#  <br> <br> CogSci 2017 <br> <br> CogSci 2017 Proceedings of the 39th Annual Meeting of the Cognitive Science Society London, UK 26-29 July 2017 

## Computational Foundations of Cognition

Richard Granger, Dartmouth
Ulrike Hahn, Birkbeck, University of London Richard Sutton, University of Alberta
http://www.cognitivesciencesociety.org/conference2017/index.html
Program Chairs: Glenn Gunzelmann, Andrew Howes, Thora Tenbrink, Eddy Davelaar

## Table of Contents

Introduction ..... lvii
Committees ..... lx
Conference Awards ..... lxiv
Invited Presentations ..... lxvii
Tutorials
Tutorial: Recent Advances in Deep Learning ..... 1
Matthew Botvinick, Peter Battaglia
Methods for Reconstructing Causal Networks from Observed Time-Series: Granger-Causality, Transfer Entropy, and Convergent Cross-Mapping ..... 3
Fermin Moscoso del Prado Martin
Dynamic Field Theory: Conceptual Foundations and Applications in Cognitive and DevelopmentalScience5
John Spencer, Vanessa Simmering, Sebastian Schneegans
Workshops
The Fine Art of Conversation ..... 7
Saul Albert, Claude Heath, Patrick Healey
Workshop: Bridging the Gap: Is Logic and Automated Reasoning a Foundation for Human Reasoning? ..... 9
Ulrich Furbach, Steffen Hölldobler, Marco Ragni, Claudia Schon
Citizen Science, Gamification, and Virtual Reality for Cognitive Research ..... 11
Jana Jarecki, Jacob Sherson, Juho Hamari, Julia A. Bopp, Julian Jarecki, Libby Heaney, Sharon Steinemann, Pinja Haikka, Carsten Bergenholtz
Cooperative Social Intelligence: Understanding and Acting with Other ..... 13
Max Kleiman-Weiner, Yibiao Zhao, Josh Tenenbaum
Building Bridges from (Ivory) Towers: Combining Academia and Industry for Cognitive Research ..... 15
Katherine Livins, Jay Martin
The Computational Foundations of Religious Cognition: A Workshop Hosted by the International Association for the Cognitive Science of Religion (IACSR) ..... 17
Ann Taves, Dimitris Xygalatas, John Shaver
Workshop proposal: Deep Learning in Computational Cognitive Science ..... 19
Ilker Yildirim, Josh Tenenbaum
Symposia
Anthropological Contributions to Cognitive Science ..... 21
Andrea Bender, Sieghard Beller, Rita Astuti, Olivier Le Guen, Karenleigh Overmann, Peter Rácz, Fiona Jordan, Mads Solberg
Static and dynamic visual narratives, by brain and by eye ..... 23
Neil Cohn, Tom Foulsham, Tim Smith, Jeff Zacks
Game-XP: Action Games as Cognitive Science Paradigms ..... 25
Wayne Gray, Ray Perez, Martin Butz, Stuart Reeves, Matthew Sangster, Tom Stafford, Fernand Gobet
Educating Spatial Thinking for STEM Success ..... 27Mary Hegarty, David Uttal, Mike Stieff, Tom Lowrie, Stella Vosniadou
Symposium on Problem Solving and Goal-Directed Sequential Activity ..... 29
Pat Langley, Richard Cooper
LUCID science: Advancing learning through human-machine cooperation ..... 31
Timothy Rogers, Charles Kalish
Intuitive Biology and Global Challenges: Applying Theoretical Insights for Public Good ..... 33
Lauren Swiney, Deborah Kelemen, Andrew Shtulman, John Coley, Nicole Betz, Stefaan Blancke
Time in the mind of a child: Perspectives on the development of temporal cognition ..... 35
Katharine Tillman, Florie Monier, Meng Zhang, Jonathan Redshaw, Teresa McCormack
Big Data and Little Learners ..... 37
John Trueswell, Linda Smith, Josh Tenenbaum, Charles Yang
Talks: Papers
Burstiness across multimodal human interaction reveals differences between verbal and non-verbal communication ..... 39
Drew Abney, Rick Dale, Chris Kello, Max Louwerse
Enactive Mechanistic Explanation of Social Cognition ..... 45Ekaterina Abramova, Marc Slors, Iris van Rooij
Human Visual Search as a Deep Reinforcement Learning Solution to a POMDP ..... 51
Aditya Acharya, Xiuli Chen, Christopher Myers, Richard Lewis, Andrew Howes
Executive function and attention predict low-income preschoolers' active category learning ..... 57
Katherine A. Adams, George Kachergis
Simulating behavioural interventions for developmental deficits: When improving strengths produces better outcomes than remediating weaknesses ..... 63
Hala Alireza, Anna Fedor, Michael Thomas
A Bayesian Model of Memory for Text ..... 69
Mark Andrews
Numbers Uniquely Bias Spatial Attention: A Novel Paradigm for Understanding Spatial-Numerical Associations ..... 75
Lauren Aulet, Sami Yousif, Stella Lourenco
Highly Proficient Bilinguals Maintain the Language-Specific Pragmatic Constraints on Pronouns:Evidence from Speech and Gesture81
Zeynep Azar, Ad Backus, Aslı Özyürek
Rise and fall of conflicting intuitions during reasoning ..... 87
Bence Bago, Wim De Neys
The Refugees' Dilemma: not all deontological moral choices are of the same kind ..... 93
Albert Barque-Duran, Emmanuel Pothos
I know what you need to know: Children's developing theory of mind and pedagogical evidence selection ..... 99
Ilona Bass, Elizabeth Bonawitz, Patrick Shafto, Dhaya Ramarajan, Alison Gopnik, Henry Wellman
Didn't know, or didn't show? Preschoolers consider epistemic state and degree of omission when evaluating teachers ..... 105
Ilona Bass, Elizabeth Bonawitz, Hyowon Gweon
Modeling human categorization of natural images using deep feature representations ..... 111
Ruairidh Battleday, Joshua Peterson, Tom Griffiths
Semantic Typology and Parallel Corpora: Something about Indefinite Pronouns ..... 112
Barend Beekhuizen, Julia Watson, Suzanne Stevenson
How Relative is the Relative Frame of Reference? Front and back in Norwegian, Farsi, German, and Japanese ..... 118
Sieghard Beller, Andrea Bender
Quantifying infants' statistical word segmentation: a meta-analysis ..... 124
Alexis Black, Christina Bergmann
Narrowing of the Cone-of-Direct Gaze Through Reinforcement Learning ..... 130
Sam Blakeman, Denis Mareschal
Functionally localized representations contain distributed information: insight from simulations of deep convolutional neural networks ..... 136
Nicholas Blauch, Elissa Aminoff, Michael Tarr
Inferential Role Semantics for Natural Language ..... 142
Peter Blouw, Chris Eliasmith
Split-Second Detection of Cooperativeness from Faces in the Trust Game ..... 148Jean-Francois Bonnefon, Astrid Hopfensitz, Wim De Neys
Diversity in a Contrast Set Increases Generalization from a Single-Item Target ..... 149
David Bosch, David Kalkstein, Tali Kleiman
Causal learning from interventions and dynamics in continuous time ..... 150Neil Bramley, Ralf Mayrhofer, Tobias Gerstenberg, David Lagnado
Harmony in a non-harmonic language: word order learning in French children ..... 156
Guillaume Braquet, Jennifer Culbertson
How can I help? 24- to 48-month-olds provide help specific to the cause of others' failed actions ..... 162
Sophie Bridgers, Sara Altman, Hyowon Gweon
Watching Non-Corresponding Gestures Helps Learners with High Visuospatial Ability to Learn about Movements with Dynamic Visualizations: An fNIRS Study ..... 168Birgit Brucker, Björn de Koning, Ann-Christine Ehlis, David Rosenbaum, Peter Gerjets
Learning on Multi-Touch Devices: The influence of the distance between information in pop-ups and the hands of the users ..... 174
Birgit Brucker, Lara Scatturin, Peter Gerjets
A Flexible Mapping Scheme for Discrete and Dimensional Emotion Representations ..... 180
Sven Buechel, Udo Hahn
Maintenance of Perceptual Information in Speech Perception ..... 186
Wednesday Bushong, T. Florian Jaeger
Task-oriented Bayesian inference in interval timing: People use their prior reproduction experience to calibrate time reproduction ..... 192
Zhenguang Cai, Ruiming Wang, Huihui Liu, Maarten Speekenbrink
The most efficient sequence of study depends on the type of test ..... 198
Paulo Carvalho, Rob Goldstone
Is there an explicit learning bias? Students beliefs, behaviors and learning outcomes. ..... 204
Paulo Carvalho, Elizabeth McLaughlin, Ken Koedinger
A Model of Cognitive Control in the Wisconsin Card Sorting Test: Integrating Schema Theory and Basal Ganglia Function ..... 210
Andrea Caso, Richard P. Cooper
Distributional learning and lexical category acquisition: What makes words easy to categorize? ..... 216Giovanni Cassani, Robert Grimm, Steven Gillis, Walter Daelemans
Knowledge transfer in a probabilistic Language Of Thought ..... 222
Samuel Cheyette, Steve Piantadosi
Cross-situational learning of novel anaphors ..... 228Karen Clothier, Satoshi Nambu, Hajime Ono, Akira Omaki
Expected Utility in Romantic Relationships: Satisfaction as a Cue for Romantic Partnership Dissolution ..... 234
Samantha Cohen, Peter Todd
Analogical gestures foster understanding of causal systems ..... 240Kensy Cooperrider, Dedre Gentner, Susan Goldin-Meadow
Characterizing spatial construction processes: Toward computational tools to understand cognition ..... 246Cathryn S. Cortesa, Jonathan D. Jones, Gregory D. Hager, Sanjeev Khudanpur, Amy L.Shelton, Barbara Landau
Mathematical invariants in people's probabilistic reasoning ..... 252Fintan Costello, Paul Watts
Experts are better than novices when imagining wines, but not odors in general ..... 258
Ilja Croijmans, Laura Speed, Artin Arshamian, Asifa Majid
The elusive odness of or-introduction ..... 259
Nicole Cruz, David Over, Mike Oaksford
A Dynamic Tradeoff Model of Intertemporal Choice ..... 265
Junyi Dai, Timothy Pleskac, Thorsten Pachur
What is Learning? A Definition for Cognitive Science ..... 271
Jim Davies
Re-representation in comparison and similarity ..... 277
Samuel Day, Jennifer Asmuth
Comprehenders Rationally Adapt Semantic Predictions to the Statistics of the Local Environment: a Bayesian Model of Trial-by-Trial N400 Amplitudes ..... 283
Nathaniel Delaney-Busch, Emily Morgan, Ellen Lau, Gina Kuperberg, Gina Kuperberg
The Role of Imagination in Exemplar Generation: The Effects of Conflict and Explanation ..... 289 Tammy Dennis, Daniel Little
A hierarchical Bayesian model of "memory for when" based on experience sampling data ..... 295
Simon Dennis, Hyungwook Yim, Vishnu Sreekumar, Nathan Evans, Paul Garrett, Per Sederberg
Refixations gather new visual information rationally ..... 301
Yunyan Duan, Klinton Bicknell
A rational analysis of curiosity ..... 307
Rachit Dubey, Tom Griffiths
Refining the distributional hypothesis: A role for time and context in semantic representation ..... 313
Melody Dye, Michael Jones, Daniel Yarlett, Michael Ramscar
Cute Little Puppies and Nice Cold Beers: An Information Theoretic Analysis of Prenominal Adjectives ..... 319
Melody Dye, Petar Milin, Richard Futrell, Michael Ramscar
Vanishing the mirror effect: The influence of prior history $\mathcal{E}$ list composition on recognition memory ..... 325
Melody Dye, Michael Jones, Richard Shiffrin
Creating words from iterated imitation ..... 331
Pierce Edmiston, Marcus Perlman, Gary Lupyan
A Model of Event Knowledge ..... 337
Jeffrey Elman, Ken McRae
The role of intentionality in causal attribution is culturally mediated: evidence from Chinese, Mayan, and Spanish populations ..... 343
Stephanie Evers, Erika Bellingham, Katharine Donelson, Jing Du, José Antonio Jódar Sánchez, Fuyin Li, Jürgen Bohnemeyer
Explaining Enculturated Cognition ..... 349
Regina E. Fabry
A Cognitive-Pharmacokinetic Computational Model of the Effect of Toluene on Performance ..... 355
Christopher Fisher, Christopher Myers, Reem Hassan, Christopher Stevens, Charles Hack, Jeffery Gearhart, Glenn Gunzelmann
Thinking about the future: The role of spatial metaphors for time ..... 361
Stephen Flusberg, Teenie Matlock, Paul Thibodeau
Early Colour Word Learning in British Infants ..... 367Samuel Forbes, Kim Plunkett
Word Identification Under Multimodal Uncertainty ..... 373Abdellah Fourtassi, Michael Frank
Could both be right? Children's and adults' sensitivity to subjectivity in language ..... 379
Ruthe Foushee, Mahesh Srinivasan
Word Embedding Distance Does not Predict Word Reading Time ..... 385
Stefan Frank
Is Conflict Detection in Reasoning Domain General? ..... 391
Darren Frey, Wim De Neys
Sequential Effects in Prediction ..... 397
Dinis Gökaydin, Anastasia Ejova
Empirical tests of large-scale collaborative recall ..... 403
Monica Gates, Jordan Suchow, Thomas Griffiths
Faulty Towers: A hypothetical simulation model of physical support ..... 409
Tobias Gerstenberg, Liang Zhou, Kevin Smith, Joshua Tenenbaum
Gaze Shifts between Text and Illustrations are Negatively Related to Reading Fluency in Beginning Readers ..... 415
Karrie E. Godwin, Cassondra M. Eng, Anna V. Fisher
A Cognitive Model of Strategic Deliberation and Decision Making ..... 421
Russell Golman, Sudeep Bhatia
How Can Memory-Augmented Neural Networks Pass a False-Belief Task? ..... 427
Erin Grant, Aida Nematzadeh, Thomas L. Griffiths
Evidence for a facilitatory effect of multi-word units on child word learning ..... 433
Robert Grimm, Giovanni Cassani, Steven Gillis, Walter Daelemans
The nature of quantities influences the representation of arithmetic problems: evidence from drawings and solving procedures in children and adults ..... 439
Hippolyte Gros, Jean-Pierre Thibaut, Emmanuel Sander
Does Mandarin Spatial Metaphor for Time Influence Chinese Deaf Signers' Spatio-Temporal Reasoning? ..... 445Yan Gu, Yeqiu Zheng, Marc Swerts
Language and Spatial Memory in Japanese and English ..... 451Harmen Gudde, Kenny Coventry
A Computational Model for the Dynamical Learning of Event Taxonomies ..... 452
Christian Gumbsch, Sebastian Otte, Martin Butz
Reverse-engineering the process: Adults' and preschoolers' ability to infer the difficulty of noveltasks458Hyowon Gweon, Mika Asaba, Grace Bennett-Pierre
Categorization, Information Selection and Stimulus Uncertainty ..... 464
David Halpern, Todd Gureckis
Perceptual contrast and response assimilation in sequential categorization without feedback ..... 470 James Hampton
Radical Embodied Cognition, Affordances, and the (Hard) Problem of Consciousness ..... 476
Valerie Hardcastle
Convention-formation in iterated reference games ..... 482
Robert X.d. Hawkins, Mike Frank, Noah Goodman
Sampling frames, Bayesian inference and inductive reasoning ..... 488
Brett Hayes, Stephanie Banner, Daniel Navarro
The adaptive evolution of early human symbolic behavior ..... 494
Katrin Heimann, Riccardo Fusaroli, Sergio Gonzalez de La Higuera Rojo, Niels Nørkjær Johannsen, Felix Riede, Nicolas Fay, Marlize Lombard, Kristian Tylén
Children's social referencing reflects sensitivity to graded uncertainty ..... 495
Emily Hembacher, Benjamin demayo, Michael Frank
Investigating the Explore/Exploit Trade-off in Adult Causal Inferences ..... 501
Erik Herbst, Christopher Lucas, Daphna Buchsbaum
Modeling transfer of high-order uncertain information ..... 507
Michele Herbstritt, Michael Franke
A Priming Model of Category-based Feature Inference ..... 513
Laura Hiatt
Quantifying the impact of active choice in word learning ..... 519
Shohei Hidaka, Takuma Torii, George Kachergis
Reference Systems in Spatial Memory for Vertical Locations ..... 525
Thomas Hinterecker, Caroline Leroy, Maximilian E. Kirschhock, Mintao Zhao, Martin Butz, Heinrich H. Bülthoff, Tobias Meilinger
Teaching by Intervention: Working Backwards, Undoing Mistakes, or Correcting Mistakes? ..... 526
Mark Ho, Michael Littman, Joseph Austerweil
Computational and behavioral investigations of the SOB-CS removal mechanism in working memory ..... 532Violette Hoareau, Sophie Portrat, Klaus Oberauer, Benoit Lemaire, Gaën Plancher,Stephan Lewandowsky
Spatial Cognition and Science: The Role of Intrinsic and Extrinsic Spatial Skills from Seven to Eleven Years ..... 538
Alex Hodgkiss, Katie Gilligan, Michael Thomas, Andrew Tolmie, Emily Farran
Moving together: in the body or the mind? ..... 544Lilla Hodossy, Jorina von Zimmermann, Daniel Richardson
Modeling Sources of Uncertainty in Spoken Word Learning ..... 550
Matthias Hofer, Roger Levy
Knowledge of Cross-Linguistic Semantic Diversity Reduces Essentialist Beliefs about Categories ..... 556Kevin Holmes, Erin Luby, Sarah Husney
Decisions based on verbal probabilities: Decision bias or decision by belief sampling? ..... 557
Hidehito Honda, Toshihiko Matsuka, Kazuhiro Ueda
Semantic diversity, frequency and learning to read: A mini-mega study with children ..... 563
Yaling Hsiao, Kate Nation
Testing Statistical Learning Implicitly: A Novel Chunk-based Measure of Statistical Learning ..... 564
Erin S. Isbilen, Stewart M. McCauley, Evan Kidd, Morten H. Christiansen
Minimal covariation data support future one-shot inferences about unobservable properties of novel agents ..... 570
Julian Jara-Ettinger, Hyowon Gweon
The Semantics and Pragmatics of Logical Connectives: Adults' and Children's Interpretations of And and Or in a Guessing Game ..... 576
Masoud Jasbi, Michael Frank
Maintaining Credibility When Communicating Uncertainty: The Role of Communication Format ..... 582
Sarah Jenkins, Adam Harris, Murray Lark
A modeling link between cognitive and biological homeostasis ..... 588
Gavin Jenkins, Jordan Barnes, Paul Tupper, Mark Blair
Viewers' Sensitivity to Abstract Event Structure ..... 594
Yue Ji, Anna Papafragou
Promoting Children's Relational Understanding of Equivalence ..... 600
Kristen Johannes, Jodi Davenport, Yvonne Kao, Caroline Byrd Hornburg, Nicole McNeil
Opponent Uses of Simplicity and Complexity in Causal Explanation ..... 606
Samuel Johnson, J. J. Valenti, Frank Keil
Principles Used to Evaluate Mathematical Explanations ..... 612Samuel Johnson, Angie Johnston, Marissa Koven, Frank Keil
Statistical and Mechanistic Information in Evaluating Causal Claims ..... 618
Samuel Johnson, Frank Keil
Touch Screen Text Entry as Cognitively Bounded Rationality ..... 624
Jussi Jokinen
Using Measurement Models to Understand Eyewitness Identification ..... 625
Matthew Kaesler, John Dunn, Carolyn Semmler
A Biologically Constrained Model of Semantic Memory Search ..... 631
Ivana Kajic, Jan Gosmann, Brent Komer, Ryan W. Orr, Terrence Stewart, Chris Eliasmith
Mechanisms of overharvesting in patch foraging ..... 637
Gary Kane, Aaron Bornstein, Robert Wilson, Amitai Shenhav, Nathaniel Daw, Jonathan Cohen
Language-users choose short words in predictive contexts in an artificial language task ..... 643
Jasmeen Kanwal, Kenny Smith, Jennifer Culbertson, Simon Kirby
Preparatory Effects of Problem Posing on Learning from Instruction ..... 649
Manu Kapur
Comparing Individual and Collaborative Problem Solving in Environmental Search ..... 650
Franziska Keilmann, Stephan de La Rosa, Stephan Schwan, Ulrike Cress, Betty J Mohler, Heinrich H Bülthoff, Tobias Meilinger
Iterated Teaching Can Optimise Language Functionality ..... 651Vera Kempe, Kamil Cichon, Nicolas Gauvrit, Monica Tamariz
Dynamic Effects of Conceptual Combination on Semantic Network Structure ..... 657
Yoed Kenett, Sharon Thompson-Schill
The provenance of modal inference ..... 663
Sangeet Khemlani, Thomas Hinterecker, Philip Johnson-Laird
Numerical and Non-numerical Magnitude Estimation ..... 669
Dan Kim, John Opfer
Variables Involved in Selective Sustained Attention Development: Advances in Measurement ..... 670
Jaeah Kim, Anna Vande Velde, Erik Thiessen, Anna Fisher
Constructing Social Preferences From Anticipated Judgments: When Impartial Inequity is Fair and Why? ..... 676
Max Kleiman-Weiner, Alex Shaw, Josh Tenenbaum
Explaining Guides Learners Towards Perfect Patterns, Not Perfect Prediction ..... 682
Elizabeth Kon, Tania Lombrozo
Selective Information Sampling and the In-Group Heterogeneity Effect ..... 688
Elizaveta Konovalova, Gael Le Mens
Exploring the decision dynamics of risky intertemporal choice ..... 694
Emmanouil Konstantinidis, Don van Ravenzwaaij, Ben R. Newell
Consistent Probabilistic Simulation Underlying Human Judgment in Substance Dynamics ..... 700
James Kubricht, Yixin Zhu, Chenfanfu Jiang, Demetri Terzopoulos, Song-Chun Zhu, Hongjing Lu
Synchronization Assessment for Collective Behavior ..... 706Maurici A. López-Felip, Tehran J. Davis, Till D. Frank
More Siblings Means Lower Input Quality in Early Language Development ..... 711
Catherine Laing, Elika Bergelson
Uncovering visual priors in spatial memory using serial reproduction ..... 712
Thomas Langlois, Nori Jacoby, Jordan Suchow, Thomas Griffiths
A core-affect model of decision making in simple and complex tasks ..... 718Othalia Larue, Alexander Hough, Ion Juvina
Generic and Universal Generalisations: Contextualising the 'Generic Overgeneralisation' Effect ..... 724
Dimitra Lazaridou-Chatzigoga, Napoleon Katsos, Linnaea Stockall
Children's semantic and world knowledge overrides fictional information during anticipatory linguistic processing ..... 730
Ruth Lee, Craig Chambers, Falk Huettig, Patricia Ganea
The impact of descriptions and incentives on the simultaneous underweighting and overestimation of rare events ..... 736
Garston Liang, Emmanouil Konstantinidis, Aba Szollosi, Christopher Donkin, Ben R. Newell
An automatic method for discovering rational heuristics for risky choice ..... 742
Falk Lieder, Paul Krueger, Tom Griffiths
Sequential Effects in the Garner Tasks ..... 748
Deborah Lin, Daniel Little
Error-based learning: A mechanism for linking verbs to syntax ..... 754Yi Lin, Cynthia Fisher
Repeated Interactions Can Lead to More Iconic Signals ..... 760
Hannah Little, Marcus Perlman, Kerem Eryilmaz
What's worth the effort: Ten-month-old infants infer the value of goals from the costs of actions ..... 766
Shari Liu, Tomer Ullman, Josh Tenenbaum, Elizabeth Spelke
Why Does Higher Working Memory Capacity Help You Learn? ..... 767
Kevin Lloyd, Adam Sanborn, David Leslie, Stephan Lewandowsky
Social Network Limits Language Complexity ..... 773
Matt Lou-Magnuson, Luca Onnis
Learning induced illusions: Statistical learning creates false memories ..... 774
Yu Luo, Jiaying Zhao
An information-seeking account of eye movements during spoken and signed language comprehension ..... 780Kyle MacDonald, Aviva Blonder, Virginia Marchman, Anne Fernald, Michael Frank
Preschoolers appropriately allocate roles based on relative ability in a cooperative interaction ..... 786
Rachel Magid, Mary Depascale, Laura Schulz
Intuitive psychophysics: Children's exploratory play quantitatively tracks the discriminability of alternative hypotheses ..... 792
Rachel Magid, Max Siegel, Josh Tenenbaum, Laura Schulz
Leveraging Response Consistency within Individuals to Improve Group Accuracy for Rank-Ordering Problems ..... 793
Brent Miller, Mark Steyvers
A Rational Constructivist Account of the Characteristic-to-Defining Shift ..... 799
Francis Mollica, Shirlene Wade, Steve Piantadosi
An incremental information-theoretic buffer supports sentence processing ..... 805
Francis Mollica, Steve Piantadosi
Different processes for reading words learned before and after onset of literacy ..... 811
Padraic Monaghan, Ya-Ning Chang, Stephen Welbourne
Multiple variable cues in the environment promote accurate and robust word learning ..... 817
Padraic Monaghan, James Brand, Rebecca Frost, Gemma Taylor
The ecological rationality of children's option generation and decision making ..... 823Lisa Musculus, Azzurra Ruggeri, Markus Raab, Babett Lobinger
Multitasking Capability Versus Learning Efficiency in Neural Network Architectures ..... 829
Sebastian Musslick, Andrew Saxe, Kayhan Ozcimder, Biswadip Dey, Greg Henselman,Jonathan Cohen
Analogical Inferences in Causal Systems ..... 835Matthew Myers, Dedre Gentner
Individual Differences in Transfer Mediated by Conceptual Priming ..... 841
Jairo A. Navarrete
When extremists win: On the behavior of iterated learning chains when priors are heterogeneous ..... 847
Daniel Navarro, Amy Perfors, Arthur Kary, Scott Brown, Chris Donkin
Calculating Probabilities Simplifies Word Learning ..... 853Aida Nematzadeh, Barend Beekhuizen, Shanshan Huang, Suzanne Stevenson
Evaluating Vector-Space Models of Word Representation, or, The Unreasonable Effectiveness of Counting Words Near Other Words ..... 859
Aida Nematzadeh, Stephan C. Meylan, Thomas L. Griffiths
Listeners integrate speech, gesture, and discourse structure to interpret the temporal structure of complex events ..... 865
Andrea Nishimi, Esther Walker, Benjamin Bergen, Tyler Marghetis
Dynamics of Affordance Actualization ..... 871Patric Nordbeck, Laura Soter, Rachel Kallen, Anthony Chemero, Michael Richardson
Broadening the Scope of Recognition Memory ..... 877
Justin Olds, Julian Marewski
A Computational Logic Approach to Human Syllogistic Reasoning ..... 883
Ana Oliveira da Costa, Emmanuelle-Anna Dietz Saldanha, Steffen Hölldobler, Marco Ragni
Speakers' gestures predict the meaning and perception of iconicity in signs ..... 889
Gerardo Ortega, Annika Schiefner, Asli Ozyurek
A Formal Approach to Modeling the Cost of Cognitive Control ..... 895
Kayhan Ozcimder, Biswadip Dey, Sebastian Musslick, Giovanni Petri, Nesreen K. Ahmed, Theodore L. Willke, Jonathan D. Cohen
Optimization of American English, Spanish, and Mandarin Chinese over time for efficient communication ..... 901
John Pate
Relational Concept Learning via Guided Interactive Discovery ..... 907
John Patterson, David Landy, Kenneth Kurtz
The Use of Iconic Words in Early Child-Parent Interactions ..... 913
Marcus Perlman, Riccardo Fusaroli, Deborah Fein, Letitia Naigles
Evidence for the size principle in semantic and perceptual domains ..... 919
Joshua Peterson, Thomas Griffiths
Modeling the Ellsberg Paradox by Argument Strength ..... 925
Niki Pfeifer, Hanna Pankka
Causation and norms of proper functioning: Counterfactuals are (still) relevant ..... 931
Jonathan Phillips, Jonathan Kominsky
Assessing the Linguistic Productivity of Unsupervised Deep Neural Networks ..... 937
Lawrence Phillips, Nathan Hodas
Opinion Cascades and Echo-Chambers in Online Networks: A Proof of Concept Agent-Based Model ..... 943
Toby D. Pilditch
Make-or-break: chasing risky goals or settling for safe rewards? ..... 949
Pantelis Pipergias Analytis, Charley Wu, Alexandros Gelastopoulos
A computational decomposition of task-irrelevant perceptual learning ..... 955Angelo Pirrone, Tom Stafford
Inferential Pitfalls in Decoding Neural Representations ..... 961
Vencislav Popov, Markus Ostarek, Caitlin Tenison
The Relational Luring Effect: False Recognition via Relational Similarity ..... 967
Vencislav Popov, Penka Hristova
Target-to-distractor similarity can help visual search performance ..... 968
Vencislav Popov, Lynne Reder
Timing Time: Why Early Vision is Cognitively Impenetrable ..... 974
Athanassios Raftopoulos
The Wason Selection task: A Meta-Analysis ..... 980
Marco Ragni, Ilir Kola, Phil Johnson-Laird
Mental Algorithms in the Historical Emergence of Word Meanings ..... 986
Christian Ramiro, Barbara Malt, Mahesh Srinivasan, Yang Xu
A cognitive analysis of deception without lying ..... 992
Keith Ransom, Wouter Voorspoels, Amy Perfors, Daniel Navarro
Connecting stimulus-driven attention to the properties of infant-directed speech - Is exaggerated intonation also more surprising? ..... 998
Okko Rasanen, Sofoklis Kakouros, Melanie Soderstrom
When does a 'visual proof by induction' serve a proof-like function in mathematics? ..... 1004
Josephine Relaford-Doyle, Rafael Nunez
Interpreting Asymmetric Perception in Speech Perception with Bayesian Inference ..... 1010
Jie Ren, Joseph Austerweil
Quantitative Models of Human-Human Conversational Grounding Processes ..... 1016
Clayton D. Rothwell, Valerie L. Shalin, Griffin D. Romigh
Comprehenders Model the Nature of Noise in the Environment ..... 1022Rachel Ryskin, Richard Futrell, Edward Gibson
Is the strength of regularisation behaviour uniform across linguistic levels? ..... 1023
Carmen Saldana, Kenny Smith, Simon Kirby, Jennifer Culbertson
Converting Cascade-Correlation Neural Nets into Probabilistic Generative Models ..... 1029
Ardavan Salehi Nobandegani, Thomas R. Shultz
Mental Representations and Computational Modeling of Context-Specific Human Norm Systems ..... 1035
Vasanth Sarathy, Matthias Scheutz, Yoed Kenett, Mowafak Allaham, Joseph Austerweil, Bertram Malle
Attractor Dynamics in Delay Discounting: A Call for Complexity ..... 1041
Martin Schoemann, Stefan Scherbaum
Strategic exploration in human adaptive control ..... 1047
Eric Schulz, Edgar Klenske, Neil Bramley, Maarten Speekenbrink
How Does Instance-Based Inference About Event Frequencies Develop? An Analysis with a Computational Process Model ..... 1053
Christin Schulze, Thorsten Pachur, Ralph Hertwig
Prior Expectations in Linguistic Learning: A Stochastic Model of Individual Differences ..... 1059
R. Alexander Schumacher, Janet Pierrehumbert
Effects of Grammatical Gender on Object Description ..... 1060Arturs Semenuks, Webb Phillips, Ioana Dalca, Cora Kim, Lera Boroditsky
Inferring Human Interaction from Motion Trajectories in Aerial Videos ..... 1066
Tianmin Shu, Yujia Peng, Lifeng Fan, Hongjing Lu, Song-Chun Zhu
Children's spontaneous comparisons from 26 to 58 months predict performance in verbal and non-verbal analogy tests in 6th grade ..... 1072
Catriona Silvey, Dedre Gentner, Lindsey Richland, Susan Goldin-Meadow
Is Play Better Than Direct Instruction? Learning About Causal Systems through Play ..... 1078
Zi L. Sim, Kuldeep K. Mahal, Fei Xu
Conditionals, Individual Variation, and the Scorekeeping Task ..... 1084Niels Skovgaard-Olsen, David Kellen, Ulrike Hahn, Karl Christoph Klauer
A case for systematic sound symbolism in pragmatics: The role of the first phoneme in question prediction in context ..... 1090
Anita Slonimska, Sean Roberts
Learning to See People like People: Predicting Social Perceptions of Faces ..... 1096
Amanda Song, Li Linjie, Chad Atalla, Gary Cottrell
A Rational Approach to Stereotype Change ..... 1102
Jake Spicer, Adam Sanborn
Population size, learning, and innovation determine linguistic complexity ..... 1108
Matthew Spike
A rational analysis of marketing strategies ..... 1114
Nisheeth Srivastava, Ed Vul
Spatial language promotes cross-domain associations in early childhood ..... 1120Ariel Starr, Mahesh Srinivasan
Preemption in Singular Causation Judgments: A Computational Model ..... 1126Simon Stephan, Michael Waldmann
Marbles in Inaction: Counterfactual Simulation and Causation by Omission ..... 1132Simon Stephan, Pascale Willemsen, Tobias Gerstenberg
A Two-Step Signal Detection Model of Belief Bias ..... 1138
Rachel Stephens, John Dunn, Brett Hayes
Rational use of prosody predicts projection in manner adverb utterances ..... 1144Jon Stevens, Marie-Catherine de Marneffe, Shari Speer, Judith Tonhauser
A Common Neural Component for Finger Gnosis and Magnitude Comparison ..... 1150
Terrence Stewart, Marcie Penner-Wilger, Rylan Waring, Michael Anderson
Flexible integration of a navigable, clustered environment ..... 1156Marianne Strickrodt, Heinrich H. Bülthoff, Tobias Meilinger
The Semantic Spaces of Child-Directed Speech, Child Speech and Adult-directed Speech: A Manifold Perspective ..... 1157
Hao Sun, John Pate
¿From Abstract to Concrete? Evidence for designing learning platforms that adapt to user's proficiencies. ..... 1163
Michael I. Swart, Sorachai Kornkasem, Nirmaliz Colon-Acosta, Amy Hachigian, Jonathan M. Vitale, John B. Black
Supporting Low-Performing Students by Manipulating Self-efficacy in Digital Tutees ..... 1169
Betty Tärning, Magnus Haake, Agneta Gulz
The impact of practice frequency on learning and retention ..... 1175
Caitlin Tenison, John Anderson
Warm (for winter): Comparison class understanding in vague language ..... 1181
Michael Henry Tessler, Michael Lopez-Brau, Noah Goodman
Neural and computational arguments for memory as a compressed supported timeline ..... 1187
Zoran Tiganj, Karthik Shankar, Marc Howard
Picturing time: Children's preferences for visual representations of events ..... 1193
Katharine Tillman, Eren Fukuda, David Barner
Computational Exploration of Lexical Development in Down Syndrome ..... 1199Angel Tovar, Gert Westermann
The temporal dynamics of base rate neglect: People may not be intuitive statisticians after all ... ..... 1205Eoin Travers, Jonathan J. Rolison, Aidan Feeney
Promoting Spontaneous Analogical Transfer by Idealizing Target Representations ..... 1206Máximo Trench, Lucía Micaela Tavernini, Robert L. Goldstone
It's all in your head: Effects of expertise on real-time access to knowledge during written sentence processing ..... 1212
Melissa Troyer, Marta Kutas
Inhibitory Control Supports Referential Context Use in Language Production and Comprehension ..... 1218
Alison Trude, Nazbanou Nozari
A Dynamic Process Model for Predicting Workload in an Air Traffic Controller Task ..... 1224
Martina Truschzinski, Maria Wirzberger
The Dynamics of Selective Integration during Rapid Experiential Decisions ..... 1230
Konstantinos Tsetsos
Cake or Hat? Words Change How Young Children Process Visual Objects ..... 1236

## Dear Cognitive Scientists,

Welcome to London for the 39th Annual Conference of the Cognitive Science Society! Our meeting brings together some of the most innovative and exciting research in cognitive science. The program features exceptional plenary talks by three leading international experts: Richard Granger (Dartmouth), Ulrike Hahn (Birkbeck, University of London), and Richard Sutton (University of Alberta). It also includes an invited symposium aimed at showcasing the theme for this year: Computational Foundations of Cognition.

CogSci 2017 received 1185 submissions, including 873 full papers, 259 member abstracts, 20 publication-based short papers, as well as 19 proposals for a symposium, 9 for a workshop, and 5 for a tutorial. After a rigorous review process, we selected 255 papers for oral presentation ( $29 \%$ ), 418 papers for poster presentation (48\%), 233 member abstracts for poster presentation, 15 publication-based talks, 9 symposia, 7 workshops, and 3 tutorials.

We hope that you enjoy the program this year and the global city of London, certainly the most vibrant and historically significant city in the United Kingdom. There are thousands of shops and restaurants near the conference venue and throughout the city. We encourage you to set aside the time to enjoy some of the many tourist attractions while you are here.

## Your Program Co-Chairs,

Glenn Gunzelmann (U.S. Air Force Research Laboratory), Andrew Howes (University of Birmingham, UK), Thora Tenbrink (Bangor University, Wales, UK), Eddy Davelaar (Birkbeck, University of London, UK)

## Acknowledgements

We are very grateful to everyone who contributed to the planning and organization of this year's meeting and to all reviewers who generously donated time to evaluate submissions. We thank the 193 Program Committee members and the 1,587 reviewers who were essential to the review process. We thank the awards committee who helped assess the prize-winning papers. All Program Committee members are listed below.

We are especially grateful for the assistance of a number of individuals and groups for many organizational aspects of the meeting. We thank Jessica Wong, the Cognitive Science Society's Conference Officer, for managing pretty much everything; Deborah Gruber, the Cognitive Science Society's Business Manager, for handling the business details; Susan Gelman, Nora Newcombe, and the Cognitive Science Society's Executive Committee and Governing Board for their constant support and advice; the Scarritt Group, Inc., for logistics and support; James Stewart of Precision Conference Solutions for maintaining the conference reviewing system; Anna Papafragou, Dan Grodner, Dan Mirman, and John Trueswell and the other members of last year's Cogsci conference committee for their helpful advice and insights; our many Committee Chairs, listed below, who enthusiastically took care of their various responsibilities; the student volunteers, listed below, who keep the conference running smoothly on site; and importantly our conference sponsors, listed below, whose generous support enabled us to focus more on the program and less on the finances.

We are also thankful for the support of the Cognitive Science community. We are sure that the suggestions and contributions we received from this community helped us to make it a more lively, engaging and fun meeting for all. Enjoy!

- Glenn Gunzelmann, Andrew Howes, Thora Tenbrink, and Eddy Davelaar Program Co-Chairs, Cognitive Science 2017

## Conference Awards

## Robert J. Glushko Dissertation Prizes

The Cognitive Science Society and the Glushko-Samuelson Foundation award up to five outstanding dissertation prizes in cognitive science each year. The goals of these prizes are to increase the prominence of cognitive science and encourage students to engage in interdisciplinary efforts to understand minds and intelligent systems. The hope is that the prizes will recognize and honor young researchers conducting ground-breaking research in cognitive science. The eventual goal is to aid in efforts to bridge between the areas of cognitive science and create theories of general interest to the multiple fields concerned with scientifically understanding the nature of minds and intelligent systems. Promoting a unified cognitive science is consistent with the belief that understanding how minds work will require the synthesis of many different empirical methods, formal tools, and analytic theories. 2011 was the inaugural year of this prize, and a new competition is held annually.

The 2017 recipients of the Robert J. Glushko Prizes for Outstanding Doctoral Dissertations / Theses in Cognitive Science are listed below.

Alexandra Carstensen: "Universals and variation in language and thought: Concepts, communication, and semantic structure", 2016 (University of California, Berkeley)

Judith Ellen Fan: "Role of cognitive actions in learning", 2016 (Princeton University)

Julian Jara-Ettinger: "The inner life of goals: Costs, rewards, and commonsense psychology", 2016 (MIT)

Samuel Johnson: "Cognition as sense-making", 2016 (Yale University)
Dave Kleinschmidt: "Perception in a variable but structured world: The case of speech perception", 2016 (University of Rochester)

The Glushko Dissertation Prize Symposium showcases the award winning PhD research projects, moderated by Adele Goldberg (Princeton).

Friday, 3:00PM-4:40PM (King Suite)

## Marr Prize

The Marr Prize, named in honor of the late David Marr, is awarded to the best student paper at the conference. All student first authors were eligible for the Marr Prize for the best student paper. The Marr Prize includes an honorarium of $\$ 1000$ and is sponsored by The Cognitive Science Society. The winner of the 2017 Marr Prize for the Best Student Paper is:

Melody Dye, Petar Milin, Richard Futrell, \& Michael Ramscar:
Cute little puppies and nice cold beers: An information theoretic analysis of prenominal adjectives
Thursday, 10:50-11:10, Linguistic Conventions (Blenheim)

## Computational Modeling Prizes

Four prizes worth $\$ 1000$ each are awarded for the best full paper submissions to CogSci 2017 that involve computational cognitive modeling. The four prizes represent the best modeling work in the areas of perception/action, language, higher-level cognition, and applied cognition. These prizes are sponsored by The Cognitive Science Society. The winners of the 2017 Computational Modeling Prizes are listed below.

## Perception \& Action:

Tianmin Shu, Yujia Peng, Lifeng Fan, Song-Chun Zhu, \& Hongjing Lu: Inferring Human Interaction from Motion Trajectories in Aerial Videos Friday, 16:00-16:20, Interaction (Blenheim)

## Language:

## Peter Blouw \& Chris Eliasmith:

Inferential Role Semantics for Natural Language
Thursday, 10:50-11:10, Semantics \& Concepts (Buckingham)

## Higher-Level Cognition:

## Simon Stephan \& Michael Waldman:

Preemption in Singular Causation Judgments: A Computational Model Saturday, 15:00-15:20, Judgement (Windsor)

## Applied Cognition:

Jane Wang, Zeb Kurth-Nelson, Hubert Soyer, Joel Leibo, Dhruva Tirumala, Remi Munos, Charles Blundell, Dharshan Kumaran, \& Matt Botvinick: Learning to Reinforcement Learn Saturday, 10:30-10:50, Learning Mechanisms (Blenheim)

## Student Travel Awards

The Robert J. Glushko and Pamela Samuelson Foundation generously sponsored $\$ 10,000$ for student travel awards. Travel awards have been provided to students whose submissions were accepted as full papers, received high rankings, and who indicated a need for travel funding. This year's travel awards went to:

Keith Ransom
Ardavan Salehi Nobandegani
Maurici López-Felip
Christian Ramiro
Katherine Adams
Anita Slonimska
Vencislav Popov
Shari Liu
Vasanth Sarathy
Rachel Magid
Matt Lou-Magnuson
Elizaveta Konovalova
Martin Schoemann
Darren Frey
Jasmeen Kanwal
Yue Ji
Tian Xu
Francis Mollica
Michael Tessler
Dan Kim

# Invited Presentations 

## Rumelhart Prize Lecture

Lila Gleitman, University of Pennsylvania
Takes Two to Tango: The Linguistic Representation of Symmetry
Friday, July 28, 17:10-18:10, King Suite

## Rumelhart Prize Symposium

Symposium in honor of Lila Gleitman:
Finding structure and meaning in language acquisition
Panelists:
Elissa Newport, Georgetown University
Cindy Fisher, University of Illinois
John Trueswell, University of Pennsylvania
Barbara Landau, Johns Hopkins University
Friday, July 28, 10:30-12:10, King Suite

## Heineken Prize Lecture

Elizabeth Spelke, Harvard University
Core Knowledge and Composition
Thursday, July 27, 17:10-18:10, King Suite

## Thursday's Keynote

Richard Sutton, University of Alberta
Reinforcement Theories of Learning and Thinking
Thursday, July 27, 9:00-10:00, King Suite

## Friday's Keynote

Richard Granger, Dartmouth
Principles of Brain Circuit Architectures, from Percept to Concept
Friday, July 28, 9:00-10:00, King Suite

## Saturday's Keynote

Ulrike Hahn, Birkbeck, University of London
Rationality and the Role of Limited Experience
Saturday, July 29, 9:00-10:00, King Suite

## Invited Symposium

## Computational Foundations

Panelists:
Peter Dayan, University College London
Karl Friston, University College London
Matt Botvinick, DeepMind, University College London
Howard Bowman, University of Kent
Ulrike Hahn, Birkbeck, University of London
Thursday, July 27, 10:30-12:10, King Suite

# Tutorial: Recent Advances in Deep Learning 

Matthew Botvinick (botvinick@google.com)<br>DeepMind, London, U.K. Gatsby Computational Neuroscience Unit, University College London

## Peter Battaglia (peterbattaglia@google.com)

DeepMind, London U.K.

