference; emergent structure; corpus analysis; metaphor hierarchies; semantic cognition; similarity; sparse representation; spatial metaphor; structure discovery; unsupervised learning.

## Introduction

In recent years, significant progress has been made in deriving meaning from statistical analyses of distributions of words (e.g., Gerow & Keane, 2011a; Landauer & Dumais, 1997; Turney, 2006; Turney & Pantel, 2010; Michel et al., 2010). This distributional approach to meaning takes the view that words that occur in similar contexts tend to have similar meanings (see Wittgenstein, 1953) and that by analyzing word usage we can recover meaning. For instance, Michel et al., (2010) argue that significant insights into human culture and behavior can be derived from analyzing very large corpora, such as the GoogleBooks repository.

Gerow and Keane (2011a-c; henceforth abbreviated as G&K) took such a distributional approach to understanding metaphorically-structured knowledge (in hierarchies and antonymic relationships) between "UP" and "DOWN" verbs from a corpus of financial news reports. Lakoff and Johnson (1980) have argued that metaphors are used to structure many domains of human experience and also many abstract conceptual domains (e.g., emotions). They specifically identified the use of the UP-DOWN metaphor opposition in accounts of wealth (e.g., WEALTH-IS-UP as in *high class*) and in the *rise* and *fall* of numbers (e.g., MORE-IS-UP; LESS-IS-DOWN).

G&K (2011a) build a corpus of 17,000+ financial articles covering a 4-year period, about the major world stock indices (Dow Jones, NIKKEI, FTSE-100) from the *Financial Times*, *NY Times* and *BBC* websites; the corpus contained over 10M words. After parsing the corpus, G&K selected all the sentential instances of the most commonly occurring UP and DOWN verbs (see G&K, 2011a, 2011b for details). Table 1 shows some of the most commonly used arguments found in the corpus, indicating the metaphoric usage of the selected verbs. G&K then analyzed the clustering in these distributions (using k-means clustering) and the overlaps between the distributions of different verbs (using the % overlap in each pair-wise comparison of verb arguments). This analysis threw up some striking regularities.

Table 1: The percentage of *rise*'s argument distribution covered each of the 10 most frequent arguments.

Rank	Argument Word	% of Corpus
1	Index	7.3
2	Share	5.6
3	Point	4.8
4	Percent	2.9
5	Price	2.4
6	Stock	2.0
7	Yield	1.9
8	Cent	1.3
9	Profit	0.9
10	Rate	0.9

## Metaphor Hierarchies

G&K (2011b) argued that if one verb-metaphor (e.g., that referred to by *rise*) was organizing another metaphoric verb (e.g., *soar*) then the argument distribution of the former should largely cover the latter, but the opposite would not be the case. They also argued that verb-metaphors at the same level of generality (e.g., a basic level), *sibling metaphors*, would have symmetrically overlapping argument distributions. Their coverage- and cluster analysis confirmed these types of structure. On coverage, they found that *rise* organized a group of metaphoric siblings (*soar, jump, climb, surge, rebound, advance*), set off from a set of other more outlying verb-metaphors (*increase, rally, recover, gain, alleviate, elevate*; see Figure 1, A). In the clustering, they found that *rise* was quite separate from all the other verbs that clustered together and that *gain* and *climb* were quite distinct (see Table 2). A similar pattern was found for *fall* and its subordinate-related verb-metaphors (*dip, retreat, sink, plunge, tumble, slide slip, slide, ease, drop, plummet*), with *decline, lose, decrease* and *worsen* being outliers (see Figure 1, B, and G&K, 2011b, for detailed results).

Figure 1: Argument coverage of (A) main UP-verbs and (B) main DOWN-verbs from G&K (2011b).

## Metaphoric Antonyms

G&K (2011c) also analyzed verb distributions for antonymic relations; arguing that preferred antonyms *rise-fall* should have more similar distributions than less preferred antonyms *rise-decrease* or *rise-lower*. G&K performed a psychological experiment to find the preferred antonyms between the UP and DOWN verbs and then formulated several different similarity measures (Euclidean

distance, cosine similarity, K-L divergence) on the argument distributions to determine which one best predicted the human choices. Given a set of 13 UP verbs and 15 DOWN verbs (as possible antonyms) people identified 114 unique antonym pairs. Of these, in 60% of cases, the cosine similarity of the argument distributions of pairs correctly identified the most preferred antonym-pair from the human ratings. This figure rose to 87% if we consider identifying the 1<sup>st</sup> or 2<sup>nd</sup> most preferred pairs (see G&K, 2011c for details). Table 3 lists some results of the human antonymy ratings.

Table 2: Top 5 clusters in k-means analysis of UP-verbs (\* rest = the remaining verbs).

Rank	Cluster Groups	% of Tot. (Freq.)
1	rise, rest*	62% (1451)
2	rise, gain, rest*	18% (702)
3	rise, [climb, gain], rest*	4% (36)
4	rise, [jump, climb, gain], rest*	3% (27)
5	all-verbs-as-one-group	2% (18)

Table 3: Some examples of people's verb antonymy ratings, conducted by G&K (2011c). Percentage measures indicate mean antonymy ratings over participants and sub-tasks (free generation and match the opposite).

Verb pair	Antonymy
rise-fall	57%
jump-fall	31%
drop-climb	13%
decline-rise	27%
slide-climb	23%
soar-plummet	17%

## Using Sparse Models Instead

G&K found a number of interesting regularities for hierarchical and antonymic relationships between the argument distributions of UP and DOWN verbs. However, their results were based on different approaches, rather than a unifying model, and do not indicate the semantic structure of the metaphoric corpus as a whole. Arguably, it is essential to understand the cognitive semantics of the corpus, as the meaning of individual concepts must depend on how they relate to one another (Kemp & Tenenbaum, 2008). Bayesian sparse models, also known as sparse graph codes (MacKay, 2003), appear to be good candidates for this task.

Bayesian sparse models basically infer an emergent structure in a probabilistic framework (Rogers & McClelland, 2004). Applied to semantics, they have been shown to perform particularly well at finding regularities for the clustering of features for very large numbers of words from different conceptual domains (Lake & Tenenbaum,

2010). These models assume that people learn a set of parameters that fit their observed data well.

Sparse models may be better at handling metaphoric structure than other structured probabilistic models for semantic cognition (e.g., Kemp & Tenenbaum, 2008). The latter generate structures as instances of forms and discover the structural instance of the form that best explains the underlying dataset; including, structural instances based on the graph grammar of trees, linear orders, multidimensional spaces, rings, dominance hierarchies, cliques, and other forms that are supposed to be the organizing principles for data of different cognitive domains. In this way, these models account for domain-specific inferences. The learned structures can then be used to model human inductive reasoning about novel properties of objects within those domains (Kemp & Tenenbaum, 2009).

However, considering a dataset of metaphors, we need to take into account that contemporary cognitive linguistics understands conceptual metaphor not as domain-specific inference but rather as mappings from one conceptual domain to another (Lakoff, 1987; Gibbs, 1994, 1996; Fauconnier & Turner, 1998, 2003). For example, mapping the directionality of movement to changes in quantity (e.g., “prices are rising”). A cognitive model of metaphoric structure would, therefore, not necessarily need to select between structural instances of domain specific forms. Since a metaphoric corpus is likely to consist of many mappings of many different conceptual domains, it would rather need to infer an emergent structure on the basis of a psychologically justified prior probability over the hypothesis space of possible structures. We think that sparseness would be a useful prior for such a model, as it accounts for the cognitive parsimony that is needed to mentally structure metaphors over the vast array of semantic domains (Lakoff, 1992); as well as for the trade off between cognitive effect and computational effort (Wilson & Carston, 2006).

### Sparse Model Analysis of Verb-Metaphors

Lake and Tenenbaum’s (2010) Bayesian sparse model was used on G&K’s verb-metaphor corpus, involving UP and DOWN verbs, extracted from the larger finance corpus (see Data Set). This metaphor corpus contained 9,700+ distinct sentence instances for these two sets of verbs. The sparse model should be able to learn and graph the structure of these verb-metaphors by determining how they covary with regard to the frequency of their argument features. Graphically, the verb-metaphors are represented as nodes in a weighted graph, where the strength of the link between two object-nodes is related to the weighted covariation of their features. The weights of the graph, denoted as the symmetric matrix  $W$ , are learned from data by optimizing an objective function that trades off the fit to the data with the sparsity of the graph. In the present study, the sparse model technique was used to build three different graphs: a graph for the UP verb-metaphors and their arguments (using a  $13 \times 386$  matrix), a graph for the DOWN verb-metaphors and their arguments (using a  $15 \times 456$  matrix), and a graph of

the combined set of UP and DOWN verb-metaphors (using a  $28 \times 605$  matrix).<sup>1</sup>

### Method

**Data Set** A total of 28 verbs were used, 13 UP-verbs with 386 distinct, unique arguments, 15-DOWN verbs with 456 distinct, unique arguments (based on those used by G&K, 2011b-c). There were 9,721 distinct sentence instances in the corpus (5803 sentences with UP verbs, 3918 sentences with DOWN verbs).

**Model Setup** The code for the model we used was written in MATLAB (provided by Brenden Lake, Department of Brain and Cognitive Sciences, MIT; see Lake and Tenenbaum, 2010, for a detailed description of the model). Formally, the undirected graph  $W$  defines a multivariate Gaussian distribution  $p(f^{(k)}|W)$  in the generative model, known as a Gaussian Markov Random Field (GMRF), where the  $n$  objects are the  $n$ -dimensions of the Gaussian. With a prior distribution on sparsity, the model then estimates the maximum a posteriori (MAP) parameters  $W$  as optimal structure based on data. Each data set  $D$  was cast in a  $n \times m$  matrix with  $n$  metaphors and  $m$  arguments. Therefore, the columns of  $D$ , denoted as arguments  $\{f^{(1)}, \dots, f^{(m)}\}$ , were assumed to be independent and identically distributed drawn from  $p(f^{(k)}|W)$ . With the  $n$ -dimensional Gaussian distribution, it is assumed that arguments vary smoothly over the graph. So, if two metaphors  $i$  and  $j$  happen to be connected by a large weight ( $w_{ij}$ ), they share similar application frequencies over arguments. As a result of sparsity, most metaphors are not directly connected in the learned graph (i.e.,  $w_{ij}=0$ ). The resulting weights allowed us to further apply a Markov Cluster Algorithm (MCA) to classify verb metaphors based on the covariation of their argument distributions. Inflation and pre-inflation settings for the MCA were held on standard (see Freeman et al., 2007; Theodoridis, Van Dongen, Enright, & Freeman, 2009).

### Results & Discussion

Figure 2 shows the resulting weight matrices illustrated as sparse graphs learned for the three different datasets: (A) UP verbs, (B) DOWN verbs and (C) UP-DOWN verbs combined (all graphs were drawn with BioLayout Express 3D; videos of rotating versions of respective graphs should be retrievable by clicking on them). In each graph, the labeled nodes represent verb-metaphors (e.g., *rise*, *fall*). The links show the connection weights and consequential distances between the nodes, denoting similarity over all

<sup>1</sup> Resulting weight matrices are available from the authors.