Keywords: Deep learning, reinforcement learning, artificial intelligence

## Overview

The past several years have seen a dramatic acceleration in artificial intelligence (AI) research, driven in large part by innovations in deep learning and reinforcement learning (RL) methods. The relevant developments, as showcased in a series of recent high-profile publications in Nature and elsewhere (e.g., Graves et al., 2016; Mnih et al., 2015; Silver et al., 2016), have generated intense interest in cognitive science, partially because they appear to have potentially far-reaching implications for understanding human intelligence. Unfortunately, the pace of innovation in AI has been so rapid that it is difficult for non-experts and sometimes even for experts - to stay abreast of the latest developments.
The present tutorial brings together five front-line researchers in AI, each with dual credentials in neuroscience and/or cognitive science, to provide an accessible overview and update on the most important recent developments in deep learning and deep RL. The tutorial will be aimed at a broad audience, ranging from graduate students to senior investigators, and spanning specialties from cognitive and developmental psychology to psychiatry, human factors research, and systems neuroscience. The focus will be on fundamental concepts and principles, and a central goal will be to maximize accessibility, in line with the tutorial format.

## Significance

Neural network modeling has played a pivotal role in cognitive science since at least the 1980's. Over the past decade or so, neural networks have been overshadowed to some extent by other techniques. Beginning around 2012, interest in neural network methods (often rebranded as 'deep learning') began to take off machine learning research, and have since then become the dominant approach in AI. In combination with RL methods, deep learning has enabled a series of breakthroughs in tasks ranging from image classification to game play (see Marblestone et al., 2016 for a review).
The implications of this tectonic shift for cognitive science are currently under intensive debate (Marblestone, 2016; Lake et al., 2016). It seems clear that AI innovations, including memory architectures, generative models, and deep RL techniques are likely to stimulate new hypotheses
about human cognition. At the same time, it seems likely that AI research would benefit from richer input from cognitive science.

Ironically, the potential for exchange between the two fields has been hindered by the very pace of innovation in AI. (Emblematic is the fact that the developments we will review in the present tutorial have almost all emerged since the last time the Cognitive Science meeting featured a tutorial on neural networks, just two years ago.) Our aim in the present tutorial is to mitigate this problem by providing an accessible update on the most recent key developments in deep learning and deep RL.

## Tutorial structure and activities

The tutorial will assume a half-day format, consisting of five tutorial lectures, each covering an area in which some of the most important recent innovations have arisen. As detailed below, all five lecturers are members of the research team at DeepMind in London (deepmind.com), with dual citizenship in AI and cognitive science. The material covered in each lecture will include recent work at DeepMind, but also related work from other groups.

## Participant credentials

Matthew Botvinick (Organizer) is DeepMind's Director of Neuroscience Research and Honorary Professor in the Gatsby Computational Neuroscience Unit. He holds a Ph.D in Cognitive Neuroscience from CMU's Center for the Neural Basis of Cognition, and has done extensive research in the computational neuroscience of reinforcement learning and decision making. His research at DeepMind focuses in part on meta-learning.
Peter Battaglia (Organizer) is a senior Research Scientist at DeepMind. He holds a Ph.D. in Brain and Cognitive Sciences from MIT and has done extensive research in scene representation, intuitive physics, and probabilistic inference. His research at DeepMind focuses on novel architectures for structured inference, with an emphasis understanding physical systems.
Tim Lillicrap is a senior Research Scientist at DeepMind. He holds a Ph.D in Neuroscience from Queen's University, and has done high profile research on deep reinforcement learning and biologically plausible neural network learning algorithms. His research at DeepMind focuses on the interface between reinforcement learning and memory.

Greg Wayne, a senior Research Scientist at DeepMind, holds a Ph.D. in Neurobiology from Columbia University. He has conducted high profile work in hierarchical planning and deep RL. His research at DeepMind focuses on integrative architectures for artificial intelligence.
Daan Wierstra is a senior Research Scientist and research team leader at DeepMind. He holds a Ph.D. in Artificial Intelligence from IDSIA, and has conducted high-profile research in RL and neural networks. His research at DeepMind focuses in part on computational models of imagination and planning.

## Presentations

As noted above, the tutorial will be comprised of five lectures, each covering a key area.

## Deep Reinforcement Learning (Tim Lillicrap)

Advances in deep RL have driven some of the highestprofile recent work in AI, including differentiable neural computers (Graves et al., 2016) and superhuman play in the game of go (Silver et al., 2016). This talk will provide a tutorial review of the cutting edge in deep RL research.

## Memory Architectures (Greg Wayne)

A major development over the past couple of years has been the incorporation of special modules for memory storage into deep learning AI systems (e.g., Graves et al. 2016; Santoro et al., 2016). This talk will review the state of the art, and consider the relationship with human episodic and working memory.

## Structured Models for Structured Domains (Peter Battaglia)

Recent work in AI has introduced structure into deep learning architectures, which biases such systems toward particular forms of representation. Such measures have allowed dramatic advances in modeling physical systems and other structured domains (e.g., Battaglia et al., 2016). The present talk will review this approach and discuss its relation to the notion of compositional representation in cognitive science.

## Deep Learning to Learn (Matthew Botvinick)

Recent work has explored the capacity of deep learning systems to 'learn how to learn,' leveraging previous experience to adapt more quickly to new challenges (e.g., Wang et al., 2016). This lecture will review recent progress toward endowing deep learning systems with this important capacity.

## Deep Generative Models (Daan Wierstra)

One of the most exciting developments in recent deep learning research has been the rapid progress in building rich and flexible generative models, models that support operations like imagination and forecast-based planning (e.g., Gregor et al., 2015). This lecture will review the most
recent techniques for building generative models, considering their many implications for cognitive science.

## Related events

Yildirim and colleagues will present a half-day workshop focusing on the interface between recent AI advances and cognitive science. This can be considered a companion to the present tutorial, in that it will also cover techniques other than deep learning/RL, and will more deeply explore applications to cognitive and neuroscience.

# Methods for Reconstructing Causal Networks from Observed Time-Series: Granger-Causality, Transfer Entropy, and Convergent Cross-Mapping 

Fermín Moscoso del Prado Martín (fmoscoso@linguistics.ucsb.edu)<br>Department of Linguistics, South Hall 3521, UCSB<br>Santa Barbara, CA 93106 USA

#### Abstract

Keywords: convergent cross-mapping; development, dynamical systems; Granger-causality; information theory; phasespace reconstruction; time series

## Objectives and Scope

A major question that arises in many areas of Cognitive Science is the need to distinguish true causal connections between variables from mere correlations. The most common way of addressing this distinction is the design of wellcontrolled experiments. However, in many situations, it is extremely difficult -or even outright impossible- to perform such experiments. Researchers are then forced to rely on correlational data in order to make causal inferences. This situation is especially common when one needs to analyze longitudinal data corresponding to historical time-series, symbolic sequences, or developmental data. These inferences are often very problematic. From the correlations alone it is difficult to determine the direction of the causal arrow linking two variables. Worse even, the lack of controls of observational data entail that correlations found between two variables need not reflect any causal connection between them. The possibility always remains that some third variable which the researchers were not able to measure, or were actually unaware of, is the actually driver for both measured variables, giving rise to the mirage of a direct relationship between them.

In recent years, it has been shown that, under particular circumstances, one can use correlational information for making sound causal inferences (cf., Pearl, 2000). In this tutorial I will provide a hands-on introduction to the use of modern causality techniques for the analysis of observational time series. I will cover causality analyses for three types of time-series that are often encountered in Cognitive Science research:

- For numerical time-series of a predominantly stochastic nature I will discuss how to perform Granger-Causality (Granger, 1981) analyses used by econometricians, using the methodology introduced by Toda and Yamamoto (1995).
- For symbolic stochastic time-series, I will introduce the Transfer Entropy measure developed in Physics (Schreiber, 2000).
- Finally, for numerical series that can be shown to have a predominantly deterministic (even if possibly chaotic) nature, I will discuss Convergent Cross-Mapping (Clark et al., 2015; Sugihara et al., 2012), a very powerful technique recently developed in the field of ecology, that relies on the Theory of Dynamical Systems to make causal inferences.

Finally, I will demonstrate how to use each of these techniques for reconstructing networks of causal relations between large sets of variables.

## Overview of Causality Methods for Time Series

 Granger-CausalityGranger-Causality (cf. Granger, 1981) is a powerful technique developed in Econometrics for assessing whether one time sequence can be said to be the cause of another one (or viceversa). If $x$ and $y$ are stationary time sequences on discrete time $(\tau)$, in order to test whether $x$ Granger-causes $y$, one tests whether the past of $x$ is able to predict the future of $y$, over and above the predictive power that can be obtained from y's own past. Between just two variables, this is assessed using Autoregressive Models. When more than two variables are involved this is naturally extended by using Vector Autoregressive Models.

This technique is useful for the analysis of numerical time series data that are generated by a process whose nature is predominantly stochastic, which is typical of data resulting from the aggregation of multiple sources. One important requirement of the Granger-causality method is that it is limited to stationary time series. This property is sometimes difficult to guarantee in the types of series that one typically encounters in Cognitive Science, which tend to exhibit a certain degree of co-integration. This limitation can, however, be addressed by using the methodology introduced by Toda and Yamamoto (1995), which I will introduce in the tutorial.

## Transfer Entropy

Often, in Cognitive Science, researchers need to analyze sequences of discrete symbols, as could for instance be the sounds uttered by a developing child. Schreiber (2000) extended the main idea of Granger-Causality to symbolic stochastic processes. Instead of analyzing correlations between variables, one moves into using mutual informations, in the sense of Shannon (1948). Even when one's data are actually of a numerical nature, it can be actually beneficial to analyze them in symbolic terms, as the mutual informations are capable of capturing non-linear relations that could be missed by linear correlation-based methods (see, HlaváčcovaSchindler, Paluš, Vejmelka, \& Bhattacharya, 2007, for a review). This later usage will be demonstrated in the tutorial using a dataset from human speech.

## Convergent Cross-Mapping

The Granger-Causality and Transfer-Entropy approaches outlined above are suitable only for stochastic systems. In some

Cognitive Science domains, especially those dealing with longitudinal developmental data, one also encounters numerical data that can be argued to originate from a predominantly deterministic Dynamical System. Such cases can be modelled explicitly using systems of coupled differential equations. However, in many cases, only a few of the variables that relevant for the system are available to the researchers (the others being unmeasurable or plainly unknown). However, Takens' Theorem (Takens, 1981) states that the crucial properties of a dynamical system's attractor can be succesfully recovered using a single one of its variables, in what is known as Phase-State Reconstruction. Using this fact, Sugihara et al. (2012) developed the Convergent-Cross Mapping (CCM) technique, which enables recovering the direction of causality between any two time sequences generated by the same dynamical system. Importantly, and in contrast with the methods discussed above, CCM is also capable of distinguishing the case when two correlated variables are not actually causally related, but rather they are both driven by a third unstudied variable. A limitation of CCM is that it requires relatively long time series, which are often unavailable in many actual research problems. Clark et al. (2015) extended CCM to allow combining multiple short time series originating from similar processes (i.e., as if considering random effects in a regression model), introducing the "multispatial" variant of the CCM method. I will demonstrate how the multispatial CCM analyses can be performed.

## Format and Organization

This tutorial is designed to cover half a day (three hours) broken into two sections of 1.5 hours each. The first session in the tutorial will discuss the theoretical basis, conditions of applicability, advantages, drawbacks of each of the three causal analysis methods. The second session will be hands-on, guiding attendants on how to perform each of these analyses, together with the necessary diagnostics, using the R statistical software. For this, I will make use of previously published datasets, covering three different timescales: historical (Moscoso del Prado Martín, 2014), developmental (Irvin, Spokoyny, \& Moscoso del Prado Martín, 2016), and the time-scale of a typical behavioral experiment (Moscoso del Prado Martín, 2011).

## Target Audience

The tutorial is aimed at advanced graduate students, postdocs, and senior researchers wishing to use this type of causal analyses in this research. A familiarity with basic statistics and with programming (preferably using R ) will be necessary to be able to follow the theoretical arguments, and to be able to perform the analyses.

## Tutor Information

Fermín Moscoso del Prado Martín is assistant professor of Linguistics at the University of California, Santa Barbara. Previously he has held positions at the Max Planck Institute
for Psycholinguistics, the Medical Research Council - Cognition and Brain Sciences Unit, and at the Cognitive Psychology Laboratory of the French National Research Center. He holds an MEng in Computer Science by the Technical University of Madrid, and a PhD in Linguistics by the University of Nijmegen, where he was a student of Prof. R. H. Baayen. Over the last decade he has published multiple papers combining information-theoretical methods, computational modeling, corpus analyses, and psycholinguistic experiments.

# Dynamic Field Theory: Conceptual Foundations and Applications in Cognitive and Developmental Science 

John P. Spencer (j.spencer@uea.ac.uk)<br>School of Psychology, University of East Anglia, Norwich NR4 7TJ, United Kingdom<br>Vanessa R. Simmering (simmering @ wisc.edu)<br>Department of Psychology, University of Wisconsin - Madison, 1202 W. Johnson Street, Madison, WI 53706 USA<br>Sebastian Schneegans (ss2361@cam.ac.uk)<br>Department of Psychology, University of Cambridge, Cambridge CB2 3EB, United Kingdom

Keywords: computational model; dynamic systems; neural field model

## Objectives and Scope

Dynamical Systems thinking has been influential in the way psychologists, cognitive scientists, and neuroscientists think about sensori-motor behavior and its development. The initial emphasis on motor behavior was expanded when the concept of dynamic activation fields provided access to embodied cognition. Dynamical Field Theory (DFT) offers a framework for thinking about representation-in-themoment that is firmly grounded in both Dynamical Systems thinking and neurophysiology. Dynamic Neural Fields are formalizations of how neural populations represent the continuous dimensions that characterize perceptual features, movements, and cognitive decisions. Neural fields evolve dynamically under the influence of inputs as well as strong neuronal interaction, generating elementary forms of cognition through dynamical instabilities. The concepts of DFT establish links between brain and behavior, helping to define experimental paradigms in which behavioral signatures of specific neural mechanisms can be observed. These paradigms can be modeled with Dynamic Neural Fields, deriving testable predictions and providing quantitative accounts of behavior.

One obstacle for researchers wishing to use DFT has been that the mathematical and technical skills required to make these concepts operational are not part of the standard repertoire of cognitive scientists. The goal of this tutorial is to provide the training and tools to overcome this obstacle. We will provide a systematic introduction to the central concepts of DFT and their grounding in both Dynamical Systems concepts and neurophysiology. We will discuss the concrete mathematical implementation of these concepts in Dynamic Neural Field models, giving all needed background and providing participants with some hands-on experience using interactive simulators in MATLAB. Finally, we will take participants through a number of selected, exemplary case studies in which the concepts and associated models have been used to ask questions about elementary forms of embodied cognition and their development.

A newly published book on Dynamic Neural Field modeling, Dynamic Thinking: A Primer on Dynamic Field Theory, covers these topics and more, with interactive simulators available to give hands-on experience to readers. We will take participants through the process of building and simulating models to illustrate key concepts in the case studies we describe in the tutorial.

## Suggested Readings

(available online, see Online Resources below)

## Target Audience

No specific prior knowledge of the mathematics of dynamical systems models or neural networks is required as the mathematical and conceptual foundations will be provided during the tutorial. An interest in formal approaches to cognition is an advantage.

## Schedule of Material Covered in the Tutorial

1. Conceptual foundations of Dynamical Systems Thinking and Dynamical Field Theory (DFT) - 30 minutes: embodied and situated cognition; stability as a necessary property of embodied cognitive processes; distributions of population representation as the basis of spatially and temporally continuous neural representations.
2. Dynamical Systems and Dynamic Field Theory Tutorial 90 minutes: concept of dynamical system; attractors and stability; input tracking; detection, selection, and memory instabilities in discrete neuronal dynamics; Dynamical Fields and the basic instabilities: detection, selection, memory, boost-driven detection; learning dynamics; categorical vs. graded mode of operation; practical implementation of DFT in simulators; interactive simulation; illustration of the ideas through robotic implementations;
3. Case study using DFT to understand brain-behavior relations in humans with functional neuroimaging - 60 minutes: mapping of neural activation patterns in dynamic neural fields to the hemodynamic response measured with fMRI and fNIRS; case study on the neural processes that underlie visual working memory in children and adults.
4. Case study using DFT to understand embodied cognition and its development - 90 minutes: visual and spatial working memory in infants, children, and adults; spatial precision hypothesis as a developmental mechanism visuospatial cognition
5. Case study using DFT to understand higher cognition 90 minutes: integrating location and feature information to form working memory representations of visual scenes; linking spatial language to visual perception

## Lecturers

John P. Spencer is a Professor of Psychology at the University of East Anglia in Norwich, UK. Prior to arriving in the UK, he was a Professor of Psychology at the University of Iowa and served as the founding Director of the Delta Center (Development and Learning from Theory to Application). He received a Sc.B. with Honors from Brown University in 1991 and a Ph.D. in Experimental Psychology from Indiana University in 1998. He is the recipient of the Irving J. Saltzman and the J.R. Kantor Graduate Awards from Indiana University. In 2003, he received the Early Research Contributions Award from the Society for Research in Child Development, and in 2006, he received the Robert L. Fantz Memorial Award from the American Psychological Foundation. His research examines
the development of visuo-spatial cognition, spatial language, working memory, and attention, with an emphasis on dynamical systems and neural network models of cognition and action. He has had continuous funding from the National Institutes of Health and the National Science Foundation since 2001 and has been a fellow of the American Psychological Association since 2007. He will lecture on the topics 1-3 above.
Vanessa R. Simmering is an Assistant Professor of Psychology at the University of Wisconsin - Madison. She obtained her B.S. with Honors in Psychology from the University of Iowa in 2001 and a Ph.D. in Psychology from the University of Iowa in 2008. Her research takes a dynamic systems approach to understanding cognition and development, with particular emphasis on how visuospatial cognition relates to other developing skills during early childhood. She will lecture on topic 4 above.
Sebastian Schneegans is a postdoctoral researcher in the Department of Psychology at the University of Cambridge. He obtained his PhD (Dr.-Ing.) at the Institut für Neuroinformatik, Ruhr-Universität Bochum, for his work on visual working memory, spatial cognition and spatial language within the framework of DFT. He is now developing population code models of visual working memory and testing them in psychophysical experiments. His work has been published in seven journal articles, six book chapters, and numerous conference contributions. Dr. Schneegans will lecture on mechanisms for feature binding and spatial transformations in DFT. He will lecture on topic 5 above.

## Computer Use

Participants who bring laptops with Matlab installed (student version is sufficient) will be able to follow demonstrations by actively working with the simulator during lectures.

## Online Resources

We will use simulators from the free Matlab toolbox Cosivina for demonstrations. Installation instructions and documentation for the toolbox can be found on the website. Related publications, lecture material, and interactive simulators can all be found at our website, http://www.dynamicfieldtheory.org/.

# The Fine Art of Conversation

#### Abstract

This workshop is aimed at giving human interaction researchers the conceptual and practical apparatus to balance their representations of data (mixes of drawings and photographs in the most part), so as to "maximally incite, but also constrain" their representations, just as artists sometimes succeed in doing (Streeck, Grothues, \& Villanueva, 2009, p.28). Why-as Streeck points out-are the drawings and visualisations of interaction researchers so halting and timid, compared to the ways artists have responded to the same kinds of representational problems? Are these heavily segmented and sparsely constructed representations of interaction the result of a prevailing positivistic outlook with regard to representing shared space, where interaction is presented as staggered and discrete physical events with apparently little to connect them. The workshop seeks to redress this situation by examining the solutions that artists have arrived at when representing human interaction, and asking participants to engage in a series of activities and discussions which will re-frame their approaches to this issue.

Keywords: cognitive science; arts; interaction; drawing; embodiment; creativity; representation; comics; art; film; photography

## Depicting Human Interaction

Detailed representations focusing on social interaction in fine art are surprisingly rare. Where they do occur, they reveal something about the artist's conception of communication and their (possibly implicit) theories about how these representations are percieved and processed. Similar issues attend the representation of interaction in the Cognitive Sciences (C. P. R. Heath, 2014). Researchers have developed a diverse range of specialized methods for describing interaction; from graphic transcripts including photographs mixed with line drawings showing joint action and embodiment (Laurier, 2014), to coupled representations of the patterns of neural activation during social interaction in the brains of participants (Dumas, Nadel, Soussignan, Martinerie, \& Garnero, 2010). For thousands of years drawing, mapping, diagramming, and other forms of visual notation have been key methods for transmitting human knowledge and culture, and line drawing has been a particularly salient and widespread form of visual communication (Craig-Martin \& Martin, 1995).

None of these representations are innocent. Drawing itself is a kind of transcription, encoding our own analytical assumptions about what we see as relevant to a reader or
viewer (Ochs, 1979). A wide range of commonalities between drawing systems have evolved, such as the practice of perspective drawing, and each system has developed its own rationale, method, and objects of enquiry (Dubery \& Willats, 1972). Importantly, these approaches to representation are rarely scrutinised as empirical methods.

It is not surprising, then, that artists have become living repositories of expertise in the practice of drawing systems of all kinds, and as such have become a valued resource (Kozbelt, 2001). Visual reasoning can be examined in the ways that drawings are commonly constructed, (Van Sommers, 1984), and the ways in which novel drawing situations are spoken of and acted upon (C. P. Heath, Cameron, \& Cain, 2008). Added to this, drawing and diagramming have become standard tools in the repertoire of participatory action research (Chambers et al., 1997) applied in diversely situated engagements, (Theron, Mitchell, \& Smith, 2011). The process of interpreting visual depictions in itself is an intersubjective phenomenon, where particular methods and practices of reading determines the consequential social meanings and practical uses of the inscription (Goodwin, 2000).

This workshop will bring together a range of perspectives from the cognitive sciences and the arts, asking whether our long legacies of drawing systems in artistic and scientific representations is telling us something about our varied approaches to mind, intersubjectivity and social interaction. Researchers explore very different phenomena of interest, often using highly specialized research methods particular to their subdomain within the cognitive sciences. Many of these are represented in the list of prospective participants in the workshop which we are submitting with this outline. The proposed workshop aims to encourage new opportunities for dissemination and collaboration within and beyond the cognitive sciences, scrutinising the received and conventional methods of depicting human interaction as a starting point for conversation and exchange.

## Goals and workshop plan

Background The organizers have participated in and run workshops, specialist conferences and presentations bridging cognitive science, human interaction and the arts, including
at the 2014 meeting of the Society ${ }^{1}$. This workshop aims to: a). build upon and extend the networks of researchers established at prior meetings, and to use the clear focus on methods of depicting human interaction as a binding theme to draw together and engage the widest possible range of fields and approaches; b). to provide an entry point into the themes and discussions for a broader audience within Cognitive Science; c). to encourage cross-disciplinary researchers and especially those just starting out in their research to collaborate with others, seeking out connection points, looking at how human interaction and communication is depicted in their fields.

Format In order to create and sustain a broadened interest in the workshop, a blog page will be set up in advance so that invitees, workshop participants and others may browse examples of artworks that have already stimulated discussion amongst the organisers and can contribute their own. The blog will also provide a centralised focus for the workshop and is intended to test and support be the impetus for an illustrated publication. The central function of the blog will be gather and examine cases in which fine art has succeeded (or failed in interesting ways) to create credible depictions of interaction. Discussions on the blog both before and after the workshop will enable participants to contribute to threaded discussions alongside each artwork (link to follow on notification of acceptance of proposal).

Practical workshop activities will centre on previously worked-up examples of interactional depictions, and will use questions and criteria suggested in the workshop presentations. Activities will involve drawing out points and patterns of interest from artworks using projections onto whiteboards and screens, the results of which can later be digitally overlaid onto source artworks and can be documented on the blog. A 3-step line drawing protocol for drawing out shared interactional spaces using field inscriptions will also be used and adapted to the available 'data' -in this case the artworks under discussion.

An overview at the end of the day will compare the outputs of different groups, and will conclude with a group visit to a London gallery to look at and discuss prime examples of the kinds of artworks and drawn phenomena encountered during the day.

## Planning committee

The planning committee consists of researchers who have been working together on related projects in human interaction research, cognitive science, psychology and the arts. Each will give a short overview presentation in order to frame the subsequent activities and discussions.

- Claude Heath, "Drawing out interaction"
- Patrick Healey, "What's so difficult about drawing interaction?"
- Saul Albert, "Representing unformulated action"

[^0]The following list of participants (partial here, since numbers who have expressed interest are growing) comprises cognitive science researchers who have dealt with depictions of human interaction in their research. It also includes scientists from other fields, and artists who can bring to their highly relevant interests and methodological approaches to the crossdisciplinary objectives of the workshop.

Toby Harris (QMUL), Daniel G. Jay (Tufts), Sophie Skach (QMUL), Rosella Paulina Galindo Esparza (QMUL), Shauna Concannon (QMUL), Lida Theodorou (QMUL), Leshao Zhang (QMUL), Melissa Bliss (QMUL), Nicola Jane Plant (QMUL), Soomi Park (QMUL), Saul Albert (Tufts), Christian Heath (KCL), Yal Kreplak (EHESS), Dirk vom Lehn (King's), Jrgen Streeck (U. Texas), Eric Laurier (Edinburgh), J.P. De Ruiter (Tufts), Michael Sean Smith (UCLA), Elizabeth Stokoe \& A Dozen Eggs (Loughborough),

# Bridging the Gap: Is Logic and Automated Reasoning a Foundation for Human Reasoning? 

Ulrich Furbach (uli@uni-koblenz.de)<br>Department of Informatik, University of Koblenz-Landau, Koblenz, Germany<br>Steffen Hölldobler (sh@iccl.tu-dresden.de)<br>International Center for Computational Logic, TU Dresden, Dresden, Germany<br>Marco Ragni (ragni@cs.uni-freiburg.de)<br>Cognitive Computation Lab, University of Freiburg, Freiburg, Germany<br>Claudia Schon (schon@uni-koblenz.de)<br>Department for Web Science and Technologies (WeST), University of Koblenz-Landau, Koblenz, Germany

Keywords: reasoning processes; logic; mental representation; cognitive reasoning theories; automated deduction

## Introduction

Reasoning is a core ability in human cognition. Its power lies in the ability to theorize about the environment, to make implicit knowledge explicit, to generalize given knowledge and to gain new insights. It is a well researched topic in cognitive psychology and cognitive science and over the past decade impressive results have been achieved. Early researchers starting with Störing (1908) often used propositional logic as a normative framework. Any deviation from it has been considered an error. Central results like findings from the Wason selection task (Wason, 1968) or the suppression task (Byrne, 1989) inspired a shift from propositional logic and the assumption of monotonicity in human reasoning towards other reasoning approaches. This includes but is not limited to models using probabilistic approaches (Oaksford \& Chater, 2007), mental models (Johnson-Laird, 2006), or nonmonotonic logics (Stenning \& Lambalgen, 2008). Considering cognitive theories for syllogistic reasoning show that none of the existing theories is close to the existing data (Khemlani \& Johnson-Laird, 2012). But some formally inspired cognitive complexity measures can predict human reasoning difficulty for instance in spatial relational reasoning (Ragni \& Knauff, 2013).

Automated deduction, on the other hand, is mainly focusing on the automated proof search in logical calculi. And indeed there is tremendous success during the last decades. Recently a coupling of the areas of cognitive science and automated reasoning is addressed in several approaches. For example there is increasing interest in modeling human reasoning within automated reasoning systems including modeling with answer set programming, deontic logic or abductive logic programming (Dietz \& Hölldobler, 2015; Dietz, Hölldobler, \& Wernhard, 2014). There are also various approaches within AI research for common sense reasoning (Furbach \& Schon, 2014, 2016).

Despite a common research interest - reasoning - there are still several milestones necessary to foster a better inter-
disciplinary research. First, to develop a better understanding of methods, techniques, and approaches applied in both research fields. Second, to have a synopsis of the relevant state-of-the-art in both research directions. Third, to combine methods and techniques from both fields and find synergies. E.g., techniques and methods from computational logic have never been directly applied to model adequately human reasoning. They have always been adapted and changed. Fourth, we need more and better experimental data that can be used as a benchmark system. Fifth, cognitive theories can benefit from a computational modeling. Hence, both fields - human and automated reasoning - can both contribute to these milestones and are in fact a conditio sine qua non. Achievements in both fields can inform the others. Deviations between fields can inspire to seek a new and profound understanding of the nature of reasoning.

This is the third workshop in a series of successful Bridging the Gap workshop ${ }^{1}$ located at previous conferences: 2015 at the International Conference on Automated Deduction in Berlin (CADE-25) focused on the automated reasoning aspects. 2016 at the International Conference on Artificial Intelligence in New York (IJCAI 2016) included an AI perspective. The Annual Meeting of the Cognitive Science Society is the central place for bringing a strong human centric perspective into discussion.

## Goal and Scope

The goal of this workshop is to bring together leading researchers from cognitive science, computational logics, and psychology interested in computational foundations of human reasoning - both as speakers and as audience members. Its ultimate goal is to share knowledge, discuss open research questions, and inspire new paths. Like its preceding event, it is intended to get an overview of existing approaches and make a step towards a cooperation between computational logic and cognitive science. Topics of interest include, but are not limited to the following:

- Benchmark problems relevant in both fields

[^1]- limits and differences between automated and human reasoning
- psychology of deduction and common sense reasoning,
- logics modeling human reasoning
- non-monotonic, defeasible, and classical reasoning

The workshop is planned as a half-day event. There will be an invited speaker, sponsored by IFIP TC 12 (this is why this Workshop would have the "(supported by IFIP TC 12)" in its announcement.

## Workshop Organization

Ulrich Furbach is a Senior Research Professor of Artificial Intelligence at the University of Koblenz. His research interests include knowledge management, automated reasoning, multi-agent systems, and e-learning. He is co-founder of the spin-off company wizAI (www.wizai.com), which develops knowledge management systems and information extraction tools. Steffen Hölldobler is professor for Knowledge Representation and Reasoning at the Technical University Dresden. He is currently Director of the International Center for Computational Logic and co-ordinator of the European Master's Program in Computational Logic. He is particularly interested in combining methods and techniques from computational logic and cognitive science to adequately model human reasoning and to develop connectionist systems for human reasoning. Marco Ragni is a DFG-Heisenberg fellow and associate professor at the technical faculty and the Center for Cognitive Science of the Albert-Ludwigs-University Freiburg and associated with Department. His research interests include qualitative spatio-temporal reasoning, knowledge representation and reasoning, cognitive modelling, and complex cognition with a special focus on analyzing why and how human reasoning often deviates from classical logical approaches. Claudia Schon is a postdoctoral researcher at the Institute for Web Science and Technologies at the University of Koblenz-Landau. During the last years, she was working in various projects in the area of artificial intelligence. One of these projects was the RATIOLOG project were she focused her research on commonsense reasoning and modeling human deduction.

## Target Audience

Our specific focus dovetails this years overall conference theme: "Computational Foundations of Cognitive Science". Hence, the target audience for this workshop overlaps significantly with the target audience of Cognitive Science conference. The workshops central topics (psychology of deduction, common sense reasoning, logic, non-monotonic reasoning, formal systems) are core topics of Cognitive Science with the multidisciplinary nature of the workshop being particularly appropriate for the multidisciplinary Cognitive Science conference.

## Confirmed Speakers

- E-A. Dietz Saldanha, TU Dresden, Germany
- S. Hölldobler, TU Dresden, Germany
- S. Khemlani, Naval Research Lab, USA
- B. Kowalski Imperial College London, GB
- A. Kakas, University Cyprus, Cyprus
- L. Pereira, Universidade Nova Lisboa, Portugal
- M. Ragni, University of Freiburg, Germany

# Citizen Science, Gamification, and Virtual Reality for Cognitive Research 

Jana B. Jarecki (jana.jarecki@unibas.ch, jj@janajarecki.com)<br>Department of Economic Psychology, University of Basel, Missionsstrasse 62A, 4055 Basel, Switzerland

Keywords: citizen science; volunteer science; experimental design, gamification; online experimentation, virtual reality; problem solving

## Introduction

This workshop discusses three distinct but related topics. The first topic is citizen science which involves volunteers all around the world generating data to address scientific problems and recently led to breakthroughs in the natural sciences. Citizen science typically involves volunteers playing online games while unknowingly solving real scientific problems. This approach can benefit cognitive research either indirecty - if volunteers implicitly solve computationally hard research problems disguised behind a game - or it benefits researchers directly - if players do experimental tasks, with the key benefit that online games are easily accessible for a diverse international subject pool. Also, the data from existing citizen science projects provide insights for cognitive scientists (e.g., one citizen science project involved classification of galaxies). Although citizen science data is limited with respect to precise experimental control, its benefits are worth discussing.
Our second topic is gamification, which citizen science often relies on. Gamification, in general, involves adding gamelike features to a task and could involve, for example, adding levels, points, or virtual characters to an experimental task. Gamified tasks are typically motivating for participants. While citizen science often uses gamification, also traditional laboratory studies can be supplemented with game-like elements and use technology from the gaming industry.
Our third topic is virtual reality (VR). This technology developed by the gaming industry enables players, equipped with a headset, to experience a controlled 3-dimensional environment that emulates being in the middle of a 3D scenario. Virtual reality typically causes subjective immersion by simulating a naturalistic experience of interacting with the world, while simultaneously offering full experimental control about the environmental structure and interactions. The link between (large-scale online) citizen science and (smaller-scale lab-based) VR research lies in that usually both approaches use gamification
How can cognitive scientists use gamification and virtual reality environments for their research?

## Goals and Scope

This workshop brings together experts from the natural and social sciences who have successfully launched citizen science platforms as well as gaming researchers and game developers from different disciplines. The aim is to introduce
citizen science to cognitive psychologists, stimulate a discussion about similarities and differences between laboratory and citizen science data, and explore the potential of existing citizen science platforms and data for cognitive research. A further goal is to gain insights into how best to conduct citizen science projects using gamification. Moreover, the workshop will explore the potential of virtual reality environments, fleshing out the challenges and opportunities of this novel technological opportunity for research. By the end of the workshop, all participants and speakers, will have been introduced to citizen science platforms, including how and where to run citizen science projects. They will understand the advantages and drawbacks of games for cognitive research, including an accessible way to design online applications. Lastly, the participants will have the knowledge to understand when and how virtual reality environments can be used to answer cognitive research questions in novel ways.

## Target Audience

The workshop targets researchers at all levels with an interest in investigating domains like problem solving, learning, attention, or decision making in settings suitable for interactive, gamified, or web studies. Note, that citizen science cannot offer maximum experimental control. Research interested in gamification in any form-offline or online-with a special focus on gamified experimental design and virtual reality are welcome. In particular researchers interested in cross-cultural data may be interested, as citizen science offers unique opportunities for international data collection. We also invite researchers interested in using virtual reality devices in the lab, and discussing its potential for cognitive research.

## Format

The full-day workshop involves short talks, hands-on experience with several of the games developed by the invited speakers, and the possibility to try out a task in virtual reality (using a HTC Vive). There will be two round table discussions. The first discussion focuses on the potentials and disadvantages of gamification and online data compared to laboratory data; the second discussion asks which of cognitive sciences' research problems can be fruitfully advanced by implementing the study within a virtual reality environment.

## Contributions

## Introduction of Concepts

Jana B. Jarecki, cognitive scientist at Basel University, will introduce the concepts citizen science and gamification.

Jacob Sherson, who has pioneered citizen science in quantum physics, will discuss how the citizen science platform ScienceAtHome, aims to exploit the clear mathematical framework of quantum physics and other natural science research challenges. This enables the construction of a suite of games bridging low-dimensional model challenges with complex relevant problem solving. He will also discuss the aim to turn ScienceAtHome into a large-scale social and cognitive science research platform offering insights into the individual minds and collective interactions.

Pinja Haikka, researcher at Aarhus University and head of outreach at ScienceAtHome, will talk about how to set up citizen science projects, with a special focus on QuantumMinds a citizen science project bridging quantum physics challenges and individual learning of volunteers participating in citizen science games.

## Where Citizen Science meets Cognitive Science

Ed Manley, who studies navigation skills with citizen science, discusses the Sea Hero Quest project, one of the most successful citizen science games in recent times. Originally developed to study navigation skills for dementia research, this project offers data on human navigation abilities from worldwide players from all age groups.

Carsten Bergenholtz from Aarhus University will introduce the Alice Challenge, a remote access experiment where volunteer players could remotely access and modify the settings of an actual instrument in the physics lab at Aarhus University. He discusses the challenges of remote experimental setups and discuss the advantages of running social science experiments on high-dimensional, real-life problems.

Oana Vuculescu, from the University of Aarhus, will introduce a game-based research project, the AlienGame, a sequential problem solving task to study the heuristics that individuals use in problem solving

## Designing and Building Games

Juho Hamari, is a Professor of Gamification (Associate \& tenure-track) and leads the Gamification Group spread across Tampere University of Technology, University of Turku and University of Tampere in Finland. He will give an overview about the academic literature on gamified crowdsourcing.

Nathaniel D. Phillips, cognitive scientist at the University Basel introduces the R Shiny platform as an easy yet powerful tool to build online experiments and games directly from R code. Through shiny, web application can directly interface with R which enables the researcher to conduct dynamic experiments in which the user interface is determined by cognitive modeling running behind the scene.

Julia A. Bopp, PhD candidate and player experience researcher at the Human-Computer Interaction Lab at the University of Basel, will introduce what game aspects may evoke
emotions and in turn how these emotions may influence good player experience.

Sharon T. Steinemann, PhD candidate at the Human-Computer Interaction Lab at the University of Basel, discusses meaningful game experiences. Her work investigates how ingame interactions shape experiences into being moving, thought-provoking, and personally meaningful. Findings and implications will be discussed using examples from current games with a focus on the relationship between game experiences and behavior change.

Julian Jarecki, virtual reality gaming developer at the University of Freiburg, introduces virtual reality with GraphVR and Ultimate Automizer. GraphVR is a virtual reality environment in which people can dynamically create and interact with near-real three-dimensional visualization of graph structures. The presentation will explore how VR creates an exciting opportunity to experience abstract concepts and structures.

Libby Heaney, virtual reality artist and research tutor at the Royal College of Art, will present a different way to use virtual reality, namely in the form of an exhibition that explains complex scientific matters to laypeople and makes these matters graspable.

## Hands-on Experience and Discussions

Experience Virtual Reality. We will additionally offer participants of the workshop the opportunity to directly experience and try out how virtual reality environments feel. We will have a live demo of Graph3D and other virtual reality environments.

## Invited Speakers

Jacob Sherson | Professor of Physics and Astronomy, Aarhus University | Founder of the citizen science platform ScienceAtHome
Juho Hamari | Professor of Gamification, Tampere University of Technology and University of Turku
Carsten Bergenholtz | Associate Professor of Management, Aarhus University
Ed Manley | PostDoc in spatial cognition, UCL London | Partner at the citizen science project SeaHeroQuest ( $t b c$ )
Julia A. Bopp $\mid \mathrm{PhD}$ candidate, gaming researcher, University of Basel
Julian Jarecki $\mid$ app and gaming developer with focus on development in VR, University of Freiburg
Libby Heaney | Digital and virtual reality artist and tutor at the Royal College of Art London
Nathaniel D. Phillips | PostDoc in cognitive science, University of Basel (tbc)
Pinja Haikka | PostDoc in Physics, Aarhus University | Head of Outreach at ScienceAtHome (tbc)
Sharon T. Steinemann | Phd Candidate | University of Basel

# Cooperative Social Intelligence: Understanding and Acting with Others 

Max Kleiman-Weiner (maxkw@mit.edu), Yibiao Zhao (ybz@mit.edu) \& Joshua Tenenbaum (jbt@mit.edu) Brain and Cognitive Science, Cambridge, MA 02139 USA

Keywords: multi-agent, cooperation, communication, coordination, theory-of-mind, social learning

## Theme

This workshop will focus on new developments and approaches to studying social intelligence with a specific focus on cooperation, theory-of-mind and social learning. With a diverse set of speakers and panelists, we anticipate these three themes will allow for connections to be made between developmental psychologists, cognitive scientists and artificial intelligence and robotics researchers.

1. Cooperation: How do we coordinate our limited individual capacities and perspectives to accomplish goals that noone could have completed on their own? How do we share the spoils of a cooperative activity fairly and equitably and how does this capacity develop in early childhood? How do we learn who is cooperative and who is not to be trusted? What special purpose representations have we evolved that make cooperation so robust?
2. Theory-of-Mind: How do we go from sparse, noisy, underdetermined observations of behavior to acquire abstract knowledge of latent mental states which generalize to novel situations and people? How does this capacity develop and what representations support these capacities in infancy and early childhood? How do we understand the actions and intentions of groups or even collectives of agents?
3. Social Learning: When and how do we realize that other intelligent agents are often the richest source of world knowledge in an environment? How do we actively learn from others? How do we efficiently share important cultural knowledge through teaching? How do norms and conventions originally form and how do we learn existing norms and conventions so quickly?

One motivation for understanding social intelligence is to re-engineer socially intelligent artificial agents that treat people like people and can be treated like people by people. While a world where artificial agents roam the sidewalks still feels far away, automated agents are already roaming the streets in self-driving cars. The above challenges to understanding our own social intelligence become challenges for engineering cooperative AI:

1. Cooperation: How can we build agents that can work with us on mixed teams? Will they need to be taught cooperative values or must these values be baked in from the start?
2. Theory-of-Mind: How can we build agents that can understand our intentions, how they unfold over time, and the ways in which they may change dynamically? Can agents without theory-of-mind robustly cooperate with humans? How can agents reveal their intentions in ways that are natural to us?
3. Social Learning: How can machine learning from teachers go beyond imitation and reinforcement? Can artificial agents take advantage of the human ability to teach and learn like children do?

## Speakers

We have already invited and received confirmations from six speakers (one tentative) that will form the core of our workshop. These speakers come from communities ranging from computer science and artificial intelligence to cognitive science and developmental psychology. Each speaker brings a unique perspective that will be of interest to the entire CogSci community. We believe these interdisciplinary interactions are a unique and positive element of the CogSci community and we hope to build on that foundation. We may invite 12 more speakers and are committed to organizing a gender balanced workshop.

Nick Chater (Professor of Behavioral Science, Warwick) Possible topics: Virtual bargaining, instantaneous conventions, one-shot communication, joint intentions

Joel Leibo and Thore Graepel (DeepMind) Possible topics: Deep learning for cooperation and competition

Stuart Russell (Professor of Computer Science, Berkeley) Possible topics: Cooperative inverse reinforcement learning, value alignment, cooperative robotics

Hyo Gweon (Professor of Psychology, Stanford) Possible topics: Social learning, social development, theory-of-mind, cooperation

Igor Mordatch (Professor of Robotics, CMU \& OpenAI) Possible topics: Emergent communication, deep reinforcement learning

Victoria Southgate (Professor of Psychology, Copenhagen) [tentative] Possible topics: Infant social cognition, action processing, Imitation and mimicry, Theory of mind, Motivation and learning

## Workshop Program

We plan to host a full day workshop consisting of talks given by $6-8$ invited speakers (depending on final commitment). Our intention is to explore having an extended lunch and allow (space permitted) for the presentations of posters in this topic area. This will allow for more informal interactions between interesting parties and will allow for researchers to have an additional opportunity to present their work. At the end of the workshop we will have a discussion panel with all of the speakers to synthesize the topics discussed throughout the workshop.

## Potential Financial Support

As this topic will be of interest to some of the industrial research labs we will also see if they are interested in providing some support to defer some of the registration costs. However as we already have confirmations from most of our speakers this funding will not be necessary and we believe we will have a very successful within the constraints of the funding provided by the conference.

# Building Bridges from (Ivory) Towers: Combining Academia and Industry for Cognitive Research 

Katherine A. Livins (klivins@netflix.com) \& Jay B. Martin (jaym@netflix.com)<br>Originals Product Innovation, Netflix<br>121 Albright Way, Los Gatos, CA 95032, US

Keywords: methods; basic and applied research; industry

## Objectives

This half-day workshop will discuss how to enrich research by marrying academic and industry-based work. Attendees will learn the theoretical, practical, and logistical complexities involved in advancing cognitive science across these distinct research sites.

This topic is relevant to the cognitive community because academia and industry often have common goals but distinct capabilities. For example, academics have the freedom to study almost any quantifiable question, and typically run small-scale studies performed in highly controlled settings with limited sets of participants. This approach results in high internal validity, but low statistical confidence, external validity, and limited replicability. Industry researchers are also often interested in human behavior (that of their users or clients) but typically need to further a company's business objectives with their work. However, these researchers have access to large-scale data sets and resources unmatched by the academic sector (Griffiths, 2014). This workshop will help attendees identify cases where cross-site collaborations might be useful, along with the methods necessary for carrying out such research.

## Workshop Outline

The workshop will begin with a series of talks highlighting a) the use of cognitive theory in industry contexts, b) the methodological considerations necessary for undertaking industry-centered research, and c) how to build holistic networks that pass information gleaned from industry activity back into academia-centered research. It will provide examples from the following industries in order to deliver a broad perspective.

Education Thinking, reasoning, and learning are central to cognitive science, however little attention is given to applied education. That said, a number of researchers have realized that watching how people process information in real learning contexts can not only help to shape better educational programs (e.g., Weitnauer et al., 2016), but also provide insights into cognition (e.g., Goldstone et al., 2008). This workshop will provide examples of how research in real learning settings can provide access to diverse research participants, and an ability to 'cache-out' learning theories.

Data Science and Machine Learning Cognitive science is broadly interested in observing human behavior to make claims about mental mechanisms. While data science and
machine learning can leverage any data, many companies are specifically interested in describing, understanding, and predicting their human users. This data can be important to basic research since, as Jones (2015) points out, social media, web-tracking, search-logs, and consumer reviews are huge sources of behavioral data that are typically inaccessible to academic researchers. This workshop will use data science and ML as examples of how industry is using cognitive science to model user behavior, as well as how those models can provide insights into cognition.

User Experience (UX) Cognitive science often specifies how cognitive mechanisms interact with external stimuli. While these interactions are typically described in terms of high-level principles, they govern real-world interactions such as those between a user and a product. UX focuses on applying these principles to optimize usability (Kujala et al., 2011). As a result, it relies on both cognitive research and methods. For example, it can consider work about perception and attention in order to lessen cognitive load on a human worker (e.g., Zheng et al., 2011), and it can be evaluated using measures such as eye-tracking, EEG, and reaction times (Oviatt, S.L., 2006). This workshop will use UX as an example of how academic learnings can be directly translated into concrete products, and how the development of those products can provide cognitive data.

The workshop will then provide participants with an opportunity to develop their own cross-site methodologies, with guidance from the facilitators. Finally, there will be a round-table discussion with both the facilitators and speakers where participants can ask further questions, get group feedback on their ideas, and further develop their understanding of cross-site research.

## Audience

This workshop will appeal to the broad cognitive community. As Jones (2015) states, 'Cognitive research is increasingly coming out of the laboratory', and increased interest has been demonstrated in past CogSci workshops, such as Mason \& Suri (2011). Thus, this workshop will be useful for experimentalists, who will learn about the methodological and operational considerations necessary for completing studies in industry contexts, as well as computational modelers who will learn how their models may be applied or developed through industry applications.

It will also benefit researchers at various stages in their careers. Graduate students may be interested in a window into research-oriented job trajectories outside of academia.

Likewise, younger professors interested in building academic/professional research networks, and professors attending to the flow of students into industry will value a venue for considering the positive benefits of increased connections across research sites.

## Presenters

This workshop will include speakers who have experience in both academic and industry research.

## Facilitators

This workshop will be run by Katherine Livins and Jay Martin. Livins's academic research focused on reasoning and perception, while Martin's focused on models of causal reasoning and categorization. They both now work as Data Scientists, leveraging cognitive science for the purpose of optimizing human decision-making in online working environments.

## Additional Speakers

David Landy - Indiana University, Department of Psychological and Brain Sciences. Landy's research focuses on computational and theoretical approaches to formal reasoning, mathematical cognition, and perception. He used this research to create an application called "Graspable Math", which teaches mathematical concepts by exploiting perceptual and gestural processes. He will speak on how real-world situations challenge academic research by providing richer contexts to develop and test the robustness of theories, with examples grounded in Graspable Math.

Noah Goodman - Stanford University, Advisor to Geometric Intelligence (now Uber AI Labs), Co-founder and advisor to Gamalon Labs and Ought Inc. Goodman's academic work spans cognitive modeling, probabilistic programming languages, categorization, and social reasoning. He also recently began working with Uber on applied AI and machine learning projects. He will speak about how these projects are interacting with his preexisting academic research.

Robert Rauschenberger - Exponent. Rauscehnberger's academic work focused visual attention in displays. He now works as a Managing Scientist on human factors and industrial engineering, applying his knowledge about the visual system to product design and human-product interface interaction. He will speak on the role of cognitive psychology in user research and experience design.

Nick Gaylord - CrowdFlower. Gaylord's academic research focused on the application of experimental design principles to the collection of training data for NLP models, and the role of domain-general decision making processes in human language comprehension. He now works as a Senior Data Scientist on how to curate human-generated data sets for algorithm consumption. He will speak on how skill sets and methods can translate between academia and industry.

## Workshop Structure

Livins will open by introducing and framing the workshop. Each speaker will then present a 25 -minute talk (including questions), before Martin closes by identifying consistent themes. Livins and Martin will then engage participants to identify cross-site opportunities in their own work, and help them develop a list of necessary methods and resources. The session will end with a 20-minute round-table discussion.

Table 1: Schedule.

| Event | Time |
| :--- | :--- |
| Opening Remarks: Livins | 20 minutes |
| Speaker 1: Landy | 25 minutes |
| Speaker 2: Goodman | 25 minutes |
| Speaker 3: Rauschenberger | 25 minutes |
| Speaker 4: Gaylord | 25 minutes |
| Closing Remarks: Martin | 20 minutes |
| Guided research development | 20 minutes |
| Round-table discussion | 20 minutes |
| Total time | 180 minutes |

## Workshop Description

Religion is of global significance, and its study requires explanations from cognitive science. Currently, the cognitive science of religion consists of researchers working in an array of disciplines, employing diverse methods, including, among others: experimental research and modelling in psychology and neuroscience, and historical, archaeological, and comparative studies of religious cognition in anthropology and religious studies. The International Association for the Cognitive Science of Religion (IACSR) seeks to advance the naturalistic and cognitive study of religion by providing settings for productive dialogue across disciplinary boundaries and methodological approaches. This half-day workshop, organized by the IACSR, has three complementary goals: 1) to expose attendees to diverse methodologies for studying the computational foundations of religious cognition, 2) to provide a forum for researchers to present recent empirical findings that bear on our understanding of religious cognition, and 3) to foster new research collaborations.

To achieve these goals, the IACSR has invited three speakers whose recent work represents cutting-edge, yet diverse, methodological approaches to the study of the foundations of religious cognition. The IACSR executive board also solicited poster submissions from members and interested researchers. The first half of this workshop will consist of the three invited lectures, and the second half will involve the presentation and critical discussion of eight posters that were the highest rated by blind peer review.

## Invited talks

## The Power of Suggestibility: Using Placebo Brain Stimulation Devices to Manipulate Subjective Experience.

Michiel Van Elk, Department of Psychology, University of Amsterdam

Effects of expectancy have been studied widely in both clinical as well as experimental settings and show the powerful effects of expectations on treatment outcomes. However, most studies on expectancy effects have focused selectively on the use of inert treatments for alleviating pain or illness. Less is known about the potential of enhancing cognitive performance or human experience through expectancy manipulations. In this talk I will present a series of studies aimed at investigating the psychological and neurocognitive basis of expectancy effects on human performance and experience. First, in three studies we used a placebo 'God-helmet' to manipulate mystical experiences and to investigate the effects of self-transcendence on selfperception. In a second research line we used a placebo cognitive enhancement device and we found that belief in cognitive enhancement was associated with a stronger externalization of agency and a change in neural responses to errors. Third, in an fMRI study we found that the tendency to get absorbed in external stimuli was associated with a decreased activity of the default mode network (DMN) and the anterior cingulate cortex (ACC), thereby indicating that a process of de-selfing and reduced cognitive control could underlie suggestibility effects. These findings are integrated in the computational framework of predictive processing, which provides a unifying theory to account for religious and spiritual beliefs and experiences.
"I once was blind..." Choice Blindness and Religious Attitude Reversals

Ryan McKay, Department of Psychology, Royal Holloway London
"Choice blindness" refers to the fact that research participants often fail to notice mismatches between an outcome they choose and an outcome they receive, while nevertheless being prepared to offer justifications for choosing the outcome they did not in fact choose. Recently this phenomenon has been demonstrated in the domain of peoples' political and moral attitudes. For example, one study 'magically' exposed participants to a reversal of their previously stated attitudes, and found that many participants not only failed to detect these reversals, but constructed coherent and unequivocal arguments supporting the opposite of their original position. In this talk I will describe some recent research adapting this paradigm to the domain of religion. Our findings reveal a dramatic potential for flexibility in our religious attitudes and beliefs. I will situate this research in the broader context of attempts to manipulate religiosity.

## Mind the Text - Retracing Mental States and Cognitive Trajectories in Historical and Text-Heavy Data

Kristoffer Nielbo, Digital Text Laboratory \& Interacting Minds Centre, Department of Culture \& Society, Aarhus University

Humans exhibit a species-unique capacity for long-term planning and future-oriented cognition. This 'deep temporality' is so fundamental to human behavior, that it can be considered the hallmark of our symbolically mediated environmental interactions. Systems of cultural norms and behavior (e.g., religious groups and traditions) have a long history and develop at a time scale, which can present a challenge to the canonical methods in cognitive and experimental anthropology. How, for instance, can we approach the historical and cognitive trajectories of adherents to a religion codified several thousand years ago? The proliferation of digitized historical and text-heavy data we are currently witnessing holds part of the solution. To illustrate this within the domain of cultural cognition, we present three studies that combine techniques from Natural Language Processing (NLP) and text data mining in order to study cognitive and affective trends at multiple time scales. Study 1 compares cognitive trajectories for historically significant religious experts; study 2 explores semantic change and concepts of mind in classical Chinese literature; and study 3 presents evidence for an evolutionary-based motivational model of religious fundamentalism. We argue that when combined with domain knowledge in language and culture, NLP and text data mining are promising approaches to cultural cognition at long time scales.

## Peer-reviewed Posters

Supernatural Agents in Predictive Minds. Marc Anderson, Aarhus University. A description of what is currently regarded as one of the most promising models of perception in cognitive neuroscience, predictive coding, and the results of three experimental studies in which this framework is operationalized.

AVM: Data Structures for the Cognitive Science of Religion. Tamás Biró, Eötvös Loránd University. Describes a method for understanding religion as a complex network of attribute-value matrices (AVMs).

Flag Identity Theory (FIT): A Cognitive Explanation for Large Scale Group Cooperation and Conflict. Michael Gantley, University of Oxford, Justin Lane, Boston University. Describes Flag Identity Theory, which relies upon cognitive mechanisms for social identification and biases of loss avoidance to explain patterns of large scale cooperation.

Culturally and Developmentally Robust Intuitions about Purpose and Intentional Design in Nature: Dual Processing Evidence from China. Deb Kelemen, Boston University, Elisa Järnefelt, University of Helsinki, and Liqi Zhu, Chinese Academy of Sciences. Describes the results of two studies conducted in China: the first replicated earlier Western-based findings of a default teleological bias. In the second, participants revealed marked tendencies to view natural phenomena as created, particularly under speeded conditions and in a non-human-made rather than humanmade condition.

Computer Simulation of Large-scale Religious Systems. Justin Lane, Boston University. Describes the use of multiagent artificial intelligence to simulate individual and group level dynamics of religious cognition.

Do forgiving God Primes Strengthen Support for State Sanctioned Punishment? Katherine O'Lone, Royal Holloway London. Describes the results of a study that investigated whether the manner in which God is believed to intervene affects people's endorsement of state-sanctioned punishment.

Cognitive Foundations of Theodicy. Karolina Prochownik, Jagiellonian University. Describes a dual-process cognitive approach to the study of theodicy.
"I can't believe she's dead": The Effects of Corpse Viewing and Corpse Condition on Vigilance for Deceased Loved Ones. Claire White, UC Northridge, Daniel MT Fessler, UCLA, Pablo Gomez-Forero, UC Northidge. Describes the results of a study that examines the effect of exposure to cues of death on vigilance for agents.

# Workshop proposal: Deep Learning in Computational Cognitive Science 

Ilker Yildirim (ilkery@mit.edu) and Joshua B. Tenenbaum (jbt@mit.edu)<br>Department of Brain \& Cognitive Sciences, MIT<br>Cambridge, MA 02130 USA

Keywords: Computational models of cognition; deep learning; Bayesian models; cognitive neuroscience; computational neuroscience; computational psycholinguistics.

## Overview and significance

A new generation of deep neural network architectures has driven rapid advances in AI over the last ten years. These architectures include convolutional neural networks (CNNs), recurrent neural networks (RNNs), and many variants and extensions. Computational cognitive scientists and neuroscientists have now begun to explore these techniques, and how they might combine with other computational tools such as Bayesian models, symbolic grammars and rule-systems, probabilistic programs, and reinforcement learning. The goal of this workshop is to bring together some of the leading researchers working at this interface, for short talks and an integrative discussion of open questions and promising directions.

Talks will cover many areas of cognition including perception, problem-solving and planning, decision-making, language and social cognition. The focus will be on models of human behavior, but the potential bridge to neural studies in humans (via fMRI) and animals (via physiology) will also be explored. Most talks will assume only a basic familiarity with neural networks, and so should be accessible to all CogSci attendees. We hope to be scheduled for an afternoon slot, and have coordinated our plans with the DeepMind's Deep Learning tutorial proposed for the morning which could serve as an introduction to more advanced methods that several talks will build on.

Workshop structure. We plan a half-day workshop comprising seven talks, each 20-25 minutes, followed by a 30 -minute panel discussion with all speakers on open questions. We will also encourage student participants to present posters on relevant work during the coffee break.

## Organizers and Presenters

Ilker Yildirim (Organizer) is a research scientist at MIT. His research spans visual and multisensory perception, computational neuroscience, and artificial intelligence
Joshua Tenenbaum (Organizer) is Professor of Computational Cognitive Science at MIT. He studies learning, perception, common-sense reasoning, and has been active in both cognitive science and artificial intelligence.
Matt Botvinick is DeepMind's Director of Neuroscience Research, and was formerly Professor of Psychology and Neuroscience at Princeton. He is a leader in computational cognitive neuroscience and reinforcement learning.

Noah Goodman is a Associate Professor of Psychology, Linguistics and Computer Science at Stanford University. His research centers on computational modeling of higherlevel cognition and probabilistic programming languages.

Thomas Griffiths is a Professor of Psychology and Cognitive Science at UC Berkeley. His group develops computational models of higher-level cognition, drawing on probabilistic, neural network, and evolutionary paradigms.

Jessica Hamrick is a PhD candidate at UC Berkeley and former intern at DeepMind. Her research focuses on mental simulation, planning and metacognition.
Tal Linzen is a postdoctoral researcher at ENS and will be Assistant Professor in the Department of Cognitive Science at Johns Hopkins starting in the fall. His research interests involve computational modeling and psycholinguistics.

Daniel Yamins is an Assistant Professor of Computational Neuroscience in the Department of Psychology at Stanford. His research lies at the intersection of neuroscience, artificial intelligence, and psychology.

## Presentations

Prefrontal cortex as a meta-reinforcement learning system (Botvinick). Two decades of neuroscience research on reward-based learning has converged on a canonical model, under which the neurotransmitter dopamine 'stamps in' associations between situations, actions and rewards by modulating the strength of synaptic connections between neurons. However, a growing number of recent findings have placed this standard model under strain. This talk draws on recent advances in AI to introduce a new theory of reward-based learning. Here, dopamine trains another part of the brain, the prefrontal cortex, to operate as its own freestanding learning system. This perspective accommodates the findings that motivated the standard model, but also deals gracefully with a wider range of observations, laying a fresh foundation for next-generation research.

Less-supervised loss functions for training models of the visual system (Yamins). Recent advances in computer vision and AI have made it possible to build deep neural networks that mimic aspects of computation in the primate and human visual system. The core idea behind these results is task-driven modeling, e.g. optimize a neural network for a complex ecologically relevant behavior, and then compare the learned model to neural responses in the brain areas thought to underlie that behavior. While this approach has produced powerful predictive models of neural representations in adult animals, its main successes so far have unfortunately relied on using heavy semantic
supervision, using large labeled datasets - data streams to which real animals do not have access. I will discuss recent work my lab has been doing to move beyond this limitation, developing less heavily supervised approaches to train deep neural network models of vision that may be more plausible models of real neural learning. These ideas rely on loss functions defined in interactive worlds that attempt to better capture the true complexities of the environment in which early juvenile development takes place.

Modeling "analysis by synthesis" in perception by combining generative models and deep inverse networks (Yildirim and Tenenbaum). In its most general form, perception can be defined as the solution to an inverse problem: identifying the world scene that gave rise to the observed retinal (or auditory, or haptic) data. It remains a mystery how the brain constructs such rich representations of the geometry of objects in a scene and their physical properties extremely quickly, in at most a few hundred milliseconds. Traditional models of how the brain solves such inference problems use iterative methods that are hard to map onto neural circuits and much too slow to explain online perception. Here we present a new approach that combines a deep neural network with a probabilistic generative model. This approach is as fast as pure feedforward models, but generates a rich description of 3D object shapes and physical properties. Applied to faces, our model explains both the tuning properties of cells in the macaque face patch system and human behavior in recognizing familiar and unfamiliar individuals.

Deep networks for amortized inference in structured probabilistic models (Goodman). I will discuss deep amortized inference for probabilistic programming languages (PPLs). This is an approach that uses a PPL to describe complex probabilistic conceptual knowledge, and captures knowledge about how to use these concepts for inference via a deep 'inference network'. I will discuss several different objectives and training methods, including variational inference and 'dream learning' (a modern variant of wake/sleep). After describing the technical setup and showing the results for a few model-learning tasks, I will speculate about the relation of deep inference networks to human procedural knowledge.

Leveraging deep learning to study representations underlying human cognition (Griffiths). Recent neural network models have resulted in significant progress in computer vision, speech recognition, and natural language processing, by learning representations of the statistical structure of complex visual, auditory, and linguistic stimuli. Understanding how the resulting models work - and how well they correspond with human perception - is an interesting scientific challenge. However, the representations that these models discover, when treated just as representations of complex stimuli, also offer the opportunity to extend the scope of psychological research.

Psychologists studying problems such as categorization or memory have tended to focus on very simple stimuli that can be carefully controlled and parameterized. This makes it possible to formulate precise theories, but at the cost of potentially losing sight of the original phenomena: Do the same models that predict how people categorize sinusoidal gratings explain how they differentiate cats and dogs? I will talk about recent work that tries to leverage representations produced by neural networks - for both images and language - to study human cognition, highlighting the promise of this approach as well as some of the challenges.

Metacontrol for Adaptive Imagination Based Optimization (Hamrick). Many machine learning systems are built to solve the hardest examples of a particular task, which often makes them large and expensive to run--especially with respect to the easier examples, which might require much less computation. For an agent with a limited computational budget, this "one-size-fits-all" approach may result in the agent wasting valuable computation on easy examples, while not spending enough on hard examples. Rather than learning a single, fixed policy for solving all instances of a task, we introduce a "metacontroller" inspired by human cognition which learns to optimize a sequence of imagined internal simulations over predictive models of the world (called "experts") in order to construct a more informed, and more economical, solution. Our approach learns to adapt the amount of computation it performs to the difficulty of the task, as well as which experts to consult by factoring in both their reliability and individual computational resource costs. The metacontroller achieves a lower overall cost (task loss plus computational cost) than more traditional fixed policy approaches, demonstrating that our approach is a powerful framework for using rich forward models for efficient model-based reinforcement learning.

Understanding neural models of human language (Linzen). Large-scale artificial neural networks have shown great promise in natural language processing, reportedly reaching human-level performance in some tasks. Yet our understanding of the capabilities of these methods is typically limited to general statistics averaged across a random sample of texts. Such coarse-grained evaluation metrics stand in marked contrast to the rich array of highly specific patterns identified by linguists and cognitive scientists. I will argue that this detailed characterization of human-level knowledge of language provides a yardstick for the desired behavior of an artificial intelligence system. Applying it to neural networks can help us understand the strengths and weaknesses of existing architectures and analyze models that are otherwise difficult to interpret. Finally, neural networks that combine powerful statistical learning with different degrees of representational assumptions can serve as useful baselines for psychological modeling. I'll discuss case studies illustrating this approach in both syntax and semantics.

# Anthropological Contributions to Cognitive Science 

Organizers<br>Andrea Bender (Andrea.Bender@uib.no) \& Sieghard Beller (Sieghard.Beller@uib.no)<br>Department of Psychosocial Science, University of Bergen, Norway<br>Presenters<br>Rita Astuti (R.Astuti@lse.ac.uk)<br>Department of Anthropology, London School of Economics (LSE), London, UK<br>Olivier Le Guen (ompleguen @ gmail.com)<br>Centro de Investigaciones y Estudios Superiores en Antropología Social, CIESAS, Mexico Ciudad, Mexico<br>\title{ Karenleigh A. Overmann (koverman@uccs.edu)<br><br>Center for Cognitive Archaeology, University of Colorado, Colorado Springs, US }<br>Peter Rácz (peter.racz@bristol.ac.uk) \& Fiona Jordan (Fiona.Jordan@bristol.ac.uk)<br>Department of Archaeology and Anthropology, University of Bristol, UK<br>Mads Solberg (Mads.Solberg@uib.no)<br>Department of Social Anthropology, University of Bergen, Norway

Keywords: anthropology; cognitive science; philosophy of science; cognition; culture; language; materiality.

Anthropology was a founding member of cognitive science (Bender et al., 2010; Gardner, 1985), sharing with other cognitive disciplines a deep interest in thinking and behavior. With its unique expertise in the cultural content, context, and constitution of cognition, it would still be essential to any comprehensive endeavor to explore the human mind (Bloch, 2012), but rather has turned into cognitive science's "missing discipline" (Boden, 2006), thus leaving important questions unanswered or even unasked. Given that substantial shares of knowledge are implicit and that cognition is situated, distributed, embodied, and grounded in various other ways, anthropological approaches provide privileged access to investigation: for arriving at reasonable hypotheses, ensuring ecological validity, and even for coming up with new research questions and paradigms (Astuti \& Bloch, 2012; Hutchins, 2010; Nersessian, 2006).
In line with recent calls for rapprochement in Topics in Cognitive Science (Bender et al., 2012; Beller \& Bender, 2015), our symposium brings together scholars that represent different branches of contemporary anthropology with distinct perspectives-including 'traditional' social anthropology, cognitive anthropology and ethno-linguistics, cognitive ecology, evolutionary anthropology, and archaeologyto present what they consider to be indispensable contributions to cognitive science.

With our selection of authors, we hope to demonstrate the value of anthropological approaches for cognitive science as well as the potential benefits of cross-disciplinary collaboration. Cognitive archaeologist Overmann discusses a theoretical perspective on how mind, behavior, and material artifacts interact to shape human cognition. Combining their expertise in linguistics and evolutionary anthropology, Rácz and Jordan investigate the design principles of kinship sys-
tems as near-universal conceptual tools. With his background in (ethno-)linguistics and cognitive anthropology, Le Guen uses Yucatec Maya sign languages to illustrate the importance of cultural practices for shaping cognitive behavior. Based on Hutchins' cognitive ecology approach, Solberg speaks to questions at the intersection of anthropology and philosophy of science by illuminating the cultural framework of science production in a biology lab. And social anthropologist Astuti concludes by taking a bird's eye view on how efforts to understand the human mind crucially benefit from acknowledging its historical origins and from taking the specific sociocultural contexts into consideration.

Based on work some of which is published in high-quality journals (such as Science, Nature, PNAS, BBS, TiCS, Current Anthropology, or Cognition), these participants will offer invaluable contributions to a more diverse, more inclusive, and hence more comprehensive cognitive science.

## Archaeology and Cognitive Science

## Karenleigh A. Overmann

Archaeology contributes to cognitive science in two key areas. First, in understanding human cognitive evolution, archaeology furnishes critical data on the timing and context of developments (Wynn, 2002). This approach assumes minds make tools: increasing complexity in material forms is an effect of, and thus signals, cognitive change related to neurological developments like encephalization. Second, archaeology provides unique insight into the ways materiality functions within the extended, enacted mind. This inverted approach-tools make minds (Malafouris, 2013)examines how material forms interact with body and brain to create meaning and experience and potentialize behavioral and psychological change. In both contributions, archaeology negotiates temporalities, centuries to millennia and longer, that can be challenging for psychological theories and methods to assimilate (e.g., Overmann, 2016).

# Cognitive and Adaptive-Historical Explanations for Kinship Diversity 

Peter Rácz \& Fiona Jordan

Kinship systems are semantic systems whose forms can be explained in terms of domain-general cognitive principles; kinship categories are optimised to be maximally distinct and as simple as possible. Kinship, then, is similar to other universal semantic categories such as colour terms. However, whereas colour terms broadly fit into one typological hierarchy, kinship systems comprise a diverse typology. Alternatively, adaptive-historical explanations emphasise how cultural traditions and social practices (particularly marriage and transfer of resources) place functional pressures on the shape of kinship systems (Jordan \& Dunn, 2010). Using a global ethnographic database of over a thousand societies we show that marriage rules and ancestry have a significant influence on the type of kinship system found in a society. This remains true if we control for the effect of lateral transmission and phylogeny. This, in turn, means that kinship is best approached by combining cognitive and historic-anthropological explanations. These results have broader implications for the understanding of lexical systems in particular and the mechanisms of human cognition in general.

## How Cultural Settings Frame Spatial Cognition: The Example of Yucatec Maya and Yucatec Maya Sign Language

On the Yucatec peninsula, the main native language is spoken Yucatec Maya (YM). However, in villages where deaf people are born, a local sign language (YMSL) was created both by deaf and their hearing kin. Although both languages are in intense contact, they are genetically different, and YMSL is not a signed version of YM. In Le Guen (2011), I showed how gestures-in addition to linguistic structures (Levinson, 2003)-can support a geocentric frame of reference. In this paper, I want to elaborate on how deaf signers using YMSL still 'inherit' the same conception of space through cultural practices.

## Exploratory Experimentation in Experimental Systems: Novel Directions for the Cognitive Anthropology of Science

Mads Solberg

It is now widely recognised that progress in many scientific disciplines, like molecular biology, are not adequately described by the hypothetic-deductive model of epistemic action through experimental falsification. Instead, cumulative progress is achieved through description and modelling of mechanisms (interacting parts that produce regularities). One view claims that mechanistic discovery proceeds through exploratory experimentation; a practice where experimentation takes on many other cognitive functions than just hypothesis-testing. Experimental systems (material,
conceptual, social, and cultural infrastructures of laboratories) set up divisions of cognitive labour and distribute cognition through time and space in ways that are critical to this process. This talk looks at how the alliance between anthropology, cognitive science, and adjacent fields like philosophy and history of science, can contribute to further developing this research area. Such collaborations are necessary for adequately explaining cultural transmission and cultural evolution in scientific knowledge, and for describing interactions between mental representation, epistemic action, and material culture in scientific experimentation. I draw on examples from a long-term cognitive-ethnographic casestudy in a community of molecular life-scientists.

## Anthropology as a Critical Friend

Rita Astuti
Anthropology is commonly listed as one of the disciplines that make up cognitive science. But what exactly is the contribution that anthropology can make to the interdisciplinary study of human cognition? The paper will argue that anthropology must take on the role of critical friend, constantly reminding other disciplines of the historical origins of all human phenomena and of the theoretical and methodological challenges that come from recognising that all aspects of human cognition develop in specific social and cultural contexts.

# Static and dynamic visual narratives, by brain and by eye 

Neil Cohn (neilcohn@visuallanguagelab.com)<br>Tilburg center for Cognition and Communication (TiCC)<br>P.O. Box 90153, 5000 LE Tilburg, The Netherlands<br>Tom Foulsham (foulsham@essex.ac.uk)<br>Department of Psychology, University of Essex<br>Tim J. Smith (tj.smith@bbk.ac.uk)<br>Department of Psychological Sciences, Birkbeck, University of London.

Jeffrey M. Zacks (jzacks@wustl.edu)
Department of Psychology, Washington University in St. Louis

Keywords: visual narratives; film; comics; event segmentation; discourse; eye-tracking

## Introduction

Narrative has been studied for millennia, though recent attention in the cognitive sciences has turned towards visual narratives like those found in comics (Cohn, 2013a) and films (Zacks, 2014). Most agree that the basic principles guiding comprehension involve principles that extend across the verbal and visual domains (Cohn, 2013b; Gernsbacher, 1990; Magliano \& Zacks, 2011). However, visual units of narrative-both drawn and moving-demand different affordances to retrieve and integrate information.

Unlike verbal information, the sequential units of visual narratives use an analog spatial representation, from which a comprehender must extract the relevant information, ignore or suppress the irrelevant information, and work to connect such information across a sequence of units. This involves the integration of complex event information and its interaction with narrative structures.

Such a process is further varied in the difference between static, drawn visual narratives (as in comics) and dynamic, moving ones (as in films). The introduction of movement to a sequence provides important cues and an additional layer of constraints on the effective communication of visual sequential information.

This symposium highlights this growing field within the cognitive sciences. First, the presentations focus on visual narratives of both types: static, drawn narratives, and dynamic, moving ones. Second, they split their focus between eye-tracking and cognitive neuroscience. Together, these presentations will highlight the relevance of visual narratives for studying many facets of cognition, including attention, events, narrative, and discourse.

## Do you see what I see? The curious absence of endogenous effects on gaze during cinematic narratives

Our first talk by Tim J. Smith, along with John P. Hutson (Kansas State University), Joseph P. Magliano (Northern Illinois University), and Lester C. Loschky (Kansas State University), explores the dynamic nature of film narratives. Cinematic narratives are ubiquitous but unlike textual narratives or static images, how we process edited audiovisual sequences is barely understood. From reading and scene processing we know that exogenous (i.e. stimulus demands) and endogenous factors (i.e. higher-cognitive factors such as individual differences and comprehension) compete over our overt attention, biasing where we fixate and how we process the information. However, eye-tracking studies of film viewing have demonstrated a surprising similarity in where multiple viewers direct their gaze; a phenomenon we call attentional synchrony (Smith \& Mital, 2013). Task instruction, individual differences such as expertise and age, and even differences in how the edited scenes are comprehended often fail to show gaze differences. This fragility of endogenous influence is at odds with emerging theories of active vision (Henderson, 2017). In this talk we will review several studies from our labs investigating the causes of attentional synchrony and show how filmmakers have intuited techniques to guide viewer attention in complex dynamic scenes. These findings will be used to extend the Attentional Theory of Cinematic Continuity (Smith, 2012) to include an appreciation of the dynamic interplay between exogenous and endogenous factors during cinematic narratives and the apparent dissociation between gaze and comprehension.

## Eye-tracking sequential context in scenes, comics and movies

The scenes that confront us in our everyday lives are highly structured in time and space. However, most of what we know about how people look at such scenes is based on experiments with isolated images presented in a random
order. This talk by Tom Foulsham will describe results from scenes, comics and movies which show how even minimal sequential context changes the way that visual attention is deployed. In natural scene viewing, the way that people look at isolated photographs can be compared to how they view dynamic video or to the gaze behaviour shown when people walk through a real environment. In these cases the differences observed reveal how expectations govern our attention. Building up expectations is also a key part of how visual narratives function in comics and movies. We have begun to examine how eye movement patterns reflect information processing of comic strips (Foulsham, Wybrow, \& Cohn, 2016). As expected, participants' viewing patterns change when a coherent narrative is available. The eye-tracking data can also be used to generate new experimental manipulations (e.g., mimicking fixations by zooming into particular content). These manipulations reveal how attention to particular features or moments can affect comprehension of the narrative. This technique is being pursued in both comics and video sequences, providing new insights into top-down control of attention and the exploitation of this in visual media.

## Event Comprehension and Memory in Healthy Aging and Early Alzheimer's Disease

Research on film has also shared methods with the study of visual events. In this presentation, Jeffrey M. Zacks explores these relations along with Heather R. Bailey (Kansas State University, and Christopher A. Kurby (Grand Valley State University). Events unfold in time, and viewers track the temporal dynamics of activity as part of event understanding. Adaptively tracking event dynamics is important for guiding action online and for forming durable episodic memories. Event perception and event memory both can be affected by healthy aging and by neurological disorders. Here, we describe a line of research aimed at characterizing how the visual comprehension of events is impacted by healthy aging and by early Alzheimer's disease (AD). One characteristic of aging is that older adults segment ongoing activity into events less well than do younger adults. However, this general pattern is moderated by individual differences, and is amplified by AD. Impaired event segmentation is associated with reduced subsequent memory and impaired action performance. Superior event perception is associated with greater neural synchrony in the right posterior temporal sulcus and left dorsolateral prefrontal cortex. These results suggest that interventions to improve event segmentation or online event memory representations may help visual comprehension and memory in aging and AD .

## Towards a processing model of visual narratives

The past decade has seen a rapid growth of studies on visual narrative in the cognitive and brain sciences, in static form often focusing on the sequential images in comics. Neil Cohn will summarize and integrate a growing literature of both behavioral and neurocognitive research into a model of sequential image processing. Complex visual narratives
involve an interaction between two processing streams. An ongoing semantic understanding builds meaning into a growing mental model of a visual discourse. Discontinuity across dimensions of spatial, referential, and event information then incur costs when discontinuous with the growing context. In parallel to these processes, a structural system organizes semantic information into coherent sequences using a narrative grammar that maps semantic information to categorical roles, which are then embedded within a hierarchic constituent structure. This system allows for specific predictions of structural sequencing on the basis of constructional schemas, independent of semantics. Together, these interacting streams engage an iterative process of retrieval of semantic and narrative information, prediction of upcoming information based on those assessments, and subsequent updating based on discontinuity. These core mechanisms are argued to be domain-general, as suggested by similar electrophysiological brain responses generated in response to sequential images, music, and language.

# Game-XP: Action Games as Cognitive Science Paradigms 

Organizer E Moderator: Wayne D. Gray<br>(wayne.gray.cogsci@gmail.com)<br>Rensselaer Polytechnic Institute

Keynote: Ray Perez
(ray.perez@navy.mil)
Office of Naval Research

Martin V. Butz<br>(martin.butz@uni-tuebingen.de)<br>Universität Tübingen

Stuart Reeves<br>(stuart.reeves@ nottingham.ac.uk)<br>University of Nottingham

Matthew D. Sangster Tom Stafford<br>(sangsm@rpi.edu)<br>Rensselaer Polytechnic Institute<br>(t.stafford@sheffield.ac.uk)<br>University of Sheffield

Discussant: Fernand Gobet<br>(Fernand.Gobet@liverpool.ac.uk)<br>University of Liverpool

Why games? How could anyone consider action games as experimental paradigms for Cognitive Science? In 1973, as one of three strategies he proposed for advancing Cognitive Science, Allen Newell exhorted us to "accept a single complex task and do all of it." More specifically, he told us that rather than taking an "experimental psychology as usual approach" that, we should "focus on a series of experimental and theoretical studies around a single complex task" so as to demonstrate that our theories of human cognition were powerful enough to explain, "a genuine slab of human behavior" with the studies fitting into a detailed theoretical picture. Action games represent the type of experimental paradigms that Newell was advocating and the current state of programming expertise and laboratory equipment, along with the emergence of Big Data (Griffiths, 2015) and Naturally Occurring Data Sets (NODS, Goldstone \& Lupyan, 2016), provide the technologies and data needed to realize his vision. Action Games enable us to escape from our field's regrettable focus on novice performance to develop theories that account for the full range of expertise through a twin focus on expertise sampling (across individuals) and longitudinal studies (within individuals) of simple and complex tasks.

This Symposium is inspired by the recent Action Games as Experimental Paradigms for Cognitive Science (GameXP), issue of Topics in Cognitive Science (topiCS), April 2017. It includes late-breaking work from some of the researchers represented in that topic as well as new work by new researchers.

## Symposium Presentations - in Brief

- Ray Perez provides our keynote and focuses on the long history and current promise of action games as

[^2]a research tool for understanding theory and as a delivery vehicle for training.

- Martin Butz introduces a new, hybrid cognitive architecture which takes as its domain the world of SuperMario Brothers ${ }^{\mathrm{TM}}$.
- Stuart Reeves introduces our field to Ethnomethodology and Conversation Analysis (EMCA) research and to the questions this community asks of games.
- Matt Sangster uses 1.9 million records from 539 thousand matches of teams of 5 vs 5 people who play the world's most popular game, League of Legends, to study the distinction between individual and team expertise.
- Tom Stafford uses data from a cellphone game to investigate the efficacy of sleep consolidation versus wake-time distributed practice.
- Fernand Gobet provides calm and perspective by discussing this recent flurry of Game-XP from the 50+ yr perspective of cognitive science research on Chess.

## Ray Perez - Prequel to Game-XP: Time Spent, Player Age, Effects of Game Play, and Understanding Expertise

Within two months of its release, the video game Call of Duty: Black Ops (Activsion Publishing Inc., 2010) was played more than 600 million hours worldwide, with sales of over one billion dollars (Albnanesius, 2010). U.S children spent on average 1 hr and 13 min playing video games every day in 2010, a $300 \%$ increase from 1999 (Rideout, Foehr, \& Roberts, 2010). The average age of game players is 31, with $29 \%$ under 18 years old, $32 \%$ in the $18-35$ year range, and $39 \%$ being 36 year or older. Video game playing is pervasive in our society; there is growing body of evidence that video gaming can have beneficial effects on the organization and
function of the brain and learning. However, very little is known about the long term effects of playing video games or what is learned from these games or for that matter what expert game playing looks like and how it develops. This symposium explores the nature of extreme expertise in game playing with the focus that understanding expert game playing should inform theories of cognition.

## Martin V. Butz - Mario becomes Cognitive

The SEMLINCS cognitive architecture uses the world of SuperMario ${ }^{\mathrm{TM}}$ as its task environment and endows Mario, himself, with agency. Mario learns a conceptual, generative model of its environment in the form of probabilistic production rule-like structures from its own, autonomously gathered, continuous sensorimotor experiences. As a result, SEMLINCS enables Mario not only to plan and control environmental interactions in a versatile, goal-directed, selfmotivated manner - focusing, for example, on rescuing the Princess or on gathering coins - but also to verbalize this knowledge and to receive additional knowledge linguistically (Schrodt, Kneissler, Ehrenfeld, \& Butz, 2017).

## Stuart Reeves - The Ethnomethodogy of Games

Like Cognitive Science, Ethnomethodology and Conversation Analysis (EMCA) focuses on human activities that occur during game play. Yet EMCA sets cognitive explanations of human action to one side and instead describes how such action is practically, witnessably achieved. The presentation will demonstrate the utility of the EMCA approach and emphasize the contrast between the questions asked by CogSci and EMCA (Reeves, Greiffenhagen, \& Laurier, 2017).

## Matthew Sangster - Finding the " $I$ " in Team

Can we study the contribution of individual performance in a team setting? Can we find the " I " in team? Using Big Data ( 1.9 million records from 539 thousand matches) from League of Legends ${ }^{\text {TM }}$ Sangster says "yes" and presents steps towards establishing a measure that can evaluate individuals performing in a team context.

## Tom Stafford - Sleep Consolidation: A Field Study

Few researchers would expect that data collected from a cellphone action game could be used to address questions of sleep consolidation in skill learning. Realizing that their data set of $\mathrm{Axon}^{\mathrm{TM}}$ games included long breaks between some games, they pulled out instances in which successive games occurred across sleep or non-sleep hours, with the former (but not the latter) being candidates for sleep consolidation
effects. The approach and results demonstrate the promise of Big Data to raise questions that have little or nothing to do with the paradigm used to collect the data (Stafford \& Haasnoot, 2017).

## Fernand Gobet - Discussant

Newell (1973) argued that progress in psychology was slow because its empirical research focused on answering binary questions rather than building theories that were powerful enough to explain "a genuine slab of human behavior". As measured by the work presented in this symposium and in its associated issue of Topics in Cognitive Science (Gray, 2017), Gobet (2017) attempts to assess the age-old question of any young field; namely, "are we there yet?"

# Educating Spatial Thinking for STEM Success 

Mary Hegarty (mary.hegarty@psych.ucsb.edu)<br>Department of Psychological and Brain Sciences, University of California, Santa Barbara<br>David Uttal (duttal@northwestern.edu)<br>Department of Psychology, Northwestern University<br>Mike Stieff (mstieff@uic.edu)<br>Department of Chemistry and Learning Sciences Research Institute, University of Illinois, Chicago<br>Tom Lowrie (thomas.lowrie@canberra.edu.au)<br>Faculty of Education, Science, Technology and Mathematics, University of Canberra<br>Stella Vosniadou (stella.vosniadou@flinders.edu.au)<br>School of Education, Flinders University

Keywords: STEM education; spatial ability; visualization, representation, strategy, transfer.

## Overview

In recent years there has been new recognition of the importance of spatial thinking in Science, Technology, Engineering and Mathematics (STEM) disciplines, in part because of evidence that spatial ability predicts success and persistence in STEM (Wai, Lubinski \& Benbow, 2009), but is not fostered in our educational systems (National Research Council, 2006). Based on this evidence, current approaches aim to increase science achievement by training the types of general spatial skills measured by spatial ability tests. However, although there is considerable evidence that these spatial skills can be trained (Uttal, et al., 2013), there has been little evidence to date that training of general spatial skills transfers to success in STEM disciplines (Stieff \& Uttal, 2015).

In this symposium, we will take a critical approach to issues of how to educate spatial thinking, both by raising some theoretical questions about the nature of spatial thinking in STEM, and by considering a range of different approaches to enhance the development of spatial thinking at different educational levels (elementary, secondary, and college) and in different STEM disciplines. The participants will discuss a broad range of spatial challenges faced by students in STEM learning, including mastering discipline-specific spatial language, novel visuospatial representations, and the interplay between visualization and analytic reasoning strategies.

The four talks will be by researchers that differ in disciplinary expertise, methodologies, and theoretical frameworks. David Uttal, an expert in cognitive and developmental psychology will describe a program that develops $12^{\text {th }}$ grade students' spatial skills through the use of Geographic Information Systems (GIS). Mike Stieff, an expert in chemistry and learning sciences will describe how he has used theories of representational competence to design laboratory studies and classroom interventions that
improved spatial thinking in college-level chemistry by targeting students' understanding of domain-specific visuospatial representations. Tom Lowrie, an expert in mathematics education and assessment will describe an intervention conducted by elementary school teachers in the Australian school system, which improved students' spatial reasoning and transferred to mathematics achievement. Stella Vosniadou will describe laboratory studies that provide evidence for a shift from visual-spatial to analytic thinking with expertise in Geometry and Chemistry. She will interpret these results as an instance of conceptual change that raises questions about the relationship of spatial reasoning to STEM problem solving as learning progresses. Mary Hegarty will introduce the topic, moderate the symposium and lead a discussion on lessons learned about the nature of spatial thinking and how it can be best fostered in our educational systems.

## Training Spatial Problem-Solving (David Uttal)

Many studies have demonstrated that spatial skills strongly predict STEM achievement and attainment, and that spatial skills can be improved through training and experience (e.g., Uttal et al., 2013). However, most of these studies have focused only on psychometrically-assessed spatial skills, such as mental rotation. Although important, it seems likely that STEM skills will involve more than these core skills. For example, learning STEM will involve higher-order spatial skills, such as reasoning about patterns and distributions, and determining how best to represent and make decisions about spatial data. Therefore, we have created a program that emphasizes the usual of spatial data and extensive mapping challenges with Geographic Information Systems (GIS) to facilitate the development of higher-order spatial skills (Jant et al, 2013). $12^{\text {th }}$-grade students in several high schools completed the curriculum. They demonstrated improvement in spatial reasoning and more general scientific problem solving, indicating that higher-order spatial skills can be enhanced.

## Improving Spatial Thinking in STEM through Representational Competence (Mike Stieff)

Using the domain of chemistry as a context, I will explore the design of interventions that enhance spatial thinking by improving students' representational competence (i.e., skills related to interpreting, transforming, and creating visuospatial representations). Spatial thinking with visuospatial representations is central to learning and problem solving in all STEM fields. Students with low spatial ability have more difficulty interpreting visual representations in STEM courses, fueling deficit models of who can succeed in STEM fields and motivating educational interventions that aim to train general spatial ability independent of disciplinary content. Interventions developed in my laboratory include alternative strategy training (Stieff, et al. 2014), modeling activities (Stieff, et al., 2016a) and gesture (Stieff, et al., 2016). Each intervention has yielded significant improvements in representational competence and student achievement on spatially-demanding assessments. In three experiments, I will show that representational competence is highly responsive to instruction and demonstrate that students who might otherwise be excluded from STEM degree programs based on their spatial ability can attain successful learning outcomes with appropriate support.

## Developing Spatial Reasoning Programs for STEM learning: Empowering Classroom Teachers to Embed Intervention into Practice (Tom Lowrie)

Although there has been considerable research on how to improve spatial ability, few studies have considered the effect of spatial training on STEM learning (Stieff \& Uttal, 2015); despite evidence that improving spatial thinking can improve skills necessary to succeed in STEM disciplines (Uttal, et al., 2013). In fact, even very limited spatial training seems to improve student's mathematics skills (Cheng \& Mix, 2014). However, current spatial intervention programs are not likely to have much impact on school curricula, since the training is not embedded within daily classroom practices. Recently, a classroom-based spatial intervention study demonstrated improvements in students' spatial and mathematics performance (Lowrie, Logan \& Ramful, in press). The intervention was implemented by students' own classroom teachers. This presentation will focus on the need for spatial intervention programs to be framed around meaningful pedagogical frameworks, informed by cognitive science, aligned to school curricula, and implemented by classroom teachers.

## The Paradoxical Relation between Spatial Reasoning and Success in STEM (Stella Vosniadou)

I will present results from two studies which used a visual/analytic strategy task to investigate changing relations in the adoption of visual/spatial and analytic strategies in geometry and chemistry. The results showed that a) there is increasing reliance on the adoption of
analytic strategies with the development of domain expertise (see also Stieff et al., 2014), and b) that this reliance seems to depend on domain knowledge rather than on individual differences in spatial reasoning (Kospentaris et al., 2016; Vlcacholia et al., 2015). Given the convincing evidence that spatial reasoning abilities can predict success in STEM disciplines (Wai et al., 2009), the finding that problem solving in expert scientists increasingly relies on specialized, domain-specific analytic approaches raises important questions about the exact relationship between spatial reasoning and scientific problem solving.