**Metaphoric Structure of UP Verbs** Figure 2 (A) shows the sparse graph for the UP verb-metaphors. Overall, it literally provides a much better picture of the semantic space of the metaphors with the relative distances between each clearly shown, compared to G&K’s (2011b, 2011c) analyses. First, note that the *rise* node stands out as being distinct and non-similar to most of the other nodes. Counter-intuitively, this occurs because though *rise* has arguments that cover many of the arguments of most other verbs *combined* (also see Figure 1, A), it has fewer arguments in common *individually* with any given verb (and, therefore, low similarity with each). Second, *rise*, *climb* and *gain* cluster separate to the remaining verb-metaphors (purple vs. green nodes). While we know that *rise* has asymmetric coverage regarding most other verbs, *climb* and *gain* have not (also see Figure 1, A). Therefore, the latter are two highly interconnected outliers.

**Metaphoric Verb Antonyms** Figure 2 (C) shows the sparse graphs for the combined UP and DOWN verb corpora. These graphs are slightly different because they deal with both categories of verbs. G&K's (2011c) analysis for antonymy worked on the basis that the key antonyms would be highly similar.

relative to other pairings across the two sets of verbs. Again, the sparse model shows this very clearly as notable key antonym pairs appear as close nodes: for instance, *rise-fall*, *gain-drop*, *climb-slip*, *gain-lose*. Further, how the verb-metaphors cluster (shown by node coloration) indicates semantic similarity in how they got applied. However, the antonymy ratings from the human subject experiment of G&K (2011c) correlate just weakly with the ones from the model (Pearson's  $r=0.4$ ; see Figure 3). This might have experimental- and model related reasons: first, the verb-metaphors from the corpus were applied by human speakers to describe financial changes. The experimental data, however, are abstract antonymy ratings of verbs, having neither applicational relation to the domains relevant to conceptualize finance, nor to any other cognitive domain. (Future experiments for metaphoric antonymy would need to take this into account.) Second, the model's antonymy ratings for the superordinates *rise* and *fall* had to be excluded, since they were 0 to all other metaphors, except to one another. Finally, in the graph are also some high-similar pairings within the same verb set, like *rally-rebound* and *slip-ease*, that are clearly “just similar” and not antonyms. The latter indicates that some prior categorization of what-are-known-to-be broadly opposite sets is required before such a merged model might be useful. Again, an additional coverage analysis is needed to isolate *rise* and *fall* as superordinates (see also Figure 1, A and B).

Figure 3: Model- versus human antonymy rating of verb-pairs in per cent. Human ratings reflect perceived antonymy of verbs (see G&K, 2011c); whereas model ratings reflect the computed antonymy of verb-metaphors used to describe financial changes. The latter are weighted entries of the model's weight matrix.

## Conclusion

The suggestion that significant parts of our conceptual systems are structured by metaphors has mainly received support from linguistic and anthropological analyses (see Lakoff & Johnson, 1980). However, cashing out these ideas

empirically in a systematic way has proven difficult. The promise of the present work is that these ideas can be empirically supported by a distributional analysis of verb arguments, with such metaphoric import. We have shown that sparse models can provide a rich and informative basis for relating these verb-metaphors together in a uniform metaphor space. We believe that this approach may be useful in modeling other cognitive tasks that rely on these metaphoric spaces (e.g., language comprehension, analogical thinking). For instance, in analogical thinking it has long been argued that conceptual slippage (Hofstadter, 1995) and re-description (Keane, 1996; Kurtz, 2006) are needed to account for human abilities: Bayesian sparse models provide a basis for allowing such slippage, assuming structural support for the slippage being considered.

However, our work has also indicated that the sparse models will still need a coverage analysis to isolate superordinate metaphors. And, because these are important for conceptually structuring the metaphor space, they should be implemented in the way sparse models generate and learn structure. This might be achievable by using hierarchical Bayesian sparse models (Chandrasekaran, Parrilo, & Willsky, 2010) that potentially discover organizing metaphoric concepts as hidden or latent variables, and further increase sparsity.

## Acknowledgments

This work was carried out as part of a self-funded MSc in Cognitive Science at UCD by the first author. We want to thank Brenden Lake for providing the code for the sparse model, Aaron Gerow for all the data, Anne Tamm for linguistic advice, and Máté Lengyel for technical suggestions.

## Abstract

While collaborative learning is common in schools, most research has focused on small group collaborative processes, in one shot practice. In order to investigate the nature and the mechanism of collaborative learning in a larger group, this paper presents analysis of a classroom discussion in which 21 third-graders (8- to 9-year-old students) collaboratively discussed predictions about the results of a series of experiments as a whole class over 12 course hours and became able to grasp a rudimentary scientific concept of atomic theory.

We analyzed students' levels of achievement, conversation patterns, selection sequences of predictions of the experimental results, and the contents of their utterances of two students who were most active. The results revealed that all the children succeeded in expressing their grasp of rudimentary atomic theory, yet their routes to this achievement were individualistic and diverse. A preliminary qualitative analysis of two children's utterances shows that while their models were similar during the first half of the course, their differences became more explicit toward the end, which resulted in intense discussion between the two. The diversity observed in the entire course of this class and these two children's explicit, focused dialogue could have contributed to the successful conceptual change for all class members.

**Keywords:** Collaborative conceptual change, HEI class, Socially constructive interaction,

## Introduction

While the amount of research on collaborative learning has increased sharply in the last 10 to 15 years, many studies deal with small groups of learners in mostly one-time practice. Studies of entire-class discussions, which are the norm in regular schools, are still few.

In regular elementary to middle school classes in Japan, it is quite common for 10 to 20 students to discuss their ideas about textbook descriptions and experiment demonstrations, under the teacher's guidance. In science classes, this is a common practice aimed at helping the students change their concepts from rules of thumb to more scientifically rigorous ones. Understanding what actually happens in these practices should be beneficial for developing practically feasible collaborative classrooms.

In the similar vein, in STEM education engaging the learners in demonstrations and experiments has been considered effective. In real classrooms, these activities

often take place in a series of course hours rather than in one time practice. Understanding how these cumulative activities may affect children's conceptual change would also be informative regarding the quality of such classes.

In order to address these needs, this paper presents analysis of the learning processes observed in a well-designed STEM class. In the class, 21 third-graders collaboratively discussed predictions of the results of a series of experiments and were able to grasp a rudimentary scientific concept of atomic theory. The children were encouraged to discuss alternative predictions of carefully ordered experiments as a whole class in order to realize that water cannot enter "where there is air and vice versa" with justifications ranging from heavily relying on their daily experiences to abstracting theory-like reasons based on accumulated observations of the results of previous experiments.

For this class, we tried to answer the following questions.

1. How well did the 21 children understand the concept at the end of the course?

2. What was the trajectory of understanding of the whole class qualitatively? More concretely, in terms of choices of the experiment results and the number of similar explanations by the children, did the class converge toward the "same" answer (as possibly expected by many teachers as well as some convergence-oriented theoreticians), or was divergence among the children maintained? Divergence here means that each individual child creates his or her own explanations of understanding, even at the very end of the course, with some different degrees of understanding underlying their seemingly or apparent "same successful" understanding (e.g., "everybody answers correctly"). It is important to make this distinction so that the teacher can create a class atmosphere that focuses on either divergence or convergence. In our own preliminary study, orientation toward more diversity has been identified as having more potential for successful collaboration.

3. What was the qualitative nature of the children's process of conceptual change, if it happened? In order to gain some insight, we analyzed the utterances of the two most active participants. We analyzed how they changed their expressions of their models as the course developed.

## Research context:

### Hypothesis-Experiment-Instruction

Our research context here is the series of science classes designed using the Hypothesis-Experiment Instruction (HEI) framework (Itakura, 1963) and the target content of the “Air and Water” unit (Itakura, 1970). The objective of this unit is to understand that water cannot enter where there is air and vice versa, to serve as the basis of a rudimentary grasp of atomic theory. HEI is a strategy to teach basic scientific concepts. An HEI “unit” consists of multiple such “problems,” or experiments, carefully ordered to guide the development of scientific concepts underlying the problem set. The teacher uses a problem set sheet for each experiment; the sheet explains the experiment and alternatives of possible answers. Each student chooses one alternative, and the result of their selections is written on the blackboard so that the students know the distribution. They then are encouraged to give reasons for their choices, to question others, and to discuss among themselves in order to make a better prediction. They are allowed to change their prediction before the experiment that will confirm the correct answer. At the end of the class, each student writes comments about the activities. By repeating this activity to cover the entire set of problems in a unit, each student in an HEI class is expected to integrate the results of the experiments in her/his own way in order to formulate an individualized “hypothesis,” or the student’s rudimentary scientific concept.

The “Air and Water” unit consists of the 11 problems explained in Table 1. These problems can be classified into two subsets, Problem 1 (P1) through Problem 6 (P6) and the rest. The first set deals with problems whose answers are justifiable with daily experiences. In contrast, situations of P7 to P10 do not occur often in children’s daily lives; thus, they are difficult for children to imagine.

Table 1: Wordings of the 11 problems in the “Air and Water” HEI unit

P1	When an empty glass is pushed into water upside down, will the water come into the glass?
P2	If you place a crumpled piece of paper in the glass and do the same as in Problem 1, will the paper get wet?
P3	An upside-down glass with water inside is in the water. When you lift it up through the surface of the water, what will happen to the water in the glass?
P4	What will happen when you suck air through a straw from an upside-down glass in the water?
P5	Which dropper sucks more water, one whose tip is deep in the water or one whose tip is shallow?
P6	Can water be sucked through a 1m straw?
P7	A can of juice has just one hole on top. When the can is turned upside down, will some juice come out of it?
P8	Will some juice come out of a can that has two holes on its top and is turned upside down?
P9	Suppose you put the can used in problem 8 deep into the water, keeping your finger tight on one of the holes. Will some water go into the can?
P10	What will happen to the can in problem 9 if you remove your finger?

P11	Will some soy sauce come out of its container if you put your finger onto the hole on its top?
-----	--

The latter problems require learners to rely on their newly formed “hypotheses,” from accumulating predictions and observations of the experimental results in the previous problems. The learners are expected to realize that water cannot enter where there is air and vice versa, with justifications starting from relying on their daily experiences to abstracting theory-like reasons. The last problem, P11, can be answered by relying on either daily experiences or newly learned understanding, or both. This is to confirm their achieved levels as well as to let the children connect the hypotheses to daily life, so that they may see that their clearer understanding is usable in everyday situations.

The targeted concept of this unit is “water cannot enter where there is air and vice versa,” according to Itakura (1970), the developer of this curriculum. From the perspective of modern science, we should use such concepts as “atmospheric pressure” and “surface tension” to fully explain the results of the P7 through P10 experiments; however, the learners were not expected to understand these concepts in this unit. Instead, the emphasis was on having the children experience “how to think scientifically.” The idea of “water cannot enter where there is air and vice versa” itself is not sufficient for high school education, but it is adequate to give a general justification to cover all of the 11 experiments. Thus, becoming able to predict the results of an experiment and to justify the prediction requires a change in concept, tying experience-based rules of thumb to more scientifically justifiable explanations.