# Symposium on Problem Solving and Goal-Directed Sequential Activity 

Pat Langley<br>Institute for the Study of Learning and Expertise<br>2164 Staunton Court, Palo Alto, CA 94306 USA<br>Richard P. Cooper<br>Department of Psychological Sciences, Birkbeck, University of London Malet Street, London, London WC1E 7HX UK

## Background and Motivation

Problem solving is one of the hallmarks of human cognition. The term covers a wide range of behaviors, including abilities for solving unfamiliar puzzles, designing new artifacts, generating extended plans, and pursuing complex routine activities. These each require people to carry out sequences of mental or physical steps to achieve their objectives. They can involve reasoning, subgoaling, recognizing alternatives, evaluating them, and guiding search through large spaces.

The study of problem solving played a crucial role in the early development of cognitive science as a field. Research on this topic revealed basic insights about the representations and processes that underlie high-level cognition. Empirical studies of human problem solving provided some of the first evidence for the computational nature of human thinking, and related computational models led to major theoretical advances concerning heuristic search, goal processing, expert performance, and production systems. There is little question that, without its early emphasis on problem solving, cognitive science would be a very different discipline.

In recent years work on this topic has been poorly represented at the annual Cognitive Science meeting. Some might draw the mistaken conclusion that research has stalled or that there remain no open issues. In fact, research has continued and has produced clear advances. Thus, problem solving or, more generally, goal-directed sequential activity is now typically understood within the context of the wider cognitive architecture, including how it uses domain-specific knowledge and heuristics in the service of goals. This symposium will draw together some of the recent work in this area, with the aims of highlighting progress and clarifying outstanding issues and contemporary research questions.

## Scope and Organization

The five talks in this symposium will report research that covers a wide range of issues within contemporary problem-solving research, from incubation processes on insight tasks to the use of heuristics by experts in goaldirected design. What the research has in common is a concern with activity over time that is goal directed but also situation aware.

Thomas Ormerod will examine the development and testing of computational models of insight, with a focus on capturing differences between problem-solving tasks with unitary or multiple architectures, the difficulty of modelling apparently non-monotonic processes, and whether insight is governed by special or general cognitive processes. A meta-analysis by Sio and Ormerod (2009) of incubation effects found differences on linguistic puzzles such as Remote Associates tasks and on visual puzzles like the nine-dot problem, and similar task-based differences occur with sleep and analogy. His presentation will examine the extent to which different architectures and mechanisms, such as activation of associative networks (Monaghan et al., 2013) or goal-directed search for problem representations (Ormerod et al., 2013), are needed for different puzzle types, and will report models developed for both types of problem.

Colleen Seifert will discuss creative problem solving in design, focusing on how designers intentionally introduce variation. Consideration of multiple candidate concepts early in the design process is linked to better solution outcomes, but creating divergent pathways within the sequential activity of problem solving requires additional processes oriented to this goal. As in many areas of expertise, use of analogies with past solutions or precedents can be usefully applied in creative problem solving. Her Design Heuristics approach (Yilmaz et al., 2016) distills knowledge of design precedents to serve as generative constraints to guide divergent thinking. The heuristics are captured from studies of successful design outcomes within a wide variety of problem settings, including award-winning products, a longitudinal case study of an industrial designer, and protocol studies of industrial and engineering designers. Compilation of 3450 design outcomes revealed 77 design heuristics that introduce intentional variation into the generation process. These 'cognitive shortcuts' guide processing towards more, and more varied, design solutions.

Dario Salvucci will examine people's ability to perform multiple tasks at the same time. Often, multitasking is viewed as involving two separate and distinct activities, and indeed such multitasking appears often in the everyday world (the literal and metaphorical "walking
and chewing gum"). However, multitasking often occurs in service of a single goal, with multiple 'threads' of processing performing different actions that eventually come together to complete a single purpose. Threaded cognition (Salvucci \& Taatgen, 2008, 2011) is a computational theory, embedded within the ACT-R cognitive architecture, that aims to explain the power and limitations of human multitasking. In his presentation, he will discuss the theory and implications of threaded cognition for problem solving and other goal-oriented sequential activities, especially in the context of concurrent multitasking and task interruptions.

Richard Cooper will consider problem solving in terms of a core distinction between routine and nonroutine behaviour. His architecture is based on Norman and Shallice's (1986) dual-systems theory of the control of thought and action. In this account, routine or overlearned behaviour, while goal oriented, is schema driven and controlled by an activation-based 'automatic' system. In contrast, nonroutine behaviour involves higherlevel cognitive processes that bias the routine system's activation in a deliberative, goal-directed fashion (Cooper et al., 2014). He will argue that human cognition requires: (a) explicit representation of subroutines, including their goals or effects, (b) hierarchically structured task knowledge, to support flexible and creative combination of subroutines in novel ways, and (c) control mechanisms that monitor progress towards goals, suppress prepotent response schemas, and recall relevant episodic memories to support analogical planning. He will contrast these features with those that underlie recent machine learning accounts of sequential activity.

Pat Langley will present a new architectural theory that addresses four issues typically neglected in accounts of problem solving. One is an embodied agents' need to represent and reason about both qualitative relations and quantitative attributes when describing states. A second is the relation between symbolic goals and numeric evaluation functions, which address different aspects of purpose-driven behavior. A third issue concerns the introduction of agents' top-level goals and their change over time. A final topic is the great variability observed in human problem solving, both across people and task settings. He will present a new cognitive architecture that incorporates ideas from earlier work but introduces new structures and processes that address these challenges (Langley et al., 2016).

In order to ensure coherence, presenters will each consider the problem-solving phenomena of interest, representational issues, and relevant architectural processes, such as retrieval, attention, and goal handling. Cooper and Langley will jointly moderate the session, summarizing the symposium aims, introducing each of the presenters, and ensuring the question-answer session remains timely and on topic.

## Concluding Remarks

Taken together, these presentations will offer a broad sample of current research on problem solving and sequential activity. Each speaker has contributed to this area for many years and is well known for his or her accomplishments. Their topics range from creativity and insight to routine behavior on complex tasks. Their research builds on empirical studies of cognition but also contributes to architectural accounts of the mind.

We believe that this diverse set of presentations will convince conferences attendees that problem solving remains a critical area of enquiry within Cognitive Science, with both continuing theoretical progress and outstanding challenges. We further hope that the symposium will motivate audience members to join the quest to understand this fundamental aspect of human cognition.

Keywords: computational methods, modeling, education, collaboration

## Introduction

This symposium presents four collaborative research projects conducted as part of LUCID, a unique crossdisciplinary graduate training program funded by the NSF's National Research Traineeship mechanism. LUCID trains scientists from computational and behavioral disciplines to advance basic and applied research in domains where machines are used to instruct, predict, understand, respond to or learn from human users. Such human-machine interactions have a remarkably broad range of applicationin public and private education across the lifespan, industry and information technology, public and private health management, social networking and communication, robotics and human-computer interaction, national security, public policy, and, of course, basic research into the nature of learning, cognition, and intelligent behavior.

The current talks all consider how machine learning, cognitive modeling, and data-science might be integrated to address core questions in human learning and education. How can computational learning models best be leveraged to speed knowledge acquisition and breadth of transfer in educational contexts? How can we efficiently measure perceptual and cognitive structures online or in the lab? How do such structures change with increasing knowledge or expertise? How can cognitive models developed to explain behavior in simple lab-based tasks be extended to aid learning in educational contexts? And, if human beings are rational learners as most models assume, how do false beliefs arise and why are they so widespread?

The speakers consider answers to these questions that arise at the intersection of computer science, engineering, psychology, and education sciences. Sen, Meng, Matthews, Alibali, and Zhu consider how state of the art search techniques in machine learning, combined with cognitive models of human learning, can yield prescriptions for the optimal "diet" of practice in any given learning task. Mason, Nowak, and Rau describe research using a novel adaptive-sampling tool to measure the perceptual similarities discerned by undergraduates amongst diagrams of molecules, with the aim of understanding which perceptual features support or undermine a good understanding of the underlying chemical structure. Binzak, Sievert, Murphy and Hubbard apply contemporary multidimensional scaling algorithms to show that single digit number concepts differ qualitatively in experts and
novices, and consider the implications for our developing understanding of numerical representation in the brain. Finally, Frigo and Rogers describe behavioral and simulation work suggesting a new hypothesis about how and why learning can go so wrong when information propagates in social networks.

Following these talks we will briefly lay out the challenges we have encountered in pursuing crossdisciplinary training of this kind with the goal of spurring a brief discussion session in which the audience can ask the program PIs and trainees about both the science and the training approach.

## Optimizing Human Learning with Machine Teaching

A long-standing but elusive goal in machine-aided education has been to exploit cognitive models of human learning to select teaching or practice experiences for students that will efficiently lead them toward the desired knowledge state. We show how contemporary optimization methods allow theorists to discover, for any implemented learning model and desired outcome, an optimal teaching set-that is, a model training set that most efficiently produces the desired outcome given the model. We then report experiments assessing whether thus approach can be used to speed human learning, taking arithmetic as an example domain. Prior work has shown that people employ different learning strategies depending upon the structure of their practice experiences. When practice is purely symbolic (e.g. flash-card learning) people acquire item-specific knowledge that does not generalize, whereas when practice highlights underlying quantitative relationships, people learn functions that transfer well to unpracticed problems. This suggests that the optimal teaching set-the practice experiences that most rapidly produce knowledge that transfers broadly-will differ qualitatively depending on whether practice is symbolic or quantitative. We describe a series of experiments testing these predictions with participants learning new arithmetic relations through a computer-mediated teaching system that controls how practice problems are sampled. The results highlight the potential for machine teaching and cognitive modeling to boost learning in important educational domains.

## Discovering perceived relations among molecular representations

To succeed in science courses, students must learn to rapidly and effortlessly translate among different visual
representations of key representational structures with a high degree of fluency. This is a difficult task because students must learn to interpret individual representations on their own while simultaneously learning the relations among different representations. To better understand these processes, we used a novel adaptive embedding algorithm to identify which molecular representations beginning undergraduate students find similar and why (e.g., Lewis structure, ball-and-stick). Each trial of the embedding task asks participants to decide which of two candidate diagrams is most similar to a third. The algorithm adaptively selects triplets for comparison in a manner that allows for efficient estimation of perceived dissimilarities amongst all diagrams. From these dissimilarities we generated models of how different molecules are embedded in a perceptual similarity space, in the eyes of the typical undergraduate student. The result revealed an otherwise inaccessible set of visual features that jointly predict the novice similarity judgments, allowing us to identify the features salient to novice students without relying on verbal mediation. The same tool can likewise be used to identify features that govern the perceptual decisions of chemistry experts, with the ultimate aim of developing interventions that guide novice perceptual attention toward the features discerned by experts.

## Beyond Magnitude: Psychological and Neural Representations of Number Properties

In classic work Roger Shepard and colleagues (1975) employed multidimensional scaling to show that, among the graduate students and colleagues who were his subjects, single-digit number concepts encode rich structure including primeness, parity, trinity, and exponentiation. This conclusion is hard to reconcile with much contemporary work suggesting that number concepts are grounded in an innate and widely-conserved approximate magnitude estimation system. In a series of studies, we used behavioral and brain imaging methods to investigate the psychological and neural mechanisms supporting adults' sensitivity to properties of number beyond magnitude, with the aim of reconciling this discrepancy. We first replicated Shepard's result in a cohort of students and colleagues, using a triadic judgment task to estimate conceptual similarities discerned amongst single-digit numbers. We then compared these representations among expert (math and CS grad students) and non-expert (Psychology undergraduates) groups, and found that rich structure was only observed in the experts. In a third study we examined whether explicit instruction can tune number concepts, with results revealing that magnitude information strongly dominates conceptual structure in non-experts but not experts. Finally, we have begun to assess what these behavioral differences suggest about the neural representation of number concepts. Participants viewed single-digit numbers while their brains were scanned in a slow event-related fMRI design. After a delay, they were instructed to think about a specific property of that number, and then were asked to judge whether that
number matched a target number on that specific property. Using multivariate pattern classification, we assessed whether magnitude, primeness, and parity could be decoded from the neural responses measured, both before and after the important property was cued on each trial. The comparison of behavioral and brain imaging results carries important implications for an understanding of numerical cognition beyond magnitude, and for the role of expertise in reorganizing conceptual representations of numbers.

## Why do false beliefs persist in crowds?

If human learning is rational as most cognitive models propose, what explains the emergence and widespread persistence of demonstrably false beliefs? We consider a new hypothesis that stems from an important difference between learning studies in the lab versus the real world. In the lab learners typically receive a single source of correct feedback, whereas in real life learners encounter many different sources of information that vary in their knowledge, motivation, and trustworthiness. How then do learners combine information from disagreeing sources? We examined how learners weight different sources when updating their beliefs, as a function of the degree to which the sources cohere with the learner's prior beliefs. The results reveal a previously undescribed learning bias that, counterintuitively, can lead groups of learners to disagree despite overwhelmingly similar learning experiences. To understand how this learning bias might lead to the emergence and persistence of false beliefs, we report simulation experiments in which many learners provide teaching labels to one another through a social network. Each simulated learner updates its beliefs in accordance with the empirically-observed learning bias, with the consequence that the cohort fractionates into mutually distrustful subgroups that adhere to different beliefs and ignore feedback from out-group members. The work thus provides a candidate mechanism for understanding how incorrect beliefs can arise and why they persist, even if individual learners behave in accordance with rational models in lab-based studies.

# Intuitive Biology and Global Challenges: Applying Theoretical Insights for Public Good 

Lauren Swiney (l.swiney@warwick.ac.uk)<br>School of Life Sciences, University of Warwick, Coventry, CV4 7AL UK<br>Deborah Kelemen (dkelemen@bu.edu)<br>Department of Psychological and Brain Sciences, Boston University, Boston, MA 02215 USA<br>Andrew Shtulman (shtulman@oxy.edu)<br>Department of Cognitive Science, Occidental College, Los Angeles, CA 90041 USA<br>John Coley (j.coley@northeastern.edu) \& Nicole Betz (betz.n@husky.neu.edu)<br>College of Science, Northeastern University, Boston, MA 02115 USA<br>Stefaan Blancke (st.blancke@gmail.com)<br>Department of Philosophy and Moral Sciences, Ghent University, Ghent, B-9000 Belgium

Keywords: intuitive biology; climate change; biotechnology; evolution; science literacy; applied cognitive science

## Motivation \& Overview

Questions about science literacy and the rejection of scientific consensus are once again in the spotlight, with freshly-ignited international debate over the facts of climate change, and continued controversy around the teaching of evolution. In recent years, cognitive scientists have made valuable contributions to these debates: a now substantial and diverse research field has implicated a range of cognitive, motivational and emotional factors that contribute to science acceptance, and researchers are increasingly concerned with the application of these insights to improve the quality of public debate and science-relevant policy.

In this symposium we focus on a specific strand of this research field - that related to the concepts and intuitions deployed in reasoning about the biological world. A defining feature of our symposium is the inclusion of nascent research programs exploring the role of biological reasoning in newly-emerging domains of public debate (e.g. synthetic biology), alongside more established research areas (e.g. climate change $\&$ evolutionary theory). Our core aims are two-fold: to advance key theoretical debates relating to reasoning in the biological domain via the presentation of new empirical data, and to highlight emerging best-practice in translating this basic research into applied tools in both formal learning and informal communication contexts. We are confident that this focus will be of interest not only to researchers in the broader areas of science literacy, reasoning and conceptual change, but also to those interested in the challenge of applying cognitive science research for the public good.

Within this theoretical and applied framework we bring together researchers from a variety of disciplinary backgrounds, including anthropology, philosophy, and psychology, to explore the themes of the symposium from the perspectives of human development, education, cognitive processing, moral reasoning, cultural variation, risk perception, and conceptual knowledge structure.

The symposium will consist of four talks and a panel discussion. Kelemen will present cross-cultural evidence for the developmental persistence of teleological biases, and describe the translation of these findings into earlyeducation tools. Shtulman will present data on the conceptual prerequisites for understanding evolution, and discuss implications for increasing support for evolutionrelevant policies. Coley \& Betz will present new work on intuitive reasoning about climate change. Swiney will present data on the interplay of intuitive biology and moral reasoning in shaping risk perceptions of synthetic biology and discuss related communication challenges. Blancke will lead the panel discussion, drawing on his own research bridging cognitive science and public understanding of biotechnology (Blancke et al. 2015). Together the participants have published several dozen papers in the area, including in PNAS, Psychological Science, Cognitive Science, Cognition, and Child Development.

## Kelemen: Purposefully Designing Materials for Teaching Children About Natural Selection

In a world where economies are increasingly fueled by biotechnological responses to rapidly adapting disease pathogens, pesticide-resistant insects, and climate change, understanding evolutionary processes is prerequisite for informed decision-making about bioethical issues. Despite this, the fundamental evolutionary mechanism of natural selection is one of the most misunderstood concepts in science. The roots of these misconceptions can be traced to intuitive cognitive biases emergent in early childhood. In this talk, I will overview evidence from Eastern (e.g. China) and Western (e.g. U.S.) cultures that suggests the universality and developmental persistence of biases to construe nature in terms of purpose and intentional design (e.g. Rottman et al., 2017; Schachner et al., 2017). I will describe the application of these child developmental and adult dual-processing findings to the design of explanationrich storybooks for teaching elementary school children about adaptation by natural selection. Findings reveal that after analogical discussion of two storybooks, young children accurately and enduringly generalize the theory of
natural selection. Implications for theories of conceptual change and early science education will be discussed.

Deb Kelemen is Professor of Psychological and Brain Sciences and Director of the Child Cognition Lab at Boston University.

## Shtulman: Why People Fail to Understand Evolution and Why it Matters

Evolutionary theory underlies several issues of global importance-biodiversity, conservation, antibiotics, chemotherapy, cybersecurity-but studies have shown that the general public misunderstands what evolution is and how evolution works (Shtulman \& Schulz, 2008; Shtulman \& Calabi, 2013). In this talk, I will explore three conceptual prerequisites for understanding evolution: geologic time, intraspecies variation, and intraspecies competition. All three concepts have been implicated in the discovery of natural selection in the history of science, and I will show that all three concepts explain a significant amount of variance in who understands evolution and who does not. Nevertheless, one concept in particular-intraspecies competition-explains nearly three times as much variance as that explained by the other two concepts combined. I will discuss the implications of these data for improving evolution education, as well as increasing public acceptance of evolution and public support for evolution-relevant policies.

Andrew Shtulman is Associate Professor of Psychology and Chair of the Department of Cognitive Science at Occidental College.

## Coley \& Betz: Intuitive Thinking Impacts Understanding of Global Climate Change

Although most US citizens believe that climate change is a serious issue, fewer engage in mitigative behaviors. One psychological barrier is lack of understanding of causes and effects (Bord, O’Connor \& Fisher, 2000). We examined the extent to which intuitive "cognitive construals" (essentialist, teleological, and anthropocentric thinking, Coley \& Tanner 2015) influence understanding of climate change. University students rated agreement with facts and misconceptions (consistent with cognitive construals) about climate change. We found that teleological thinking about the climate was negatively related to understanding the causes of climate change while anthropocentric thinking was positively related. Further, we found that essentialist and teleological thinking were negatively related to understanding the effects of climate change, while anthropocentric thinking was positively related. We discuss these findings in the context of broader debates about biological reasoning, and consider options for leveraging or mitigating intuitive beliefs to increase sustainable behavior.

Nicole Betz is a doctoral candidate and John Coley is Associate Professor and Director of the Conceptual Organization, Reasoning and Education Lab at Northeastern University.

## Swiney: Essentialism, Moral Reasoning, and Evaluations of Synthetic Biology

The field of Synthetic Biology (SB) is already realising its promise to re-engineer living things from the bottom-up, creating new life forms, drastically changing existing organisms, and heralding a level of human intervention in biology that challenges entrenched distinctions between the evolved and the designed. The cognitive sciences have much to offer the now-urgent public debates about the risks and benefits of such technologies, but cognitive research in this area remains in its infancy (Blancke et al., 2015). I introduce a research program drawing on theories from distinct areas of the cognitive sciences, including intuitive biology, risk perception, and moral psychology, highlighting the rich test-ground that SB provides for investigating the interplay of cognitive processes across these domains. I present data from a series of experiments in which participants evaluate specific SB technologies varying across dimensions such as the source of genetic material and the extent of genetic change. I show that both psychological essentialism and moral purity concerns shape moral judgments and risk assessments of SB, and I explore the unique challenges of applying these insights to public debate about biotechnology.

Lauren Swiney is a cognitive anthropologist and Research Career Development Fellow in the Warwick Integrative Synthetic Biology center.

## Introduction

The ways in which we experience and reason about time are fundamental aspects of human cognition. In the industrialized world, keeping track of time is vital to successful functioning in society. Ideas about the nature of time underlie many aspects of adult life: how we communicate with others, how we schedule our days, how we plan for the future, how we interpret and react to autobiographical events, and how we reason about cause and effect. Both philosophers and cognitive scientists have struggled to explain the nature and origins of this rich, multifaceted, and highly abstract concept of time. One means of exploring the nature of time in the adult mind is by asking how the ability to mentally represent and reason about time develops in children. Although some aspects of temporal cognition, like low-level duration perception, are present at birth, others, like using a clock, take children up to a decade to learn. By tracking how different time-related cognitive phenomena emerge and change across development, we may gain a fuller picture of how the many facets of time interrelate, including the biological and cultural factors that underlie them. To this end, this symposium brings together researchers from around the world to discuss five different aspects of children's temporal cognition, each of which change dramatically during the preschool years.

Each case study presented in the symposium investigates time in the context of a different cognitive system, including motor planning, spatial cognition, language, emotion, event representation, and prospective reasoning. First, Monier will discuss children's developing capacity to synchronize their movements to external temporal rhythm. Next, Tillman will examine the development of culture-specific spatial representations of time, such as the left-to-right "mental timeline." Zhang will explore how children learn time-related language, including the words "yesterday" and "tomorrow." Redshaw will investigate how children become able to hold two alternative possible futures in mind. Finally, McCormack will discuss her work on the development of emotional and value judgments about past
and future events. A leader in the field of temporal cognitive development, McCormack will also serve as symposium moderator.

## The role of motor and cognitive capacities in developmental differences in rhythmic <br> synchronization <br> Florie Monier \& Sylvie Droit-Volet

Rhythmic synchronization is the ability to synchronize a movement to an external rhythm. Prior studies have shown that, relative to older children and adults, younger children have a faster and more variable spontaneous motor tempo, and they have more difficulty slowing down their motor tempo to synchronize it with a slow external tempo. Rhythmic synchronization involves both motor and cognitive capacities. Here, we ask which of these factors drives developmental change. In a series of studies, 3- to 8-year-old children were given a spontaneous motor tempo (finger tapping) task, a synchronization task involving differing inter-stimulus-intervals (ISI), and a continuation task, in which they were asked to maintain the tempo initiated in synchronization. Neuropsychological tests were used to assess their motor and cognitive capacities. Our results showed that the variability of children's inter-tapintervals (ITI) decreased with increasing age, and that 8 -year-olds were better able to slow down their motor tempo with an external tempo than 3- or 5-year-olds. Both motor and cognitive abilities predicted individual differences in the length of ITI on the synchronization and continuation tasks. However, only cognitive capacities (i.e., short-term memory, attention-concentration) accounted for children's variability on the continuation task. These results reveal that improvement in synchronization capacities is related to the development of both motor and cognitive capacities, but that the continuation task is more cognitively demanding.

## The development of the mental timeline Katharine Tillman, Nestor Tulagan, Eren Fukuda, \& David Barner

When reasoning about time, English-speaking adults often invoke a "mental timeline" stretching from left to right. Although the direction of the timeline varies across cultures, linear representations of time have been argued to be
ubiquitous and primitive. On this hypothesis, we might predict that children also spontaneously invoke a spatial timeline when reasoning about time. However, little is known about how and when the mental timeline develops, or to what extent it is variable and malleable in childhood. We used a sticker placement task to test whether preschoolers spontaneously produce linear representations of temporal events (breakfast, lunch, and dinner) and deictic time words (yesterday, today, tomorrow), and to what degree those representations are adult-like. At age 4, children were able to make linear mappings between time and space with minimal spatial priming. However, unlike older children and adults, most preschoolers did not adopt linear representations spontaneously. Lines produced by children were also more variable in orientation and children could be easily primed to adopt an unconventional vertical timeline. Our findings suggest that preschoolers can readily form linear mappings between time and space to represent temporal sequences and past/future relationships when prompted to do so, but most do not yet do so automatically. These representations are initially flexible, and become increasingly automatic and conventionalized in the early school years.

## Children's understanding of 'tomorrow' and 'yesterday' <br> Meng Zhang and Judith Hudson

Children's use of temporal language is often taken as an indication of their understanding of time. This study used a picture-sentence matching paradigm to test children's understanding of the temporal adverbs yesterday and tomorrow. Children viewed two pictures of an object, e.g., a carved pumpkin and an intact pumpkin, while listening to a sentence, e.g., "I carved the pumpkin yesterday" or "I'm gonna carve the pumpkin tomorrow". They were asked to select one picture to match the sentence. Experiment 1 showed that 3-, 4-, and 5-year-olds all performed better when sentences were in the past tense than in the future tense. In Experiments 2 and 3, the sentences contained conflicting cues from tense and temporal adverbs, e.g., "I carved the pumpkin tomorrow". While adults selected pictures based on the temporal adverbs they heard, 4- and 5-year-olds tended to select pictures showing the outcome of actions, regardless of both tense and temporal adverb. In Experiment 4, children completed two additional tasks involving temporal reasoning. The Before \& After Task served as a baseline measure of temporal sequencing and the Yesterday \& Tomorrow Task tested children's understanding of yesterday in backward reasoning and tomorrow in forward reasoning. Results indicated that forward temporal reasoning is easier for children than backward temporal reasoning, and linguistically, they understand the term yesterday better than tomorrow.

## Young children's capacity to envision and prepare for mutually exclusive future possibilities Jonathan Redshaw, Talia Leamy, Phoebe Pincus, Jessica Crimston, \& Thomas Suddendorf

Because future events can be difficult to predict, adults often envision and prepare for multiple, even mutually exclusive alternatives. To investigate the emergence of this capacity in children, we developed a minimalist paradigm in which participants were given the opportunity to catch a ball dropped into a forked tube with two possible exits. The initial study showed that 2- and 3-year-olds often covered only one exit when preparing to catch the ball, whereas most 4 -year-olds spontaneously covered both exits from the first trial onwards. A follow-up study revealed a similar developmental pattern when the mechanism controlling the uncertain outcome was visible, rather than hidden within the tube. Additional follow-up studies, however, showed that 2- and 3-year-olds were much more likely to cover two exits when two balls were certain to drop from separate locations. These findings suggest that young children are not generally limited in reasoning about multiple future events, but rather they are specifically limited in reasoning about mutually exclusive possibilities. One potential explanation is that older children, unlike younger children, possess a metarepresentational understanding that their representations of future events can be incorrect, and so they take the opportunity to prepare for alternative versions.

## Temporal asymmetries in children's past and future thinking

Teresa McCormack, Agnieszka Jaroslawska, Patrick Burns, Aine Fitzpatrick, Jemma McGourty, \& Eugene Caruso
There are striking asymmetries in the way adults think about the past versus the future: adults typically (i) report stronger emotion when thinking about the future than the past (ii) place greater value on a future event than a past event and (iii) judge that a future event feels closer than a past event at an equivalent distance. These future biases suggest that adults are more oriented toward the future than the past. In this talk, I will describe the first developmental studies to examine whether these biases exist in children. We have found that the tendency to judge future events as feeling closer in time than equivalent past events is very robust, and can be demonstrated in children as young as 4-5 years. Children from around 6-7 years, like adolescents and adults, also report stronger emotions when thinking about the future versus the past. We also found that children from 9-10 years place greater value on future than past events. We will discuss what these findings suggest about children's thinking about the past and future, and their implications for theoretical accounts of temporal asymmetries.

# Big Data and Little Learners 

John C. Trueswell (trueswel@psych.upenn.edu)<br>(Symposium Organizer) Department of Psychology University of Pennsylvania, USA

Joshua B. Tenenbaum (jbt@mit.edu)<br>Department of Brain and Cognitive Sciences<br>Massachusetts Institute of Technology, USA

Charles Yang (charles.yang @ling.upenn.edu)<br>Department of Linguistics and Computer Science<br>University of Pennsylvania, USA

Keywords: data science; deep learning; poverty of the stimulus; indirect negative evidence; language development

## Introduction

Recent advances in the data sciences, particularly within the area of language technology, have been impressive and nonincremental. For example, within the domain of language translation, the application of deep Long Short Term Memory (LSTM) neural networks to large bodies of text have resulted in a $60 \%$ reduction in translation errors from traditional methods, significantly closing the gap between machine and human performance (Wu et al., 2016). Similarly impressive advances have been observed in, e.g., speech recognition (Hinton et al., 2012), syntactic parsing (Dyer et al., 2015) and automatic content extraction (Berant et al., 2015).

Clearly, excitement is justified as a new era of linguistic technology is emerging. But should this excitement lead to a fundamental rethinking of our theories of child language and cognition? Doesn't the "poverty of the stimulus" still pose a problem for human language learners? What role do hierarchical linguistic formalisms play within statistical theories of language learning and use? This symposium brings together leading figures in cognitive science who offer different informed perspectives on these matters.

## The data and the learner from a developmental perspective

## Linda Smith (Indiana University)

The world offers data to learning systems that is massive in total scale and that comes in many forms. However, the relevant data for any learning system are only those that actually engage the learning mechanisms of that system. For living and breathing learners, this engagement begins with their sensory systems. Sensory systems are on bodies that move through the world - constrained by the physics of space and time - and thus the sampled data are constrained and ordered by space in time. Human infants learn their first words during a period in which their bodies (and brains) change dramatically and systematically and do so in ways that put those sensory systems in different parts of the data space at different points in development. The data for learning - and the learning tasks to be solved - are systematically ordered by development itself. This talk will present evidence from a large corpus of head-camera data recorded in infants' homes (over 500 million frames
extracted at 1 Hz ) that illustrate how human development (and the reality of bodies learning in space and time) fundamentally changes the questions to be asked and the computational answers to how language is learned.

## Existence proofs and computational mechanisms

## Charles Yang (University of Pennsylvania)

Mathematicians have always drawn a useful distinction between existence and constructive results. An analogy can be made in the study of language acquisition, especially in the age of Big Data and Big Machines. While distributional regularities can be captured by idealized statistical models, it is a different matter whether, and how, such regularities are exploited by computational mechanisms available to human children.

Consider the use of indirect negative evidence in language acquisition. A specific example concerns the predicative and attributive use of the so-called a-adjectives in English: "the cat is asleep/away" vs. "*the asleep/away cat". Indirect negative evidence can be formulated in certain probabilistic models of inference: the conspicuous absence of forms such as "the asleep cat" reduces the learner's confidence in the hypothesis that permits such expressions. While these models are presented as existence proofs without commitments to psychological mechanisms, they are still unlikely to succeed when evaluated against realistic statistical distribution of adjectives in a large corpus of child-directed English speech.

The alternative approach is to avoid the use of indirect negative evidence, and to develop a transparently mechanistic models that can be readily tested. I review the Tolerance Principle, a parameter-free model of inductive generalization, and its application to morphological and syntactic acquisition, including artificial language learning (joint work with Kathryn Schuler and Elissa Newport). Furthermore, the Tolerance Principle suggests that language acquisition may succeed only with small data, the kind similar to the small vocabularies of young children. This supports the view that cognitive and maturational constraints support rather than hinder language development.

## On what you can't learn from (merely) all the data in the world, and what else is needed

## Josh Tenenbaum (University of Edinburgh)

Recent successes with recurrent neural networks and other big-data techniques in AI applications raise the question of whether similar approaches might explain human language acquisition. How far can the data of language take us alone, with little other structure? I will first describe some experiments testing RNN models developed by Google that can perform some truly impressive feats in language technology, yet at the same time fail a number of basic tests of understanding syntax and semantics that cognitive scientists have long been interested in, as well as some new benchmarks that we have come up with. They often fail for interesting reasons, based on the differences between their linear (sequential) processing architecture and the hierarchical structure of thought, their emphasis on characterlevel modeling as opposed to words and phrases, and their lack of interfaces to core cognition outside language. Their successes and failures illustrate how both advocates and critics of early statistical language learning were correct Chomsky and Gleitman and Pinker were right after all, but Elman and Hinton were also right. They were just right about different things, and we can learn much by re-interpreting early debates.

As a way forward, I argue for combining smart statistics with more structured, hierarchical representations, interfacing to a cognitively grounded semantics. I report some promising results, although we are far from being able to implement this at the scale Google requires. I will also sketch ideas for how RNNs can make these more structured approaches work better, with the hope of integrating these often-opposing traditions to best make progress.

#### Abstract

Recent studies of naturalistic face-to-face communication have demonstrated temporal coordination patterns such as the synchronization of verbal and non-verbal behavior, which provides evidence for the proposal that verbal and non-verbal communicative control derives from one system. In this study, we argue that the observed relationship between verbal and non-verbal behaviors depends on the level of analysis. In a re-analysis of a corpus of naturalistic multimodal communication (Louwerse et al., 2012), we focus on measuring the temporal patterns of specific communicative behaviors in terms of their burstiness. We examined burstiness estimates across different roles of the speaker and different communicative channels. We observed more burstiness for verbal versus non-verbal channels, and for more versus less informative language sub-channels. These findings demonstrate a new method for analyzing temporal patterns in communicative behaviors, and they suggest a more complex relationship between verbal and non-verbal channels than suggested by prior studies.

Keywords: burstiness, multimodal communication, verbal and non-verbal communication

## Introduction

In cognitive science, a considerable number of studies have investigated the role of non-verbal communication in relation to verbal communication. The majority of these studies suggest an intrinsic relationship between verbal and non-verbal communication. For instance, a strong link has been shown between lexical access and gesturing, such that when people gesture, lexical access is facilitated (Rime \& Schiaratura, 1991). Also, the time gap between gesture and a familiar word is considerably shorter than the gap between gesture and an unfamiliar word (Morrel-Samuels \& Krauss, 1992), and when speech is disrupted, gestures are halted (Mayberry \& Jaques, 2000). Gesture is thought to be intrinsically related to language processing (Butterworth \& Morrissette, 1996) because most gestures occur when
people speak (McNeill, 1992), and because of evidence linking gesture with language development (Butcher \& Goldin-Meadow, 2000). In fact, non-verbal and verbal communication are sometimes argued to be so interwoven that gesture and speech are co-expressive manifestations of one integrated system, forming complementary components of one underlying process that helps organize thought (Goldin-Meadow, 2005; McNeill, 1992).

Louwerse, Dale, Bard, and Jeuniaux (2012) investigated the temporal relationship between matching behaviors in dialog partners, such as manual gesture in one speaker vs. the same manual gesture in the other speaker. By applying a cross-recurrence analysis, Louwerse et al. showed synchronized matching behavior in all categories (language, facial, gestural) that were investigated at temporal lags short enough to suggest imitation of one speaker by the other. Louwerse et al. concluded that the similarities between the different channels - verbal and non-verbal - demonstrated that the temporal structure of matching behaviors provided low-level and low-cost resources for human interaction.

So far, all studies focusing on the similarities between verbal and non-verbal communication, including Louwerse et al. (2012), focused on the temporal matching of verbal and non-verbal behavior. They tend not to investigate the temporal distribution of independent behavioral event dynamics. Complex behaviors such as human interaction tend not to show the strictest forms of synchrony, but instead are more loosely, functionally coupled (e.g., Fusaroli et al., 2014). Instead, the overall pattern of behavior, expressed in the distribution of events, may reflect particular local patterns of interaction - when one interlocutor gestures, it may sustain itself for a given period of time before waning; when another person speaks, this burst of behavior may look quite different, sustaining itself for longer, more regular periods of time. These event dynamics might paint a different picture of the relationship between verbal and non-verbal channels.

## The Property of Burstiness

Most work studying human communication is based on dyadic analyses that focus on temporal patterns across partners rather than the temporal patterns of specific behaviors produced by each partner. In the current study, the large multimodal corpus of human communication collected and reported in Louwerse et al. was re-analyzed to focus on the quantification of a particular property of behavior, burstiness.

Using the framework developed by Goh and Barabasi (2008) and extended by others (e.g., Jo, Karsai, Kertész, \& Kaski, 2012), we estimated the burstiness of verbal and nonverbal behaviors. The burstiness parameter, $B$, provides an estimate of a system's activity patterns spanning from periodic $(B=-1)$, to random ( $B=0$ ), to theoretically maximal burstiness $(B=1)$ (see Figure 1). Goh and Barabasi (2008) observed that human phenomena like human texts and email patterns have positive burstiness estimates, $B>0$, whereas human cardiac rhythms were found to have periodic burstiness estimates, $B<0$.

Figure 1: Overview of system's activity patterns spanning from periodic, to random, to theoretically optimally bursty.

## The Current Study

The goal of the current study was to investigate the temporal dynamics of behavioral events across verbal and non-verbal communicative modalities during face-to-face human interaction. We focus on the measure of burstiness, now widely used in statistical physics to capture the temporal patterns of point processes in complex network interactions.

In the first analysis section, we investigated whether or not there were differences in the burstiness of behaviors that are categorized into verbal and non-verbal channels. It is possible that verbal and non-verbal channels have similar degrees of burstiness, which would be consistent with previous work suggesting a strong intrinsic relationship. However, if the channels exhibit different degrees of burstiness, such results would suggest a more complex relationship between verbal and non-verbal communication. To further explore and understand the burstiness measure,
we also investigated the burstiness of sub-channels that constitute the language communicative channel. Our results indicate that burstiness is different for verbal versus nonverbal behaviors, and also for different aspects of language behaviors.

## Methods

## Multimodal Communication Corpus

The original task developed to collect these multimodal data is described by Louwerse et al. (2008) and Louwerse et al. (2012), who were interested in collecting multimodal structure of human interaction in order to inform avatar design for intelligent tutoring systems and other technologies. In the task, $N=24$ pairs of participants helped each other navigate a map. Each pair of participants completed 8 rounds of navigation. For each round, one participant was chosen as the "Information Giver", and other the "Information Follower." The Information Giver had a complete map, and the Information Follower had a noisy and partial map. This mismatch between maps was intended to elicit communication and predict the points at which misunderstandings were likely to occur. The participants had to use language and gesture via webcam so that the Information Follower could reconstruct a map route with the help of the Information Giver. The corpus was developed by taking these 192 recordings of interactions and coding a wide variety of behaviors. These codings were based on well-known or adapted coding schemes in discourse, along with some other semi-automated procedures (see Louwerse et al., 2008 for details). All behaviors were coded in 250 ms to encompass relatively fast behaviors such as nodding, acknowledgements, and smiling. The output from this coding procedure was a multicolumnar data format of binary point series that represented the occurrence of different behaviors at a 250 ms interval. These 250 ms intervals were the subject of our burstiness analyses.

We chose 39 behaviors that fit into four specific behaviors channels (as did Louwerse et al., 2012). Behavioral channels were categorized into two factors, Channel and Role. For the Channel factor, channels were identified as either "Face \& Head," "Manual Gesture," "Face Touch," or "Language." For the Role factor, channels were identified as either Giver or Follower. For the levels of the Role factor, all channels were included for the Giver and the Follower. See Table 1 for the behaviors that were included into each channel. The language sub-channels were annotated at the utterance-level.

Table 1: List of Channels, Sub-channels, and Behaviors

## Construction of Multivariate Spike Trains and Inter-event Intervals

We are interested in estimating the burstiness of multimodal communicative behavior and are therefore working with a multivariate class of spike trains. To our knowledge, the current study provides the first steps towards dealing with burstiness in multivariate spike train corpora. The protocol converts multivariate spike trains into inter-event interval (IEI) distributions. These interval distributions help quantify the temporal clustering of communicative events across channels.

First, for each behavior, we created a spike train of onset events which excludes successive ' 1 's for prolonged events. Second, for each communicative channel (Face \& Head, Manual Gesture, Face Touch, Language), we summed the spike trains from each behavior, yielding a multimodal event series where a ' 0 ' represents a sample when no event occurred, a ' 1 ' represents a sample when one event occurred, and any number greater than 1 represents a sample when two or more events occurred. For example, a sample with a "Laughing" event and a "Nodding" event would have a " 2 " in the event series. Any sample with two or more events is considered a sample of simultaneous communicative behavior which we discuss below. Finally, IEI's were computed from the multimodal event series to construct an IEI distribution for each channel for each map task role (Giver or Follower).

An IEI is computed by considering two consecutive events, $t_{j}$ and $t_{j+1}$, and finding the temporal difference
between them, $\tau=t_{j+1}-t_{j}$. For an IEI that contains simultaneous communicative behavior (2 or more events in the same sample), an IEI, $\tau$, was computed and added to the distribution in addition to a zero for each additional event. For example, when an IEI with the second sample has 3 events, we would add to the IEI distribution (1) the corresponding $\tau$ and (2) two zeros $(0,0)$. We chose to add this component to the protocol because we wanted to treat simultaneous communicative behavior as quantitatively 'more bursty'. Adding zeros to an IEI distribution will amplify a burstiness estimate. IEI distributions for each communicative channel and each map task role were submitted to estimates of burstiness.

## Estimation of Burstiness

The burstiness parameter, $B$, is defined as,

$$
B=\frac{\sigma_{\tau}-m_{\tau}}{\sigma_{\tau}+m_{\tau}}
$$

where $\sigma_{\tau}$ is the standard deviation of the IEI distribution and $m_{\tau}$ is the mean of the IEI distribution (Goh \& Barabási, 2008; Jo, Karsai, Kertész, \& Kaski, 2012). Alternative measures of burstiness have been employed in previous studies in computational linguistics (Altmann, Pierrehumbert, \& Motter, 2009; Pierrehumbert, 2012) utilizing parameter fitting from a stretched exponential distribution (Weibull distribution). These alternative measures have provided unique insights into the dynamics of linguistic levels of description. Our decision to utilize the burstiness parameter, $B$, is twofold. First, parameter estimation from a distribution requires a minimum number of data points or IEIs. Therefore, with the properties of our corpus, parameter estimation from distribution fitting requires the implementation of confidence intervals, which can be avoided with the utilization of the burstiness parameter, $B$. Second, one goal of this study is to account for simultaneous communicative behavior as a higher degree of burstiness. The burstiness parameter, $B$, is amplified when zeros are added to the IEI distribution and therefore an ideal option for the current study. $B$ is bounded from $[-1,1]$, where $B=1$ for a theoretical maximum bursty behavior, $B=-1$ for completely regular behavior (e.g., metronome), and $B=0$ for a homogeneous Poisson process, i.e., independent events. We omitted trials that did not include reliable burstiness estimates for any of the four channels across the MapTask roles in the first analysis section ( $1.24 \%$ of trials) and for any of the three channels across the MapTask roles in the second analysis section ( $1.00 \%$ of trials).

Figure 2a and 2b: Burstiness across channels with a) Information Giver (G) and Follower (F) combined, and b) the roles separated. Error bars reflect 95\% CIs.

## Investigating Differences in Burstiness across Verbal and Non-verbal Channels

Mixed effects models (Bates et al., 2014; Team R., 2013) were utilized to determine if burstiness differed across different channels. The first set of analyses was conducted to compare burstiness estimates across role structure and communicative channels. Linear models were utilized to predict burstiness estimates. Fixed effects for these models included map task role (leader or follower), communicative channels (Face \& Head, Manual Gesture, Face Touch, and Language), and event count for each communicative channel. Event count was added into the model as a covariate to control for the potential relationship between burstiness estimates and the number of behavioral events going into the analysis. Dyad and map type were included as random effects.

If there are differences across communicative channels, we can observe such differences in a variety of ways: are there differences in the temporal structure across communicative modalities (1) collapsing burstiness estimates across MapTask roles? (2) within MapTask roles (e.g., Follower:Manual Gesture vs. Follower:Language)? and/or (3) across MapTask roles (e.g., Follower:Manual Gesture vs. Giver: Manual Gesture)?

Collapsing burstiness estimates across MapTask role, we observed a significant main effect of communicative channel, $F(3,1030)=162.55, p<.0001$ (Figure 2a). See Table 2 for results from multiple comparison tests. Overall, the language channel ( $M=.16, S E=.003$ ) was observed to be more bursty relative to the manual gesture channel ( $M=.14$, $S E=.01), b=.08, p=.009$.

Table 2: Multiple Comparisons from the random mixed effects model: ${ }^{*} p<.05,{ }^{* *} p<.01,{ }^{* * *} p<.001$.

|  | Multiple Comparisons | Beta | Z-score |
| :---: | :---: | :---: | :---: |
| Channel | Man. Gest. v. Face/Head | .08 | $7.9^{* * *}$ |
|  | Touch Face v. Face/Head | .11 | $9.6^{* * *}$ |
|  | Language v. Face/Head | .17 | $16.7^{* * *}$ |
|  | Touch Face v. Man. Gest. | .02 | $2.2^{* *}$ |
|  | Language v. Man. Gest. | .08 | $7.5^{* * *}$ |
|  | Language v. Touch Face | .05 | $4.6^{* *}$ |
| Role | Leader v. Follower | .01 | .7 |
| Int. | F:Man. Gest v. F:Lang | -.07 | $-4.79^{* * *}$ |
|  | G:Man. Gest. v. G:Lang | .05 | $3.17^{*}$ |
|  | F:Man. Gest v. G:Lang | .06 | $3.08^{*}$ |
|  | G:Man. Gest v. F:Lang | .04 | 2.79 |

The communicative channel x map task role interaction was significant, $F(3,1030)=20.97, p<.0001$, therefore, we tested for multiple comparisons using Tukey Honestly Significant Difference tests to investigate differences within and across MapTask roles (Figure 2b). At this level of the analysis, we were specifically interested in the differences between language and manual gestures, so we limit our report to those subsets of the analysis. We observed withinrole differences between language and manual gesture burstiness estimates for the Follower role ( $b=-.07, p<$ $.001)$ and for the Giver role ( $b=.05, p=.03$ ). We also observed a between-role difference for Follower: Manual Gesture v. Giver: Language ( $b=.06, p=.04$ ). The results from this analysis suggest that, across map task role, the verbal channel (i.e., language channel) had higher burstiness estimates relative to the non-verbal channels, and specifically the manual gesture channel.

## Investigating the Relative Magnitude of <br> Burstiness in the Language Channel

In the last section, we established that communicative channels exhibit temporal patterns of behavior that (1) vary across verbal and non-verbal channels and (2) are all bursty relative to exhibiting random or periodic temporal patterns. But what does it mean to be more bursty? It is important to note that these channels are made up from specific subchannels that are further made up from individual behaviors. In an effort to better understand the relative magnitude of burstiness, in this section, we focused on the language channel because this channel exhibited the highest estimates of burstiness. Specifically, we zoomed into the language channel and investigated the temporal patterns of the subchannels.

The language channel is made up of three specific subchannels: dialogue acts, discourse connectives, and descriptions. We expected to observe higher burstiness estimates for the 'descriptions' sub-channel relative to the other two channels. This hypothesis is motivated by previous research that focused on the burstiness of various linguistic levels in texts (Altmann, Cristadoro, \& Esposti,

2012; Altmann, Pierrehumbert, \& Motter, 2009). Altmann et al. (2009) observed that burstiness increased across semantic classes where 'entities' like proper nouns had higher burstiness estimates relative to predicates like in, which in turn had higher estimates than higher level operators like the. If the results observed in texts are consistent with human dialogue, we should expect to observe that descriptions like providing a relative direction will have higher burstiness estimates relative to dialogue acts like saying no or discourse connectives like saying um.

Figure 3a and 3b:
Burstiness across language channels with a) Information Giver (G) and Follower (F) combined, and b) the roles separated. Error bars reflect 95\% CIs.

Linear models were utilized to predict burstiness estimates. Fixed effects for these models included map task role (Giver or Follower), language sub-channels (Dialogue Acts, Discourse Connectives, Descriptions), and event count for each communicative channel. Similar to the previous analysis section, event count was added into the model to act as a covariate to control for the potential relationship between burstiness estimates and the number of events going into the analysis. Dyad and map type were again included as random effects. We observed that descriptions ( $M=.08, S E=.005$ ) had higher burstiness estimates relative to discourse connectives $(M=-.06, S E=.004, b=.06, p<$ .001 ) and dialogue acts ( $M=-.11, S E=.004 ; b=.17, p<$ .001) (Figure 3a). Discourse connectives and dialogue acts were both more periodic than bursty, and dialogue acts were more periodic (closer to -1) relative to discourse connectives ( $b=.11, p<.001$ ). These results suggest that various levels of verbal dialogue have different temporal patterns and such patterns have interesting parallels to previous research studying the burstiness of text corpora. We discuss these parallels in addition to the insights gained from the analysis section to better understand the pattern of results in the previous analysis section.

## Discussion

The primary goal of the current paper was to better understand the temporal patterns of verbal and non-verbal behaviors during face-to-face multimodal human communication. We submitted the multimodal corpus to an analysis of burstiness. In the first analysis section, we observed that communicative channels differed in the degree of burstiness, with the verbal channel having higher burstiness estimates relative to non-verbal channels like manual gestures, face \& head, and face touch. To add nuance to this result, in the second analysis section, we focused on better understanding the magnitude of burstiness, and zoomed into the language channel. In this analysis, we observed that a more informative sub-channel, 'descriptions', had higher burstiness estimates relative to sub-channels that focused on operators and modifiers.

Much work in the cognitive sciences has argued that verbal and non-verbal behaviors are intrinsically related via the same communicative system (Golden-Meadow, 2005; McNeill, 1992). Recent work (Louwerse et al., 2012) has made this argument by focusing on evidence of synchronization across verbal and non-verbal channels. In the current paper, we observed that, verbal and non-verbal channels differ in terms of estimates of their temporal burstiness. An important question is what these differences reflect. To begin to find an answer to this question, we examined certain language sub-channels and found higher degrees of burstiness for descriptive productions compared to pragmatic productions like dialog acts or connectives.

Considering the latter results, there are a few possible explanations for the observation that verbal and non-verbal channels exhibit different types of temporal patterns, with the verbal channel exhibiting higher burstiness estimates. The first possible explanation is that increased estimates of burstiness for the verbal channel means that more information is contained within this communicative channel relative to the non-verbal channels. This suggestion is influenced by the observations of higher degrees of burstiness in higher-level semantic classes in texts (Altmann, et al., 2009) and higher degrees of burstiness in descriptive sub-channel in dialogue (the current paper's second analysis section). If this is the case, our results point to the proposal that verbal channels during human communication are more informative relative to non-verbal channels. However, this possibility seems unlikely because our own results show that the direction of burstiness estimate differences for the language and manual gesture channels are not consistent: higher estimates for language relative to manual gesture for the information giver and higher estimates for manual gesture relative to language for the information follower.

The second possible explanation is that an important property of multimodal communication is having a collection of different types of temporal patterns across communicative channels. This proposal, what we call the
'temporal heterogeneity' hypothesis, suggests that successful communication emerges from a diverse suite of information channels that vary in temporal properties. An important adaptive property of a complex system, such as a dyadic communicative system (Dale, Fusaroli, Duran, \& Richardson, 2013; Fusaroli, Raczaszek-Leonardi, \& Tylén, 2013), is the ability for multiple components with specific intrinsic properties to self-organize to form higher-level structures (Kello \& Van Orden, 2009; Kugler \& Turvey, 1987). This proposal is amenable to the hypothesis that verbal and non-verbal channels are part of the same integrated system (Golden-Meadow, 2003; McNeill, 1992) and that gesture and speech are complementary communicative channels important for the resolution of referential expressions (Louwerse \& Bangerter, 2010; Seyfeddinipur \& Kita, 2001). The current paper contributes to this line of argument by showing, at a specific level of analysis, that verbal and non-verbal channels have different types of temporal patterns and that the heterogeneity of these temporal patterns might be important for successful communication. Another important contribution is the introduction to a simple analysis of the temporal structure of behavioral event dynamics, the burstiness analysis. Future work is required to better understand the connection between varying degrees of burstiness across diverse types of human behavioral patterns.

#### Abstract

In this paper we examine an enactive approach to social cognition, a species of radical embodied cognition typically proposed as an alternative to traditional cognitive science. According to enactivists, social cognition is best explained by reference to the social unit rather than the individuals that participate in it. We identify a methodological problem in this approach, namely a lack of clarity with respect to the model of explanation it adopts. We review two complaints about a mechanistic explanatory framework, popular in traditional cognitive science, that prevent enactivists from embracing it. We argue that these complaints are unfounded and propose a conceptual model of enactive mechanistic explanation of social cognition.

Keywords: enactivism; social cognition; mechanistic explanation

## Introduction

Embodied Cognition (EC) is most generally a plea to acknowledge that the states of the body and the environment can influence cognition and that lower sensorimotor knowledge plays a role in higher cognition like language and reasoning (e.g. Eerland, Guadalupe, \& Zwaan, 2011). Radical Embodied Cognition (REC) is the claim that the body and the environment are actually part of cognition and as a result, for example, there is no need to have internal representations of the environment (Wilson \& Golonka, 2013; van Dijk, Kerkhofs, van Rooij, \& Haselager, 2008). Enactivism is a strand of REC that stems from the early work in philosophy of biology of Maturana and Varela (1980) and was popularized as an alternative to traditional cognitive science by Varela, Thompson, and Rosch (1991). It shares theoretical commitments with complex systems theory, phenomenology and Buddhist tradition in, on the one hand, grounding cognition on the organizational principles of living systems while at the same time giving a prominent role to the investigation of human experience. Three main principles adopted by enactivism are (1) challenging the dichotomy between internal components of the system and its external conditions, instead stressing the interaction between the two, (2) emphasizing emergent properties on higher levels of organization and (3) viewing the organism as an active autonomous entity that is able to adaptively maintain itself in the environment ${ }^{1}$.

We think enactivism has a lot to offer to the study of cognition because it is an approach that is both naturalistic and

[^3]non-reductionist. However, in this paper we highlight its methodological weakness that might be preventing it from gaining popularity, namely a lack of explicit commitment to how cognitive phenomena are to be explained. We exemplify this issue using a case of enactive accounts of social cognition. We further point out that contemporary cognitive science has two major explanatory frameworks on offer: a deductive-nomological framework, typically associated with REC, and a mechanistic framework, typically adopted by traditional cognitive scientists. We suggest that given the similarity between enactivists and other REC-ers, it is likely that enactivists implicitly subscribe to the deductive-nomological framework. In contrast to this, we argue that the mechanistic framework is not only compatible with enactivism but also preferable. We consider two main objections raised by RECers against mechanistic explanation and show that they rely on a misunderstanding of what such an explanation entails. We end the paper with a preliminary picture of enactive mechanistic explanation of social cognition.

## Enactive Social Cognition

In broadest terms, a non-EC view on social cognition assumes that humans can interact with others successfully only if they are able to see other people as beings with mental states, can infer these states using a so-called 'theory of mind' or simulation and plug in the results of such inferences in planning their own actions. A regular EC view denies the need for such complex representations and inferences emphasizing real-time interaction with other people and perceptual information available in such settings. Certain varieties of simulation accounts of mindreading fit into this framework.

What distinguishes a REC approach is an insistence that the particular dynamics of social interaction themselves play a crucial role in explaining social cognition. This is because "becoming a temporary unit of social action with another person also involves creation of a new perception-action system with new capabilities " (Marsh, Johnston, Richardson, \& Schmidt, 2009, p. 1219). Theoretically this has lead to a claim that there is no need to represent other people or their perspective on the world in order to coordinate with them successfully. Methodologically, it has been suggested that the correct level of analysis in the study of social cognition is the social unit, rather than an exclusive focus on the individuals that comprise it. Instead of searching for internal properties

Figure 1: Perceptual crossing experiment.
A pair of blind-folded participants (call them A and B) are asked to interact in a one-dimensional horizontal field in which they can move using a computer mouse. The field is perceived solely via tactile feedback: encountering a stimulus produces a vibration. Participant A can sense 3 kinds of stimuli: a static object, B's avatar and B's "shadow" that follows B's avatar movement but does not provide $B$ with sensation (the situation is analogous for B). Participants are asked to click when they think to be in contact with the other's avatar. A typical strategy is to move back and forth, especially when a stimulus is encountered. This allows for discriminating between a static and mobile object (if the stimulation changes despite the participant staying in place, the object is not static). The results also show that participants click more often when encountering the other's avatar compared to the other avatar's shadow. However, this increased correct clicking is not due to better recognition (the relative probability of clicking on the avatar is not higher) but rather because the avatars spend more time in front of each other. This effect emerges because the situation of 'sensing the other' while 'being sensed' is more stable than sensing an insensitive shadow. The task is solved globally even if participants are not conscious of this effect and if the solution does not appear in an individual behavioral measure.
of individual independent cognizers, we are to investigate the social interconnectivity that emerges as a result of the interaction and constrains individual-level behavior from the level of a new overarching structure.

One of the most distinctive empirical paradigms that exemplifies this idea is a perceptual crossing (PC) study (Auvray \& Rohde, 2012) presented in Figure 1, in which the task is to distinguish another agent from inanimate objects. A frequent assumption in traditional explanations of social cognition is that such a recognition is accomplished by some special cognitive module (e.g. a module of agency or animacy detection) that is a precondition for interacting successfully. The results of the PC experiment (see Figure 1 caption and the original article for details) have been interpreted to show the reverse: that the social interaction itself and its particular dynamics constitute a solution to such a task. Therefore, in the oftrepeated claim by enactivists, social interaction constitutes social cognition.

Despite a theoretical and empirical research program on social cognition, we believe so far enactivists have not been sufficiently explicit about the explanatory methodology they subscribe to, by which we mean clarity on what is their explanatory target and what constitutes an explanation (Cummins, 2000; Wright \& Bechtel, 2007).

Since social interaction is proposed as an explanation, it cannot be what enactivists are trying to explain. It would mean that the explanandum is perhaps social cognition or experience but these are traditionally understood as individuallevel phenomena ${ }^{2}$. If an explanandum is to be re-construed on a supra-personal level, we need an account of social cognition on that level (without equating it with social interaction). Enactivists could, for example, take more precisely defined types of interaction as their phenomena of interest (cooperation, competition, exchange) and then seek non-individual explanations for their emergence. Our proposal discussed in the last section is to shift to a multi-level explanandum.

Moving on to the model of explanation, an explicit commitment on what constitutes an (good) explanation is important so that any given instance can be judged as to whether it succeeds. In contemporary cognitive science two explanatory frameworks have been discussed most widely: a deductivenomological (DN) and a mechanistic one (Cummins, 2000) ${ }^{3}$.

According to a DN framework, explaining a particular phenomenon proceeds by citing relevant general laws, the details of particular circumstances, and how the phenomenon is to be expected given these two pieces of knowledge. Such an explanation has a form of a deductive argument that derives the explanandum from a certain law taken as a premise (Hempel, 1965). Many REC-ers have explicitly argued for adopting the DN framework for explaining cognition (Walmsley, 2008).

By contrast, in a mechanistic framework, one wants to know not just that a certain regularity holds and what it is but also why it holds and how it is implemented. An answer to this question is sought in identifying a mechanism, where:

A mechanism is a structure performing a function in virtue of its component parts, component operations, and their organization. The orchestrated functioning of the mechanism is responsible for one or more phenomena (Bechtel \& Abrahamsen, 2005, p. 423).

Enactivists have not explicitly accepted or rejected either of the frameworks. However, given the similarity between them and other proponents of REC, it seems safe to assume that their implicit notion of explanation is likely closer to the DN framework. We now proceed to considering the reasons behind this preference and show that in fact there can be enactive mechanistic explanations.

[^4]
## Enactivist Worries about Mechanistic Explanation

Since space is limited we will focus on just two worries that prevent enactivists from adopting a mechanistic approach. We acknowledge that there are other issues that could be raised (e.g. the role of representations in mechanistic explanation) but our reply to them would be similar in spirit to what we offer here: that the notion of mechanism is richer and more flexible than typical complaints about it presuppose.

## The Decomposability Worry

The main worry enactivists and other REC-ers seem to have with the mechanistic approach is that it allegedly views cognitive systems as decomposable or near-decomposable while in reality they are non-decomposable. For example, Lamb and Chemero (2014) argue that according to the mechanists, producing an explanation requires (1) "decomposition [that] involves developing a model of a system's behavior by identifying discrete component parts and their linear, or weakly non-linear, interactions" and (2) "localization [that] involves mapping those discrete components and interactions onto features of a physical system" (pp. 809-810). What is often added to this charge is that such an explanatory strategy views cognitive systems as component-dominant, i.e. the behavior of the whole is a simple additive result of the behavior of its components, whose properties and functions are rigid and pre-determined (Favela, 2015). Therefore, a single component can be analyzed in isolation as responsible for some particular capacity of the system.

In an opposition to this view on the brain and cognition, REC-ers argue that in fact living cognitive systems are nondecomposable into components and interaction-dominant. That is, the behavior of the whole is more than a simple sum of the parts because interactions between parts are mostly non-linear, the behavior of each part dynamically depends on all other parts of the system and it is not possible to assign any specific task to any component. Therefore, interactions between components are more important than the components themselves (Richardson \& Chemero, 2014) ${ }^{4}$.

If neural and cognitive systems are indeed nondecomposable and mechanistic framework can only be applied to decomposable systems, then obviously enactivists cannot make use of it. However, these arguments betray a misunderstanding of the mechanistic framework and explicit dismissal of the new developments in this field.

First of all, mechanists explicitly argue against mere aggregation of components and place heavy emphasis on their organization (Wimsatt, 1997). It is because the way parts are organized in space and time that they together can exhibit be-

[^5]havior that they cannot exhibit on their own. It is because the parts are on a lower level than the whole they comprise that they cannot have the same properties (cf. the properties of hydrogen and oxygen vs water).

Second, there is no reason to suppose that only linear and sequential modes of organization are allowed in mechanisms. Especially when dealing with biological mechanisms, nonlinear and cyclic modes are ever-present. Such a focus on biology has led mechanists to stress the necessity for dynamic mechanistic explanation because in a system organized nonlinearly "the operations performed by parts of the mechanism vary dynamically, depending on activity elsewhere in the mechanism" (Bechtel, 2011, p. 551). Therefore, an explanation has to include not just a static diagram of components and their organization but also a description of how the functioning of these parts is orchestrated in time, including potential shifts of the overall functional organization. Adding dynamics to a mechanistic explanation does not turn it into a law-based explanation (Bechtel \& Abrahamsen, 2010, 2011).

The general thrust of these extensions of the mechanistic framework is to stress that cognitive systems are likely to lie on a continuum between the extremes of non-decomposable and fully-decomposable. They are, instead, integrated systems, in which it is still possible to identify components but their functions are not necessarily predetermined and fixed. Nor is there a trivial additive relationship between component sub-functions and the overall phenomenon. Rather, their contribution to the operation of the whole might dynamically depend on other parts of the system, the larger context and be variable in time. It does not mean that when studying a mechanism for a particular phenomenon it is impossible to identify these contributions (see also Menary, 2007).

In reply to such arguments, Lamb and Chemero (2014) state that

If a neo-mechanist wishes to discard the condition of decomposability, then she does so at the cost of discarding the feature of neo-mechanistic explanations that makes them distinct from more general accounts of naturalistic explanation (p. 813).

We wish to oppose this complaint. First, it is unreasonable to expect that a certain concept or theory once proposed cannot be developed further. Second, what is distinctive about mechanistic explanations is not decomposability but a concern for causal structure underlying the phenomenon ${ }^{5}$, and for explaining how things work rather than merely stating what are the laws. Finally, specific for the topic of this paper, a REC-er has yet to justify to what extent non-decomposability applies to social cognition, even if it holds for the brain.

[^6]
## The Extended Cognition Worry

The second major worry enactivists have about mechanistic explanation has to do with the claim that social interaction itself constitutes social cognition. This is in line with a general REC view that cognition is not done by the brain alone but by an extended brain-body-environment system. In the case of social cognition, it is rather an extended brain-body-environment-body-brain system (Froese, Iizuka, \& Ikegami, 2013). The fear is that perhaps mechanistic framework somehow precludes such an extended conception of cognition.

The worry is seemingly justified by the following critique by Herschbach (2012). In his article on social cognition sub-titled "A mechanistic alternative to enactivism" (emphasis added), he very acutely points out that enactivists have not been very clear on what they mean by constitution in their claim that "social interaction constitutes social cognition". Constitution is standardly taken to imply a part-whole relationship and if the claim is that supra-personal interaction constitutes individual cognition, then it is somehow a category mistake and a confusion of levels of organization. On the other hand, if constitution is aimed at emphasizing the causal links between agents engaged in the interaction, then enactivists are committing a well-known couplingconstitution fallacy (Adams \& Aizawa, 2010). In this fallacy, frequently ascribed to proponents of extended cognition in general, one points out extensive causal coupling between a cognitive agent and some external factors and then concludes that therefore these factors are part of cognition. Such a conclusion is thought to be unwarranted because coupling and constitutive relations are in general not equivalent.

Herschbach proposes that adopting a mechanistic framework can capture everything that enactivists want to say about social interaction without committing the fallacy. He states that perceptual crossing example would be described by a mechanist as a network composed of interacting agents to be explained by focusing on the agents, their behavior and organization. A mechanist would then move one level down to the internal mechanisms of the agents and how they produce the particular behavior observed in the experiment in response to particular sensory input. The main point of difference between enactivists and mechanists, according to Herschbach, is that while the former would like to say that the environmental input constitutes social cognition, the latter would say that only the agent-internal mechanism constitutes the phenomenon of interest (the behavior exhibited in the experiment) while the environmental input is merely an external influence on that mechanism. That is, the mechanism succeeds only when situated in the appropriate social context of having contact with another agent.

Herschbach grounds this conclusion on the fact that only parts that participate in a self-organized autonomous individual can be truly said to constitute cognition. He follows Bechtel (2009) who has argued that it is the autonomous living system that is the proper "locus of control", differentiated from the environment, because it is the living system
that needs to maintain itself as a unity in constantly changing external conditions.

If adopting a mechanistic framework were to indeed preclude speaking of social interaction playing a constitutive role, enactivists would not be able to accept it. However, we believe there are reasons to oppose Herschbach's conclusion.

The first most obvious reply to Herschbach is that he is replacing the enactive explanandum with his own by switching from the phenomenon of interest being social interaction as a whole to the behavior of the individual. Even though enactivists have not been very clear on their exact explanandum, they would definitely resist this move from the higher to the lower level.

Furthermore, regarding autonomy as a guide to the boundaries of cognition, both Herschbach and Bechtel misunderstand the notion of autonomy adopted by enactivists. Living systems are autonomous in being self-determined rather than being steered from outside (Bechtel's "locus of control"). However, they are also autonomous in being operationally closed, that is, organized in a circular manner, in which the processes and components that constitute the system are themselves constituted by that system. This, however, applies not just to the bio-chemical processes of selfmaintenance, but also to the closure of the sensorimotor loop of the organism. This loop is closed not to the environment but through the environment, which is merely an additional step in the loop, not an input or output external to the system (see Villalobos \& Ward, 2015, for a more detailed argument). The point here is that enactivist autonomy does allow for the constitutive role of the environment in the cognitive process.

Finally, to respond to Herschbach from within a mechanistic framework itself is to point at the recent literature that treats the coupling-constitution fallacy as an instance of a general problem of demarcating the boundaries of a mechanism (Kaplan, 2012). In short, what is required to allow for deciding what constitutes part of the mechanism is an account of constitutive explanatory relevance, i.e. a way to determine which components and processes are relevant to a particular mechanistic explanation (Craver, 2007). This does not need to be a priori based on deciding what cognition really is and whether it really extends beyond the brain. In fact, it is even possible to develop a deflationary (yet still mechanistic) account which shows how certain kinds of dynamic non-linear coupling just are constitutive (Kirchhoff, 2016).

In sum, contra Herschbach (2012), adopting the mechanistic framework does not in fact necessitate abandoning the constitutive role of social interaction in social cognition.

## The Enactive Mechanisms Proposal

We believe enactive mechanistic explanation is possible as there is sufficient basis on both sides of the debate for such a reconciliation. Constructing such an account requires two things. First, it requires disambiguation of the notion of 'composition' involved in mechanistic explanations to recognize its compatibility with enactivist claims about non-

Figure 2: Traditional social cognition.
decomposability of cognitive systems. Identifying components in a cognitive system does not necessarily entail that these components are self-contained, so that the mechanism is a mere linear addition and causal interrelation of them. We can just as well identify components that are defined by their role in the overall whole. This latter, holistic, notion of 'component' is in line with enactivism. Crucially, though, it does leave room for a mechanistic explanation. Secondly, a tailoring of the mechanistic framework is required to fit wider enactivist commitments, such as, for example, making room for cognitive mechanisms that are non-representational and extended. This reorientation towards mechanisms can be advantageous to enactivists for several reasons.

First, it equips enactivism with an explicit and coherent explanatory framework, which comes with specific tools and strategies for constructing explanations of cognitive phenomena. For example, mechanistic literature on mutual manipulability as a guide to constitutive relevance (Craver, 2007) can help make clear what elements of individual cognition and social interaction are essential to particular tasks. Similarly, discussions on how to think of inter-level causation (Craver \& Bechtel, 2007) can help understand the autonomy of the supra-personal level that enactivists consider important.

Second, the claim that social interaction itself should constitute the primary level of explanation in enactive work on sociality to some extent encourages ignoring the individual mechanisms. By contrast, mechanistic emphasis on working parts and their operations highlights the need to provide a distinctively enactive account of what goes on in the individual brains and bodies, i.e. offer a truly multi-level explanation for a multi-level explanandum. Otherwise, a traditional cognitive scientist might well acknowledge the role of interaction but combine that with a non-enactive account of internal mechanisms, thereby defying the whole purpose of constructing an explanatorily complete enactive cognitive science.

Third, enactive mechanistic explanation promotes integration with the rest of cognitive science while at the same time making clear how enactive explanations are different from traditional ones. That is, competing explanations could now be formulated in the same language and compared, instead of two communities adopting completely different explanatory frameworks and talking past each other. This is not to say that dynamical, more law-oriented approaches are to be

Figure 3: Enactive social cognition.
eliminated and we definitely see value in a pluralistic attitude (Dale, Dietrich, \& Chemero, 2009). However, we think at least some intersection is essential for continued progress.

The 'commensurability' of mechanistic enactivism and traditional cognitive science can be illustrated schematically. Figure 2 represents a traditional cognitive science approach to social cognition. All the components of the cognitive mechanisms (differently colored cogs) are located inside the agents' brains. Succeeding in a social task requires one agent to "replicate" the cogs of the other agent inside their own brain, i.e. internally represent the mental states of the other by means of "theory of mind" or simulation. The replicated cogs will not be the same as the original ones (hence the blurriness) but need to be sufficiently close if the agents are to interact successfully. The unfolding of the interaction is then explained in terms of the operations of this internal machinery, giving a strong impression that once all the cogs are in place, the whole process might as well proceed offline.

The contrasting enactive mechanistic view is depicted in Figure 3. Here the explanandum is particular kinds of social interactions in which the individuals participate. The explanation is to be achieved by specifying all the components of the picture that contribute to the realization of such interactions. The components of the cognitive mechanisms (the cogs) are distributed across the brain and the body of both agents and dynamically coupled (the toothed belt), respecting the enactivist rejection of the internal-external dichotomy. The contribution of the individual brains to the overall social interaction is diminished with respect to the previous figure, suggesting a need for an alternative account of such internal mechanisms. The fact that the coupling is a constraint on individual mechanisms rather than an additional cog, expresses the idea that interaction consists of interacting individuals yet allowing for emergent effects. Furthermore, the picture includes the possibility that the coupling might be affected by contextual factors (the tension pulley), such as the layout of the environment in which interaction unfolds, or some sociocultural circumstances.

To restate the point of our paper in terms of the second figure above, we believe the current state of the matters in enactivist theorizing about social cognition is an exclusive focus on the toothed belt. We think the time is ripe to start examining the rest of the picture.

#### Abstract

When people search for a target in a novel image they often make use of eye movements to bring the relatively high acuity fovea to bear on areas of interest. The strategies that control these eye movements for visual search have been of substantial scientific interest. In the current article we report a new computational model that shows how strategies for visual search are an emergent consequence of perceptual/motor constraints and approximately optimal strategies. The model solves a Partially Observable Markov Decision Process (POMDP) using deep Q-learning to acquire strategies that optimise the tradeoff between speed and accuracy. Results are reported for the Distractor-ratio task.

Keywords: Computational Rationality; Deep Reinforcement Learning; Deep Q-Learning; Visual Attention.

## Introduction

One of the many tasks for which people use vision is to search for items in the environment. Visual search might be used to locate a phone on a table, a car in a parking lot or a family member in a crowd. In a typical laboratory visual search task, participants are asked to find a visual target amongst distractors. For example, searching for a Gabor patch in a high contrast noisy background (Najemnik \& Geisler, 2008), or searching for a red coloured letter O in a display that consists of red Xs and green Os (Shen, Reingold, \& Pomplun, 2000). Many, though not all, visual search tasks require a number of fixations and saccades before the target is found.

From a cognitive science perspective, visual search is interesting because data from visual search experiments can be used to inform theories of the underlying constraints on vision (e.g (Geisler, 2011) and also to inform theories of how people adapt eye movement strategies to these constraints (e.g (Najemnik \& Geisler, 2005). Human behaviour is a consequence of both the constraints and the adapted strategies and explanations of behaviour require both (Lewis, Howes,
\& Singh, 2014). In fact, there is a long history of cognitive science research on visual search and there are a number of competing theoretical approaches.

First are the map-based approaches described by (Kowler, 2011), such as salience maps (Itti \& Koch, 2000) and activation maps (Pomplun, Reingold, \& Shen, 2003; Wolfe, 2007), where the perceived visual information is represented as a topological distribution in a graphical map form. The salient area or peaks in the map represent items that significantly differ from their neighbouring items, that may contain attributes of interest. These peaks in the map are then used to guide the eyes through the display using some selection rules, such as a greedy heuristic (Pomplun et al., 2003) or a winner-take-all heuristic (Itti \& Koch, 2000). To summarize, the map based approach assumes that saccades are programmed to move the fovea to those areas in the display that stand out from surroundings.

Second are the Bayes optimal state estimation approaches (Myers, Lewis, \& Howes, 2013; Najemnik \& Geisler, 2008), in which it is assumed that visual information is recorded as a Bayesian estimate of the state of the world. On each fixation the estimated state is updated by optimally integrating information (Bayes rule) from the previous state and from the fovea and from the periphery according to its reliability. The eye movements are then made using these states and applying a heuristic decision rule (e.g., 'Maximum A Posteriori' (MAP)) to navigate. This rule generates a behaviour in which attention is directed to areas which have the highest probability of target present. Alternatively, Najemnik and Geisler (2005) observed that the number, and spatial distribution, of saccades could be better explained by a model in which each saccade was directed to an 'ideal' location (i.e., a location that maximises information gained). Their model was sensi-
tive to known human constraints on vision, i.e., the accuracy of perceiving a feature degrades with eccentricity.

Third are the optimal control approaches (Butko \& Movellan, 2008; Hayhoe \& Ballard, 2014; Nunez-Varela \& Wyatt, 2013; Sprague, Ballard, \& Robinson, 2007), in which it is assumed that the eye movements are not made to estimate some statistics about the world but rather the goal is to maximize the overall performance utility. The maximum reward/utility an individual can attain throughout the task is bounded by the noisy encoding of the visual information by the human brain. In contrast to map-based and optimal state estimation approaches, where prior assumptions about eye movement decisions are made by heuristic rules, the control strategy emerges as a consequence of bounds imposed by the human visual system. To summarize, the optimal control approach assumes that the saccades are programmed to move the fovea so as to maximise task utility/reward.

In the current article we report a novel (approximately) optimal control model of the distractor ratio task. The purpose of this model is to (1) explain phenomena not previously explained as optimal control, (2) to further elucidate the framing of visual search as a Partially Observable Markov Decision Process (POMDP) (Kaelbling, Littman, \& Cassandra, 1998), and (3) to explore the role of deep Q-learning (Mnih et al., 2015) in solving the tractability problems with previous optimal state estimation and optimal control approaches. The model goes beyond the optimal state estimation model of Myers in that it is applied to the full display size used by (Shen, Reingold, \& Pomplun, 2003). The model uses deep Q-learning to solve a POMDP. It attempts to maximise a reward signal given constraints imposed by the human visual information processing system. We compare the performance of the optimal control model to a model that uses MAP-like heuristics. We show that the optimal control model offers higher utility and better fits to the human data than the heuristic model. Lastly, we use the model to explain phenomena associated with the distractor ratio paradigm (Bacon \& Egeth, 1997; Shen et al., 2000; Zohary \& Hochstein, 1989). A phenomena that has previously been explained using the salience-map based approach.

## The Distractor Ratio Task

In the distractor ratio task the display consists of a target object, which is randomly positioned amongst distractor objects each of which shares at least one common feature with the target. The goal is to respond whether the target is present or absent. An example display is shown in Figure 1 where the target is a red letter O . The distractors in this display share either a same-colour or same-shape feature with the target.

In a number of studies it has been observed that people respond more quickly, and with fewer eye movements, for extreme ratios of same colour to same shape distractors (Egeth, Virzi, \& Garbart, 1984; Shen et al., 2003). In Figure 1, the target - a red letter O - can be located easily in display (a) and (c) with ratios 3:45 and 46:2 respectively as compared to

(a)

(b)

(c)

Figure 1: Distractor ratio stimuli with ratio distributions: (a) 3:45, (b) 24:24, (c) 46:2 and target stimuli: red coloured letter O.

Figure 2: (a) Average number of fixations per trial as a function of the number of distractors sharing colour with the search target in target-absent trials and target-present trials for high discriminability condition. (b) Saccadic bias (the difference between the observed frequency and chance performance) as a function of the number of same-colour distractors in target- absent trials for high discriminability condition (Shen et al., 2003)
display (b), for which a response takes a relatively long time. The distractor ratio effect reported by Shen et al. (2003) is shown in Figure 2.

In addition to the distractor-ratio effect, Shen et al. (2003) also observed a saccadic selectivity effect. In Figure 2, the frequency of saccades to same-colour distractors is plotted against the number of same-colour distractors. In the plot, the saccade frequencies are higher for rare features (colour or shape) than should be expected by chance (represented by the horizontal line). When the same-colour distractors are rare in the display, the participants were more likely to make eye movements towards them than when they were common. Conversely, when the number of same-colour distractors was high, the participants were more likely to make eye movement towards same-shape distractors.

## The Model

In the following sections we describe the individual components of the model for performing a 36-element distractorratio task, and provide a walk-through of the model process before presenting the model results.

## External Display

In the model, we represent the display by randomly distributing the target and the distractors in a grid, where each cell consists of either a target object, a distractor object with common colour or a distractor object with common shape. In the display, there is only one target object and the number of distractors are determined by randomly sampling a ratio per trail.

The display is represented by two feature vectors, one for colour and one for shape. The presence or absence of a feature in each cell in the model is represented numerically by the number 1 for presence and 0 for absence. The random distribution of these features in the environment was achieved by sampling randomly from the following set of ratios, $r=R$ (3:33, 6:30, 9:27, 12:24, 15:21, 18:18, 21:15, 24:12, 27:9, 30:6, 33:3).

## Actions

The action space consists of (1) fixate on a cell, (2) respond present and (3) respond absent. In our study there was a grid of $6 \times 6$ coloured shapes and there were therefore a total of 36 possible fixation actions. A trial was terminated by the choice of the present or absent action.

## Reward

A reward was given after choosing a present or absent action. The reward distribution was defined as a value 10 for a correct response, a value of -10 for an incorrect response and a value of -1 for each fixation. The penalty on each fixation imposes a speed-accuracy trade-off. More fixations gives greater accuracy but at a cost.

## Observation Model

Every time the model fixates, it also makes an observation. The observation obtained by the model is constrained by the noise in the human visual system. Two types of noise are added to the signal: spatial smearing noise and feature noise.

1. Feature Noise: The human eye's ability to discriminate and perceive object features degrades with eccentricity according to a hyperbolic function (Strasburger, Rentschler, \& Jüttner, 2011). To model this function we added Gaussian white noise with mean 0 and standard deviation as eccentricity, i.e., a function of visual angle ' $\theta$ ' between the fovea and the given location, and a scalar weight ' $w_{\text {featural }}$ ' to scale the effect of distance to the fovea for feature noise. Therefore, the equation for the observation after adding feature noise at location $j$ given that the eye is focused on location k is as follows,

$$
\begin{gathered}
\delta_{\text {featural }}\left(S_{t}, j\right)=v\left[s_{t}\right]+N\left(\theta, \sigma_{f}\left(\theta_{j k}, w_{\text {featural }}\right)\right) \\
\sigma_{\text {featural }}\left(\theta_{j k}, w_{\text {featural }}\right)=\frac{\theta_{j k}}{\left(w_{\text {featural }}\right)}+c
\end{gathered}
$$

where, $v\left[s_{t}\right]=1$ if the location $s_{t}$ contains a target feature, else $v\left[s_{t}\right]=0, c$ is a constant with value $10^{-4}$ to avoid 0
variance in the model, $\sigma_{f}\left(\theta, w_{f}\right)$ is the variance to simulate the degrading eccentricity and ' $\theta$ ' is the distance between the fixated cell and location $j$.
2. Spatial Smearing: Another source of uncertainty in the human visual system is the localization error (Levi, 2008), where information in the parafovea may erroneously combine features from one location with adjacent locations. Therefore, for each location in the colour and shape vector a weighted sum is calculated for the location and its adjacent eight locations. For example, If a red X is surrounded by green Os in the parafovea then, as a consequence of spatial smearing, the participant would be uncertain whether they are actually looking at a red X or a green O .
In the model, spatial smearing is represented by a weighting function (Gaussian kernel) with standard deviation as a function of visual angle ' $\theta$ ' between the fovea and the given location, and a scalar weight ' $w_{\text {spatial' }}$ ' to scale the effect of distance to the fovea for spatial noise. The weighting function here is a normalised function. As ' $\theta$ ' (distance) increases the acuity decreases and the standard deviation of the Gaussian kernel increases, this means that the percept of the item at a given location suffers greater interference from surrounding items. This encoding is done for each location in the display. Thus, the equation for the observation after adding spatial noise at location $j$ given that the target features are at location $S_{t} \in(1,2, \ldots, n)$ and the eye is focused on location $k$ is as follows,

$$
\begin{gathered}
\delta_{\text {percept }}\left(S_{t}, j\right)=K\left(s, \sigma_{s}\left(\theta_{j k}, w_{\text {spatial }}\right)\right) \times \delta_{\text {featural }}\left(S_{t}, j\right) \\
\sigma_{\text {spatial }}\left(\theta_{j k}, w_{\text {spatial }}\right)=\frac{\theta_{j k}}{\left(w_{\text {spatial }}\right)}+c
\end{gathered}
$$

where, K is the Gaussian kernel with kernel size $s=1$, $\sigma_{s}\left(\theta_{j k}, w_{s}\right)$ is the variance. $\delta_{\text {percept }}\left(S_{t}, j\right)$ is calculated separately for both shape and colour feature vectors. $c$ is a constant with value $10^{-4}$ to avoid 0 variance in the model. Now each percept ( $\delta_{\text {percept }}$ ) (one for colour and one for shape) is represented as a vector of noisy observations for each location. A consequence of introducing the noise is uncertainty in the content of the location.

## State Estimation

At each time step $t$ on which a fixation is made the model receives a noisy observation for each location. The values for perceived colour and shape are then combined (Hadamard product) for each location $[i, j]$. We refer to these combined values as relevance scores, where a higher score in a location signifies high relevance to the task. These scores are then integrated across fixations, using naive Bayesian inference (Kalman filter), to get the current state $B_{t}$ which is a vector of estimated relevance scores across fixations ${ }^{1}$.

[^7]
## Heuristic Control Model

The Heuristic control model makes fixations and observations as described above. In order to decide which fixations to use and when to respond it makes use of two heuristics. The first uses a MAP-like strategy to determine where to fixate next, and the second uses a thresholded stopping rule.

## Optimal Control Model

As we have said, at each point in time, the model observes the external environment through a noisy percept with a high resolution fovea and low resolution parafovea and receives an observation $o_{t}$. The model then extract the high resolution local information from the environment by taking actions $a_{t} \in A$ ( $A$ is the set of actions) to move the fovea (e.g., choose where to move the fovea). Since the environment is only partially observed the model needs to integrate information over time in order to determine how to act and how to make eye movements most effectively. It does this using the Bayesian state estimator described above.

At each step, the model receives a scalar reward $r_{t}$ (which depends on the action taken by the agent), and the goal of the agent is to maximize the total sum of such rewards $R=$ $\mathbb{E}\left[\Sigma \gamma^{t-1} r^{t}\right]$, where $\gamma \in(0,1)$ is the discount factor.

The most important aspect of the Optimal Control model is that rather than using heuristics to choose what to do next, it learns an approximately optimal policy using Deep Qlearning.
Deep Q-learning The Deep Q-learner made use of the following network architecture.

The relevance score estimate $B_{t}$ ( 36 element vector) from the state estimator (above) was taken as the input. This input was connected to a fully connected hidden layer consisting of nodes equivalent to number of elements in the display, i.e., 36 , with rectifier activation function. This is followed by a second fully connected hidden layer consisting of again nodes equivalent to number of elements in the display, i.e., 36 , with sigmoid activation function. Finally, the output layer was a fully connected linear layer of 38 nodes with single output for each action in the task. To avoid over-fitting of the network $l 2$ regularization of the weights was applied with value $10^{-5}$.

During the training process a fixed size batch of transitions $<s, a, r, s^{\prime}>$ were sampled from a replay memory and used for learning. For each time step $(t)$, the deep Q-network (with parameters $\theta$ ) is trained to approximate the action-value $(\mathrm{Q}-$ value) function from the sampled transitions by minimizing the loss functions $L\left(\theta_{i}\right)$ :

$$
L\left(\theta_{i}\right)=\mathbb{E}_{s, a \sim \pi_{\theta}}\left[\left(y_{i}-Q(s, a ; \theta)\right)^{2}\right]
$$

where $y_{i}=r+\gamma \max _{a^{\prime}} Q\left(s^{\prime}, a^{\prime} ; \theta^{\prime}\right)$ is the target Q -value estimated from a target Q-network $\left(\theta^{\prime}\right)$. The parameters of target Q-network $\left(\theta^{\prime}\right)$ is copied over from the learned network ( $\theta$ ) after a fixed number of iterations.

```
Algorithm 1 Deep Q Network Algorithm

    \(\theta\) and target network \(\theta^{\prime}\).
    observe the initial state s.
    repeat
        select an action a
            with probability epsilon select \(a\) random action.
            otherwise select \(a=\operatorname{argmax}_{a^{\prime}} Q\left(s, a^{\prime} ; \theta\right)\).
        perform the action \(a\).
        observe the reward \(r\) and new state \(s^{\prime}\) for action \(a\).
        store transition \(<s, a, r, s>\) in the replay memory \(D\).
        sample random transitions \(\langle s, a, r, s\rangle\) from the re-
    play memory D.
        calculate the target value \(t\) for each sampled transi-
    tion.
        if \(s^{\prime}\) is the terminal state then
            \(t=r\)
        else
            \(t=r+\gamma Q\left(s^{\prime}, \max _{a^{\prime}} Q\left(s^{\prime}, a^{\prime} ; \theta\right) ; \theta^{\prime}\right)\)
        end if
        update the network using \((t-Q(s, a ; \theta))^{2}\) as the loss.
        \(s=s^{\prime}\)
        after every fixed steps \(\theta^{\prime}=\theta\)
    until terminal state
```

## Model Results

The Heuristic control model was run for 30,000 trials and 10 regression runs to check for consistency. The Optimal control model was run for 20 million trials. We first tested the accuracy of the models. Accuracy is the proportion of trials on which the model correctly responded either present or absent. The best fitting optimal control model achieved an accuracy of $96 \%$ in its last 50000 trials. In comparison, human participants achieved $98 \%$ accuracy. The accuracy of the best fitting Heuristic control model was $94 \%$. Accuracy and utility of both models is plotted in Figure 3. The plots show a clear advantage of the Optimal control model for all explored parameter settings. In other words, the approximately Optimal control model outperforms the Heuristic control model in all cases.

Plots of fixation frequency versus same colour distractorratio at different levels of spatial and feature noise are shown in Figure 5. The results show that both model Heuristic and Optimal control model generate similar distractor ratio curves to humans (Figure 2) for target absent, where more fixations are required for ratios close to 1 . While the RMSEs for the Heuristic control model were smaller than for the Optimal control model (Optimal: $R M S E=0.81$; Heuristic $R M S E=0.41$ ), the goodness of fit against Human performance for the Heuristic control model was $R^{2}=0.95$ and for the Optimal control model was $R^{2}=0.98$. A weakness of the Heuristic control model was that it produced DR effects for both target present and target absent. In contrast, the Optimal control model predicted a DR effect in the absent condition

Figure 3: (a) Mean accuracy achieved by both models plotted against different noise parameter settings. (b) Mean utility gained by both models plotted against different noise parameter settings. Where, FN is Feature noise, SN is Spatial Noise and TH is the threshold set for heuristic control model.

Figure 4: Saccadic bias as a function of the number of same colour distractors for Target Absent.
only. In terms of the shape of the DR curve and saccadic selectivity curve, the similarity between humans and Optimal control model is greater than the similarity between Heuristic control model and humans (see Figure 2).

The saccadic bias effect is shown in Figure 4. For the explored parameter settings, the Heuristic control model generated higher levels of saccadic bias than generated by the Optimal control model and these levels were nearer to those generated by humans (Optimal: $R M S E=8.93$; Heuristic $R M S E=6.93$ ). However, the Optimal control model explained more of the variance. The goodness of fit of the best fitting Heuristic control model was $R^{2}=.94$. In contrast, the best fitting Optimal control model had a goodness of fit of $R^{2}=0.97$. While the Heuristic control model predicts a magnitude of saccadic bias that corresponds to that of humans at extreme levels of same-color (around 30\%), it is the Optimal control model that has the better fit. This is likely due to the extreme curvature (sinusoidal) of the saccadic bias for the Heuristic model which is not present in the humans.