In order to identify the levels of conceptual change discussed here, we use the four-level model that ties the children’s daily experiences and the scientific concepts (Miyake, 2009) listed in Table 2. The learner can create a rule of thumb based on one incidence of experience (e.g., coming too close to a heated stove lets the child create a useful rule of thumb of “red, warm, could be extremely hot, to be avoided”). Usually these experiences should be repeated numerous times so that the child can create a more stable rule of thumb and understand the world around her/him. These are individually created, experience-based “concept” levels of Level 1 (based on one incident) and 2 (repeated and summarized). The other side of the model, Level 4, includes the consensus reached by the scientific community, the state-of-the-art concepts shared by professionals. These are the concepts explained in textbooks and expected to be taught at school. In between, at Level 3, is a wide zone for learners needing to change their Level 2 basic experience-based rules of thumb to Level 4 scientifically community-shared concepts. Many instructional methods have been developed and tested to facilitate this conceptual change (Vosniadou, 2008). Some of these methods heavily utilize the power of social construction in the form of collaborative design (c.f., Roschelle, 1992; Howe, et.al. 2005; Vosniadou, et.al.2007; Miyake, 2008). HEI is such a method (Saito & Miyake, 2011).

According to this model, the targeted conceptual change for the “Air and Water” unit is to reach Level 3, starting from Level 2.

Table2 : Four-stage model of conceptual change

Theories constructed through collaboration	Lv.4	Scientific concept, created and shared in the scientific community
	Lv.3	A socially constructed, yet individually understandable “story” tying abstracted ideas created on their own as well as borrowed from others and the the rules-of-thumb accumulated in daily life.
Knowledge and rules from individual experience	Lv.2	A rule of thumb created by accumulating one’s own (yet many) experiences from different situations
	Lv.1	A rule -of- thumb based on one incidence

## Children’s conceptual change

### Data

The data come from the “Air and Water” unit in an HEI class conducted in May and June 2002. Twenty-one third graders participated in 12 lessons taught by a highly experienced HEI teacher, Yuko Saito, who voluntarily kept records of the distributions of students’ predictions before and after the class discussions, the students’ discussions using hand-written notes, and voice recordings. She also kept copied records of the notes taken by all the students during class. The transcribed voice recordings and the copied notes are the data we analyzed here.

### Predictions of answers to the problems

Fig. 1 plots the percentage of correct predictions made by the children upon reading the explanation of the experiment, prior to discussion.

Figure 1: The percentage of correct predictions.

All the children made correct predictions for the last experiment, whose result was not readily obvious from daily

experiences. It could be assumed that the entire class somehow successfully formed a rudimentary concept of physical identity, at least with regard to whether or not air and water could share the same physical space.

However, this conceptual shift did not occur smoothly. For P7 and P8, the problem situation significantly deviated from the children’s daily experiences, thus making it particularly difficult for them to make correct predictions. After their complete failure on these problems, the children somehow recovered their performance over P9 and P10, and were able to correctly predict 100% on the transfer problem of P11.

### Shift of levels of the children’s concepts

Because the shift pattern of predictions indicated successful learning at least at the end, we could expect to observe a corresponding shift of concept levels in the children’s utterances and the note descriptions. We coded the contents of the students’ discussions during the classes and the written comments after the classes according to the levels described in Table2. The operational definition used for this coding and the corresponding example of each level are presented in Table3. The correspondence rate of coding by two coders was 94%.

Table3: Categorization for level of conceptual change in “Air and Water”

	Operational definition	Examples
Lv.3	Explanation based on understanding of “water cannot enter where there is air and vice versa, “which could lead the learners to correctly answer one or more problems.	“The seal stops the air. When the air can’t move, the water won’t move, either” for P11
Lv.2	Explanation based on generalized rules of thumb	“When the can has two holes, water can move” for P10
Lv.1	Explicit reference to a particular experience	“I have tried such an experiment with a wash bowl in the bath.” for P1

Figure 2: The accumulated number of Lv3 expressions

If the class successfully changed their concept, each student could express Lv 3 understanding at least once. Figure 2 plots the accumulated number of students whose justification fell at Lv 3 for each problem.

Twenty of the 21 children's expressions of reasons for their choices were coded as Lv 3 explanations at the end. Thus, we could conclude that the class was successful in helping each child construct a starting scientific model about air and water.

## Quantitative analysis of the children's collaborative learning paths

### Shift pattern of predictions of each student

What was the qualitative trajectory of this successful conceptual shift in the whole class? In terms of choices of alternatives of the experiment results and the similarities of explanations given by the children, did the class converge to the "same" answer, or did the individual students diverge?

Each student could choose one of three possible predictions for each problem. This allowed many possible paths of choices, but for 7 of the 11 problems, more than half of the students chose the same prediction (Fig. 1). If students had chosen the same prediction because they understood in a similar manner, there could not have been so many patterns of choices. When we asked teachers who often teach HEI classes how many courses there could be for an 11-problem unit, they typically said there would be only three or four paths in one class of 20 to 30 students. For analysis, we checked the alternative that each child chose for each problem. We then compared the sequence of such predictions for each child against that of the other children. Every child had a unique sequence of alternatives for the 11 problems; thus, we concluded that there were 21 paths of selections. For P1, P5, and P10, student's selections were evenly distributed among the three alternatives. Thus, they did not tend to converge to fewer selections toward the end of the unit. This diversity could have made the interaction among students constructive, promoting conceptual change in the class, as confirmed above.

### Similarity of models used in discussions

As for the similarity of explanations given by the children, did the class converge to the "same" answer, or did it diverge among them? A simple prediction could indicate convergence, as some previous research indicates (c.f., Roschelle), however, a detailed analysis of individual paths of understanding indicates the opposite, that they diverge as the discussion progresses (c.f., Miyake, 1986). In order to test this idea, we counted each child's utterances for each problem, as an indicator of convergence of their models. When their models converge, the learner who sufficiently explains one problem would not be motivated to repeat it for another, while a new member who comes to a definite understanding based on the model might wish to express it for a different problem. This would give us a relatively even

number of utterances among the children, as well as a relatively smooth decline of the number of utterances from the beginning problems to the ending ones.

Fig. 3 plots the number of utterances for each problem. We do not observe any clear decline of utterance frequencies across the problems. The children seem to have been motivated to speak up for some problems and not for others, even in the middle of the course, though a clear decrease is observed toward the end.

Figure 3: Number of utterances during discussion for each problem in the "Air and water" unit

When we counted the number of utterances for each child, we found a clear pattern of some kids talk more while some don't. The pattern may mean that the children could learn a lot while just being silent, attentively listening the others' talks and discussions (Saito&Miyake,2011).

## Qualitative aspects of the process of collaborative conceptual change among the core members

### Shift pattern of predictions

In order to investigate the qualitative aspects of the conceptual change process in this class, we selected the two most active children (A and B), and analyze the contents of their utterances. The purpose of this analysis is to understand the results described above. Quantitative analysis of the pattern indicates more diversity than normally expected by both teachers and researchers who believe in a convergent pattern of collaborative conceptual change. The qualitative aspects of the processes imply value in this diversity. We would like to know whether the most active two worked as a convergent target model for final success, or if their divergence contributed to their success. Were the two similar to each other in making predictions by choosing similar alternatives, sharing similar models for justification at the beginning, and gradually converging and uttering their understanding to compensate each other so that the rest of the class could use their model as a target and "learn" after them? Or were they different until the end to stimulate the thinking of the rest of the

class? For analysis, we examined their prediction paths from their chosen alternative for each problem, and inferred the cognitive models they could have adopted, based on their utterances.

First, we compared the prediction paths of A and B, and then inferred their models based on what they said and how they said it (Table 4).

Table 4 : Predictions and justifications of A and B for each problem

	A	B
P1	○ I tried this yesterday in the bath. There was no water at the top of the turned-over bucket; there could be air there.	○ I tried this also. The turned-over bucket is heavy to pull up. There may be air in it (to make it heavy).
P2	○ The paper would not get wet, when even half the cup is filled with air.	○ Air comes first, so the paper in the cup would not get wet.
P3	○ I tried this; the water was to the top of the glass, maybe because of the buoyancy force.	○ Just pulling up the glass would not do anything. The water inside stays there.
P4	○ When sucked there would be nothing in the glass, so the water should come up.	○ The air would escape if there is enough time (for the air to do so).
P5	○ The strength of push does not have anything to do with it.	○ I have tried this with a toy; when I pushed it hard, the water rushed out.
P6	○ Where there is no air, water should come up, even when the length is 1m.	○ Teacher said she would do her best, so I think she could do it.
P7	× If there were a hole on top, the juice would come out, but with a little hole on the bottom, the juice would only drip.	× When I made a hole in a small drink bottle, the juice dripped. When I made the hole bigger, then juice came out continuously.
P8	× (SEE TABLE 5 for detail)	× (SEE TABLE 5 for detail)
P9	○ Because the upper hole is covered, the water would not go in.	○ (no mention of justification)
P10	○ Now there is a hole on top, so the water pushed in, and pushed the air out.	× Water will come in about halfway. → ○ This time a large amount of water will come in.
P11	○ When some air goes in, it pushed the soy sauce. If you cover the hole, no air goes in, so no sauce would come out.	○ I tried a similar thing, and only a little soy sauce came out, so it would not come out.

N.B. ○ is the correct prediction, × indicates a wrong choice

Both students chose correct answers from the beginning to the middle (P1 to P6), indicating they possibly shared the model correctly enough to choose the correct answer. Yet in the latter part of the course, they did not answer correctly, and their choices differed for P8 and P10. This pattern could mean at least two things. First, they were similar to each other when they based their judgments on their experiences (i.e., they shared more or less the same set of experience-based rules of thumb), but their shifted concepts differed. Second, they may have held different models or rules of thumb from the very beginning, both of which were correct enough for each to choose the correct answer (for different reasons); and the difference became sharper as the problems

became more difficult and required more sophisticated use, or expressions of justification for their choices.

### Diversity of models

A closer look at the students' utterances indicates that for P1 through P6, though both students based their justifications on their daily experience, they apparently formed some generalizable model of "when air goes out, water gets in." This explanation became more sophisticated as the problem progressed. Both talked about their bath experiences in P1. However, for P5 student A mentioned "when there is the same amount of force to push, the amount of air coming out should also be the same," whereas student B said "because the same amount of air is lost, so should be the amount of water." These explanations were applicable not only to the problem at hand but also to previous problems, indicating increased abstraction levels.

Yet slight differences were observed even in these early-stage justifications. While A repeatedly used the word "top" in his explanation, B did not use it at all. This difference becomes more readily apparent in their justification explanations after P7, where the children's models stopped working.

For P7, A's repeated use of the word "top" indicated that he was trying to use the same model until P6. However, B began to consider the size of the hole, introducing a new factor in his model (he did not mention size before P7). For P8, their explanations clearly differed as they engaged in a lively discussion in front of the class. Table 5 presents details of the beginning of their explanations.