One of the effects in the human data that is not captured by either the Optimal or the Heuristic control model is the asymmetric effect of shape and colour (see Figure 2). This is very

Figure 5: Number of fixations as a function of same-colour distractors for (a) the Heuristic model with target present, (b) the Control model with target present, (c) the Heuristic model with target absent, (d) the Heuristic model with target present.
likely due to the fact that we used the same noise parameter values for both shape and colour in the model's observation function. Further work is needed to explore the effect of the known differences in acuity functions for shape and colour (Kieras \& Hornof, 2014).

## Discussion and Conclusion

While the results presented here are preliminary, they offer some evidence that the distractor-ratio effect is the consequence of an approximately optimal adaptation to the constraints imposed by the human visual information processing system. Unlike previous work, including Myers et al. (2013), our results are based on a model that makes approximately optimal control decisions to choose fixation locations rather than a model that uses MAP-like heuristics.

Achieving these results required two contributions to cognitive modeling. The first is the novel application of POMDPs to the framing of the distractor-ratio problem, further extending the work of Butko and Movellan (2008). The POMDP framing is important because it provides a rigorous basis for exploring the computationally rational adaptation of human strategies to known information processing constraints (Lewis et al., 2014; Howes, Lewis, \& Vera, 2009). It thereby helps make the crucial link between cognitive mechanism and rationality that supports deep explanations of behaviour.

The second contribution is the novel application of Deep

Q-Learning (Mnih et al., 2015) to determine the optimal policy given a theory of human visual information processing capacities. The role of reinforcement learning based algorithm's have previously been proposed as means of explaining human learning processes (Dayan \& Daw, 2008) and also, as means of deriving rational analyses of what a person should do in particular task (Chater, 2009). Our work is more aligned with the goals of (Chater, 2009). The purpose of our reinforcement learner was not to model the step-by-step learning process, but rather to model the rational outcome of the learning process - an approximately optimal adaptation to information processing limits.

There is a substantial amount of work to be done. While the best fitting Optimal control model explained $98 \%$ of the variance, to be fully confident that it is better than the Heuristic control model, we need to more fully explore the parameter space of both models. For example, for the Heuristic control model, it might be the case that even higher feature noise, and lower spatial noise, might further improve the fit. We also need to find a fit that reduces the RMSE of the Optimal control model.

In conclusion, we have demonstrated that framing the visual search problem as a POMDP and solving this problem with deep Q-learning is a viable approach to explaining effects such as distractor-ratio and saccadic selectivity.

# Executive function and attention predict low-income preschoolers' active category learning 

Katherine A. Adams ${ }^{1}$ (kat.adams@ nyu.edu), George Kachergis ${ }^{2,3}$<br>${ }^{1}$ Department of Applied Psychology, New York University<br>${ }^{2}$ Department of Artificial Intelligence, Radboud University<br>${ }^{3}$ Donders Institute for Brain, Cognition and Behavior

#### Abstract

Recent studies find that school-age children learn better when they have active control during study. Yet little is known about how individual differences in strategy or cognitive control skills may affect active learning for preschoolers, nor if experimental measures of active learning map onto real-world learning outcomes. The current study assesses 101 low-income 5 -year-olds on an active category learning task, and measures of executive function, attention, and school readiness. We find that preschoolers use an informative sampling strategy for categories defined by stimuli features in 1D and when presented with a distractor dimension (2D). Children accurately classify in 1D, but show mixed performance in 2D. Attention predicts sampling accuracy, and working memory and inhibitory control predict classification accuracy. Performance in the active learning task predicts early math and pre-literacy skills. These findings suggest that trial-by-trial learning decisions may reveal insight into how cognitive control skills support the acquisition of knowledge.

Keywords: active learning; executive function; attention; cognitive development; education

## Introduction

From the enthusiastic preschooler who asks "why?" to the infant who turns her head to attend to a novel toy, children learn by actively exploring the world around them. Experimental studies show that children are engaged problem-solvers and employ strategies such as hypothesis testing, for example playing more with a toy after being shown confounded information about how it works (Schulz \& Bonawitz, 2007).

Research in cognitive science suggests that active information gathering boosts children's performance in learning experiments (Partridge, McGovern, Yung, \& Kidd, 2015; Sim, Tanner, Alpert, \& Xu, 2015). For example, Sim and colleagues (2015) recently found that 7-year-old children learn categories better after self-selecting examples of category membership than when passively presented with a random sequence of examples. Yet little is known about how variation in children's abilities to optimally sample information may affect learning outcomes. Do young children differ in their information sampling strategies? What skills help children be good active learners? How do experimental measures of active learning map onto real-world learning outcomes? These questions have important implications within cognitive science and may inform targeted education interventions, particularly for children from under-resourced backgrounds who are at increased risk for poor academic outcomes (Blair \& Raver, 2014). This study takes a first step in addressing these questions by examining low-income preschool children's active sampling strategies in a category learning task. We then
ask how individual differences in a series of executive function, attention, and school readiness measures relate to active learning performance.

Educational research has long been interested in how young children's abilities to actively attend and engage during learning affect academic outcomes. One set of factors identified are executive functions (EF), higher-order cognitive control skills such as the ability to hold items in working memory, inhibit a prepotent response, and flexibly shift attention. Higher EF is associated with higher socioemotional and cognitive skills, and predicts early math and pre-literacy skills (Blair \& Raver, 2014). Similarly, individual differences in preschool children's sustained and selective attention are important predictors of cognitive and academic skill (Steele, Karmiloff-Smith, Cornish, \& Scerif, 2012). The neural networks that underlie EF and attention undergo tremendous growth during the preschool years. Several successful preschool interventions capitalize on this neurocognitive plasticity by targeting EF and attention as a means to boost school readiness and close income-based academic achievement gaps (Ursache, Blair, \& Raver, 2012). Importantly, these intervention programs promote children's active engagement in learning as a key mechanism to support both EF and academic skills. However, this research is limited both by conceptualizing active learning in global behavior terms and by operationalizing learning outcomes with static standardized assessments.

Active learning paradigms from the cognitive science and machine learning literature offer a higher resolution to examine how young children actively learn and employ cognitive control processes. Here, active learning is defined as allowing learners to generate or make decisions about the information they want to experience trial by trial (Gureckis \& Markant, 2012). Trial-by-trial analyses of active information gathering can reveal meaningful variation in learning strategies. For example, Gureckis and Markant (2009) investigated adult learners' ability to gauge information value during an active search task similar to the children's game battleship. The authors found that participants' information generating behaviors took two forms: one relatively fast and undirected and another slower, more effortful, that exploited local information constraints. Moreover, response time and search efficiency differed across these "modes."

Benefits of active control during information gathering are that learners can ask targeted questions to avoid redundant examples or content too difficult, creating learning situations to
best fill their personal knowledge gaps (Gureckis \& Markant, 2012). Active control also supports learning by enhancing the encoding of episodic representations which increases the likelihood of retrieving information about the experienced stimuli from memory (Markant, Ruggeri, Gureckis, \& Xu, 2016). Adult learners can benefit from even subtle control over timing by coordinating the presentation of new information with their optimal attentional state so they are alert and ready to encode (Markant, DuBrow, Davachi, \& Gureckis, 2014). Moreover, active control during memorization is associated with increased coordination in the neural networks that support executive control, attention, and memory encoding (Markant et al., 2016).

A limitation to active learning is that benefits can vary based on learners' abilities and task demands. For example, learners may be biased when sampling data, creating an uninformative feedback loop. Markant (2016) manipulated the hypothesis generation process in a series of category learning tasks to assess the impact on adults' ability to learn simple and complex rules. Results showed successful active learning depended on a match between the target rule and salient perceptual and abstract features of the task stimuli, and poor learning was due to generation of hypotheses that followed a non-relevant rule. That is, adult participants benefited from active learning opportunities under complex task demands when they were able to shift their attention to relevant rules or dimensions while ignoring others-a central EF skill.

To our knowledge, no studies to date have examined the coordination of EF and attention in children during active learning. Moreover, very little is known about how individual differences in active learning relate to sampling strategies or school readiness. Identifying the mechanisms supporting successful active learning may inform both cognitive science theory and educational interventions to support school readiness. The current study addresses these research gaps by examining active learning in a large sample of low-income preschoolers using a multi-dimensional category learning task, as well as a well-validated battery of EF, attention, and school readiness measures.

## Method

## Participants

One hundred and one preschoolers $(M=61 \mathrm{~m}$; Range $=55-$ 67 m ; Male $=46$ ) were tested as part of a school readiness study run in collaboration with two Head Start preschool centers. Participants came from low-income backgrounds, with an average reported yearly income of $\$ 11,968$ (Range $=733-$ 34,486). The sample was predominantly African American ( $\mathrm{N}=86$ ).

Children were tested in their preschools by trained assessors using a touchscreen laptop. Administration of the tasks was divided over two testing days within a one week period. EF tasks were administered on day 1 , and the category learning task and school readiness assessment were administered on day 2.

Figure 1: Examples of 1D trials varying by size dimension.

## Category Task

Materials The category task (a modified version from Sim et al., 2015) was presented as a multi-slide questionnaire using the Qualtrics survey system. First, Block 1D presented two forests of trees that varied by one stimuli feature. The color row showed 10 images, identical in size and shape, but with varied leaf color, ranging from orange to green (left to right). The size row of 10 images were identical in color and shape, but progressed in size from smallest to largest (left to right). Block 2D presented a 7-by-6 grid of trees that varied horizontally by size (smallest on the left) and vertically by color (orange on top). In this task, worms and snails live in different groups of trees. The goal of the task is to classify trees based on the type of animal that lives there. Small worm and snail icons were displayed above exemplar trees in the sampling phase, and appeared as two larger button choices at the bottom of the screen in the test phase.
Procedure The 1D and 2D blocks each began with a demonstration phase, followed by two testing sequences which switched the dimension of categorization. In the 1D block, the first sequence featured the color row of stimuli and the second used the size row. In the 2D block, the first sequence was categorized by the size dimension and the second by color. Each sequence began with a 2 -trial sampling phase followed by a classification phase (4 1D trials, 82 D trials).
Block 1D Demonstration phase. To introduce the task, children were told to pretend they were scientists and figure out where two types of animals, worms and snails, liked to live. First, children were shown the the 1D color row. To demonstrate an example categorization of the trees, children were shown a small worm or snail icon above each and every tree (see Fig. 1). A red circle appeared around the group of trees with worms and another around the group with snails to em-
phasize that the animals were grouped separately. Children were asked to point to the category boundary, described as the "edge between the trees where the worms and the snails live." Once the child guessed, they were shown the boundary with a red arrow. This sequence was repeated with the 1D size row of trees and a new category boundary. Following the Sim et al. (2015) task design, these practice trials were meant to establish that (1) the animal icon above the tree indicated that the animal lived in that tree, (2) there was an invisible category boundary that divided the trees into two groups, and (3) the category boundary moved with each new forest.

Sampling phase. Children were first presented with the 1D color row of trees. In sampling trial 1, a worm and a snail icon appeared over 2 exemplar trees. The letters A, B, and C appeared under possible trees to sample. One sampling option was informative to find the category boundary, while the other two were non-informative because their category membership could be inferred by the position of the exemplars. By limiting learners to three sampling options, we increased our power to differentiate informative vs. uninformative sampling strategies over fewer trials, reducing noise and task demands for this very young sample.

To complete the sampling selection, the child was prompted, "Here's where a worm lives and here's where a snail lives. If you want to find the edge between the trees, would you want to learn about what lives in tree $\mathrm{A}, \mathrm{B}$, or C?" Once the child touched the sampling tree option of their choice, the selection was automatically logged in the Qualtrics database. Sampling trial 2 revealed the correct worm and snail icons above the three sampling tree options of the previous trial, and three new trees were shown as sampling options (see Fig. 1). Children selected a sampling option and the task advanced to the classification phase.

Classification phase. Children were presented with the 1D color row of trees without exemplars. At the bottom of the screen, a larger image of a worm and snail were shown vertically aligned. To reduce task demands, only 4 of the 10 trees were queried for classification. On each classification trial, the test trial number (1-4) appeared underneath one of the trees as a cue to guess the category membership of that tree. Children indicated their response by touching either the worm or snail response icon. Together, these responses demonstrated where each child believed the category boundary was generally located.

The sequence of sampling and classification phases was repeated for the 1 D size row of trees, with a new category boundary and locations for exemplars and test trials.
Block 2D To introduce the 2D block, children were shown the $6 \times 7$ grid of trees and instructed, "In big forests, you have to find out if the worms and snails live in groups based on the SIZE of the trees or the COLOR of the trees. They only care about the size OR color!" The demonstration phase was identical to that in the 1D block (see Fig. 2). Sampling and classification phases in 2D followed the same procedure as 1D. Children were not told whether color or size was the rel-

Figure 2: Examples of 2D trials with horizontal category boundary (classification trial not shown).
evant dimension for categorization.
The first 2D sequence had a category boundary determined by tree size, following a vertical axis. Sampling trial 1 featured 3 category exemplars and 4 sampling tree options. The location of the exemplars made categorization only possible by the vertical dimension (i.e. by size). One sampling option was informative to the vertical category boundary. The category membership of the three other non-informative options could be inferred by the locations of the exemplars. After 2 sampling trials, children completed 8 classification test items. The number of exemplars, sampling options, and classification trials were increased compared to the 1D block to include a variety of positions across the 2 D grid.

The second 2D sequence had a category boundary determined by tree color, following a horizontal axis (see Fig. 2). This dimensional switch (i.e., requiring attention to horizontal relations between exemplars to infer category boundary, not vertical as in past trials) is a feature of dimensional card sort games, classic EF tasks which require the participant to flexibility shift attention to the new relevant dimension and inhibit response to the old dimension.
Coding Selection trials were coded as correct if the child selected the option informative to finding the category boundary. Aggregate scores were computed for overall task accuracy and overall sampling and classification accuracy, and for sampling and classification accuracy on 1D vs. 2D blocks.

## EF, Attention, and School Readiness Tasks

Working Memory. Digit Span is a widely used executive function task that assesses children's working memory (WM). Children are instructed to repeat number sequences of sequentially longer length in forward and backward conditions. Children in this sample were largely unable to repeat sequences backwards, so only correct responses on the forward condition are reported here.

Attention and Inhibitory Control. In the Continuous Performance Test (CPT), one hundred pictures are randomly presented on a touch screen one at a time for 300 ms followed by blank response screen for 1500 ms . Children are instructed to touch the screen as soon as an animal appears. Stimuli in-
clude 20 presentations of the target stimuli (animals) and 80 presentations of nontarget stimuli (objects). We report reaction time on correct touches to targets, a measure of attention processing speed (APS). We reverse-coded percent of missed responses to targets (omission error) and incorrect touches to distractors (commission error) as indices of sustained attention (SA) and inhibitory control (IC), respectively.

Math and Pre-Literacy Skills. The Woodcock Johnson III Tests of Achievement (WJ-III) is a well-validated assessment of school readiness skills. The Applied Problems subtest assesses children's early mathematical reasoning. The Letter Word subtest requires children to identify letters and words to measure their pre-literacy skills. A sum of the total correct answers is computed for each subtest and then translated into a standardized W-Score.

## Results

## Sampling Performance

We first ask if preschoolers can strategically sample in a category learning task. In the 1D block, children are significantly above chance in accurately choosing the informative sampling option $(\mathrm{M}=.48$, chance $=.33 ; t(99)=4.06, p<0.001)$. Within the 1D block, mean sampling accuracy is not different for color $(\mathrm{M}=.45)$ and size $(\mathrm{M}=.51), t(99)=-1.37, \mathrm{p}=$ .18. Children also chose the informative sampling option in the 2 D block $(M=.35$, chance $=.25 ; t(98)=3.5, p=0.001)$. Within the 2D block, mean sampling accuracy is also not different for color $(\mathrm{M}=.33)$ and size $(\mathrm{M}=.37), t(99)=-1.07$, $\mathrm{p}=.29$. We find that sampling accuracy in 1 D is related to sampling accuracy in 2D, $r=.26, p=.01$.

Figure 3 shows participants' mean accuracy on sampling questions (left panel) and subsequent categorization questions (right panel) by stimulus dimension and dimension of the sampling space.

## Classification Performance

Overall, children are above chance in correctly classifying test items in 1D $(\mathrm{M}=.66$, chance $=.5 ; t(99)=6.3, \mathrm{p}<$ $0.001)$ but not in 2D $(\mathrm{M}=.51$, chance $=.5 ; t(98)=.97$, p $=.337$ ). Mean classification accuracy in the 1D block is significantly higher than mean classification accuracy in the 2D block $(t(97)=5.14, \mathrm{p}<.001)$. Within the 1D block, mean classification accuracy is significantly higher for color ( $\mathrm{M}=$ $.71)$ than for size $(\mathrm{M}=.63), t(99)=2.23, \mathrm{p}=.03$. Within the 2 D block, children are at chance on the size condition $(\mathrm{M}=.47$, chance $=.5 ; t(98)=-1.35, \mathrm{p}=.18)$ but interestingly above chance on the subsequent color condition, which includes a dimension switch on the category boundary ( $\mathrm{M}=$ .55 , chance $=.5 ; \mathrm{t}(98)=2.15, \mathrm{p}=.034)$. Mean classification accuracy is significantly higher for color in the 2 D block than for size $(t(98)=2.24, \mathrm{p}=.03)$. Note that effects of size vs. color dimensions should be interpreted with caution, as the blocks were presented in fixed order.

## Does Sampling Predict Classification?

We next ask if sampling accuracy benefits subsequent classification accuracy, as suggested in previous active category

Figure 3: Accuracy on sampling questions (left) and categorization test (right) for each relevant stimulus dimension (color/size) and dimensionality of the stimulus space. Dotted lines show chance (sampling chance: $1 \mathrm{D}=33 \%, 2 \mathrm{D}=25 \%$ ).
learning studies with both adults and school-age children. Surprisingly, sampling accuracy is not related to classification accuracy. Children who choose the most informative sampling strategy in 1D are not better at 1D classification, $r=.06, p=.58$, nor are 2D sampling and classification accuracy related, $r=-.03, p=.81$. Comparing classification accuracy on 1D of good samplers ( $M_{a c c}>.7$ ) vs. poor samplers $\left(M_{a c c}<.3\right)$ yielded no significant differences, $t(72.9)=.84$, $p=.41$, nor for good vs. poor samplers in $2 \mathrm{D}, t(35.7)=.2$, $p=.84$.

## Relations Between EF and Active Learning

We next examined the role of executive function and attention in predicting active learning performance using a series of exploratory logistic mixed-effects regression models to the item-level with subject as a random factor. Age, sex, EF, and attention measures were fixed predictors. Prior to analyses, we scaled and centered all variables. Table 1 presents descriptives of executive function, attention, and school readiness measures.

First, we predicted overall accuracy, including both sampling and classification trials $(\mathrm{N}=2,632 ; \mathrm{R}$ syntax: $\quad$ Correct $\sim$ age + sex $+W M+A P S+S A+$ IC $+(1 \mid$ Subject $)$ ). There was a significant positive effect for $\mathrm{WM}(\beta=.11, Z=2.11, p=.04)$, showing that participants with higher working memory perform better overall in the task. Next, we predicted accuracy on all sampling trials ( $\mathrm{N}=676$ ), adding overall classification accuracy as an additional fixed predictor (R syntax: Correct $\sim$ age + sex + WM + APS + SA + IC + class Acc + (1|Subject)). There was a significant positive effect

Table 1: Descriptives of Executive Function, Attention, and School Readiness Measures.

|  | Mean (SD) | Range |
| :--- | :---: | :--- |
| Digit Span (\% correct forward) | $44 \%(13)$ | $0-67 \%$ |
| CPT Omission Errors (\%) | $47 \%(28)$ | $0-100 \%$ |
| CPT Commission Errors (\%) | $12 \%(14)$ | $0-78 \%$ |
| CPT Reaction Time (ms) | $824(166)$ | $474-1364$ |
| WJ-III Applied Probs (W-Score) | $407(17)$ | $350-440$ |
| WJ-III Letter Word (W-Score) | $333(20)$ | $276-369$ |

for attention processing speed (APS) $(\beta=.38, Z=2.57$, $p=.01$ ), showing that participants with faster attention processing are more accurate at sampling. We then predicted accuracy on all classification trials $(\mathrm{N}=1956)$, substituting in overall sampling accuracy as an additional fixed predictor. There was a significant positive effect for WM ( $\beta=.12$, $Z=2.14, p=.03$ ), showing that participants with higher working memory are more accurate at classification.

We next ran the models by 1D and 2D blocks. Predicting 1D sampling ( $\mathrm{N}=339$ ) with 1D classification accuracy as the additional fixed predictor revealed no significant effects. For 1D classification trials ( $\mathrm{N}=598$ ) with 1D sampling accuracy as the additional fixed predictor, there was a surprising significant negative effect for sustained attention (SA) ( $\beta=-.37$, $Z=-1.98, p=.048$ ), such that children who were less responsive to targets during a sustained attention task had better classification accuracy in the 1D block.

Predicting to 2 D sampling ( $\mathrm{N}=337$ ) with 2 D classification as the additional fixed predictor also revealed a positive effect of attention processing speed ( $\beta=.357, Z=2.026$, $p=.043$ ). For 2D classification trials with 2D sampling accuracy as the additional fixed predictor, there was a significant effect of inhibitory control (IC) ( $\beta=.131, Z=2.087$, $p=.037$ ), showing that children who are better at inhibiting a prepotent response are more accurate at 2D classification.

## Predictors of School Readiness

How does active learning performance relate to school readiness? To examine this question, we use an exploratory linear mixed-effects model fit by REML (nlme package) at the subject level to predict to math and pre-literacy scores on the WJ-III assessment. First, we predict to math scores using subject as a random effect, and age, sex, EF, attention, and overall sampling and classification accuracy as fixed predictors ( R syntax: math $\sim$ age + sex $+\mathrm{WM}+\mathrm{APS}+\mathrm{SA}+\mathrm{IC}$ + class Acc + Sampling Acc, random= $\sim 1 \mid$ subject). We found significant positive effects for overall sampling accuracy $(t(77)=3.85, p<.001)$, and overall classification accuracy $(t(77)=2.64, p=.01)$, suggesting that children who are better at active learning in the category task are have better early math skills over and above the contributions of EF, attention, and demographics.

We ran the same exploratory linear mixed-effects model
to predict pre-literacy scores but did not find any relations between pre-literacy and sampling or classification accuracy. We modified the predictors, collapsing over sampling and classification trials to examine the effect of overall active learning performance. Here, we find that overall accuracy in the active learning task is a positive predictor of pre-literacy skills $(t(78)=2.03, p=.046)$.

## Discussion

We found that 5-year-olds from low-income backgrounds use an informative sampling strategy in an active category learning task. Preschoolers are able to accurately classify the category membership of test items in 1D, but show mixed performance in the 2D classification blocks. Sampling accuracy across dimensions hangs together: children who choose the most informative option in 1D are also better at sampling in 2D. However, children who are good at classification in 1D are not more likely to be good at classification in 2D. Contrary to past active learning studies, we do not find that better sampling accuracy benefits classification accuracy in either 1D or 2D blocks. However, individual differences in children's EF and attention skills shine a light on potential cognitive control processes that support success in active learning. We found that attention processing speed largely supports sampling accuracy and better working memory is linked to higher accuracy on classification. Notably, better inhibitory control supports classification accuracy when the categories are presented with a distractor dimension (2D).

Previous published work has found active learning benefits in categorization tasks for 7-year-olds (Sim et al., 2015), but little research has examined preschool-aged children. One concern was that younger children would struggle with the metacognitive organization needed to plan and follow an informative sampling strategy. Despite variability, our data show that many preschool children made queries that were informative to finding a category boundary.

It may be that categorization within a 2D space was especially difficult to navigate for children at this age, however we found that children had above chance classification accuracy within the 2D block after the dimensional rule switch from a vertical to horizontal category boundary. Although surprising, one possibility is that children became accustom to categorization within a 2D space over multiple trials, and thus increased accuracy was partially due to practice. A limitation to this study is that the task order was fixed, and thus size vs. color performance is confounded with practice effects. It is interesting to note that practice effects may be present in the 2D condition despite the added complexity of a categorization switch. Additional study is needed to understand how variation in boundary options and stimuli characteristics may affect children's active category learning.

Exploratory analyses examining the role of executive function and attention skills add nuance to understanding children's performance in this task. We found that attention processing speed supports children's sampling strategies. The link between attention processing and active learning benefits
is discussed in Markant et al. (2014), who found that learners benefit from even minimal control of timing during learning by matching the presentation of information to their optimal attentional state. It is possible that those children who were able to maintain a ready state of attention processing were better able to encode information about sampling parameters than those whose attention processing was slower.

We found that higher working memory supports both overall task accuracy and classification across 1D and 2D blocks. Working memory may help children to remember the relative locations of exemplars within the 1D and 2D spaces, which is necessary to infer both the category boundary and test items' class. Inhibitory control significantly predicts classification accuracy in the 2D block. Dimensional shifting requires the learner to inhibit a learned response or rule and attend to new information. To attend to the category boundary and correctly classify exemplars in a 2D space, this task requires children to determine how exemplars related to each other along the relevant dimension, while ignoring relations on the non-relevant dimension. These exploratory findings suggest that inhibitory control may help children attend to relevant features under complex learning demands.

The lack of relation between category learning sampling and classification is at odds with previous studies which found better sampling led to better performance in active learning (e.g., Ruggeri et al., 2016). In fact, our design was meant to decouple sampling performance from categorization performance: the category memberships of all sampling choices are revealed once the selection is made. Thus a child who makes a bad selection is not penalized-they see the exemplar of the informative choice as well as the uninformative choices. Because we were limited to a fixed task across all administrations, this design allowed us to make sure all children's sampling choices were revealed and that they all saw the same information about the boundary leading into the classification phase. Thus, this design removed the necessity of good sampling to support classification accuracy within the task. We found that children's memory skills, likely related to remembering the location of exemplars, appeared to play a more important role in classification accuracy.

Our results also suggest that children's performance in the active learning task is related to their early math and preliteracy skills. Both overall sampling and overall classification accuracy significantly predict math scores, above and beyond demographics, executive function, and attention skills. Overall active learning accuracy predicts pre-literacy skills. These exploratory findings suggest that trial-by-trial performance in a lab-based measure of active learning may be related to children's acquisition or implementation of academic knowledge. Children's development and use of learning processes and problem solving strategies may rely in part on cognitive control skills. The benefits of good active learning skills may cascade overtime to support children's acquisition and practice of domain-specific knowledge. Importantly, these correlational data are only the first step in investigat-
ing active learning in relation to school readiness and additional research should examine this potential link, as it could be highly informative to educational intervention efforts.

While most education and developmental researchers examine EF and learning by way of standardized school readiness tests, the current study's findings suggest that details of children's trial-by-trial learning decisions may reveal important details of how cognitive control skills support the acquisition of knowledge. We note several limitations to this study. First, the sample is low-income and the restricted range of socio-economic status (SES) may lower generalizability, although examining the relations between learning processes and school readiness is of particular importance for this population. We plan follow-up studies including a high income cohort to examine the relations between SES, cognitive control skills, and active learning. Second, this work is both correlational and uses concurrent measures. Our future studies include experimental active learning paradigms for young children that vary aspects of cognitive control processes to better tease apart the role of EF and attention on active learning.

#### Abstract

Computational models of cognitive development have been frequently used to model impairments found in developmental disorders but relatively rarely to simulate behavioural interventions to remediate these impairments. One area of controversy in practices of intervention is whether it is better to attempt to remediate an area of weakness or to build on the child's strengths. We present an artificial neural network model of productive vocabulary development simulating children with word-finding difficulties. We contrast an intervention to remediate weakness (additional practice on naming) with interventions to improve strengths (improving phonological and semantic knowledge). Remediating weakness served to propel the system more quickly along the same atypical trajectory, while improving strengths produced long-term increases in final vocabulary size. A combination yielded the best outcome. The model represents the first mechanistic demonstration of how interventions targeting strengths may serve to improve behavioural outcomes in developmental disorders. The observed effects in the model are in line with those observed empirically for children with word-finding difficulties.

Keywords: artificial neural networks; developmental disorders; intervention; vocabulary development; wordfinding difficulties

## Introduction

## Theories of deficits versus theories of intervention

In the field of developmental disorders, there are extensive theories about the causes of behavioural deficits. However, these have played a relatively small role in intervention practices. Indeed, theories of treatment have often developed relatively independently of theories of deficit (Laws et al., 2008; Michie \& Prestwich, 2010). The gap between a mechanistic understanding of the causes of deficits and everyday therapeutic practice exists for a number of reasons. Most obviously, the primary focus of intervention is on behavioural outcomes, which do not in themselves necessitate an understanding of underlying cause. In addition, there are diverse real-world constraints influencing the interventions that are selected. And it is
difficult to apply causal principles to the complex therapeutic situation involving treatment of the whole child via a social interaction with the therapist. Nevertheless, it remains an important ambition to narrow the gap between theories of deficit and practices of intervention.

## Improve strengths or remediate weaknesses?

One area of controversy in practices of intervention is whether it is better to attempt to remediate an area of weakness or to build on the child's strengths. For example, in the field of developmental language disorders, Leonard (2014) argues that generally, therapists prefer to work on developing compensatory strategies through targeting the child's strengths rather than trying to improve his or her area of weakness (see also Bishop, Nation \& Patterson, 2014).

To take a more specific case, where children have difficulties in producing words that they already know (so called word-finding difficulties; WFD), therapists may simply require the child to spend more time practicing naming, the area of weakness. Alternatively, they have the option of targeting children's knowledge of word sounds (phonology) or word meanings (semantics). Therapists have found that interventions that elaborate the semantic aspect of words (e.g., McGregor \& Leonard, 1989) or interventions that focus on the phonological component of word finding (e.g., Best, 2005) both alleviate WFD to some extent. In a survey, Best (2003) asked therapists what kind of difficulties they found most often co-occurring with WFD in the children they saw. Phonological problems were reported to co-occur $46 \%$ of the time, while semantic problems cooccurred only $13 \%$ of the time. Nevertheless, when asked which types of intervention they most often used, therapists reported more often using techniques to improve semantic knowledge than phonology ( $79 \%$ of the time compared to $54 \%$ ). In this case, then, therapists frequently sought to buttress areas of strength to improve naming skills.

One explanation for the tendency of therapists to work less on areas of weakness and more often on areas of strength is to improve the child's confidence in a domain
where he or she is struggling. However, from a theoretical perspective, one might ask through what mechanisms could improving a strength serve to remediate a behavioural impairment in a developing cognitive system?

There are at least three ways that improving a strength could remediate a behavioural impairment. First, the 'strength' could represent an alternative cognitive system or pathway to deliver a similar behavioural outcome. Improving a strength then translates to encouraging a compensatory strategy. Second, the target behavior may be delivered by an interactive system in which multiple sources of knowledge combine to drive behavior. Stronger input from one source might then make up for weaker input from another. Third, the target behavior may require mappings to be learned between representations. Improving the structure of the representations might serve to make learning those mappings easier. In this article, we use computational modeling to investigate the third of these options.

## Computational modeling of interventions

Computational modeling, particularly the use of artificial neural networks, has been extensively applied to understanding the mechanisms underlying developmental deficits, in disorders such as dyslexia, Specific Language Impairment, and autism (Thomas \& Karmiloff-Smith, 2002). Relatively few models of developmental deficits have been extended to the simulation of behavioural interventions to remediate these deficits, and the framework for doing so has only recently been laid out (Thomas et al., 2017). Two notable exceptions are Harm, McCandliss and Seidenberg's (2003) simulation of an intervention for dyslexia, and Best et al.'s (2015) model of interventions for productive vocabulary deficits. In both cases, a typical model established the developmental trajectory under normal circumstances; an atypical model was created in which a computational constraint limited development; and a behavioural intervention was simulated by adding further input-output mappings to the model's training set for a discrete period, usually relatively early during training. Here, we adapt Best et al.'s model of vocabulary development to contrast the effects of improving strengths versus remediating weaknesses.

## Connectionist models of vocabulary development

Sentence production involves a sequence beginning with a planned message, followed by selection of major lexical concepts, assigning syntactic functions, assembling phonologically realized words and morphemes into a sentence frame, and programming articulatory processes (e.g., Bock \& Levelt, 1994). Connectionist models of word production have tended to focus on the step involving the retrieval of phonological forms given a semantic specification of the desired lexical item (e.g., Dell, Schwartz, Martin, Saffran, \& Gagnon, 1997). Developmental models have simulated the learning of mappings between pre-specified semantic and phonological codes (e.g., Plunkett et al., 1992), or between semantic and
phonological representations emerging in self-organizing maps (e.g., Li, Zhao \& MacWhinney, 2007; Mayor \& Plunkett, 2010). Best et al. (2015) used a similar approach, but implemented the semantic and phonological components of the model via 3-layer autoassociator networks trained using backpropagation (Rumelhart, Hinton \& Williams, 1986). The hidden unit representations of the semantic component were then mapped to the hidden units of the phonological component, via an intermediate layer of hidden units, to provide a pathway for the development of naming. A reverse pathway simulated comprehension. Naming behavior began to emerge while the semantic and phonological representations were themselves still developing. By restricting learning in the semantic component, the phonological component, or the pathway between them (for example, by reducing hidden unit numbers or the learning rate), Best et al. were able to capture various patterns of atypical naming development observed in a sample of children with WFD.

## Simulations

## Simulation design

Using the same architecture, we followed the Best et al. (2015) model in simulating productive vocabulary development in children with WFD by restricting the computational capacity of the pathway mapping between semantic and phonological representations. The semantic and phonological components themselves developed typically. Early in development - when slow vocabulary growth was already detectable - a behavioural intervention was applied for a limited period during training. Five different interventions were contrasted, of three types: (1) remediating the weakness - the model was provided with additional training on the naming pathway; (2) improve the strength - the model was provided with additional training to improve the semantic representations, the phonological representations, or both at once; (3) both types 1 and 2 were combined into an intervention that sought to simultaneously improve strength and remediate weakness. We observed the immediate effect of intervention, in terms of potentially accelerated vocabulary growth, and the eventual outcome, in terms of the largest vocabulary size achieved following each type of intervention.

The original Best et al. (2015) model used a fairly abstract rendition of semantics and phonology and a training set of only 100 items. Here, we used more realistic semantic and phonological representations, and scaled up the training set slightly to around 400 items. The typically developing model was designed in such a way that it reflected salient properties of vocabulary growth, including a comprehension-production asymmetry (Bloom, 1973) and a vocabulary explosion / exponential growth in vocabulary size (e.g., McMurray, 2014).

The model contained three assumptions not in the Best et al. (2015) model. First, phonological representations were required to be more accurate than semantic outputs to drive
a behavioural response, under the assumption that phonological output needs to drive motor assemblies, while semantic comprehension only requires that the output fall in the correct attractor basin (Hinton \& Shallice, 1991). This assumption generated the production-comprehension asymmetry.

Second, we implemented a sensitive period in the development of the components but not the pathways in the model, through pruning of network connectivity after a given point in development. This created the potential for early training to create enriched lower level representations by utilizing the then-available rich connectivity. Pathways did not experience this pruning, under the view that sensitive periods are characteristic of lower but not higher cognitive systems (Takesian \& Hensch, 2013). The effect of timing of intervention was subsequently evaluated.

Third, plasticity was set higher in the pathways than the components (via the learning rate parameter), so that the development of semantic and phonological representations would be the limiting factor on the development of naming. If the semantic and phonological representations were to quickly reach ceiling before naming had developed, interventions targeting phonology and semantics would have no scope to improve naming performance. The effects of both the second and third assumptions were evaluated by also running the model in their absence.

Finally, we explored whether the five types of intervention would enhance performance in a typically developing model, or whether they only had the potential to improve performance in systems exhibiting delayed development.

## Simulation details

Architecture: The architecture of the vocabulary development model is shown in Figure 1. It comprised four linked backpropagation networks. The semantics component comprised a 3-layer autoassociator with 1029 input and output units and 45 hidden units. The phonology component was an autoassociator with 456 input and output units and 60 hidden units. The naming pathway linked the semantic hidden units with the phonological hidden units via an intermediate layer of 175 units. Naming constituted activating semantic inputs and measuring phonological outputs. The comprehension pathway ran in the other direction and also contained 175 units. In the atypical model, the number of hidden units in the naming pathway was reduced to 90 prior to training.

Additional parameters: The learning rate in the semantic component was .015 and in the phonological component was .025 . In the pathways, the learning rate was .15 . Sigmoid activation functions had a temperature of 1.5 in the components and 1 in the pathways. In the components, after epoch 75, any connection weights with an absolute magnitude of less than .5 had a $5 \%$ chance of being permanently removed each epoch. Initial weights were given random values via a Gaussian distribution with mean 0 and standard deviation 0.5 . Gaussian noise with a standard
deviation of .15 was added to the net input of units in the components, and noise with a standard deviation of .05 in the pathways, to provide a stochastic basis for naming errors in normal functioning. Continuous activation values on the phonological output were converted to responses by finding the nearest legal phoneme in each slot and assessing whether the full phoneme string was the correct name. If the average root mean square error between the activation vector for each phoneme and the nearest legal phoneme code exceeded 0.03 , that phoneme was coded as no response. A nearest neighbor technique was also used to assess the accuracy of semantic outputs. These parameters were selected to calibrate the typical model.

Figure 1: Architecture of the productive vocabulary model, with phonological and semantic components and linking pathways

Training set: The training set comprised 397 words, each with a phonological and a semantic representation. It was generated by combining two sources, a set of 1029 speaker generated semantic feature norms for 456 words collected by Vinson and Vigliocco (2008) from 280 adults; and the Children's Printed Word Database (Masterson et al., 2010), which is an online database of the vocabulary in reading materials used by 5-9 year old children in the UK. The 397 words represent those present in both resources. The semantic representations comprised the 1029 feature set, where a feature was set to 1 if any adult rated it as a characteristic of a given word meaning, and 0 otherwise. The phonological representations used a 19-bit articulatory code for phonemes (Thomas \& Karmiloff-Smith, 2003) and a left-justified slot-based CCCVVCCC syllabic scheme to capture words up to three syllables in length, with $3 \times 8 \times 19=$ 456 phonological features in total.

Training schedule: Networks were trained for 1000 epochs, with random presentation and pattern update. Training of autoassociators and pathways was interleaved. Weights were updated using the backpropagation algorithm with the cross entropy error measure.

Simulation of interventions: For atypical networks, an intervention began at 100 epochs of training and lasted for 100 epochs. For the main condition, at this point TD models had acquired a productive vocabulary size of 67 words, while atypical models had a vocabulary size of 36 words.

For the intervention, one or more components or pathways were trained with 5 times the frequency of the rest of the system. The extra training could be on the semanticsphonology naming pathway, the semantics component alone, the phonological component alone, both semantics and phonological components, or all of these combined.

Conditions: To test the importance of timing, interventions were compared at 100,250 and 750 epochs. To test the effect of plasticity assumptions in the model, the first variant removed connectivity pruning from the components. The second variant removed the higher plasticity of the pathways, setting their value to .025 .

Replications: All conditions were replicated three times with different random seeds. The full design took approximately 100 days of simulation time. Results graphs are shown averaged over replications; individual data are included in the following tables.

## Results

Figure 2 displays developmental trajectories for naming and comprehension in the typical and atypical models. For the typical model, naming lagged behind comprehension, exhibiting the expected comprehension-production asymmetry. Naming itself showed an accelerating rate of development, consistent with a vocabulary explosion. The atypical model with WFD exhibited delayed development in naming but not comprehension (the slightly better comprehension was just a chance difference).

Figure 2: Development of naming and comprehension in the typical and atypical models. The dotting line depicts the point at which the intervention was applied

Figure 3 shows the effects of the intervention to remediate weakness, with extra training on the naming pathway, compared to the impaired model without treatment. The intervention produced accelerated development, but there was no gain in final productive vocabulary level. Figure 4 shows the result of improving strengths - extra training on the otherwise typically developing semantic and phonological representations, which are respectively the inputs and outputs of the naming pathway. These interventions produced slower effects during the intervention itself, but led to long-term (if relatively modest) increases in final productive vocabulary levels. Figure 3 also
contains the combined strength-and-weakness intervention. The combined intervention showed the initial immediate gains of the remediation intervention as well as the longterm elevated final level of the strengths intervention. Figure 5 includes the effects of these interventions on typically developing models. Extra practice in naming accelerated development but did not raise the final level. Extra elaboration of semantic and phonological representations by contrast increased the final productive vocabulary size even for the typically developing networks.

Tables 1 and 2 show the final level performance, split by replication, contrasting the intervention targeting weakness (Naming), the intervention targeting strengths ( $\mathrm{S}+\mathrm{P}$ ), and the intervention targeting both strengths and weaknesses (Both). Table 1(a) contains the data for the above base condition; 1 (b) demonstrates that when plasticity reductions in the components were removed as a model assumption, the same pattern of results held. Table 1(c) shows that without the assumption of greater plasticity in the pathways, the same pattern also held. Table 2 contrasts the effect of interventions at different points in training. The strengths intervention ( $\mathrm{S}+\mathrm{P}$ ) diminished in size and disappeared the later in development it was applied. The weakness intervention (Naming) showed the opposite pattern, increasing in size the later it was applied. The combined (Both) showed a uniform effect across development. Within each condition, the three replications demonstrated a common profile.

## Discussion

We used an artificial neural network model of impaired vocabulary development to explore the relative merits of a behavioural intervention to remediate weakness versus one to improve strengths. The two interventions yielded contrasting patterns. The intervention to remediate the weakness - more practice on naming itself - produced an
immediate improvement in naming accuracy, but did not raise the ceiling vocabulary size that could be attained by the model. Intervention had served to propel the model more quickly along the same atypical trajectory. This is because the (lower) ceiling level of performance was constrained by the reduced computational capacity of the naming pathway. By contrast, either improving the semantics representations or the phonological representations - which were otherwise developing typically - produced slower changes during the intervention period, but then long-term gains in the size of the productive vocabulary that the model could acquire. Improving both semantic and phonological representations together gave the largest gains. These gains occurred because semantic and phonological representations became more delineated (or less confusable) through additional training, so that a pathway with limited capacity could achieve higher accuracy. Combining intervention on weakness and strengths gave both immediate gains during intervention and a long-term improvement in the vocabulary size that could be attained.

|  |  |  |  |  |  |
| Avg | $86 \%$ | $51 \%$ | $55 \%$ | $55 \%$ | $54 \%$ |

We included assumptions about plasticity in the model that there would be sensitive periods in the components but not pathways, that the lower plasticity of the components would be the limiting factor on naming development - but neither proved essential for producing the above effect. We also altered the timing of intervention, and here showed that improving strengths yielded greatest gains early in development, while remediating weaknesses yielded the
greatest gains late in development. Combining both produced a uniform effect across development.

This model represents the first mechanistic demonstration of how working on strengths may serve to improve behavioural outcomes in developmental disorders. The observed effects of improving semantic and phonological representations are in line with those observed empirically for children with WFD (Best, 2005; McGregor \& Leonard, 1989). Two further methods by which improving strengths might improve behavioural outcomes remain to be explored: encouraging compensatory mechanisms through intervention, and bolstering convergent sources of information in interactive systems.

The model nevertheless demonstrated relatively modest accuracy gains through intervention - certainly there was no elimination of the deficit (it was reduced from $35 \%$ to $29 \%$ ). This is in line with general arguments made by Thomas et al. (2017): with some exceptions, where deficits arise through neurocomputational constraints in developing systems, behavioural interventions alone are unlikely to be successful in fully alleviating deficits. The conditions of optimal outcome are, however, a fruitful avenue for computational investigations, in the wider context of narrowing the gap between mechanistic theories of deficit and clinical practices of intervention.

# A Bayesian Model of Memory for Text 

Mark Andrews (mark.andrews@ntu.ac.uk)

Department of Psychology, Nottingham Trent University
Nottingham, NG1 4FQ, UK

#### Abstract

The study of memory for texts has had an long tradition of research in psychology. According to most general accounts of text memory, the recognition or recall of items in a text is based on querying a memory representation that is built up on the basis of background knowledge. The objective of this paper is to describe and thoroughly test a Bayesian model of this general account. In particular, we develop a model that describes how we use our background knowledge to form memories as a process of Bayesian inference of the statistical patterns that are inherent in a text, followed by posterior predictive inference of the words that are typical of those inferred patterns. This provides us with precise predictions about what words will be remembered, whether veridically or erroneously, from any given text. We then test these predictions using data from a memory experiment using a relatively large sample of randomly chosen texts from a representative corpus of British English.

Keywords: Bayesian models; Memory; Reconstructive memory; Text memory;

## Introduction

The seminal study on memory for text ${ }^{1}$ is usually attributed to Bartlett (1932). In this now classic work, Bartlett argued that a person's memory for what they read is based on a reconstruction of the information in the text that is strongly dependent on their background knowledge and experiences. From this seminal work, but especially since the widespread adoption of schema based accounts of text memory beginning in the 1970's (e.g., Mandler \& Johnson, 1977; Schank \& Abelson, 1977; Bower, Black, \& Turner, 1979), there has been something close to a consensus on the broad or general characteristics of human text memory. According to this general account - which we can summarize by the following schematic:

- the recognition or recall of items in a text is based on querying a representation of the text that is built up on the basis of background knowledge and experience.