Table5: Example of utterances of A and B during P8 discussion

A	B
This time, there are two holes at the bottom of the can. I think, if one hole is above the other, it is easy for the air to enter from that hole and the juice would come out from the other hole below. But in this problem, both of the holes are on the bottom so no air could get in. That is, because the air is outside, no juice could come out, or no air could go in either. The two are separated at the bottom.	For me, it does not matter which hole lets the juice out, but the air goes in from here, it goes up to fill half of the can, then the juice would get pushed out from the other hole and drips out.

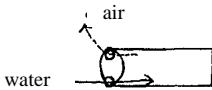

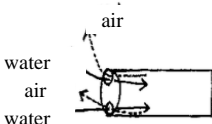

A distinguished between the positions of the two holes punched in the can. This distinction enabled him to explain "if one hole is above the other, it is easy for the air to enter from that hole," and "the juice would come out from the other hole below." From these utterances, we infer that A's model has components like "air is above, while water is below." His perspective is on the relative positioning of the air and water. We call this model the "positioning model." In contrast, B mentioned that "it does not matter which hole

lets the juice out.” Thus, we infer that he did not pay attention to the positions. Instead his explanation that “air goes in ...to push the juice out” indicates that he focused more on the interaction between air and water. We call this model the “interaction model.”

For the entire discussion of P8, A kept using the same model, emphasizing the significance of the relative positions. His last comment was “if there were any air in the can, it stays on top, so no juice would come out. In contrast, toward the end of this discussion, B began referring to the relative positions of the two holes in his model as “the air, when it somehow gets in, may move through there to reach the top, and the air on the top would let the juice come out from the bottom,” indicating his awareness of the possible integration of A’s model into his. Many questioned B’s choice, so B had to explain his position repeatedly. This could have contributed to B’s refinement of his model, while A could stay with his older model.

Preliminary analysis indicates that A and B preserved their differences and never converged to the same model. At the end of class, their explanations solicited by the teacher made this difference clear. Both drew their models on the blackboard, with explanations (Table 6).

Table 6: Last drawings and comments of A and B during P10 discussion

A	B
 <p>Though my choice is the same as B, the air becomes foamy when water comes, doesn't it? As the foam climbs up and up, stops on top and goes out. The bottom hole lets out not air, but water. The bottom is water first.</p>	 <p>Because there are holes on both, perhaps a lot goes in. Water goes in like this, and the water rushes out.</p>

This difference between A and B was maintained even at the very end of this course. We cannot deny the possibility that this difference kept both A and B engaged in the discussion, which remained the focus for the rest of the class and made everyone stay on task, thus fostering successful conceptual change for the whole class.

## Conclusion and Discussion

Analysis of the data gained from this HEI class on “Air and Water” indicated three patterns. Through the course of 12 classes covering 11 experiments or problems, the 21 children discussed their predictions of possible answers. This design successfully led them to change their experience-based rules of thumb into more scientific understanding of “air and water do not share the same space.”

Each child’s path of this conceptual change was unique, allowing each to create her/his own understanding. As indicated by qualitative analysis of the utterances of the two most active students, each could preserve her/his own model, possibly from the very beginning to the end. Yet this diversity among the children could be the source of prolonged discussion on the same topic for the length of this course, allowing both fast and slow learners to change their models. We plan to devise a better way to infer the cognitive models from these sporadic yet rich and complex utterances of children, in an effort to determine conditions for successful classroom discussion patterns that lead to conceptual change for every individual child in regular classes.

# Strategy Changes in Causal Structure Learning: The Role of Task Complexity

Motoyuki Saito (m-saito@kwansei.ac.jp)

## Abstract

Saito and Shimazaki (2012) found that people rely upon covariation information rather than temporal order information as cues to causal structure, whereas Lagnado and Sloman (2006) reported an opposite finding, indicating relatively greater influence of temporal order cues. The present research examines the hypothesis that such conflicting findings result from differences in task complexity. Specifically, it is proposed that covariation information becomes less influential as the number of variables increases. Experiment 1 investigated the relationship between the judgment strategy (i.e., covariation vs. temporal order) and the number of variables comprising a causal structure. As a result, people favored covariation cues primarily in tasks with simple causal structure. Experiment 2 used more complex causal structure. The results demonstrated that the tendency to emphasize covariation cues or to rely upon temporal order cues changes as a function of task complexity. These results were consistent with both previous findings and discussed in terms of causal Bayes net theories and heuristic models.

**Keywords:** causal structure learning; causal reasoning; covariation; temporal order; task complexity.

## Introduction

Many psychological studies have shown that both children and adults easily form representations of causal relations (Sloman, 2005; see also Holyoak & Cheng, 2011 for a review). Causal relations lead to associations of various kinds of events and they may form part of complex causal structures. Knowledge about the causal structure plays an important role in explanations, predictions, control, as well as decision making (Pearl, 2000). Despite its importance, in many cases, actual causal connections among constituent elements are often difficult to discern or to tease out of a complicated pattern of contingencies. For instance, if one hears a bit of gossip from colleague, X, and then hears same story from another colleague, Y, this might lead to the inference that X had passed the rumor to Y (i.e.,  $X \rightarrow Y$ ) based on the temporal order in which one receives this information. However, it is also possible that, earlier, Y had initially gossiped to X and then it is heard from X prior to seeing Y (i.e.,  $Y \rightarrow X$ ). Or, a third party, such as the boss, Z, may have spread this rumor (i.e.,  $X \leftarrow Z \rightarrow Y$ ). In light of this, how might be people acquire knowledge about causal structure?

As Hume (1739/2000) has argued that causal relations are unobservable and therefore must be induced from

observable events, covariation among observable events serves as a fundamental cue to learn causal structure. Covariation is formally represented as a joint probability distribution and is specifically explained as patterns of presence and absence for binary variables. When a causal relation exists, strong covariation between a cause and its effect will be expected except for the possibility that both variables are caused by a common cause. In contrast, the absence of covariation indicates that two variables are not related to each other—except for the effects of other variables. However, there are several limitations to the use of covariation cues. First, covariation information becomes more complex as the number of variables increases. With two binary variables, for example, covariation is represented by a  $2 \times 2$  contingency table of 4 data patterns; however, 32 data patterns result from five binary variables. In addition, covariation itself is inadequate for distinguishing a unique causal structure from models that represent the same joint probability distribution (i.e., Markov equivalent). When event X covaries with event Y, for instance, it is difficult to determine the precise cause. These examples suggest the difficulty of learning causal structure using only covariation cues.

In addition to covariation, another important cue to causal structure is temporal order in which people observe the states of variables. Because causes are often observed to happen prior to their effects, when event X precedes event Y, it is probable that X causes Y. However, the observed temporal order does not always serve as an accurate cue. First, temporal order may mislead people with regard to the direction of causal relations. In situations where people observe effects prior to their causes, temporal order information indicates the opposite causal direction. A second issue concerns spurious correlation. Even if event X precedes event Y, their co-occurrence might be the result of a hidden common cause Z. In this case, a temporal delay between two variables will result in a false belief that the earlier event causes the later, despite the fact that no causal relation exists. Thus, although temporal order cues can facilitate causal structure learning, they may also mislead causal inferences.

Combined with information indicating hidden causes are absent, both kinds of information become more useful. When event X covaries with event Y, three possible causal structures are presumed (i.e.,  $X \rightarrow Y$ ,  $X \leftarrow Y$ , or  $X \leftarrow Z \rightarrow Y$ ). The absence of hidden causes enables people to exclude the

possibility that both events are caused by a hidden cause. If event X occurs alone in this situation, then it is suggested that X causes Y. Since nothing happens without a cause (i.e., necessity), an event that occurs alone must be a cause variable but not an effect variable.

Previous studies on causal structure learning have provided conflicting evidence regarding the use of covariation cues and temporal order cues (e.g., Lagnado & Sloman, 2006; Saito & Shimazaki, 2012; White, 2006). On one hand, Lagnado and Sloman (2006) demonstrated that people preferred temporal order cues to covariation cues. In their experiment, participants were required to send messages from a master computer to one of four computers in a network (e.g., computer A), to observe whether other computers also received the messages (e.g., computer B, C, & D), and then to infer the structure of network. Participants observed the states of the computers in the order different from the causal order (e.g., temporal order:  $A \rightarrow D \rightarrow C \rightarrow B$ , causal order:  $A \rightarrow B \rightarrow C \rightarrow D$ ). Although participants were given instructions including information on the unreliability of temporal order and the absence of hidden causes, their judgments were based on temporal order cues rather than covariation cues. White (2006) reported similar results indicating that participants relied heavily on temporal order information, in spite of the fact that they received explicit instructions regarding the way in which causal structures are induced from covariation information.

On the other hand, Saito and Shimazaki (2012) showed the opposite results that people use covariation cues rather than temporal order cues. The experimental task was to observe occurrences of two types of bacteria and to infer their causal relationship. As in Lagnado and Sloman (2006), participants were instructed that temporal order cues were unreliable and that there were no hidden causes. In the condition in which covariation cues contradicted temporal order cues, participants heavily favored covariation information over temporal order information. Furthermore, these judgments were made after several observations.

A possible interpretation of these conflicting findings involves differences in task complexity, especially as this is reflected by number of variables. It is possible that task complexity modulates an individual's judgment strategy. A critical difference between the preceding experiments is the number of variables that constitute the causal structure. Whereas Lagnado and Sloman (2006) required participants to learn causal directions among four variables, and White (2006) adopted five variables in constituting a causal structure, the design of Saito and Shimazaki (2012) presented a causal structure involving only two variables—the minimum unit for causal structures. Since increasing the number of variables complicates covariation information, it therefore would be difficult to induce a complex causal structure based solely on covariation cues.

Several studies have revealed the role of task complexity in causal learning and inference (e.g., Marsh & Ahn, 2006; Reips & Waldmann, 2008). Marsh and Ahn (2006) demonstrated that the task complexity served as a

determinant of a primacy effect and a recency effect. When a few variables were observed, information presented earlier weighted more than information presented later (i.e., primacy effect); in contrast, information presented later was emphasized more than information presented earlier when many kinds of variables existed (i.e., recency effect). In a similar vein, Reips and Waldmann (2008) showed that accurate diagnostic inferences depended on the number of variables in the experimental task. These studies suggest the importance of task complexity in causal judgment.

The purpose of the present study is to investigate the relationship between task complexity and the judgment strategy in causal structure learning. In order to manipulate task complexity, the number of variables composing the causal structures was manipulated in Experiment 1. Experiment 2 employed different forms of causal structures. The hypothesis predicts that people use covariation cues rather than temporal order cues in learning simple causal structures whereas they rely more upon temporal order cues than covariation cues in inferring complex causal structures.

## Experiment 1

Experiment 1 was designed to investigate how strategies change as a function of the number of variables in learning a causal structure. The experimental task was to observe states of the variables and to infer causal relations among these variables. The number of variables in the causal structure was varied for the manipulation of task complexity. The authors predicted that when the number of variables was small covariation would be more emphasized rather than temporal order and that when the number of variables was large temporal order would be more reflected than covariation.

## Method

**Participants and design** A total of 24 undergraduates from Kwansei Gakuin University received course credit for taking part in this experiment. The number of variables (three, four, and five) was manipulated within participants. Each participant performed three causal learning tasks with different causal structures.

**Instructions** Participants received verbal and written instructions in Japanese. An English translation of outlines of the instructions was as follows:

Imagine that you are a scientist who is attempting to reveal causal relations among several newly discovered bacteria. Whether one bacterium propagates another bacterium, or whether they are irrelevant to each other are unknown to you. In order to investigate the relations among the bacteria, you put one type of bacterium into the 40 containers of liquid nutrient medium. Then you observe the states of other bacteria under the microscope. Before performing each task, you will be informed about which bacterium is put into the nutrient medium. (The bacterium serves as a first cause.)

Additionally, the following three facts should help you consider causal relations among bacteria. First, it is not always true that one bacterium is certain to propagate other bacterium even if there is a causal relation between them. That is, a causal relation among bacteria is probabilistic. Second, there are no hidden causes as this is a controlled situation. Therefore, when a bacterium exists, except for the one originally put into the liquid nutrient medium by yourself (i.e., first cause), there is another bacterium that acts to propagate it. Third, the states of bacteria develop in order. This is either because it takes time for a bacterium to propagate another bacterium or because it takes time to identify the presence and absence of bacteria due to their invisibility without the use of microscope. Therefore, it could be that a bacterium has propagated another bacterium before it turned out to be present.

Your task is to observe the occurrences and non-occurrences of these bacteria and to infer causal relations among them. Note that the experimental task does not require any knowledge of biology. (The remaining instructions describe how to progress through the learning phase and test phase.)

After receiving the instructions, participants were asked whether they understood the instructions. In this cover story, the number of variables (three vs. four vs. five) corresponded to the number of bacteria participants observed in each task.

**Learning phase** At the beginning of the learning phase, participants were taught how many kinds of bacteria would appear (e.g., three, four, or five) and which bacterium would be put into the 40 containers of nutrient medium (i.e., first cause) in each condition. The learning phase consisted of 40 trials that presented information about the presence and absence of the bacteria. Participants were asked to observe the states of the bacteria and to consider their causal relations. First, a button labeled “NEXT” was displayed on a screen. After clicking the button, the shapes of the several number of bacteria labeled with question marks were shown (i.e., they remained unknown). The number of bacteria varied across conditions. There were three bacteria in the three variables condition, four bacteria in the four variables condition, and five bacteria in the five variables condition. Then, information about the state of the bacterium was given in order. The presence of bacteria was indicated by the appearance of bacteria; in contrast, the absence of bacteria was represented by the appearance of bacteria labeled with a cross mark. The inter-stimulus interval was 1s, and the screen was returned to its primary state (i.e., “NEXT”) 2s after the all bacteria appeared.

Figure 1 illustrates the causal order in which causes produced effects and the temporal order in which participants observed the states of variables. Covariation information was arranged based on these causal structures and the causal strength of the relation. As the instructions

3 variables condition 4 variables condition 5 variables condition

Figure 1: Causal structures in Experiment 1. Continuous lines represent causal relations, whereas dotted lines indicate temporal orders.

stated causal relations among bacteria were probabilistic, the probability that causes produced effects was 80 percent. In the three variables condition in which participants observed 40 cases, for example, 26 cases included the presence of bacteria A, B, and C. In 6 cases, bacteria A and B were present; bacteria A and C were present in additional 6 cases. The remaining 2 cases included the presence of bacterium A and the absence of bacteria B and C. While the first cause was always present, other variables did not occur unless their specific cause was present. As the number of variables increased, covariation information became more complex. As is evident in Figure 1, temporal order was inconsistent with causal order. Arranging the temporal order to be different from the causal order enabled assessment of the degree to which covariation cues and temporal order cues were used to infer causal structure.

**Test phase** After observing 40 cases, participants were told to infer causal structure in the test phase. Participants received a sheet in which bacteria were displayed in the same way as they were shown in the learning phase, with light gray lines between the bacteria. The instructions required participants to judge whether a casual relation existed and to draw an arrow from a cause to an effect on the line when a causal relation was assumed. Participants had to consider three lines in the three variables condition, six lines in the four variables condition, and ten lines in the five variables condition.

## Results and Discussion

To investigate judgment strategy in causal structure learning, the authors defined usage rates as measures of the degree to which participants used covariation cues and temporal order cues. The usage rate of covariation was calculated by dividing the number of links drawn by participants to be consistent with covariation cues by the number of all links suggested by covariation information. In the three variables condition, for example, the link from A to B and the link from A to C were supported by covariation cues (see Figure 1). If participants gave these two links as their answer, their covariation usage rates were 100 percent; in contrast, when they failed to answer both links, the usage rates were 0 percent. The usage rate of temporal order was calculated in

a similar manner. In the above example, temporal order cues sustained the link from B to C and the link from C to A respectively (see Figure 1). If participants responded either of the links, their temporal order usage rates were 50%. These indices represent the amount of use of each cue by participants.

Figure 2 shows the usage rates of two types of cues in each condition. When the number of variables was three or four, participants used covariation rather than temporal order; however, there seemed to be no difference in the five variables condition. A two-way repeated measures ANOVA with the type of cue (covariation vs. temporal order) and the number of variables (three vs. four vs. five) as within-participants factors revealed a significant main effects of the type of cue,  $F(1, 23) = 14.01, p < .01$ , and the number of variables,  $F(2, 46) = 4.43, p < .05$ . The interaction between the type of cue and the number of variables was also significant,  $F(2, 46) = 6.76, p < .01$ . Subsequent tests of the simple main effect of the type of cue were significant in the three and four variables condition,  $F(1, 69) = 21.03, p < .001, F(1, 69) = 10.11, p < .01$  respectively, but not in the five variables condition,  $F < 1$ , indicating the task complexity served as the modulator of the judgment strategy.

Although the judgment strategy varied across the number of variables, the result of the four variables condition was inconsistent with previous findings in which the temporal order information had a greater impact than covariation in learning the causal structure composed of four variables (Lagnado & Sloman, 2006). In their experiment, the 58% usage rate of temporal order cues was higher than the 39% usage rate of covariation cues when the causal order ( $A \rightarrow B \rightarrow C$  &  $D$ ) differed from the temporal order ( $A \rightarrow D \rightarrow C \rightarrow B$ ). The opposite results might stem from differences in cover stories. Whereas the present study dealt with the causal relations of several types of bacteria, the previous study used computer networks in which participants sent a message to one computer and observed whether other computers received. Prior knowledge and experience about computer message would give more

weight to temporal order cues. In fact, Saito and Shimazaki (2012) have reported that the use of temporal order cues depends on its reliability.

In summary, Experiment 1 showed that covariation cues were used more often than temporal order cues when participants learned causal relations among three or four variables. However, when the causal structure consisted of five variables, the preference for covariation disappeared. This pattern of results supports the claim that judgment strategy changes as a function of increasing the number of variables.

## Experiment 2

The results of Experiment 1 demonstrated that task complexity modulates participant's judgments about causal structures. However, these findings did not reveal a tendency to rely upon temporal order rather than covariation. The goal of Experiment 2 was to provide further evidence about the relationship between task complexity and the judgment strategy. In order to ascertain whether temporal order cues were more influential than covariation cues in learning complex causal structures, different forms of causal structures were used. Specifically, causal structures with multiple causal links were adopted. This is because increasing the number of causal links leads to more complicated covariation information. Again, the authors predicted that participants' judgments will be based more on covariation than on temporal order when the causal structure was relatively simple, whereas temporal order cues should be more influential than covariation cues when participants inferred the complex causal structure.

## Method

**Participants and design** A total of 24 undergraduates from Kwansei Gakuin University participated for course credit. None of them took part in Experiment 1. As in Experiment 1, the number of variables (three, four, and five) was varied within participants. Participants were asked to perform three causal learning tasks with different causal structures.

**Procedure** Each participant completed the tasks of observing states of the bacteria and inferring their causal relations. The procedure was identical to Experiment 1 with the exception that different forms of causal structures were used. Although the number of variables was constant across two experiments, the number of causal links in Experiment 2 was larger than that in Experiment 1 (see Figure 1 and 3). Increasing causal links resulted in more complex patterns of covariation information. For example, the four variables condition in Experiment 2 provided seven types of co-occurrence information, whereas there were five kinds of co-occurrence information in the four variables condition in Experiment 1.

Instructions explained the cover story and indicated to the participants that they were required to judge causal relations among bacteria. As in Experiment 1, participants were informed that causal relations were probabilistic, that there were no hidden causes, and that temporal order was

Figure 2: Usage rates for covariation cues and temporal order cues in Experiment 1. Error bars reflect standard errors.

Figure 3: Causal structures in Experiment 2. Continuous lines represent causal relations, whereas dotted lines indicate temporal orders.

not always an accurate cue. In the learning phase, participants received information on 40 cases of bacteria states through observation. Each condition differed in the number of bacteria participants observed. As can be seen in Figure 3, there were three variables with two causal links in the three variables condition, four variables with four causal links in the four variables condition, and five variables with six causal links in the five variables condition. Moreover, the causal order differed from the temporal order in each condition, allowing assessment of the degree to which each cue was used. In the test phase, participants were told to infer the causal structure in the same way as in Experiment 1.

## Results and Discussion

Participants' responses were analyzed in a manner similar to Experiment 1. Figure 4 shows the usage rates of covariation cues and temporal order cues in each condition. The results of the three variables condition indicated that covariation cues were emphasized over temporal order cues, replicating this effect in Experiment 1. In contrast, participants in the four and five variables conditions based their judgment more upon temporal order than upon covariation. A 2 (the type of cue: covariation vs. temporal order)  $\times$  3 (the number of variables: three vs. four vs. five) repeated measures ANOVA yielded a significant main effect of the number of variables,  $F(2, 46) = 9.31, p < .001$ , and a significant interaction between the type of cue and the number of variables,  $F(2, 46) = 9.66, p < .001$ . To explore the interaction, an analysis of the simple main effect of the type of cue was conducted for each condition. The tendency to emphasize covariation rather than temporal order was marginally significant in the three variables condition,  $F(1, 69) = 3.36, p < .10$ . There was no significant difference in the four variables condition,  $F(1, 69) = 1.75, ns$ . In the five variables condition, however, the usage rate of temporal order cues was reliably higher than that of covariation cues,  $F(1, 69) = 7.94, p < .01$ . These results suggest that task complexity determines whether participants rely on covariation cues or temporal order cues.