Although some variant of this general account is widely held, it is essentially an informal and untestable theory. Certainly, there has been ample evidence showing that we use our background knowledge to make inferences and associations concerning text content and that these inferences then influence our memory (e.g. Bransford, Barclay, \& Franks,

[^8]1972; Graesser, Singer, \& Trabasso, 1994; Zwaan \& Radvansky, 1998; Rawson \& Kintsch, 2002, to name but a few). However, in most studies, even fundamental concepts such as memory schemas are not formally defined (see, e.g. Ghosh \& Gilboa, 2014), and ostensibly formal models of knowledge influences on text representation, such as the well known work of Kintsch (1988), often require hand-coding of background knowledge and text structures and can only be applied to small and contrived examples. Consequently, there is no formal or computational account of how background knowledge is used to infer a representation of text content and how memories are then derived from this representation that is sufficiently precise to lead to testable empirical predictions.

In this paper, following general principles followed by Hemmer and Steyvers (2009a, 2009b, 2009c) in their studies on memory for visual objects and natural scenes, we describe a probabilistic model that uses Bayesian inference to infer a representation of a text's content on the basis of background knowledge and then uses posterior predictive inference to represent the memories of that text. This provides us with precise predictions about what words will be remembered, whether veridically or erroneously, from any given text. We then test these predictions using data from a memory experiment using a relatively large sample of randomly chosen texts from a representative corpus of British English.

## Probabilistic Model

We begin with the assumption that our background knowledge that is relevant for our memory of text is primarily knowledge of the statistical patterns across spoken and written language. Given any probabilistic language model that specifies these statistical patterns, as we explain below, we may then use Bayes's rule to infer which patterns are inherent in any given text. From this, we may then predict, via posterior predictive inference, which words are and are not typical or compatible with the inferred statistical representation of the text. This effectively serves as the memory of the content of the text. As such, this provides a computational description of the previous schematic, i.e.,

In practical terms, we have many options for our choice of probabilistic language model. However, probabilistic topic
models (see, e.g. Griffiths, Steyvers, \& Tenenbaum, 2007; Steyvers \& Griffiths, 2007; Blei, 2012) have proved highly effective in capturing the statistical patterns that characterize the coarse-grained "discourse topics" across spoken and written language. Here, we use a type of probabilistic topic model known as a hierarchical Dirichlet process mixture model (HDPMM) (Teh, Jordan, Beal, \& Blei, 2006).

A HDPMM is a probabilistic generative model of bag-ofwords ${ }^{2}$ language data. It treats a corpus of language data as a set of $J$ texts $w_{1}, w_{2} \ldots w_{j} \ldots w_{J}$, where text $j$, i.e., $w_{j}$, is a set of $n_{j}$ words from a finite vocabulary, represented simply by the $V$ integers $\{1,2 \ldots V\}$. From this, we have each $w_{j}$ defined as $w_{j}=w_{j 1}, w_{j 2} \ldots w_{j i} \ldots w_{j n_{j}}$, with each $w_{j i} \in\{1 \ldots V\}$. As a generative model of this corpus, the HDPMM treats each observed word $w_{j i}$ as a sample from one of an underlying set of component distributions, $\phi_{1}, \phi_{2} \ldots \phi_{k} \ldots$, where each $\phi_{k}$ is a probability distribution over $\{1 \ldots V\}$. Each $\phi_{k}$ effectively identifies a "discourse topic". For example, here is a sample of 6 topics from an inferred model, where we show the 7 most probable words in each topic:

| theatre | music | league | prison | rate | pub |
| :---: | :---: | :---: | :---: | :---: | :---: |
| stage | band | cup | years | cent | guinness |
| arts | rock | season | sentence | inflation | beer |
| play | song | team | jail | recession | drink |
| dance | record | game | home | recovery | bar |
| opera | pop | match | prisoner | economy | drinking |
| cast | dance | division | serving | cut | alcohol |

The identity of the particular topic distribution from which $w_{j i}$ is drawn is determined by the value of a discrete latent variable $x_{j i} \in\{1,2 \ldots k \ldots\}$ that corresponds to $w_{j i}$. The probability distribution over the possible values of each $x_{j i}$ is given by a categorical distribution $\pi_{j}$, i.e., $\pi_{j}=\pi_{j 1}, \pi_{j 2} \ldots \pi_{j k} \ldots$, where $0 \leq \pi_{j k} \leq 1$ and $\sum_{k=1}^{\infty} \pi_{j k}=1$, that is specific to text $j$. Each $\pi_{j}$ is assumed to be drawn from a Dirichlet process prior whose base distribution, $m$, is a categorical distribution over the positive integers and whose scalar concentration parameter is $a$. The $m$ base distribution is assumed to be drawn from a stick breaking distribution with a parameter $\gamma$. As such, the generative model of the corpus is as follows:

$$
\begin{array}{lll}
w_{j i} \mid x_{j i}, \phi \sim \operatorname{dcat}\left(\phi_{x_{j i}}\right), & x_{j i} \mid \pi_{j} \sim \operatorname{dcat}\left(\pi_{j}\right), \quad i \in 1 \ldots n_{j} \\
& \pi_{j} \mid a, m \sim \operatorname{ddp}(a, m), \quad j \in 1 \ldots J \\
& m \mid \gamma \sim \operatorname{dstick}(\gamma),
\end{array}
$$

where dcat is a categorical probability distribution, ddp is a Dirichlet process, and dstick is a stick breaking distribution. The prior on the component distributions $\phi_{1} \ldots \phi_{k} \ldots$ was a Dirichlet distribution with concentration parameter $b$ and length $V$ location parameter $\psi$.

Having inferred a HDPMM on the basis of a corpus of language data $\mathcal{D}$, given any new text, $w_{j^{\prime}}$, we can use Bayes's rule to infer the posterior probability over $\pi_{j^{\prime}}$, which is the probability distribution over the discourse topics in $w_{j^{\prime}}$ :

$$
\mathrm{P}\left(\pi_{j^{\prime}} \mid w_{j^{\prime}}, \mathcal{D}\right) \propto \mathrm{P}\left(w_{j^{\prime}} \mid \pi_{j^{\prime}}, \mathcal{D}\right) \mathrm{P}\left(\pi_{j^{\prime}} \mid \mathcal{D}\right)
$$

[^9]We may then use the posterior predictive distribution to infer the words that are typical of the topics inherent in $w_{j^{\prime}}$. The predicted probability of word $w_{j^{\prime} i^{\prime}}$ given text $w_{j^{\prime}}$ is given by

$$
\mathrm{P}\left(w_{j^{\prime} i^{\prime}} \mid w_{j^{\prime}}, \mathcal{D}\right)=\int \mathrm{P}\left(w_{j^{\prime} i^{\prime}} \mid \pi_{j^{\prime}}, \mathcal{D}\right) \mathrm{P}\left(\pi_{j^{\prime}} \mid w_{j^{\prime}}, \mathcal{D}\right) d \pi_{j^{\prime}}
$$

Corpus As our language corpus, we used the British National Corpus (BNC) (BNC Consortium, 2007). From the entire BNC, we extracted all sections that were tagged as paragraphs. This gave us a corpus with a total word count of $87,564,696$ words. From this, we created a set of 184,271 texts, each between 250 and 500 words long. These were created by using either single paragraphs in this count range, or concatenating consecutive paragraphs until they were within this range. The total word count of this set of texts was $78,723,408$ words. We then restricted the word types by excluding words that occurred less than 5 times in total, and any words on either of two lists of stopwords, and any words that were not listed in a dictionary of $\approx 60 \mathrm{~K}$ English words. This lead to a final vocabulary of 49,328 word types. For more information, see Footnote ${ }^{3}$.

Inference We used a Gibbs sampler to infer the posterior distribution over the values of latent variables, i.e., $\left\{x_{j i}: j \in\right.$ $\left.1 \ldots J, i \in 1 \ldots n_{j}\right\}$, as well as the hyper-parameters $m, a, b, \psi$, and $\gamma$. For more information, see Footnote ${ }^{4}$

Prediction From the entire set of paragraphs in the BNC, we randomly sampled 50 paragraphs whose length was $150 \pm 10$ words, where at least $90 \%$ of the words are in the aforementioned dictionary of English words, and where at least 75\% of the words were in a set of words for which word association norms exists (see the following section for more details on the word association norms we used). For more information, see Footnote ${ }^{5}$.

For each of the 50 sampled texts, we then used posterior predictive inference, as described above, to obtain the probability distribution over words that are typical or compatible with the topic based representation of each text. As explained above, this distribution effectively provides the inferred model's memory of the content of the text. A Gibbs sampler was used to infer each text's posterior distribution over $\pi$, which is the probability distribution over discourse topics in that text. Two example texts and their posterior predictive inferences are shown in Figure 1. For more information, see Footnote ${ }^{6}$.

[^10]Improve your mood and counteract stress: Ask anyone who exercises regularly and they will tell you that they always feel exhilarated at the end of a session even if they had begun by feeling that they were not in the mood for exercise and had almost forced themselves to continue. Physical fitness also provides considerable protection against stress and the illnesses it can cause. So, however busy your life, perhaps you could try and fit some regular exercise into your day. Let it be something which is in complete contrast to the way you normally spend your time. One word of warning though: if you are someone whose daily life involves a strong competitive element, you would do well to avoid too much in the way of competitive sport (squash, tennis and so on) as your form of exercise as these will only tend to maintain an already high level of stress. routine walk $_{\text {swinming }}$ fit training weight aerobics health yoga anxiety programme rest session fitness increase life running week jogging rate level
 ${ }_{\text {begin }}$ muscles ${ }_{g y m}$ minutes mood heart strength body muscle physical day time

Developmental norms are an attempt to provide an indication of the ages at which one might expect ordinary children to show evidence of certain skills or abilities. Since children vary with respect to the ages at which they demonstrate any particular behaviour, norms represent an average obtained from an examination of the developmental changes occurring in a large number of children. Data from a large sample will show the earliest age at which a child would be expected to gain control of a particular aspect of language, and the age by which 90 per cent or 95 per cent of non-handicapped children might be expected to show evidence of the same ability. If children who have already been diagnosed as suffering from some specific handicapping condition are included, the data will show the expected age delay before this group matches the performance of the normally developing children.

Figure 1: An example of two of the texts used in the memory experiment, and samples from the HDPMM's posterior prediction for each one. The predicted words are scaled as a function of their predicted probability, and we show the 50 most highly predicted words (excluding stopwords and words not in the vocabulary) for each text. Words in italics are predicted words that were not in the text itself. These, in effect, are the model's false memories.

## Comparison models

The focus of our analysis is whether the probability of recognizing or recalling any given word having read a particular text is predicted by our HDPMM's posterior predictive distribution over words for that text. To properly evaluate the model's predictions, it is necessary to compare them to those of other plausible models. Here, we will compare the Bayesian model to predictions made by two associative models. Both of these models predict that the words that are remembered from a text are those that are most associated, on average, with the text's content. Associative models are strong models to compare to the Bayesian model because associative strength has been repeatedly shown to a strong predictor of memory for words in word lists (e.g., Roediger, Watson, McDermott, \& Gallo, 2001; Gallo, 2006).

The statistical co-occurrence probability of two words, $w_{k}$ and $w_{l}$, which we will denote $\mathrm{P}_{\mathrm{C}}\left(w_{k}, w_{l}\right)$, is defined as the empirical probability of observing word $w_{k}$ and $w_{l}$ in the same text ${ }^{7}$ in the language. Here, we calculate $\mathrm{P}_{\mathrm{C}}\left(w_{k}, w_{l}\right)$ using

[^11]the same BNC corpus as was used above, i.e. with the same 184,271 texts each between 250 and 500 words. From this, we can calculate
$$
\mathrm{P}_{\mathrm{C}}\left(w_{k} \mid w_{l}\right)=\frac{\mathrm{P}_{\mathrm{c}}\left(w_{k}, w_{l}\right)}{\mathrm{P}_{\mathrm{C}}\left(w_{l}\right)}
$$
which is the conditional probability of observing $w_{k}$ in any text given that $w_{l}$ has been observed. From this, if text ${ }_{j}=$ $w_{j 1}, w_{j 2} \ldots w_{j n_{j}}$, the predicted association probability of word $w_{k}$ according to text ${ }_{j}$ is
$$
\mathrm{P}_{\mathrm{C}}\left(w_{k} \mid \operatorname{text}_{j}\right)=\frac{1}{n_{j}} \sum_{i=1}^{n_{j}} \mathrm{P}_{\mathrm{C}}\left(w_{k} \mid w_{j i}\right)
$$

We can interpret this value intuitively as the average association between $w_{k}$ and text ${ }_{j}$, with association defined in terms of statistical co-occurrences in the language.

An alternative means to calculate the average association between $w_{k}$ and text ${ }_{j}$ is using word association norms, rather

[^12]than statistical co-occurrences. If $A_{k l}$ is the frequency that word $w_{k}$ is stated as associated with word $w_{l}$, then the conditional probability of word $w_{k}$ given $w_{l}$ is
$$
\mathrm{P}_{\mathrm{A}}\left(w_{k} \mid w_{l}\right)=\frac{A_{k l}}{\sum_{i=1}^{V} A_{i l}},
$$
where $V$ is the total number of words in our vocabulary of response words. Now, given text ${ }_{j}=w_{j 1}, w_{j 2} \ldots w_{j n_{j}}$, we can calculate
$$
\mathrm{P}_{\mathrm{A}}\left(w_{k} \mid \operatorname{text}_{j}\right)=\frac{1}{n_{j}} \sum_{i=1}^{n_{j}} \mathrm{P}_{\mathrm{A}}\left(w_{k} \mid w_{j i}\right)
$$
which we can interpret as the average association between $w_{k}$ and text ${ }_{j}$, with association now defined in terms of word association norms rather than statistical co-occurrences. Though a large set of English word association norms are available from the widely used Nelson norms (Nelson, McEvoy, \& Schreiber, 2004), we used an even larger set that is a prerelease of the English small world of words association norms (De Deyne \& Storms, 2017). This provided word associates, produced by 101,119 participants, to 10,050 word types. For more information, see Footnote ${ }^{8}$.

## Experiment

Our aim in this experiment is to measure participants' memory of the 50 sampled texts described in the previous section. Participants read these texts at their normal reading speed and then their memory for what they have read is tested using both recall and recognition tasks. We will then compare the pattern of results from our participants with the predictions of the models.

## Methods

Participants 216 people ( 113 female, 103 male) participated in the experiment. The ages ranged from 17 to 78 years, with a median of 34 years. Participants were recruited from the student and general populations, with the only restriction being that they be native English speakers.
Design Pre-experiment sample size determination calculations showed that, given the reasonable assumptions of both inter-text and inter-subject variability in memory performance, a relatively large number of texts and participants was necessary. In particular, we showed that there is a high probability of detecting effects, even when these effects are relatively weak, if we have at least 50 texts and at least 150 subjects are used. Importantly, these results hold even when each subject sees only a small subset of total number of texts, and this subset can be as low as 3 texts per each participant. We therefore used all 50 texts described above, and initially aimed for approximately 200 participants, with each participant being tested with a randomly sample of 3 texts.

[^13]Materials The texts used as stimuli for this experiment were the above mentioned 50 texts.

For the recognition tasks, test word lists with 20 words each were created. Of the 20 words in each list, 10 were present in the to-be-memorized text, while the remaining 10 were not present in it. For each text, the list was created as follows. Key words were extracted from each text and also from the surrounding paragraphs to that text in the BNC. This was done by calculating the tfidf (term frequency, inverse document frequency) value for each word, and then applying a threshold to exclude the less informative words. 10 words were then randomly selected from the key words of each text. A further 10 words were randomly sampled from the key words of the surrounding paragraphs excluding any words the in the main text itself. This set of 10 words were therefore not present in the text to be memorized, but given that they were selected from surrounding paragraphs, they were likely to be meaningfully related to it. As such, they would serve a useful items on the recognition memory test as they could not easily be dismissed without a proper search of memory. For more information, see Footnote ${ }^{9}$.

Figure 2: The task diagram of one block in the experiment: Participants read a randomly assigned text, perform a filler task, and then have their memory tested using either a recognition or recall test, with the test type being randomly chosen. This process is repeated three times for each participant.

Procedure Each experiment session proceeded as follows (see also Figure 2):

- After initial information and instructions, which informed participants that they would be engaging in memory tasks, one of the sample texts appeared on screen. Participants were instructed to read this text at their normal reading. The text stayed on screen for a maximum of 90 seconds,

[^14]but after 45 seconds, participants were able to move on the next screen if they so wished.

- On the following screen participants were asked to play the computer game Tetris for exactly 60 seconds.
- At the completion of the game, participants proceeded to the memory task. For each participant and for each text, the memory test was randomly chosen to be either a recognition or a recall task.
- For the recognition test, the 20 test items were presented on screen, one word at a time, with an inter-stimulusinterval of 2 seconds. They remained on screen for 5 seconds or until the subject indicated with a button press whether the word shown was present or absent from the text. No feedback was given after each response.
- If the participant was assigned to the recall test, a screen of a list of small empty text boxes was presented where and they were asked to type as many words as they could remember, one word into each text box. Initially, 10 empty texts boxes were presented, and more boxes could be added with a button press.
- Upon completion of the memory test, participants were given the option of pausing or proceeding to the next test. Each participant performed three tests in total, with the three texts to which they were assigned being always randomly sampled from the set of 50 texts.
The experiments were presented using the Wilhelm ${ }^{10}$ webbrowser based experiment presentation software that was hosted at https://www.cognitionexperiments.org. This software allowed the experiment to be done any web-browser based device, e.g., phones, tablets, laptops and desktops.

## Results

For more information about the results, see Footnote ${ }^{11}$.
Descriptives In the recognition memory tests trials, the overall accuracy rate was $76 \%$. Overall, the false positive rate, i.e. where participants responded "present" to words that were not present in the text they read, was $27 \%$. The false negative rate, i.e. where participants responded "absent" to words that actually were present in the text, was $22 \%$. For the recall tests, the median number of recalled words per each test was 7 , with between 2 and 15 words recalled in $95 \%$ of tests. The overall accuracy of recall was $70 \%$, and thus there was an overall false recall rate of $30 \%$.

Model evaluation For the recognition memory data, we model how well each model predicts the behavioural results using a random effects logistic regression model. In other words, for each of the models being evaluated, we fit the

[^15]recognition memory data using the same random effects logistic regression but using a different predictor variable in each case. The logistic regression model is
$$
\log \left(\frac{p_{i}}{1-p_{i}}\right)=\alpha+\alpha_{s_{i}}+\alpha_{t_{i}}+\left(\beta_{s_{i}}+\beta_{t_{i}}+\beta\right) \phi_{i}+b x_{i}
$$
where $i$ indexes the experiment trial, $p_{i}$ is the probability of the participant responding "present" to the word presented on trial $i, s_{i}$ is the identity of the participant on trial $i, t_{i}$ is the identity of the text on trial $i, \phi_{i}$ is the log of the model's predicted probability of the word on trial $i, x_{i}$ indicates if the word on trial $i$ was present in text $t_{i}$. The random effects regression coefficients are $\alpha_{s_{i}}, \alpha_{t_{i}}, \beta_{s_{i}}, \beta_{t_{i}}$, which are modelled as drawn from zero-mean Normal distributions.

Having fit the logistic regression model using the predictions of the HDPMM topic model, the co-occurrence based model, the association norm based model, and a null model (where $\phi_{i}$ is set to 0 for all $i$ ), we calculate model fit statistics such as BIC, AIC, and Deviance. They are shown in the following table:

|  | HDPMM | Co-occur | Assoc | Null |
| ---: | :---: | :---: | :---: | :---: |
| BIC | 5775.68 | 5824.33 | 6083.58 | 6212.77 |
| AIC | 5715.97 | 5764.62 | 6023.87 | 6186.23 |
| Deviance | 5697.97 | 5746.62 | 6005.87 | 6178.23 |

We will concentrate on the BIC results as the $\log _{e}$ of the Bayes Factor comparing any model $\mathscr{M}_{0}$ to model $\mathscr{M}_{1}$ can be approximated by half the difference of the BIC of models $\mathcal{M}_{1}$ and $\mathcal{M}_{0}$. Thus, the $\log _{e}$ of the Bayes factor comparing the HDPMM predictions to those of the co-occurrence based association model is 24.32 . By any standard, this is overwhelming evidence in favour of the predictions of the HDPMM relative to those of the co-occurrence model. For example, Kass and Raftery (1995) argue that a $\log$ Bayes factor on a $\log _{10}$ scale that is greater than 2.0 is already decisive evidence in favour of the better model. In our case, our $\log _{e}$ result of 24.32 is 10.42 on a $\log _{10}$ scale. As the BIC of the association norm model is even greater than that of the co-occurrence model, there is overwhelming evidence in favour of the HDPMM relative to the comparison models.

For the recall memory task results, each set of recalled words by a participant on any given test $j$, which we will denote by $\omega_{j}=\omega_{j 1}, \omega_{j 2} \ldots \omega_{j n}$, can be reasonably viewed as draws from a subjective probability distribution that is the participant's memory representation of the contents of the text. We can calculate the likelihood of this data according to the probability distribution defined by any of our models, denoted generically by $\psi$, as follows:

$$
\mathrm{P}\left(\omega_{j} \mid \psi\right)=\prod_{i=1}^{n} \prod_{v=1}^{V} \psi_{v}^{\mathbb{I}\left(r_{i}=v\right)}=\prod_{v=1}^{V} \psi_{v}^{r_{j v}}
$$

where $\mathbb{I}(\cdot)$ is an indicator variable that takes the value of 1 if its argument is true, and $r_{j v}$ is the number of times that word $w_{v}$ occurs in $\omega_{j}$, which in this case will be either $r_{j v}=1$ if
word $w_{v}$ was recalled and $r_{j v}=0$ otherwise. The $\log _{e}$ of the likelihood of all the recall memory task data is

$$
\log _{e} \prod_{j=1}^{L} \mathrm{P}\left(\omega_{j} \mid \psi\right)=\log _{e} \prod_{j}^{L} \prod_{v=1}^{V} \psi_{v}^{r_{j v}}=\sum_{j}^{L} \sum_{v=1}^{V} r_{j v} \log _{e} \psi_{v}
$$

These results are presented in the following table:

|  | HDPMM | Co-occur | Assoc |
| ---: | ---: | ---: | ---: |
| logLik | -14109.02 | -15100.94 | -16039.98 |
| Deviance | 28218.03 | 30201.88 | 32079.96 |

Given that the deviance is equal to the BIC plus a constant term, the difference of the deviances is identical to the difference of the corresponding BIC's. Approximating the $\log _{e}$ of the Bayes factor by half this difference, we therefore calculate a $\log _{10}$ Bayes factor for the evidence for the HDPMM predictions relative to those of the nearest model, the co-occurrence based association model, as 430.79 . On the basis of the interpretation described above, this is again overwhelming evidence in favour of the HDPMM.

## Discussion

In this paper, we have proposed - and then tested using a high powered behavioural experiment - a Bayesian account of how we form memories for spoken and written language. This account models how we use our background knowledge to form memories as a process of Bayesian inference of the statistical patterns that are inherent in each text, followed by posterior predictive inference of the words that are typical of those inferred patterns. We have implemented this model specifically as a HDPMM and applied it to an approximately 80 m word corpus of texts taken from the BNC. This allowed us to make predictions of the probability of remembering any given word in each text from a sample of texts taken from the BNC. We tested these predictions in a behavioural experiment with 216 participants. The results of the analysis from both the recognition and recall data provided overwhelming evidence in favour of the Bayesian model relative to non-trivial alternative models.

#### Abstract

Over the past two-and-a-half decades, numerous empirical studies have demonstrated a relationship between numbers and space. A classic interpretation is that these spatialnumerical associations (SNAs) are a product of a stable mental number line (MNL) in the mind, yet others have argued that SNAs are a product of transient mappings that occur in working memory. Importantly, although the latter interpretation has no implications for the representation of number, the former suggests that the representation of number is inherently spatial. Here, we tease apart questions of spatial representation (à la an MNL perspective) and spatial strategy (à la alternative accounts). In a novel place-the-number task, we demonstrate that numbers automatically bias spatial attention whereas other ordinal sequences (i.e., letters) do not. We argue that this is evidence of an inherently spatial representation of number and explore how this work may help answer future questions about the relationship between space and number.

Keywords: spatial-numerical associations (SNAs); mental number line (MNL); automaticity; working memory; polarity correspondence; synesthesia

## Introduction

Since the seminal work of Dehaene, Bossini, and Giraux (1993), the link between space and number has inspired a wealth of research (for recent review, see Fischer \& Shaki, 2014). In the classic paradigm, participants made parity judgments (odd/even) of Arabic numerals using left and right response keys, finding that participants responded faster to smaller numbers when using the left key and faster to larger numbers when using the right key. This general finding has since been replicated using numerous paradigms. One such example is the magnitude comparison task in which participants indicated whether the digit shown is greater than or less than some value (e.g., 5; Fitousi, Shaki, \& Algom, 2009). Later work demonstrated that simply perceiving numbers biases spatial attention: participants were faster to detect a leftward target when primed with a small digit and faster to detect a rightward target when primed with a large digit
(Fischer, 2003; but see, e.g., Zanolie \& Pecher, 2014, for replication failure). Further, changes in spatial attention bias number generation: when asked to randomly generate numbers while making alternating left/right head movements, participants more frequently generate small numbers when their head is oriented to the left and large numbers when their head is oriented to the right (Loetscher, Schwarz, Schubiger, \& Brugger, 2008).

A common theory of the spatial-numerical associations (SNAs) described above is that they are the product of a stable mental number line (MNL), wherein smaller numbers are represented on one side of space and larger numbers are represented on the other (in Western cultures, smaller numbers are represented on the left and larger numbers on the right; e.g., Dehaene et al., 1993). Yet there remain objections to this theory. Proctor and Cho (2006), for example, argued that polarity correspondence (a +/- categorization of stimulus and response) can explain the observed associations. Indeed, many tasks rely on a dichotomous response (e.g., left/right keys, left/right head position), and may be explained in this way. Another view, which has posed an even greater challenge to the MNL account, argues that SNAs are a product of task-specific associations established online within working memory (WM; van Dijck \& Fias, 2011). The crux of this debate is whether the observed SNAs are driven by a stable spatialnumerical link (e.g., MNL) or by transient mappings of number onto space (e.g., polarity correspondence, or a WM account; for further discussion, see Cheung et al., 2015).

In general, those who argue in favor of a WM account argue that the ostensibly transient mappings are, at least in part, a product of task demands. For example, in the classic parity judgment task, participants respond using leftward and rightward oriented keys. One may argue that the relative orientation of these keys is sufficient to induce a spatial mapping (see Viarouge, Hubbard, \& Dehaene, 2014 for discussion on the induction of spatial reference frames in SNA tasks).

Table 1: SNA tasks and their task demands.

| Category | Examples | Task demands |  |  | Ordinal control |
| :---: | :---: | :---: | :---: | :---: | :---: |
|  |  | Dichotomous Categorization | Directional prime | Magnitude salience |  |
| Parity Judgment | Dehaene et al., 1993 <br> Marghetis et al., 2013 | $\checkmark$ | $\checkmark$ | $\checkmark$ | $\checkmark$ |
| Mag. Judgment | Fitousi et al., 2009 <br> Marghetis et al., 2013 | $\checkmark$ | $\checkmark$ | $\checkmark$ | X |
| Lat. Comparison | Lavidor et al., 2004 Cheung et al., 2015 | $\checkmark$ | $\checkmark$ | $\checkmark$ | X |
| Numerical Posner | Fischer et al., 2003 <br> Ruiz Fernández et al., 2001 | X | $\checkmark$ | X | X |
| Num. Bisection | Fischer et al., 2001 Calabria \& Rossetti, 2005 | X | $\checkmark$ | X | X |
| Number generation | Loetscher et al., 2008 <br> Cheung et al., 2015 | X | $\checkmark$ | $\checkmark$ | X |
| Eye-tracking | Holmes et al., 2016 <br> Schwarz \& Keus, 2004 | X | X | $\checkmark$ | X |
| Place-the-number |  | X | X | X | $\checkmark$ |

In particular, a polarity correspondence account would be concerned about the use of a dichotomous response. Indeed, many of the SNA tasks mentioned above possess some kind of task demand. Parity judgment tasks and magnitude comparison tasks involve both a dichotomous manual response (left key/right key) and a dichotomous judgment (less than/greater than). Other parity and magnitude judgment tasks have utilized a go/no-go paradigm to circumvent the spatial information provided by the response keys, but these tasks nevertheless depend on a dichotomous response scheme (e.g., Marghetis, Kanwal, \& Bergen, 2013). This dichotomous response, though not spatial, nevertheless lends itself to a polarity correspondence account. Furthermore, even tasks that do not require a dichotomous response still have certain features that may instantiate a left-to-right reference frame. For example, in the work of Fischer and colleagues (2003), a left-to-right frame may be induced by the locations of the target (as either on the left or right side of fixation). The same may be said for the paradigm utilized by Ruiz Fernández and colleagues (2011), wherein, after presentation of a number, they made an arbitrary selection between items construed on the left and right sides of space. In the work of Loetscher and colleagues (2008), a left-to-right frame is being specifically induced by the turning of the head. (For a more complete list of SNA paradigms and their task demands, see Table 1). Thus, it is unclear whether there is any evidence of an SNA (and consequently, a stable MNL) in the absence of any such task demands.

Eye-tracking paradigms have been promising in this regard. For instance, Holmes, Ayzenberg, and Lourenco (2016) had participants play a virtual blackjack game while their eye gaze was being tracked. It was found that both the value of a card on a given trial as well as the overall value
of one's hand at a given time significantly predicted eye gaze in a manner consistent with observed SNAs for Western participants (i.e., smaller magnitudes produced more leftward eye movements and larger magnitudes produced more rightward eye movements). This study provides strong evidence for a left-to-right oriented MNL by demonstrating that number representations bias spatial attention even in the absence of a directional prime and a dichotomous response scheme (see Table 1). Other eyetracking studies have yielded similar results (e.g., Schwarz \& Keus, 2004; Loetscher et al., 2010). Yet in Holmes et al. (2016), the task requires the explicit processing of numerical value (e.g., value of a card or hand). Though the processing of numerical magnitude may not be explicitly required in the other tasks above, they do invoke some property of number (e.g., parity). As such, two questions remain: do numbers automatically bias spatial attention in the absence of a directional prime and even when numerical properties are irrelevant to the task at hand? Furthermore, and critically, is this bias specific to number?

## Automaticity as a criterion for representation

Understanding whether SNAs manifest automatically (i.e., in the absence of task demands) is crucial for understanding the relationship between space and number, in large part because automaticity suggests that the relationship is representational (as an MNL hypothesis would predict) rather than transient (as a polarity correspondence or WM account would predict). Nowhere is this criterion more apparent than in the literature on synesthesia. Automaticity, here, is where many have drawn the line between a relationship that is merely associative as opposed to truly synesthetic (see Grossenbacher \& Lovelace, 2001; Mattingley, 2009). We argue that the spatial-numerical
relationship should be considered in similar terms (see also, Cohen Kadosh \& Henik, 2007). By this criterion, automaticity helps us to understand the nature of the relation between space and number: namely, whether they share representational space (as an MNL hypothesis predicts), or whether the two are only transiently associated with one another (as alternative hypotheses predict).

Here, we present evidence from a novel SNA paradigm -the place-the-number task -- which suggests that numbers do in fact automatically bias spatial attention. Very simply, participants viewed a number on a screen, memorized its location, and, after a delay, placed the number back in its original location. This task revealed a robust spatialnumerical relationship. In two additional control experiments, we found no consistent mapping of letters to space, suggesting that these attentional biases are specific to number and not ordinal sequences (a control which has not always been tested with other paradigms). Predictions made by MNL and WM accounts of SNAs diverge in such conditions: an MNL account predicts that this spatial bias is specific to number whereas a WM account predicts that this bias generalizes to any ordinal sequence (e.g., letters, months, etc.; van Dijck et al, 2014).

## Experiment 1: Place-the-number task

## Method

In this novel paradigm, participants viewed an Arabic numeral (1-9) presented in black font within a rectangle (white fill with black outline; $918 \times 495$ pixels). This task was created in Visual Basic and presented on a 19in computer monitor. Participants sat approximately 65 cm from the monitor. Each digit was presented 20 times, for a total of 180 trials, randomly ordered. On each trial, participants were instructed to remember the location of the digit. The digit remained on screen until participants clicked a button located at the bottom of the screen, at which time the digit disappeared. Participants were then instructed to click the remembered location to place the digit at that location. These instructions were presented in a pop-up dialog box, which also ensured that participants did not fixate on the original location of the digit. Participants could further adjust this initial placement by dragging and dropping the digit. Participants then confirmed their final placement by clicking another button on screen and immediately proceeded to the next trial.

Thirty-seven undergraduates participated in this task for course credit. All participants had normal or corrected-to normal vision. Procedures were approved by the Institutional Review Board (IRB). One participant was excluded from the statistical analyses due to poor accuracy ( $>2.5$ SD from the group mean), where accuracy is calculated as the distance between the digit's original location and the participant's final placement.

## Results

The remaining participants $(N=36)$ had a mean accuracy of 18.76 pixels ( $\mathrm{SD}=13.67$ ). The variable of interest was participants' accuracy along the horizontal axis ${ }^{1}$. For each trial, we calculated accuracy as the difference between the x-coordinate of the participant's final placement and $x$ coordinate of the digit's original location, such that a negative value represents a more leftward placement, in comparison to the original location, and a positive value represented a more rightward placement, in comparison to the original location. For each participant, we calculated the mean accuracy for each digit and calculated a slope by regressing these values onto their corresponding numerical value (See Fig 1). Thus, in this paradigm, a positive slope represents the canonical, left-to-right SNA. Participants' slopes were significantly greater than zero, $t(35)=2.11, p<$ $.05, d=.35$. Furthermore, a significant number of participants $(N=24)$ showed this effect (binomial test, $p<$ .05). In other words, participants placed smaller numbers more leftward than larger numbers, consistent with a left-toright $\mathrm{SNA}^{2}$. To determine whether the SNA shown here is unique to number (as an MNL account predicts) or occurs for any ordinal sequence (as a WM account predicts), we conducted a control experiment (Exp. 2A) with letters.

Figure 1: Scatterplot displaying mean spatial bias (final original placement) for digits 1-9 including the best-fitting regression line.

[^16]
## Experiment 2A: Letter control (A-I)

## Method

The procedure for Experiment 2 A was identical to Experiment 1 except instead of Arabic numerals as stimuli, participants were presented with the first nine letters of the alphabet (A-I). Thirty-eight undergraduates participated for course credit. One participant was excluded from the statistical analyses as they did not complete all trials. One participant was excluded from the statistical analyses for poor accuracy.

## Results

The remaining participants ( $N=36$ ) had a mean accuracy of 14.25 pixels $(\mathrm{SD}=7.62)$. Importantly, unlike Experiment 1, participants' slopes were not significantly different from zero, $t(35)=-.85, p=.40$. These results demonstrate that letters, although ordinal, do not generate a spatial association in this paradigm. However, since the letters used only spanned the beginning of the alphabet, it remains possible this sequence was not comparable to the Arabic numerals used in Experiment 1. The following experiment was designed to address this concern.

Figure 2: Scatterplot displaying mean spatial bias (final original placement) for letters A-I including the best-fitting regression line.

## Experiment 2B: Letter control (A-Z)

## Method

The procedure for Experiment 2 B was identical to Experiment 1 and 2A but instead of Arabic numerals as stimuli, nine letters evenly spaced throughout the alphabet (A, D, G, J, M, P, S, V, Y) were presented, as we hypothesized participants could more easily distinguish between the ordinal position of "A"/"Y" than "A"/"I", for
example. Thirty-eight undergraduates participated for course credit. One participant was excluded from the statistical analyses as they did not complete all trials. One participant was excluded from the statistical analyses for poor accuracy.

## Results

The remaining participants $(N=36)$ had a mean accuracy of 13.65 pixels $(\mathrm{SD}=9.11)^{3}$. Consistent with the findings of Experiment 2A, participants' slopes were not significantly different from zero, $t(35)=-.14, p=.89$, confirming that letters do not generate a spatial association in this paradigm.

Figure 3: Scatterplot displaying mean spatial bias (final original placement) for letters evenly distributed in the alphabet including the best-fitting regression line.

## General Discussion

A primary goal of this study was to demonstrate an SNA in the absence of any sort of task demand. In the place-thenumber task, participants' responses are non-dichotomous, there is no left-right directional prime, and the value of the stimulus is not necessary to complete the task. Yet participants nevertheless exhibited an SNA consistent with past results. Our two control experiments demonstrate that this effect is specific to number and not other ordinal sequences such as letters.

Consistent with our hypotheses, these findings demonstrate that numbers - but not letters -automatically bias spatial attention in accordance with an MNL account. The fact that this effect occurs in the absence of relevant task demands is critical. Those who posit alternative accounts of SNAs often offer explanations that rest on demand characteristics of the tasks themselves, but there are

[^17]no such demands here. Therefore, we conclude that the automaticity of the spatial bias in this task sheds light on the nature of numerical representations - that they are inherently spatial unlike other ordinal sequences. Though other accounts exist, we believe these results provide strong evidence in favor of an MNL account of SNAs.

This interpretation is consistent with recent neural work which has explored the relation between space and number (Harvey et al., 2013). Harvey and colleagues (2013) found evidence of a topographic map for numerosity in the posterior superior parietal lobule, akin to topographic maps for sensorimotor systems (Udin \& Fawcett, 1988). Within this area, medial regions preferred small numerosities and lateral regions preferred large numerosities. Importantly, the location and numerosity preference of this topographic map was consistent across participants. These data support the growing body of evidence not only that number and space are deeply related in the mind, but, additionally, that numerical representations have an inherently spatial organization.

## Spatial representation versus spatial strategy

One question that arises from this interpretation is why others have demonstrated effects of ordinal sequences (e.g., Gevers, Reynovet, \& Fias, 2003; van Dijck \& Fias, 2011). To answer this question, we want to make a critical distinction. On the one hand, we might ask what things we can organize spatially; on the other hand, we might ask what things are inherently spatial. It is only in the context of the latter question that we argue numbers are unique. That we can organize ordinal sequences spatially should come as no surprise. People can organize items in any number of spatial arrangements and this type of spatialization has often been considered important for reasoning (Johnson-Laird, 1983). But the question that concerns the authors here is whether numbers are unique in the sense that they are automatically represented spatially in the mind.

This dichotomy is reminiscent of the so-called "dualprocess" model of SNAs (e.g., Ginsburg \& Gevers, 2015) which entail both long-term SNAs as well as spatialization in working memory. Abrahamse, van Dijck, and Fias (2016) have argued against this view, suggesting that their WM account is more parsimonious - that it "captures the complexity of the empirical database" without the need for long-term associations (p. 7). Indeed, if the mind were constructed for the sole purpose of representing number, then it may have evolved to do so in a parsimonious manner. Yet, Abrahamse and colleagues (2016) ignore the possibility that multiple mechanisms, some of them domaingeneral, may be at play. As we suggest, all ordinal sequences can be represented in space, but only numbers are automatically represented in this manner.

A working memory account of SNAs suggests that we have the propensity to organize sequences spatially in order to minimize the load of maintaining the sequence in the mind at once. This idea is reminiscent of the "method of loci" - a means of improving memory per spatial
visualization - is at least two millennia old (as in Cicero's De Oratore), but it has nothing to do with intrinsic characteristics of the representation. Thus, it becomes important to differentiate questions of spatial representation and spatial strategy. Previous tasks, some rife with potential task demands, failed to make a distinction between these two perspectives, yet have been interpreted as evidence of spatial representation. van Dijck and Fias (2011) have argued, partially on account of these task demands, that SNAs are merely transient mappings that occur in working memory - which, within our framework, falls under the purview of spatial strategy. In pursuing the latter issue of strategy, those who have espoused this WM perspective have overlooked the former, more crucial question of representation. That is, while we have argued that numbers are unique insofar as they are inherently spatial, van Dijck and Fias have succeeded only in showing that other sequences can, in certain contexts, be mapped spatially.

## Empirical horizons

What does the distinction between spatial representation and spatial strategy buy us? As a starting point, it establishes that numbers are in fact unique: they bias spatial attention automatically which suggests that their representation is inherently spatial in a way that other ordinal sequences are not. With this in mind, we are able to ask more nuanced questions about the underlying relationship between space and number. For example, why are numbers unique in this way? Do we come into the world with the propensity to represent numbers spatially, or is it learned? Perhaps more critically: what is the utility of a spatial-numerical mapping? For example, despite the seeming ubiquity and permanence of SNAs, it is unclear whether this spatial-numerical bias is related to math performance, with some studies reporting a positive relationship, some a negative relationship, and some no relationship at all (for review, see Cipora, Patro, \& Nuerk, 2015).

Not only does the place-the-number task play a part in raising these questions, it may also help to answer them. To further understand the phylogenetic and ontogenetic development of these associations, it is necessary to examine them in early childhood as number concepts are still being acquired. This has proven challenging, however, given that many SNA tasks are difficult to administer to children. The place-the-number task alleviates these concerns and might allow for the study of SNAs at a time in development when they have greater utility.

In sum, we have shown that numbers, but not letters, bias spatial attention in a manner that is consistent with an MNL hypothesis of SNAs. We argue that previous work which has posited alternative explanations to this account have been inadvertently answering a separate question - one about spatial strategy rather than spatial representation. Here, we have clarified the difference between these two accounts and suggested how the place-the-number task may be used to guide future research on the deep relationship between space and numbers in the mind.

#### Abstract

The use of subject pronouns by bilingual speakers using both a pro-drop and a non-pro-drop language (e.g. Spanish heritage speakers in the USA) is a well-studied topic in research on cross-linguistic influence in language contact situations. Previous studies looking at bilinguals with different proficiency levels have yielded conflicting results on whether there is transfer from the non-pro-drop patterns to the pro-drop language. Additionally, previous research has focused on speech patterns only. In this paper, we study the two modalities of language, speech and gesture, and ask whether and how they reveal cross-linguistic influence on the use of subject pronouns in discourse. We focus on elicited narratives from heritage speakers of Turkish in the Netherlands, in both Turkish (prodrop) and Dutch (non-pro-drop), as well as from monolingual control groups. The use of pronouns was not very common in monolingual Turkish narratives and was constrained by the pragmatic contexts, unlike in Dutch. Furthermore, Turkish pronouns were more likely to be accompanied by localized gestures than Dutch pronouns, presumably because pronouns in Turkish are pragmatically marked forms. We did not find any cross-linguistic influence in bilingual speech or gesture patterns, in line with studies (speech only) of highly proficient bilinguals. We therefore suggest that speech and gesture parallel each other not only in monolingual but also in bilingual production. Highly proficient heritage speakers who have been exposed to diverse linguistic and gestural patterns of each language from early on maintain monolingual patterns of pragmatic constraints on the use of pronouns multimodally.

Keywords: bilingualism; heritage speakers; gesture; crosslinguistic influence; pronoun; pragmatics; discourse

## Introduction

The use of subject pronouns by bilingual speakers of a prodrop (e.g. Spanish) and a non-prop language (e.g. English) in contact situations has been a commonly studied test case of cross-linguistic influence. Pro-drop languages habitually drop arguments and use overt pronouns mainly to mark
pragmatic information such as contrast and emphasis (e.g. Enç, 1986). The alternation between overt pronouns and dropped arguments is determined by discourse-pragmatics in those languages unlike in non-pro-drop languages such as English. Studies looking at heritage speakers who had lower proficiency in their pro-drop language than in their non-prodrop language found an increase in the frequency of pronouns or a loss of the pragmatic constraints on the use of pronouns in the pro-drop language (Paradis \& Navarro, 2003; Polinsky, 1995; Silva-Corvalan, 1994). On the other hand, studies looking at heritage speakers who are exposed to the pro-drop language more regularly and who have high proficiency in both languages found no cross-linguistic influence (CerrónPalomino, 2016; Keating, Jegerski \& van Patten, 2016; Montrul, 2004). Most studies, however, have focused on Spanish as a pro-drop language and English as a non-prodrop language in the United States.
In this paper, we look at language contact influence on subject pronouns studying Turkish heritage speakers in the Netherlands. Pronouns are less frequently used in pro-drop Turkish than in non-pro-drop Dutch, and they are pragmatically marked forms in Turkish (Enç, 1986) (similar to Spanish) but not in Dutch. Additionally, unlike previous studies in this domain, we examine not only patterns in the pro-drop language but also in the non-pro-drop language. We ask whether bilingual speakers maintain differences between Turkish and Dutch in terms of pragmatic constraints on the use of pronouns. Furthermore, as a novel contribution to research on cross-linguistic influence on subject pronouns, we extend our investigation to the visual modality of language, i.e. co-speech gestures. Studies of multimodal narratives have shown that speakers' gestures are sensitive to the amount of information encoded in speech. When referents are maintained in discourse, speakers not only reduce content of the referring expression by using pronouns or null forms,
but they also reduce the frequency of gestures related to referents (Azar \& Özyürek, 2015; Perniss \& Özyürek, 2015). Additionally, referents that are uniquely identified in speech are more likely to be accompanied by gestures (So, Kita \& Goldin-Meadow, 2009), suggesting gesture is tightly linked to speech. Whether this link extends to pragmatic marking of pronouns, that is whether languages that mark pronouns pragmatically in speech are more likely to mark them with gestures as well, has not been investigated so far. Furthermore, nothing is known about the multimodal nature of the cross-linguistic transfer in this domain.
As for gestures of bilingual speakers, in particular proficient L2 learners have been reported to show crosslinguistic influence in how frequently they gesture overall (So, 2010; see Cavicchio \& Kita, 2013 who found no crosslinguistic influence) and in their motion verb expressions (Brown \& Gullberg, 2008; Özçalışkan, 2016). Gestural transfer in the contexts of language contact and for differential pragmatic marking of pronouns on the other hand is an unexplored research topic. Thus, as a novel contribution to bilingualism research, we investigate whether heritage speakers who are highly proficient in their two languages maintain pragmatic constrains on the use of subject pronouns in speech and gesture or whether there is cross-linguistic influence in the two modalities.