In order to investigate effects of forms of causal relations on judgment strategy, a 2 (causal structure: Exp.1 vs. Exp.2)  $\times$  2 (the type of cue: covariation vs. temporal order)  $\times$  3 (the

Figure 4: Usage rates for covariation cues and temporal order cues in Experiment 2. Error bars reflect standard errors.

number of variables: three vs. four vs. five) mixed ANOVA was performed, with causal structure as a between-participants factor and the type of cue and the number of variables as within-participants factors. As a result, a main effect of the number of variables,  $F(2, 92) = 12.03, p < .001$ , an interaction between causal structure and the type of cue,  $F(1, 46) = 11.21, p < .01$ , and an interaction between the type of cue and the number of variables,  $F(2, 92) = 15.11, p < .001$  were significant. To explore the interaction between causal structure and the type of cue in greater detail, the simple main effects of causal structure were tested. The usage rate of covariation cues in Experiment 1 was higher than that in Experiment 2,  $F(1, 92) = 5.92, p < .05$ . On the contrary, the usage rate of temporal order cues in Experiment 1 was lower than that in Experiment 2,  $F(1, 92) = 8.14, p < .01$ . These results indicate that forms of causal structures also modulate judgment strategy.

Taken together with the results of Experiment 1, Experiment 2 provides further evidence on the relationship between task complexity and the judgment strategy. Participants in the three variables condition emphasized covariation over temporal order; on the other hand, temporal order cues were given more weight than covariation cues in the five variables condition. These results bridge the gap between the findings about the preferential use of covariation (Saito & Shimazaki, 2012) and about the preferential use of temporal order (Lagnado & Sloman, 2006; White, 2006). In addition, the comparison between experiments demonstrates that judgment strategy is affected not only by the number of variables but also by the form of the causal structure.

## General Discussion

The present study clarifies conflicting evidence concerning the use of covariation cues and temporal order cues in causal structure learning. Lagnado and Sloman (2006) showed temporal order to be more influential on judgments than covariation; however, Saito and Shimazaki (2012)

reported that covariation was favored over temporal order. In the present study, the authors interpreted these results from the viewpoint of the task complexity and manipulated the number of variables which consisted of a causal structure. Experiment 1 demonstrated that covariation cues were carried more weight than temporal order cues in learning simple causal structure and that this preference disappeared as the number of variables increased. In addition, Experiment 2 investigated the relationship between the judgment strategy and the number of variables with different forms of causal structures. The results of Experiment 2 are consistent with both findings concerning the preferential use of covariation cues in a simple task (Saito & Shimazaki, 2012) and the preferential use of temporal order cues in a complex task (Lagnado & Sloman, 2006; White, 2006). These results show the task complexity, composed of the number of variables and the form of the causal structure, serves as a modulator of the judgment strategy in causal structure learning.

The results of the present study can be interpreted in terms of salience and validity in multiple-cue probability learning (Kruschke & Johansen, 1999). According to Kruschke and Johansen (1999), irrelevant cues have a deleterious effect on the use of valid cues and this effect becomes more apparent as the salience of irrelevant cues increase. In the present experiment, covariation served as valid cue whereas temporal order was high salient but less reliable cue. Increasing the number of variables in the causal structure brought lower salience of covariation and higher salience of temporal order, which resulted in a deleterious effect on the use of covariation cues. These similar findings imply the tight coupling between causal learning and category learning.

The present study has several implications for models in causal structure learning. The use of covariation cues is easily explained by constraint-based methods (Gopnik, Glymour, Sobel, Schulz, Kushnir, & Danks, 2004) and Bayesian methods (Steyvers, Tenenbaum, Wagenmakers, & Blum, 2003) in causal Bayes nets and broken link heuristics (Mayrhofer & Waldmann, 2011). Whereas Constraint-based methods compute independence and dependence in bottom-up process, Bayesian methods make probabilistic inferences for each causal model using Bayes' theorem in top-down process. Broken link heuristics offers a simple explanation with a determinism bias and a sufficiency bias. In contrast, the use of temporal order cues is well accounted for by local computations (Fernbach & Sloman, 2009). According to this heuristic model, people focused not on covariation cues but instead on temporal order cues because of their quick accessibility and lower computational demands. The tendency to use temporal order cues is also explained by temporal strategy (Rottman & Keil, 2012), which induces causal directionality from temporal change over time. Although these models focus on either covariation cues or temporal order cues, the present results suggest the importance of both cues in causal learning. An intriguing question for future research concerns how people integrate

covariation with temporal order for inferring causal structure.

## Abstract

Previous metaphor studies have paid much attention to nominal metaphors and predicative metaphors and little attention has been given to adjective metaphors. The most adjective metaphor studies have only examined how the acceptability of adjective metaphors can be explained by the pairing of adjective modifier's and head noun's modalities. Sakamoto & Utsumi (2009) showed that adjective metaphors, especially those modified by color adjectives, tend to evoke negative meanings. Sumihisa et al (2011) examined whether evoking negative meanings is the unique feature of adjective metaphors through comparison among nominal metaphors and predicative metaphors for the Japanese language and revealed that meanings of metaphors are basically affected by meanings of vehicles, but when vehicles themselves had neutral meanings, negative meanings were evoked more frequently for adjective metaphors among the other types of metaphors. The purpose of this study, therefore, explores the reason why adjective metaphors evoke negative meanings more frequently than the other types of metaphors. For this purpose, we examined what kind of meanings associated with topics or vehicles affect the comprehension of metaphors. Our psychological experiments revealed that meanings associated from vehicles affect the comprehension of metaphors. And when metaphorical expressions have vehicles with positive or negative meanings, metaphorical expressions show the same meanings as the vehicles. On the other hand, when metaphorical expressions have vehicles with neutral meaning, only adjective metaphors evoke negative meanings. Our results suggest that the comprehension of adjective metaphors is selectively affected by the negative meanings associated with adjectives as vehicles.

**Keywords:** adjective metaphors; nominal metaphors; predicative metaphors; Japanese language; negative meanings.

## Introduction

Metaphor studies in the domain of cognitive science have paid much attention to nominal metaphors such as “*My job is a jail*” (e.g., Bowdle & Gentner, 2005; Glucksberg, 2001) and predicative metaphors such as “*He shot down all of my arguments*” (e.g., Lakoff & Johnson, 1980).

Previous metaphor studies, however, have paid little attention to adjective metaphors such as “*sweet touch*” and how they are comprehended. Some models have been proposed to explain the mechanism of metaphor comprehension in cognitive science. Glucksberg and his colleagues (Glucksberg & Keysar, 1990) propose categorization theory. This theory addresses mainly nominal metaphors and argues that people understand nominal metaphors by seeing the target concept as belonging to the superordinate metaphorical category exemplified by the source concept. As for the mechanism of adjective metaphors, Utsumi & Sakamoto (2007) propose a two-stage categorization theory and argue that the comprehension process of adjective metaphors could be explained as a two-stage categorization process.

Many studies focusing on adjective metaphors have examined how the acceptability of adjective metaphors can be explained by the pairing of adjective modifier's and head noun's modalities. Ullmann (1951), in a very early study on adjective metaphors, proposes a certain hierarchy of lower and higher perceptual modalities. His thesis of directionality asserts that a metaphor with a source domain lower in the hierarchy of sense modalities than the target domain should tend to be cognitively more accessible than a metaphor with the reverse direction of domains. Williams (1976) makes a more differentiated claim of directionality, in which a similar order of sense modalities is proposed. Recently, Yu (2003) highlights cross-linguistic differences when he makes different directionality claims for different languages (English as compared to Chinese). Werning, Fleischhauer, & Beşeoğlu (2006) explore the factors that enhance the cognitive accessibility of adjective metaphors for German. Very few studies, however, have attempted to explore meanings evoked by adjective metaphors.

Sakamoto & Utsumi (2009) is one of the few studies which have explored meanings evoked by adjective metaphors. They compare the actual semantic changes observed through their psychological experiments with the semantic changes predicted by Abstract Performance Grammar (APG) model. APG proposed by Osgood (1980) states the crucial rules to evoke semantic changes through fine semantic interactions in the processing of linguistic expressions.

158 Japanese adjective metaphors were used for their psychological experiment. Participants were asked to rate

the assigned expressions against 15 SD scales such as “uncomfortable – comfortable” and “dark – light”. The ratings were made on a 7-point scale ranging from -3 through 0 to +3. The value -3 was regarded as the negative semantic pole and the value +3 as the positive semantic pole. All the mean values of vehicles and topics rated on the 15 SD scales were classified into T=V, T<V, T>V (T : topics, V : vehicles). Using t-test (two-tailed, the alpha level .05), the cases which have no significant difference between the mean value of T and V were regarded as T=V.

The other codes such as T<V and T>V fall to the cases which have significant differences between the mean values of T and V. In order to compare the actual semantic changes resulting from their experiment with the semantic changes predicted by APG model, Sakamoto & Utsumi (2009) classified the actual semantic changes resulting from their experiment as show in Table 1. Using t-test (two-tailed, the alpha level .05), they regarded the cases which have no significant difference between the mean values of T and metaphors as ‘no change’ (0) and the cases which have significant differences between them as changes either to the negative pole (-) or to the positive pole (+). Table 1 shows the comparison between the predicted semantic changes and the actual semantic changes observed through their experiment.

Table 1: Comparison between predicted semantic changes and actual semantic changes

semantic intensity	predicted change	actual change			Sum
		0	+	-	
T=V	0	331	17	261	609
T<V	+	366	230	76	672
T>V	-	119	9	961	1089
Sum		816	256	1298	2370

numbers = cases of SD scales

In order to see the tendency for adjective metaphors to evoke positive or negative meanings, Sakamoto & Utsumi (2009) classified all the cases showing different changes from the APG prediction either into positive meaning or negative meaning. The cases showing no change as against the prediction of changing to - were regarded as evoking a weakly positive meaning, and were classified into the positive meaning category in the same way as those which changed to + against the prediction of changing to -. The cases showing no change against the prediction of changing to + were regarded as evoking weakly negative meaning, and were classified into the negative meaning category in the same way as those which changed to - against the prediction of changing to +. As a result, 848 cases which showed changes different from the APG prediction were classified into 145 positive meanings and 703 negative meanings. A Chi-square test showed that the cases showing negative meanings were significantly more frequent than those showing positive meanings,  $\chi^2 (1, N=848) = 367.175, p < .001$ . Based on this result, Sakamoto & Utsumi (2009) suggest that adjective metaphors tend to evoke negative meanings.

Sumihisa et al. (2011) examined whether evoking negative meanings is the unique feature of adjective metaphors. In the experiments, Sumihisa et al. (2011) first selected nouns as topics to make Japanese metaphorical expressions. They selected four nouns (e.g. *smell* ('nioi'), *moment* ('genzai'), *footstep* ('ashito'), and *pose* ('shisei')) with neutral meanings among 54 nouns by psychological experiment. They also conducted another psychological experiment in which participants were asked to rate meanings of vehicles only. Verbs, nouns and

adjectives were selected respectively as vehicles with positive meanings, neutral meanings and negative meanings. They combined the topics and the vehicles and made metaphorical expressions.

Sumihisa et al. (2011) conducted a psychological experiment in which participants evaluate the meanings of metaphors. Participants were asked to rate the assigned expressions against 9 SD scales (7 SD scales given in Table 2 and additional scales “difficult – easy” and “unfamiliar – familiar”). The ratings were made on a 7-point scale ranging from -3 through 0 to +3. They regarded the value -3 as the negative semantic pole and the value +3 as the positive semantic pole.

Table 2: List of SD scales used for the experiment

dislike – like	inelegant - elegant
ugly - beautiful	uncomfortable - comfortable
dark - light	bad - good
sad - glad	

Sumihisa et al. (2011) focused on the metaphorical meanings evoked by the semantic interaction between topics and vehicles. They classified metaphorical expressions into the cases showing no semantic change, those showing the change to the positive semantic pole or those showing the change to the negative semantic pole. They conducted t-test (two-tailed, the alpha level .05) to see semantic changes evoked by the semantic interaction between topics and vehicles. Since only the topics with neutral meanings were selected through the pre-experiment, metaphorical expressions which have no significant difference between their mean value and value 0 were regarded as metaphors showing no semantic change (0). And metaphorical expressions which have significant difference between their mean values and value 0 were classified into either metaphors showing the change to the positive semantic pole or those showing the change to the negative semantic pole.

As a result, when vehicles have positive or negative meanings, all types of metaphors tend to evoke positive or negative meanings. However, when vehicles have neutral meanings, although nominal metaphors tend to evoke neutral meanings, predicative metaphors and adjective metaphors tend to evoke negative meanings. Especially adjective metaphors tend to evoke negative meanings more frequently. They also classified the metaphors either into metaphors showing negative meanings or the others and compared among the three types of metaphors as shown as Table 3.

Table 3: Number of expressions showing negative meanings and the other meanings

	-	+ or 0	sum
nominal metaphors	7	19	26
predicative metaphors	8	19	27
adjective metaphors	17	11	28
sum	32	49	81

They revealed that adjective metaphors evoke significantly more frequently negative meanings than the other two types of metaphors,  $\chi^2 = (1, N = 54) = 6.234, p < .05$  for adjective metaphors vs. nominal metaphors,  $\chi^2 = (1, N = 55) = 5.357, p < .05$  for adjective metaphors vs. predicative metaphors.

Based on this result, Sumihisa et al. (2011) suggest that nominal metaphors and predicative metaphors basically tend to show neutral meanings, while adjective metaphors tend to show negative meanings.

This study explores the reason why adjective metaphors evoke negative meanings more frequently than the other types of metaphors. Utsumi & Sakamoto (2007) argue that the comprehension process of adjective metaphors can be explained as a two-stage categorization process. They speculate the comprehension process of “red voice” created from the neutral vehicle “red” as follows: the adjective “red” first evokes an intermediate category “red things” to which “blood”, “fire”, “passion”, “apple” and “danger” typically belong. Then exemplars relevant to the noun “voice” are selected and they evoke a final abstract category of property like “scary”, “screaming” and “dangerous”. In this way, adjective metaphors are understood by not be directly mapped onto the topics from ad hoc category of vehicles but mediating to an intermediate category. When meanings of adjective metaphors were processed in the two-stage categorization process, exemplars with negative meanings might be selected among various exemplars belonging to the intermediate category evoked by adjectives as vehicles.

In this study, therefore, we conducted a psychological experiment in which participants were asked to choose words related to meanings of adjective metaphors among those associated from vehicles and topics. We hypothesize that even if there were negative and positive exemplars in an intermediate category, exemplars with negative meanings tend to be selected to process meanings of adjective metaphors. As for nominal metaphors, on the other hand, prototypical exemplars associated with vehicles tend to be selected since the people understand nominal metaphors via the categorization process, namely by seeing the target concept as belonging to the superordinate metaphorical category exemplified by the source concept.

## Pre-experiment

### Topics and Vehicles

We decided to use 4 nouns as topics which were tested as having neutral meanings by Sumihisa et al. (2011); *smell* (“nioi”), *moment* (“genzai”), *footstep* (“ashioto”), and *pose* (“shisei”).

Candidates of vehicles of nominal, predicative and adjective metaphors were selected from the Japanese thesaurus (yamaguchi, 2003). We selected 50 adjectives, 50 nouns and 50 verbs to be used as vehicles.

In order to see the meanings of vehicles we conducted a psychological experiment. In the experiment, 15 Japanese males and females, aged 20 – 25, were asked to rate 150 words (50 adjectives, 50 nouns and 50 verbs) against the 9 SD scales; dark-light, dislike-like, inelegant-elegant, sad-glad, ugly-beautiful, uncomfortable-comfortable, bad-good, difficult-easy and unfamiliar-familiar. These SD scales were selected by a psychological experiment (Sumihisa et al., 2011) in which participants were asked to choose SD scales for which they can easily see one of semantic pole as positive and the other semantic pole as negative.

The ratings were made on a 7-point scale ranging from -3 through 0 to +3. We regarded the value -3 as the negative semantic pole and the value +3 as the positive semantic pole. We conducted t-tests (two-tailed, the alpha level .05) and regarded the words which have no significant difference between the mean semantic values of the words and “0” as words with neutral meanings. And the words which have significant difference between their mean value and value 0 were classified into either words with the positive meaning or those with the negative meaning.

We selected 5 vehicles with positive meaning, 5 vehicles with negative meaning and 5 vehicles with neutral

meaning to make nominal, predicative and adjective metaphors respectively.

As for nominal metaphors, nouns such as *fortune* (“kouun”), *freedom* (“jiyuu”), *justice* (“seigi”), *life* (“inochi”) and *dream* (“yume”) were selected as vehicles with positive meaning. Nouns such as *faith* (“shinkou”), *joke* (“joudan”), *patience* (“nintai”), *transient* (“mujou”) and *philosophy* (“tetsugaku”) were selected as vehicles with neutral meaning. And nouns such as *evil* (“aku”), *hell* (“jigoku”), *dissatisfied* (“fuman”), *self-preservation* (“hoshin”) and *downfall* (“metsubou”) were selected as vehicles with negative meaning.

As for predicative metaphors, verbs such as *appear* (“arawareru”), *believe* (“shinjiru”), *flutter* (“tokimeku”), *clear* (“hareru”) and *laugh* (“warau”) were selected as vehicles with positive meaning. Verbs such as *make merry* (“ukareru”), *dry* (“kawaku”), *cut fine* (“kizamu”) and *cry* (“naku”) were selected as vehicles with neutral meaning. And verbs such as *be irritated* (“iradatsu”), *doubt* (“utagau”), *remain* (“todomaru”), *betray* (“negaeru”) and *warp* (“yugamu”) were selected as vehicles with negative meaning.

As for adjective metaphors, adjectives such as *new* (“atarashii”), *sweet* (“airashii”), *cool* (“kakkoii”), *white* (“shiroi”) and *equal* (“hitoshii”) were selected as vehicles with positive meaning. Adjectives such as *black* (“kuroi”), *hard* (“katai”), *fine* (“komakai”), *long* (“nagai”) and *deep* (“fukai”) were selected as vehicles with neutral meaning. And adjectives such as *stinking* (“kusai”), *dull* (“nibui”), *worn-out* (“boroi”), *shabby* (“misuborashii”) and *disgraceful* (“mittomonai”) were selected as vehicles with negative meaning.

### Words associated from vehicles and topics

We examine what kind of meanings associated with topics or vehicles affect the comprehension of metaphors. In order to research the words associated from vehicles and topics, we conducted a pre-experiment. 30 Japanese males and females, aged 20 – 24, were asked to answer 3 or more words associated from 45 vehicles and 4 topics. We decided to use for the later experiment the words associated from vehicles and topics chosen by 2 or more participants. Then we conducted another pre-experiment to evaluate the meaning of the words associated from vehicles and topics. 60 Japanese males and females, aged 20 – 26, were classified into 2 groups. 107 or 108 words assigned to each group and participants were asked to rate the assigned words against 7 SD scales (in table 2). Based on the result of this experiment, we classified the words into the words with positive meaning, the words with negative meaning and the words with neutral meaning. We conducted t-tests (two-tailed, the alpha level .05) and regarded the words which have no significant difference between the mean semantic values of the words and “0” as words with neutral meanings. And the words which have significant difference between their mean value and value 0 were classified into either words with the positive meaning or those with the negative meaning.

## Experiment

### Metaphorical expressions

We combined vehicles and topics which were selected by pre-experiments and made nominal, predicative and adjective metaphors. Then we conducted a psychological experiment in order to see what kind of meanings associated with topics or vehicles affect the comprehension of metaphors. In the experiment, 60 Japanese males and females, aged 20 - 26, were assigned to 180 metaphorical expressions and were asked to choose words which they believe to be related to the

meaning of each metaphorical expression among those associated from vehicles and topics. Participants were also asked to rate meanings of the 180 metaphorical expressions respectively against 9 SD scales (7 SD scales given in table 2 and additional scales “difficult – easy” and “unfamiliar – familiar”).

## Results and Discussion

### Meanings evoked by metaphors

We classified metaphorical expressions into the metaphorical expressions which have vehicles with neutral meaning, positive meaning and negative meaning. Then, we analyzed the meaning of metaphorical expressions and the words associated from vehicles and topics. We conducted t-test (two-tailed, the alpha level .05) to see semantic changes evoked by the semantic interaction between topics and vehicles. Since only the topics with neutral meanings were selected through the pre-experiment, metaphorical expressions which have no significant difference between their mean value and value 0 were regarded as metaphors showing no semantic change (0). And metaphorical expressions which have significant difference between their mean values and value 0 were classified into either metaphors showing the change to the positive semantic pole or those showing the change to the negative semantic pole.

### Metaphors using vehicles with neutral meanings

Table 4 shows the number of 3 types of metaphors which show the positive, negative or neutral meanings when vehicles are neutral.

Table 4: Number of metaphors showing positive, negative and neutral meanings when vehicles are neutral

	positive	negative	neutral	sum
nominal metaphors	1	1	18	20
predicative metaphors	4	9	7	20
adjective metaphors	2	11	7	20
sum	7	21	32	60

As for the metaphors in which vehicles of their own have neutral meanings, the proportion of the metaphors showing the neutral meanings was the highest.

As for the total number, a Chi-square test was conducted among the expressions showing positive (+), negative (-), and neutral (0) meanings. As a result, there were significant differences between the number of nominal metaphors and that of predicative metaphors ( $\chi^2(1, N=40)=8.533, p<.05$ ) and also between the number of nominal metaphors and that of adjective metaphors, ( $\chi^2(1, N=40)=11.905, p<.05$ ). However, there was no significant difference between the number of predicative metaphors and that of adjective metaphors, ( $\chi^2(1, N=40)=0.400, p>.05$ ).

As for nominal metaphors, the result of Chi-square tests showed that the metaphorical expressions with neutral meaning were significantly more than the other expressions, ( $\chi^2(1)=15.211, p<.05(+ \text{ vs. } 0), \chi^2(1)=15.211, p<.05(- \text{ vs. } 0)$ ). As for predicative metaphors, there was no significant difference among the number of metaphorical expressions which showed positive meaning, negative meaning and neutral meaning, ( $\chi^2(1)=.181, p>.05(+ \text{ vs. } 0), \chi^2(1)=.250, p>.05(0 \text{ vs. } -)$ ,  $\chi^2(1)=1.923, p>.05(+ \text{ vs. } -)$ ). As for the adjective metaphors, there was significant difference among the number of metaphorical expressions which showed positive meanings and neutral meanings ( $\chi^2(1)=2.778, p<.05(+ \text{ vs. } 0)$ ), and the number of metaphorical expressions which showed positive

meanings and negative meanings, ( $\chi^2(1)=6.231, p<.05(+ \text{ vs. } -)$ ). However, there was no significant difference between the number of metaphorical expressions which showed neutral meanings and negative meanings, ( $\chi^2(1)=.889, p>.05(0 \text{ vs. } -)$ ).

These results show that nominal metaphors are basically affected by the meaning of vehicles and tend to show neutral meanings. Adjective metaphors show negative meanings, although meanings of vehicles are neutral.

### Metaphors using vehicles with positive meanings

Table 5 shows the number of metaphors which show the positive, negative and neutral meanings when vehicles are positive. As for the metaphors in which vehicles of their own have positive meanings, the proportion of the metaphors showing positive meanings was the highest. As for the total number, Chi-square tests were conducted among the expressions showing positive (+), negative (-), and neutral (0) meanings. As a result, there was no significant difference between nominal metaphors, predicative metaphors and adjective metaphors, ( $\chi^2(4, N=60)=4.034, p>.05$ ). The result shows that, as for vehicles with positive meanings, the three types of metaphors tend to show positive meanings.

Table 5: Number of metaphors showing positive, negative and neutral meanings when vehicles are positive

	positive	negative	neutral	sum
nominal metaphors	20	0	0	20
predicative metaphors	19	1	0	20
adjective metaphors	19	0	1	20
sum	58	1	1	60

### Metaphors using vehicles with negative meanings

Table 6 shows the number of metaphors which show the positive, negative and neutral meanings when vehicles are negative. As for the metaphors in which vehicles of their own have negative meanings, all the metaphors showed negative meanings.

Table 6: Number of metaphors showing positive, negative and neutral meanings when vehicles are negative

	positive	negative	neutral	sum
nominal metaphors	0	20	0	20
predicative metaphors	0	20	0	20
adjective metaphors	0	20	0	20
sum	0	60	0	60

### Words associated with metaphors

The results described so far showed that negative meanings were evoked more frequently for adjective metaphors among the other types of metaphors when vehicles were neutral. This section discusses the results of the psychological experiment in which participants were asked to choose words related to meanings of metaphorical expressions among those associated from vehicles and topics. We want to see, even if negative and positive exemplars were associated with vehicles or topics, exemplars with negative meanings tend to be selected to process meanings of adjective metaphors.

### Nominal metaphors

The second left column of Table 7 shows the total number of the words associated from vehicles or topics and the second right column the number of words which participants selected as those related to meanings of nominal metaphors.

Table 7: the number of the words which were associated from vehicles or topics

	all words	selected words	rate
vehicles	810	749	92.50%
topics	735	348	47.30%

A Chi-square test was conducted among the words which were associated from vehicles and topics. The result showed that words associated with vehicles were selected significantly more frequently than those with topics, ( $\chi^2(1, N=1545)=381.063, p<.05$ ).

We examined the frequency in which positive, neutral or negative words associated with vehicles or topics were selected by participants when they process the meanings of nominal metaphors created from vehicles with positive meaning. Table 8 shows the results. The result of Chi-square tests showed that the associative words with positive meaning were significantly more frequently selected than the others, ( $\chi^2(1, N=436)=76.926, p<.05 (+ vs. 0), \chi^2(1, N=431)=104.972, p<.05 (+ vs. -)$ ).

Table 8: the number of the associative words when vehicles have positive meaning

	all words	selected words	rate
positive	336	284	84.50%
neutral	100	41	41.00%
negative	95	30	31.60%

Table 9 shows the frequency in which positive, neutral or negative words associated with vehicles or topics were selected by participants when they process meanings of nominal metaphors created from vehicles with neutral meaning.

Table 9: the number of the associative words when vehicles have neutral meaning

	all words	selected words	rate
positive	242	195	80.60%
neutral	119	90	75.60%
negative	130	87	66.90%

As for the number of the associative words when vehicles have neutral meaning, there was no significant difference among each number of the associative words with positive, neutral and negative meaning, ( $\chi^2(1, N=361)=1.175, p>.05 (+ vs. 0), \chi^2(1, N=249)=2.292, p>.05 (0 vs. -), \chi^2(1, N=372)=8.598, p=.05 (+ vs. -)$ ).

When the vehicles have negative meaning, table 10 shows the result of the number of the associative words. The results of Chi-square tests showed that the associative words with negative meaning were significantly more frequently selected than the others, ( $\chi^2(1, N=348)=29.264, p<.05 (0 vs. -), \chi^2(1, N=392)=106.940, p<.05 (+ vs. -)$ ).

Table 10: the number of the associative words when vehicles have negative meaning

	all words	selected words	rate
positive	167	73	43.70%
neutral	123	85	69.10%
negative	225	206	91.60%

The results so far suggest that the comprehension of nominal metaphors is basically affected by the prototypical exemplars associated with vehicles.

## Predicative metaphors

The second left column of Table 11 shows the total number of the words associated from vehicles or topics and the second right column the number of words which participants selected as those related to meanings of predicative metaphors.

Table 11: the number of the words which were associated from vehicles or topics

	all words	selected words	rate
vehicles	715	644	90.10%
topics	735	403	54.80%

The result of Chi-square tests showed that words associated with vehicles were selected more frequently than those with topics, ( $\chi^2(1, N=1450)=224.275, p<.05$ ).

We examined the frequency in which positive, neutral or negative words associated with vehicles or topics were selected by participants in the same way as nominal metaphors. Table 12 shows that in the comprehension of predicative metaphors created from vehicles with positive meaning words with positive meanings were significantly more frequently selected than the others, ( $\chi^2(1, N=409)=44.675, p<.05 (+ vs. 0), \chi^2(1, N=412)=69.834, p<.05 (+ vs. -)$ ).

Table 12: the number of the associative words when vehicles have positive meaning

	all words	selected words	rate
positive	318	272	85.50%
neutral	91	48	52.70%
negative	94	41	43.60%

Table 13 shows the frequency in which positive, neutral or negative words associated with vehicles or topics were selected by participants when they process meanings of predicative metaphors created from vehicles with neutral meaning. The results of Chi-square tests showed that there was no significant difference among each number of the associative words with positive, neutral and negative meaning, ( $\chi^2(1, N=387)=.000, p>.05 (+ vs. 0), \chi^2(1, N=233)=.104, p>.05 (0 vs. -), \chi^2(1, N=384)=.131, p>.05 (+ vs. -)$ ).

Table 13: the number of the associative words when vehicles have neutral meaning

	all words	selected words	rate
positive	269	194	72.10%
neutral	118	85	72.00%
negative	115	85	73.90%

Table 14 shows the frequency in which positive, neutral or negative words associated with vehicles or topics were selected by participants when they process meanings of predicative metaphors created from vehicles with negative meanings. The results of Chi-square tests showed that words with negative meaning were selected significantly more frequently than the others, ( $\chi^2(1, N=245)=25.136, p<.05 (0 vs. -), \chi^2(1, N=352)=40.022, p<.05 (+ vs. -)$ ).

Table 14: the number of the associative words when vehicles have negative meaning

	all words	selected words	rate
positive	194	118	60.80%
neutral	87	56	64.40%
negative	158	143	90.50%

These results for predicative metaphors suggest that the

comprehension of predicative metaphors is basically affected by the exemplars associated with vehicles.

### Adjective metaphors

Table 15 shows the total number of the words associated from vehicles or topics and the number of words which participants selected as those related to meanings of adjective metaphors.

Table 15: the number of the words which were associated from vehicles or topics

	all words	selected words	rate
vehicles	724	627	86.60%
topics	735	444	60.40%

The result of Chi-square tests showed that words associated with vehicles were selected more frequently than those with topics, ( $\chi^2(1, N=1459)=128.193$ ,  $p<.05$ ).

Table 16 shows the frequency in which positive, neutral or negative words associated with vehicles or topics were selected by participants when they process meanings of adjective metaphors created from vehicles with positive meanings. Chi-square tests showed that words with positive meaning were selected significantly more frequently than the others, ( $\chi^2(1, N=400)=32.967$ ,  $p<.05$  (+ vs. 0),  $\chi^2(1, N=408)=141.638$ ,  $p<.05$  (+ vs. -)).

Table 16: the number of the associative words when vehicles have positive meaning

	all words	selected words	rate
positive	325	283	87.10%
neutral	75	44	58.70%
negative	83	19	22.90%

Table 17 shows the frequency in which positive, neutral or negative words associated with vehicles or topics were selected when participants process meanings of adjective metaphors created from vehicles with neutral meanings. Although vehicles were neutral, words with negative meaning were selected significantly more frequently than the others, ( $\chi^2(1, N=262)=7.162$ ,  $p<.05$  (0 vs. -),  $\chi^2(1, N=360)=9.089$ ,  $p<.05$  (+ vs. -)).

Table 17: the number of the associative words when vehicles have neutral meaning

	all words	selected words	rate
positive	227	161	70.90%
neutral	129	92	71.30%
negative	133	113	85.00%

Table 18 shows the frequency in which positive, neutral or negative words associated with vehicles or topics were selected by participants when they process meanings of adjective metaphors created from vehicles with negative meanings. Chi-square tests showed that words with negative meaning were selected significantly more frequently than the others, ( $\chi^2(1, N=277)=27.380$ ,  $p<.05$  (0 vs. -),  $\chi^2(1, N=378)=30.959$ ,  $p<.05$  (+ vs. -)).

Chi-square tests showed that words with negative meaning were selected significantly more frequently than the others, ( $\chi^2(1, N=277)=27.380$ ,  $p<.05$  (0 vs. -),  $\chi^2(1, N=378)=30.959$ ,  $p<.05$  (+ vs. -)).

These results suggest that adjective metaphors are different from nominal and predicative metaphors in the comprehension where words with negative meanings tend to be selected although vehicles themselves are neutral.

Table 18: the number of the associative words when vehicles have negative meaning

	all words	selected words	rate
positive	199	128	64.80%
neutral	98	61	62.20%
negative	179	159	88.80%

### Conclusion

This study explored the reason why adjective metaphors evoke negative meanings more frequently than the other types of metaphors. The results showed that exemplars with negative meanings among various exemplars tend to be selected to process meanings of adjective metaphors. This result suggests that, unlike nominal metaphors processed by the categorization theory, adjective metaphors are processed by the two-stage categorization theory (Utsumi & Sakamoto, 2007), in which exemplars with negative meanings are selected among various exemplars belonging to the intermediate category evoked by adjectives as vehicles. We still do not know why exemplars with negative meanings are used to process meanings of adjective metaphors.

## Abstract

A study of the literacy-generated cognitive cultural gap was carried out on subjects of different literacy background ranging from illiterate individuals to university students in different majors. The characteristics that aid literate and illiterate people in solving mathematical problems efficiently were identified and analyzed. A field research was carried out in the field of algorithmic problem solving and in the reasoning domain, followed by constructing a software cognitive model to represent the findings. Findings showed that in both domains cognitive ability did not improve with level of literacy, rather the formality of the problem solving strategy selected demonstrating a link between these two domains.

## Introduction