An earlier study that looked at the use of subject pronouns by adult Turkish heritage speakers in the Netherlands (Doğruöz, 2007) found no cross-linguistic influence in the quantity of subject pronouns in informal interviews, though a few cases of the 1 st person pronoun were attested where monolinguals would not use a pronoun, e.g. in the immediately preverbal positions. We contribute to the literature on the use pronouns by Turkish-Dutch bilingual adult speakers in the Netherlands with a more controlled study (with respect to the discourse content) and in the context of narratives eliciting third-person references. Furthermore, we study not only Turkish narratives but also Dutch narratives produced by the same set of speakers. Finally, we take the multimodal aspects of reference production into account and investigate the use of gestures to mark subject referents by Turkish-Dutch bilinguals for the first time.

## Method

## Participants

20 Dutch monolingual speakers studying in Nijmegen (14 females; age mean $=21.5$ ), 20 Turkish monolingual speakers studying in Istanbul ( 17 females; age mean $=22.2$ ) and 20 bilingual speakers ( 14 females; age mean $=23.3$ ) studying in Nijmegen participated in our study in return for payment or course credits. Note that "monolingual" speakers in our study have some knowledge of English but they speak only one of the two languages that are of interest for this study.

Bilingual participants filled in a survey regarding their language history, current language use, and language proficiency in Turkish and Dutch. All bilingual speakers were born and raised in the Netherlands; their parents immigrated from Turkey to the Netherlands as young adults. Bilinguals were exposed primarily to Turkish at home until they started school at around the age of 4. They reported to mainly speak Dutch at school and mostly mix the two languages at home and among friends. Bilinguals rated their overall reading, speaking and comprehension proficiency higher in Dutch than in Turkish on a 5-point Likert scale (see Table 1). As a measure of oral fluency, we calculated articulation rate (number of syllables/ articulation time) (cf. De Jong, \& Wempe, 2009 for the script) for each participant using samples of around 30 seconds from the narratives we collected (the stimuli and procedure explained below). Bilinguals did not differ significantly from monolinguals in Turkish $t(38)=1.994, p=.053$ or in Dutch $t(38)=0.934, p=$ .356. Bilinguals' articulation rate was not significantly different between their Turkish and Dutch, either, $t(19)=$ 2.047, $p=.954$, suggesting they have similar levels of oral fluency in both languages (see Table 2).

Table 1
Self-rated Bilingual Proficiencies (1 = native; $5=$ beginner), Mean (SD)

|  | Speaking | Comprehension | Overall |
| :---: | :---: | :---: | :---: |
| Turkish | $2.50(1.32)$ | $2.25(0.79)$ | $2.40(1.27)$ |
| Dutch | $1.30(0.47)$ | $1.10(0.31)$ | $1.50(0.76)$ |

Table 2
Monolingual and Bilingual Speakers' Articulation Rates, Mean (SD)

|  | Monolingual | Bilingual |
| :---: | :---: | :---: |
| Turkish | $4.81(0.55)$ | $4.44(0.63)$ |
| Dutch | $4.62(0.71)$ | $4.42(0.57)$ |

## Stimuli

We used two short silent videos (cf. Azar, Backus \& Özyürek, 2016) to elicit narratives. Three characters were engaged in joint activities; cooking in one video and office work in the other. Figure 1 illustrates stills from each video.

Figure 1: Stills from the stimulus videos featuring kitchen (upper row) and office activities (bottom row)

## Procedure

Participants were invited to a quiet room in pairs and were assigned the role of either speaker or addressee (the assignment was random in monolingual sessions). The speaker watched the stimulus videos one by one on a computer screen. Once each video ended, the computer screen turned white and the speaker told the addressee what they had watched. The addressees were instructed that after each narrative, they could ask clarification questions and that they would be given two short written questions about each narrative. The purpose of this was to ensure that the speakers included enough details in their narratives and that the addressees paid attention. Once the instructions were given, the experimenter left the room and came back after each narrative with the questions for the addressee. The bilingual participants repeated the task once in Turkish with a Turkish monolingual addressee and once in Dutch with a Dutch monolingual addressee. The addressees were not confederates and there was at least two weeks between the two sessions. The order of the two videos was counterbalanced across participants. For bilinguals, the order of language was counterbalanced as well. All sessions were videotaped.

## Data Coding

We coded and analyzed speech from the speakers of each pair. We transcribed the video narratives using the standard orthography of each language and coded gestures with the frame-by-frame video annotation software ELAN (cf. Lausberg., \& Sloetjes, 2009).

Speech Coding We divided the narratives into clauses, utterances with a single subject argument and a single predicate. We coded only clauses with an animate subject argument (referring to the human characters in the stimulus videos) and marked whether the subject argument was maintained from the previous clause or not. We analyzed only clauses with maintained subjects since pronouns as reduced forms are used most frequently in those contexts (cf. Azar et al., 2016 for Turkish and Dutch). We further coded each maintained subject argument for one of the three possible referring expression types: noun phrase (NP), pronoun (third person and demonstrative pronouns) and null form. (1b) in Dutch and (2d, 2e) in Turkish illustrates clauses with maintained subjects. Subject arguments are underlined and subscripts index coreferentiality. Following Paradis and Navarro (2003), we coded Turkish subjects for pragmatic marking: contrast (disambiguation between two possible referents) or emphasis (highlighting information). Additionally, we also coded whether pronouns referring to subjects that are marked for emphasis were accompanied by the emphatic marker $d A$ 'also' (as in 2e). This clitic has been suggested to be a focus marker in Turkish (Enç, 1986) and has been shown to accompany pronouns when used for maintained subject arguments by monolingual Turkish speakers (Azar et. al., 2016). We did not code pragmatic marking for Dutch subjects because we expect Dutch
speakers to maintain subjects with pronouns as defaults forms rather than using pronouns to mark pragmatic information due to Dutch being a non-pro-drop language.
(1) a. Een meisje ${ }_{i}$ probeerde een pot open te maken. A irll $_{\mathrm{i}}$ tried to open a jar.
b. Die kreeg hem niet open.

That $_{\mathrm{i}}$ (the girl) did not open it.
(2) c. Ondan sonra $\underline{k} 1 Z k^{k}$ geliyor. Then irl $_{\mathrm{k}}$ is coming.
d. $\emptyset_{\mathrm{k}}$ çocuğa yardım ediyor.
null form
$\left(\right.$ She $_{\mathrm{k}}$ is helping the boy.
e. $\underline{\mathrm{O}}_{\mathrm{k}}$ da kağıtları diziyor.
pronoun

Gesture Coding We coded gestures temporally aligning with maintained subjects in speech, specifically with subject pronouns. We analyze gestures that anchored subjects in gesture space (i.e. index-finger and whole hand points). In Figure 2, the subject in (b) is maintained from (a) and marked with a pronoun in speech in Turkish and with an index-finger pointing gesture. The pronoun in speech is given in bold and the gesture and the character the pronoun refers to are highlighted in pictures.

Figure 2: Index-finger pointing gesture referring to the character in the video (highlighted) and temporally aligning with maintained subject pronoun in speech (in bold)

## Predictions

With regard to monolinguals, we expect speech and gesture to parallel each other in terms of the information they encode and therefore we expect cross-linguistic differences in the frequency of pronouns in speech and frequency of gestures marking pronominalized referents. In speech, we expect to find few pronouns in Turkish and in contexts where subject arguments are pragmatically marked for contrast or emphasis. Considering pronouns are marked forms in Turkish but not in Dutch, we predict that Turkish monolingual speakers will mark subject pronouns with gestures more than Dutch speakers. In terms of bilinguals we can anticipate the following scenarios for speech.

Influence of Dutch on bilingual Turkish: Based on studies that found cross-linguistic influence from non-pro drop English on pro-drop Spanish in subject pronouns of Spanish
heritage speakers in the States (e.g., Silva-Corvalan 1994), we expect bilinguals to have loosened the pragmatic constraints on the use of pronouns. Bilinguals in Turkish might use pronouns also when the subjects are not pragmatically marked and might accompany subjects that are marked for emphasis with the emphatic marker $\mathrm{d} A$ less frequently than monolinguals.

No cross-linguistic influence: Taking into account the literature which did not find cross-linguistic influence on subject pronouns for bilinguals with high proficiency in both languages (e.g. Cerrón-Palomino, 2016; Keating, Jegerski \& van Patten, 2016), we predict that bilinguals will maintain pragmatic constraints on the use of pronouns.

As for gestures, based on theories suggesting that speech and gesture parallel each other in production (Kita \& Özyürek, 2003; So et al., 2009), we expect the crosslinguistic influence on gestures to align with patterns of influence in speech. Alternatively, considering some L2 studies have found cross-linguistic transfer on gesture but not on speech (Özçalışkan, 2016), we may observe crosslinguistic influence on gesture modality only. Speakers may extend the pragmatic marking of pronouns with gestures from Turkish to Dutch and gesture with Dutch pronouns more frequently than Dutch monolinguals. Alternatively, bilinguals might loosen the pragmatic marking of gestures in Turkish as an influence from Dutch and gesture with pronouns less than monolinguals in Turkish.

## Analyses and Results

We performed arcsine transformation on ratio values for analyses though we report untransformed values. We analyzed the data using Linear Fixed Effects Models in IBM SPSS statistics 20 . We started with the simplest model with fixed effects only, and built more complex models by adding random intercepts. We compared each 'more complex' model to the previous simpler one in each step and in case of a significant difference we picked the model with the lower log-likelihood value. Bonferroni correction for multiple comparisons was applied for each model.

## Pronouns in Speech

We calculated the ratio of subject arguments referred to with a pronoun (subject pronouns) out of all maintained subject arguments in narratives per participant. We performed linear mixed model on subject pronouns with the following fixed effects: language type (Turkish vs. Dutch), language status (monolingual vs. bilingual) and the interaction between language type and language status. We started with the fixed effects only, and built more complex models by adding random intercepts and slopes for participants, language type and language status. The model that best described the variance of the data had random intercepts for participants and random intercepts for language type (Turkish or Dutch) varying by participants random slopes.
We found a significant effect for language type $F(1$, $66.657)=316.119, p<.001$ and for language status $F(1$, $45.204)=4.600, p=.037$ and a significant interaction
between the two $F(1,66.657)=4.174, p=0.045$. We further broke down the interaction and performed mixed linear models for Turkish and Dutch with language status (monolingual vs. bilingual) as fixed effect, following the same procedure as before. The model that best explained the variance for both Turkish and Dutch data was the simplest model with fixed effect language status. We did not find a main effect for language status $F(1,40)=0.852, p=.362$ for Turkish but for Dutch $F(1,40)=4.721 . p=.036$. Bilingual speakers used more pronouns in Dutch than monolinguals. Figure 3 illustrates the mean proportions of pronouns referring to subject arguments in monolingual and bilingual narratives by language.

Figure 3: Mean proportions of maintained subject pronouns in monolingual and bilingual narratives across Turkish and Dutch. The error bars represent standard errors of the mean.

Since we did not predict the findings in bilingual Dutch, we compared the use of the other two referring expressions we coded in speech, noun phrase (NP) and null form, across monolingual and bilingual Dutch to understand whether the higher use of pronouns by bilinguals could be driven by the lower use of one of the other two forms. We found that the bilinguals used null forms less frequently (although marginally) than monolinguals in Dutch $t(30.790)=-2.047$, $p=.049(M=0.132 ; 0.246$ respectively $)$.
Next, we looked at whether monolingual and bilingual speakers differed in the pragmatic marking of pronouns in Turkish. Out of all subjects that were encoded as pronouns, $82 \%$ in monolingual and $78 \%$ in bilingual narratives was marked for either emphasis or contrast. In total, there were 49 subject referents in monolingual Turkish and 44 subject referents in bilingual Turkish that were marked for emphasis and referred to with pronouns in speech. $88 \%$ of those pronouns in monolingual Turkish and $84 \%$ in bilingual Turkish was accompanied by the emphatic marker $\mathrm{d} A$. Thus, bilinguals were similar to monolinguals in Turkish in terms of the pragmatic constrains on the use of pronouns in speech.

## Pronouns Marked with Gestures

We calculated the ratio of gesturally marked subject pronouns out of all subject pronouns in speech per participant. We performed linear mixed model on gesturally marked subject pronouns with fixed effects language type, language status and the interaction of the two, following the same procedure as in our speech analyses. The model that best described the variance of the data had random intercepts for participants and language type (Turkish or Dutch) varying by participants random slopes. We found a significant effect for language type $F(1,69.358)=10.062, p$ $=.002$, showing Turkish speakers were more likely to mark pronouns with gestures than Dutch speakers. We did not find a significant effect for language status $F(1,92.697)=0.078$, $p=.781$ and no significant interaction between the fixed effects (language type and language status) $F(1,64.913)=$ $.001, p=.979$, suggesting bilinguals did not differ from monolinguals in terms of marking pronouns with gestures in either language. See Figure 4 for the mean values of gesturally marked pronouns.

Even though we found pronouns were more likely to be gesturally marked in Turkish than in Dutch, both in monolingual and bilingual speech, this could be due to an overall higher frequency of gestures in Turkish than in Dutch rather than an effect modulated by pragmatics. As a control, we looked at whether speakers per language group differed in how likely they are to gesturally mark a noun phrase (NP), the other overt referring expression type that we coded for speech. We performed mixed linear models on the ratio of gesturally marked NPs, following the same procedure as in our pronoun analyses. We did not find a main effect for language $F(1,56)=0.410, p=.525$, suggesting Turkish and Dutch speakers did not differ in how likely they were to mark NPs with gestures, contrary to what we found for pronouns. Turkish monolingual speakers gestured with NPs ( $M=0.33$, $S E=.083$ ) as often as Dutch monolinguals ( $M=0.28, S E=$ .126), suggesting the cross-linguistic difference we found for pronouns can be explained by the difference in the pragmatic status of pronouns across Turkish and Dutch and this effect is sensitive to the referring expression type used in speech. We did not find a main effect for language status $F(1,56)=$ $2.551, p=.116$ or an interaction of language and language status $F(1,56)=1.144, p=.289$. Bilinguals did not differ from monolinguals in Turkish $(M=0.42, S E=.120)$ or in Dutch ( $M=0.31, S E=.135$ ) in terms of how frequently they marked NPs with gestures.

## Discussion

In this study, we investigated whether there is cross-linguistic influence on the use of pronouns in narratives by heritage speakers who have high proficiency in both languages they speak. We specifically focused on the pragmatic constraints on the use of pronouns and we studied both speech and gestures for the first time in this domain looking at narratives

Figure 4: Mean proportions of gesturally marked maintained subject pronouns in monolingual and bilingual narratives across Turkish and Dutch. The error bars represent standard errors of the mean.
of Turkish heritage speakers in the Netherlands. We compared bilingual speech and gesture productions to those of monolinguals in Turkish and Dutch.

We showed that monolingual Turkish speakers used pronouns infrequently to maintain subject referents in narratives and mostly when the referents were pragmatic marked. Additionally, in line with our predictions, Turkish monolingual speakers were more likely to gesturally mark pronouns than Dutch monolingual speakers, suggesting linguistic forms that are pragmatically marked in speech (i.e. pronouns in pro-drop Turkish) are more likely to be marked with gestures as well.
Bilingual speakers did not differ from monolinguals in their pro-drop language, Turkish, in terms of how likely they were to use pronouns to maintain subject referents. Furthermore, we did not find any differences between monolingual and bilingual speakers in Turkish in terms of pragmatic constraints on the use of pronouns. Bilinguals used pronouns in Turkish to maintained referents that were marked for pragmatics, either for emphasis or contrast and they used the emphatic marker $\mathrm{d} A$ in similar ways to monolinguals. Our findings suggest that heritage speakers who were raised bilingually and who have high proficiency in both languages as well as using them daily, seem to have mastered the pragmatic constraints on the use of pronouns and to maintain them.
Although we did not expect any differences between monolingual and bilingual Dutch speech, we found that bilingual speakers used more pronouns and fewer null forms in Dutch than monolingual speakers. We suggest that bilingual speakers might have used coordinated clauses which allows null forms in Dutch less often than monolinguals and therefore dropped referents less often. However, since the use of null forms is not the main focus of our paper, we will not investigate this possibility further.
As for the visual modality, bilinguals maintained pronouns as marked forms in Turkish similar to monolingual speakers.

Bilinguals did not extend Turkish gestural marking to their Dutch narrative productions, either. Our findings are in line with those of Cavicchio \& Kita (2013) who looked at the overall gesture rate in L2 narratives, but differ from others which found cross-linguistic transfer of gesture with regard to the overall gesture rate (So, 2010) or motion verb expressions (Brown \& Gullberg, 2008; Özçalışkan, 2016).
To conclude, we show that speech and gesture parallel each other at the discourse-pragmatic level: Forms that are pragmatically marked in speech are more likely to be marked with gestures as well, extending the literature on crosslinguistic gestural differences in monolingual narratives.
Furthermore, we provide the first evidence that the parallel relation between speech and gesture (cf. So et al., 2009) extends to the domain of crosslinguistic influence in contact situations: When the influence is not evident in speech, it is not observable in gesture as well, at least with regard to pronoun use in the narratives of heritage speakers. Heritage speakers with high proficiency in both languages maintain pragmatic constraints on the use of subject pronouns, both in speech and gesture. Our findings therefore align with the studies that did not find cross-linguistic influence on the speech of highly proficient heritage speakers (e.g. CerrónPalomino, 2016; Keating, Jegerski \& van Patten, 2016). This suggests that proficiency in the heritage language may be an important determinant of the cross-linguistic influence on the use of pronouns in narratives in both modalities of language.
We suggest that studying bilingual gestures in addition to speech, especially in domains that show cross-linguistic influence in speech, will contribute to more complete theories of bilingualism. A better understanding of whether spoken and visual modalities undergo the same processes will provide valuable insight into the scope of cross-linguistic influence and language change beyond what we can learn from studies of speech alone.

## Acknowledgments

This research is funded by the Center for Language Studies, Radboud University Nijmegen, the Netherlands and partially by the Erasmus Staff training grant granted to the first author by the International Office Radboud University. The Max Planck Institute for Psycholinguistics also provided technical support. We thank Dr. Pamela Perniss for the stimulus video featuring cooking activities. We also thank Dr. Ayşe Caner and Dr. Nihan Ketrez for providing the location and participants for data collection in Istanbul, Turkey.

# Rise and fall of conflicting intuitions during reasoning 

Bence Bago (bencebago@ed-alumni.net)<br>Paris Descartes University - Sorbonne Paris Cité<br>LaPsyDE (CNRS unit 8240)

Wim De Neys (wim.de-neys@ parisdescartes.fr)<br>Paris Descartes University - Sorbonne Paris Cité<br>LaPsyDE (CNRS unit 8240)

#### Abstract

Recent dual process models proposed that the strength of competing intuitions determines reasoning performance. A key challenge at this point is to search for boundary conditions; identify cases in which the strength of different intuitions will be weaker/stronger. Therefore, we ran two studies with the two-response paradigm in which people are asked to give two answers to a given reasoning problem. We adopted base-rate problems in which base rate and stereotypic information can cue conflicting intuitions. By manipulating the information presentation order, we aimed to manipulate their saliency; and by that, indirectly the activation strength of the intuitions. Contrary to our expectation, we observed that the order manipulation had opposite effects in the initial and final response stages. We explain these results by taking into account that the strength of intuitions is not constant but changes over time; they have a peak, a growth, and a decay rate.

Keywords: reasoning; conflict detection; hybrid dual process model

## Introduction

Decades of research in thinking and reasoning has revealed that people are usually subject to errors. Consider for example the following situation:
"There is a party with 1000 people. Jo is a randomly chosen participant from the party. We know that Jo is 23 years old and is finishing a degree in engineering. On Friday nights, Jo likes to go out cruising with friends while listening to loud music and drinking beer. We also know that 900 people attending the party are women. What is most likely: Is Jo a man or a woman?"

This is a so-called base rate problem. Based on the "normative" ${ }^{1}$ principle that a randomly drawn individual

[^18]will more likely come from the largest group, one should favor the conclusion that Jo is a woman. However, the majority of people tend to err on this problem by going with the presented stereotype (which cues that Jo is a man). Dual process theories provide an explanation for general thinking bias on problems such as the base rate task. They distinguish two types of processing, Type 1 and Type 2. One should note that there are many dual process theories, but in this study, we will focus on the most influential dual process theory, the default-interventionist theory. Type 1 processes (also referred to as intuitive processes) are thought to be completely autonomous, while Type 2 processes (also referred to as analytic processes) are more controlled. Type 1 processing generates responses cued by stereotypes or common beliefs; relying on this intuitive, initial response is what makes people biased in such situations. After Type 1 processing produced a response, in some cases, Type 2 processing gets engaged; this type of processing has the ability to override and correct the response generated by Type 1 processing. In general, it is assumed that Type 2 processing has the ability to generate responses based on logic or probabilities, while Type 1 processing has not been considered to be able to handle information such as logical properties of the task, or probabilities (Kahneman, 2011; Stanovich \& Evans, 2013).

However, recently, conflict detection studies (De Neys, 2012 , 2014) indicated that the assumption that Type 1 processing is not able to handle probabilistic or logical information might not hold. These studies showed that even biased reasoners were able to detect the conflict between intuitive "heuristic" cues (e.g., stereotypes) and "normative" logical and probabilistic principles (e.g., base rate probabilities). These studies usually contrast conflict and no-conflict reasoning problems. In conflict problems, heuristic processing and normative principles cue different responses as in the base rate problem above. In a no-conflict problem normative principles and heuristic processing cues the same response; for example, imagine that the abovepresented base rate problem would state that there are 900 men and 100 women. In this case, both the stereotype and
simplicity, we stick to the traditional labeling. In the same vein, we use the term "logical" as a general header to refer both to standard logic and probability theory.
base rate probabilities would cue the same response (that Jo is a man). In conflict problems, studies showed that even incorrect reasoners (compared to correct reasoners in noconflict problems) showed elevated response times, decreased post-decision confidence, and higher activation in brain areas mediating conflict detection across a range of tasks (for review see De Neys, 2012).

These results made some authors suggest that there occurs some kind of elementary processing of logical/probabilistic information even during Type 1 processing. De Neys (2012) argues that conflict detection happens as a result of two conflicting Type 1 outputs, generated by two kinds of intuitions. He argues that one of these intuitions is based on stereotypes or common beliefs (heuristic intuition) the other one is based on logico-mathematical principles (logical intuition).

Recently, Bago and De Neys (2017a) went a step further and argued that people are not just able to detect the conflict intuitively but some of them are able to give the logically correct response intuitively. Our so-called hybrid dual process model argues that the two different intuitions differ in activation strength (or "salience"), and the actual intuitive response that the person provides will be the one which gained more strength. The relative difference between the strength of the heuristic and logical intuitions defines how pronounced the conflict is; the smaller the relative difference, the more pronounced the conflict will be; the larger the relative difference, the less pronounced it will be.

A key question at this point is to search for boundary conditions; identify cases in which the strength of different intuitions will be more or less pronounced. One way to do so is to manipulate the presentation order of base rate information and stereotypes. Let us explain why. In a previous study, Pennycook, Fugelsang, and Koehler (2015) argued that a "given piece of information is at its most salient just prior to judgement" (Pennycook et al., 2015, p. 57). Pennycook et al. (2015) further argued that this would mean that base rate information is most salient if presented right before the decision was made (after the stereotypical description had been presented). The authors observed that presenting the base rate information at the end of the problem indeed boosted participants' accuracy compared to the condition when it was presented first. To help us explain these results, one could operationalize saliency as the strength of a given intuitive response. Hence, whatever information was presented later, would be the more salient, therefore the intuition cued by this piece of information would be the stronger one.

In this study, we wanted to test the robustness of these findings - will we get the same effects after purely intuitive Type 1 processing? Thus, to test this question, one needs to use a research design which is able to separately measure intuitive Type 1 responses from analytic Type 2 responses. For this reason, we used the two response paradigm (Thompson, Prowse Turner, \& Pennycook, 2011). In the two response paradigm, participants are presented with the same item twice. First, they are asked to give a very quick
intuitive, initial response. Then, the same task is presented again and now they can take as much time as they want before providing their final response. One also needs to be sure that the initial response is truly intuitive; we achieved this by applying a strict response deadline ( 3 seconds) and a secondary task that burdens reasoner's (executive) cognitive capacity during the initial response. With these manipulations we can experimentally knock out Type 2 processing during the initial responding (Bago \& De Neys, 2017a).

Our hypothesis was that if presentation order indeed affects the strength of an intuition, we should observe the same effect after purely intuitive processing as has been observed previously after deliberative thinking. That is, if base rates are presented last, the strength of the base rate intuition should be higher, and therefore more correct responses should be observed both at the initial and final response stages.

## Study 1

## Method

## Participants

In total, 149 participants took part in the experiment ( 86 female, $M=39.3$ year, $S D=12.7$ year). Participants were recruited online, via Crowdflower, and received $\$ 0.25$ for their participation. Subjects were randomly assigned to one of the two conditions. Note that data in the S-BR condition were taken from the study of Bago \& De Neys, (2017b). A total of $44.5 \%$ of participants reported having high school as highest completed educational level, while $52.1 \%$ reported that they have a post-secondary educational degree (3.4\% reported less than high school).

## Materials

Reasoning task. Participants solved a total of eight baserate problems. All problems were taken from Pennycook, Cheyne, Barr, Koehler, and Fugelsang (2014). Participants always received a description of the composition of a sample (e.g., "This study contained I.T engineers and professional boxers"), base rate information (e.g., "There were 995 engineers and 5 professional boxers") and a description that was designed to cue a stereotypical association (e.g. "This person is strong"). Participants' task was to indicate to which group the person most likely belonged.

The problem presentation format we used in this research was based on Pennycook et al.'s (2014) rapid-response paradigm. In this paradigm, the base rates and descriptive information are presented serially and the amount of text that is presented on screen is minimized. Pennycook et al. introduced the paradigm to minimize the influence of reading times and get a purer and less noisy measure of reasoning time per se. Participants received 3 pieces of information in a given trial. First, the names of the two
groups in the sample (e.g., "This study contains clowns and accountants"). This sentence stayed on the screen and was always presented first. Participants were presented with stereotypical descriptive information (e.g., Person 'L' is funny) as well. The descriptive information specified a neutral name ('Person L') and a single word personality trait (e.g., "strong" or "funny") that was designed to trigger the stereotypical association. Participants also received the base rate probabilities. In this experiment, we manipulated the presentation order of the base rate probabilities and stereotypes. So, for one group the base rates were presented first (BR-S), for the other group, the base rates were presented last, after the stereotype (S-BR). Presentation order was manipulated between-subject. The following illustrates the full problem format in the S-BR condition:

## This study contains clowns and accountants. <br> Person 'L' is funny. <br> There are 995 clowns and 5 accountants. <br> Is Person 'L' more likely to be: <br> o A clown <br> o An accountant

Half of the presented problems were conflict items and the other half were no-conflict items. In no-conflict items, the base rate probabilities and the stereotypic information cued the same response. In conflict items, the stereotypic information and the base rate probabilities cued different responses. Three kinds of base rates were used: 997/3, 996/4, 995/5.

Each problem started with the presentation of a fixation cross for 1000 ms . After the fixation cross disappeared, the sentence which specified the two groups appeared for 2000 ms . Then the first information appeared, for another 2000 ms , while the first sentence remained on the screen. Finally, the last information appeared together with the question and two response alternatives. Note that we presented the last information and question together (rather than presenting the last information for 2000 ms first) to minimize the possibility that some participants would start solving the problem during the presentation of the last part of the problem. Once all the parts were presented, participants were able to select their answer by clicking on it. The position of the correct answer alternative (i.e., first or second response option) was randomly determined for each item. The eight items were presented in random order.

Confidence in the correctness of the response was recorded after the initial and the final response stages by asking participants to indicate their confidence level on a scale ranging from $0 \%$ to $100 \%$.
Cognitive load task. We used a concurrent load task - the dot memorization task - to burden participants' executive cognitive resources while they were solving the reasoning tasks. The idea behind the load manipulation is straightforward. One of the defining features of Type 2 processing is that it requires executive (working memory) resources (e.g., Evans \& Stanovich, 2013; Kahneman, 2011).

Hence, if we burden participants' cognitive resources with a secondary load task while they are solving the reasoning problems, we reduce the possibility that they can engage in Type 2 thinking (De Neys, 2006).
In every trial, after the fixation cross disappeared, participants were shown a matrix in which 4 dots were presented in a complex interspersed pattern in a $3 \times 3$ grid for 2000 ms . Participants were instructed to memorize the pattern. Previous studies established that this demanding secondary task successfully burdens executive resources during reasoning (De Neys, 2006). After the matrix disappeared, the reasoning problem was presented as described above and participants had to give their first response. Then participants were shown four matrices with different dot patterns and they had to select the correct, to-be-memorized matrix. Participants were given feedback as to whether they recalled the correct matrix or not. Subsequently, the problem was presented again and participants selected their final response and response confidence. Hence, no load was imposed during the second, final response stage. All trials on which an incorrect matrix was selected ( $9.5 \%$ of trials) were removed from the analysis.
Response deadline. In order to minimize the possibility of Type 2 engagement during the initial response, we used a strict response deadline ( 3000 milliseconds), based on a reading pre-test (see Bago \& De Neys, 2017a). 1000 ms before the deadline, the background turned yellow to alert the participants to the approaching deadline. If participants did not select an answer within 3000 ms they got feedback to remind them that they had not answered within the deadline and they were told to make sure to respond faster on subsequent trials. Obviously, there was no response deadline on the final response, but only on the initial response. All trials where participants did not manage to provide a response were excluded from the analysis (8.7\% of trials).
Procedure. The experiment was run online. People were clearly instructed that we were interested in their first, initial response to the problem. Instructions stressed that it was important to give the initial response as fast as possible and that participants could afterwards take additional time to reflect on their answer. After the instructions, participants were presented with practice problems to familiarize them with the procedure. At the end of the experiment, demographic questions were collected.

## Results

Our main interest concerns the response accuracy analysis. Table 1 gives an overview of the findings. As one can see, we replicated the findings of Pennycook et al. (2015) at the final response stage for the conflict problems: Final accuracies on conflict problems are higher (41.6\%) when the base rates are presented last vs. first ( $24.3 \%$ ). However, contrary to our expectations, we do not observe the same effect at the initial response stage; there is even a trend towards fewer correct responses in the "base rates
last" S-BR condition ( $29.7 \%$ ) vs BR-S ( $31.8 \%$ ) condition. Indeed, the final conflict response accuracies in the S-BR condition were higher than the initial conflict response accuracies, whereas the reverse trend can be observed in the BR-S condition. In other words, the condition with the highest final accuracy (S-BR) was the one with the lowest initial accuracy, while the condition with the lowest final accuracy (BR-S) was the one with the highest initial accuracy.

Finally, as expected, note that accuracies on the noconflict problems were always very high. Not surprisingly, in the absence of conflict, both the stereotype and base-rates can cue the correct response whatever order the information is presented in.

Table 1. Percentage of correct initial and final responses for conflict and no-conflict items in both order conditions.

|  | Response | Order |  |
| :--- | :--- | :--- | :---: |
|  |  | S-BR | BR-S |
| Conflict | Initial | $29.7 \%$ | $31.8 \%$ |
|  | Final | $41.6 \%$ | $24.3 \%$ |
| No-conflict | Initial | $93.4 \%$ | $90.1 \%$ |
|  | Final | $93.7 \%$ | $91.4 \%$ |

Note. $\mathrm{S}-\mathrm{BR}=$ base rates last/ BR-S = base rates first.
We used mixed effect logistic regression (logit) models to analyze the data and entered accuracy as a dependent variable. The order manipulation (S-BR/BR-S), response number (initial/final response), and their interaction were entered as predictors into the model. We also accounted for the random effect (random intercept) of subjects. We concentrated our analysis on the critical conflict problems. Only the interaction improved model fit significantly $\chi^{2}$ (5) $=20.18, p<0.0001, b=1.94$, but not the main effect of order $\chi^{2}(3)=0.19, p=0.66$ or response number $\chi^{2}(4)=$ $0.38, p=0.54$. These results confirm our visual inspection that order affects initial and final accuracies differently.

Table 2. Frequency of each direction of change category (number of trials) for conflict items in both conditions.

| Direction of change | Order |  |
| :--- | :--- | :--- |
|  | S-BR | BR-S |
| 11 | $26.7 \%(54)$ | $19.7 \%(47)$ |
| 00 | $55.4 \%(112)$ | $63.6 \%(152)$ |
| 10 | $3 \%(6)$ | $12.1 \%(29)$ |
| 01 | $14.9 \%(30)$ | $4.6 \%(11)$ |

Note. S-BR = base rates last/ BR-S = base rates first.
For completeness, one could also test the direction of change in every trial (Bago \& De Neys, 2017a). Specifically, people can give correct or incorrect responses on both response stages; this means that one could give two correct (" 11 "), two incorrect ("00"), an initial correct but final incorrect ("10"), or an initial incorrect but final correct (" 01 ") response. The results of the direction of change analysis are summarized in Table 2. In both order
conditions, the most frequent categories were the " 00 " and " 11 " cases. In line with previous observations (Bago \& De Neys, 2017a; Thompson et al., 2011) people rarely changed their initial response (i.e., taken together the " 10 " and " 01 " cases account for $16 \%-18 \%$ of the trials). Interestingly, the direction in which people changed also tended to be reversed; in the S-BR condition most people who did change, changed from an incorrect to correct response (i.e., " 01 " category, $14.9 \%$ vs " 10 " category, $3 \%$ ). However, in the BR-S condition most people who changed their initial response, changed it to an incorrect response (i.e., " 10 " category dominates with $12.1 \%$ vs $4.6 \%$ for the " 01 " category). Hence, this fits with the overall trend towards the higher likelihood of an initial incorrect and final correct response when the base rates are presented last. A Chisquare test of independence revealed that the distribution of the direction of change categories in the two order conditions significantly differed from each other $\chi^{2}(3)=$ $27.56, p<0.0001$.

## Discussion

Contrary to our expectations, we did not observe the expected accuracy effect at the initial response stage; we only observed it in the final response stage. However, we wanted to be sure that the findings were robust before drawing any conclusions. Note that Pennycook et al. (2015) already observed that their order findings were robust against manipulations of the extremity of the base rates. That is, they found the same order effect on (final) accuracies when they used so-called "moderate" base rates (e.g., base rate probabilities of 700 men and 300 women) instead of the "extreme" base rates (e.g., e.g. base rate probabilities of 995 men and 5 women) that were adopted in our (and their) Study 1. In Study 2 we therefore also adopted the moderate base-rates and examined whether the unexpected reversal of the order effect on initial, intuitive responses would still be observed.

## Study 2

## Method

## Participants

In total, 162 participants took part in the experiment (98 female, $M=40.2$ year, $S D=14.6$ year). Participants were recruited online, via Crowdflower, and received $\$ 0.25$ for their participation. Subjects were randomly assigned to one of the two conditions. Note that data in the S-BR condition were taken from the study of Bago and De Neys (2017b). A total of $46.3 \%$ of participants reported having high school as highest completed educational level, while $52.5 \%$ reported that they have a post-secondary educational degree (1.3\% reported less than high school).

## Materials

Reasoning task. The identical experimental design was used as in Study 1. The only difference is that we used moderate base rates instead of extreme ones, namely $700 / 300,710 / 290$ and $720 / 280$. In $16.7 \%$ of the trials participants did not provide the correct response for the dot matrix task, and in $10.5 \%$ of the trials, participants did not manage to produce an initial response within the deadline. These trials were excluded from further analysis. Overall, $24.6 \%$ of the trials were excluded and 977 were analyzed.

## Results and discussion

Table 3 summarizes the accuracy results. As the table indicates, no-conflict response accuracies are again very high overall and we also replicated the conflict problem pattern we observed in Study 1: As Pennycook et al. (2015) found, presenting the base rates last led to increased accuracy on the final response. However, as in Study 1, the opposite trend was observed in the initial response. We also observe again that there were more initial than final incorrect response in the BR-S condition, whereas the opposite trend is observed in the S-BR condition. Statistical analysis on the conflict problems confirmed our visual inspection; neither presentation order $\chi^{2}(3)=0.04, p=0.84$, nor response number improved model fit significantly, $\chi^{2}$ (4) $=0.05, p=0.83$, only their interaction $\operatorname{did} \chi^{2}(5)=9.73, p=$ $0.0018, b=1.4$.

Table 3. Percentage of correct initial and final responses for conflict and no-conflict items in both order conditions.

|  | Response | Order |  |
| :--- | :--- | :--- | :---: |
|  |  | S-BR | BR-S |
| Conflict | Initial | $16.4 \%$ | $18.3 \%$ |
|  | Final | $23 \%$ | $13.2 \%$ |
| No-conflict | Initial | $90.9 \%$ | $90.9 \%$ |
|  | Final | $90 \%$ | $92.5 \%$ |

Note. S-BR = base rates last/ BR-S = base rates first
Table 4 summarizes the results of the direction of change results for conflict items. Here too we observe the same trend as in Study 1. Among the few people who changed their response, the direction in which they changed are reversed as a function of presentation order; in the S-BR condition most people who did change, changed from an incorrect to correct response. But in the BR-S condition, more people changed to an incorrect response. A Chisquare test of independence revealed that the distribution of the direction of change categories in the two order conditions significantly differed from each other $\chi^{2}(3)=$ $18.22, p=0.0004$.

Table 4. Frequency of each direction of change category (number of trials) for conflict items in both order conditions.

| Direction of change | Order |  |
| :--- | :--- | :--- |
|  | S-BR | BR-S |
| 11 | $14.2 \%(32)$ | $8.2 \%(21)$ |
| 00 | $74.8 \%(169)$ | $76.7 \%(197)$ |
| 10 | $2.2 \%(5)$ | $10.1 \%(26)$ |
| 01 | $8.8 \%(20)$ | $5.5 \%(13)$ |

Note. S-BR = base rates last/ BR-S = base rates first

## General Discussion

In this paper, we tested whether manipulating the presentation order of the base rates and stereotypes had the same effect after purely intuitive processing (i.e., initial response) as had been observed previously after deliberative thinking (i.e., final response). In two studies, we replicated the findings of Pennycook et al. (2015) at the final response stage: Final accuracies on conflict problems were higher when the base rates were presented last. However, contrary to our expectations, in both studies this effect consistently reversed at the initial response stage. Why is this the case? We believe that these results draw attention to a simple but somewhat neglected issue in reasoning models, namely that intuitive responses are not generated instantly at full strength.

The hybrid dual process model that we presented in the introduction (e.g., Bago \& De Neys, 2017a) argues that reasoning performance in the initial response stage is determined by the strength of different intuitions, for example. The implicit assumption here is that the strength of these intuitions is "instant" and "constant". That is, the idea is that the intuition is readily generated with full force and maintains this strength level.

However, upon some further reflection, this assumption might be quite naïve. It is reasonable to assume that even a quickly generated intuition needs some time to reach its peak. Keeping this feature in mind might suffice to explain the current findings. Have a look at Figure 1. In this illustration, the strength of two intuitions $\left(I_{1}, I_{2}\right)$ change over time - they have a peak, a growth and a decay rate. The $y$ axis represents the strength, the x -axis represents time, while T 1 and T 2 represent the time of initial and final response, respectively.
$\mathrm{I}_{1}$ and $\mathrm{I}_{2}$ will start gaining strength when the relevant cue is presented (in the $S-B R$ condition $I_{1}$ is the heuristic intuition cued by the presentation of the stereotype, and $\mathrm{I}_{2}$ is the logical intuition cued by the base rate information). So, in the S-BR condition, the stereotype is presented first. When the stereotype is presented, the intuition $\left(\mathrm{I}_{1}\right)$ cued by it starts gaining strength. Subsequently, the presentation of the base rate information cues the logical intuition $\left(\mathrm{I}_{2}\right)$ and its strength will also start rising. Both intuitions grow until they reach their peak. At T1, $\mathrm{I}_{1}$ has already reached its peak, and is stronger than $I_{2}$ (which has not reached its peak yet); as a result, $\mathrm{I}_{1}$ will be the initial response. But after T1, the
strength of $I_{1}$ starts decaying, while the strength of $\mathrm{I}_{2}$ is still increasing, and it reaches its peak at T 2 . At $\mathrm{T} 2, \mathrm{I}_{2}$ will be the stronger intuition, so people will more likely pick I2 as their final response. Hence, the mere growth and decay of an intuition - or it's "rise and fall" as we labelled it in the title implies that (ceteris paribus) the most recently cued intuition will be weaker earlier on in the reasoning process (e.g., initial response stage) and dominate later in the reasoning process (e.g., final response).

Clearly, we have presented and illustrated the most generic and general case in which two intuitions have the same peak level, growth, and decay rate. Obviously, these features might vary. One intuition might have a higher peak than the other, or a faster/slower growth/decay than the other. In addition, we believe that deliberation might also modulate the strength level. For example, one can imagine that one functional consequence of deliberation might be to boost or sustain the peak activation level of one intuition and decrease activation of the other. These more specific features have to be tested and validated in future studies. For example, one could try to test the role of deliberation by examining the impact of cognitive load on the presentation order findings in the second response stage. However, in all these more specific cases the general principle holds that we have to keep in mind that intuitions are not necessarily generated instantly but "rise and fall"; we need to consider their growth and decay. We believe this should motivate further research in the area by trying to determine what the growth and decay functions look like exactly.

Figure 1. Illustration of how the strength of intuitions might change over time. The $y$-axis represents the activation strength while the $x$-axis represents time. $I_{1}$ and $I_{2}$ represent the two cued intuitions. Note that in the BR-S condition $\mathrm{I}_{1}$ is the logical intuition cued by the base rate probabilities, while $\mathrm{I}_{2}$ is the heuristic intuition cued by the stereotypes. Consequently, in the S-BR condition, $\mathrm{I}_{1}$ is the heuristic and $\mathrm{I}_{2}$ is the logical intuition. $\mathrm{T}_{1}$ and $\mathrm{T}_{2}$ represent the time of initial and final response, respectively.

# The Refugees' Dilemma: not all deontological moral choices are of the same kind 

Albert Barque-Duran and Emmanuel M. Pothos<br>Department of Psychology, City, University of London, London EC1V 0HB, UK. albert.barque-duran@city.ac.uk

#### Abstract

The focus of the present work concerns the nature of deontological decisions. We test the hypothesis that it is possible to specify deontological moral choices based on an unemotional rule, norm or principle and that such moral choices can be distinguished from emotion-driven ones. Using a novel paradigm for moral choice that we call The Refugees' Dilemma, we provide evidence for such a rulebased route to moral choice. We show that participants with high scores in a Cognitive Reflection Test (CRT) were more likely to adopt utilitarian or rule-based responses, as opposed to emotional ones. We also found that rule-based respondents reported the highest average psychological distance, more so that even utilitarian respondents. These findings show how emotional and rule-based influences can be separated with the appropriate scenario and challenges the approach of assuming both influences can be combined into a single deontological route in dual-process models.

Keywords: Dual-Process Models; Deontological Ethics; Moral Judgment; Moral Psychology.

## Introduction

Moral decision-making is at the heart of modern democracies. Therefore, understanding the principles underpinning moral judgment is fundamentally important. Consider the recent refugee crisis. The number of forcibly displaced people worldwide reached 59.5 million at the end of 2014, the highest level since World War II. Of these 59.5 million, 19.5 million were refugees, and 1.8 million were asylum-seekers. How do individuals in destination countries form opinions regarding refugees and asylum seekers? At the very least, understanding the influences shaping moral choice should provide individuals with better insight (and possibly control) into their ultimate determinations.

The established theory is that moral decisions are driven by two complementary influences (Singer, 1991; Chaiken \& Trope, 1999). Such so-called dual-process theories contrast utilitarian responses, resulting from controlled cognitive processes, with non-utilitarian (considered deontological) responses, assumed to be driven by automatic/intuitive emotional processes (Greene et al., 2001; Greene \& Haidt, 2002; Greene et al., 2004; Koenigs et al., 2007). Utilitarian/consequentialist judgments are aimed at maximizing benefits and minimizing costs across affected individuals (Mill, 1861/1998), while the deontological perspective (Kant, 1785/1959) emphasizes rights and duties.

We focus on deontological decisions. It seems there is a fundamental inconsistency in current understanding of such
decisions. On the one hand, they are meant to be based on some rule, principle or norm. On the other hand, the deontological route is meant to be automatic and rely on the emotional content of the situation. However, evaluating a decision in terms of consistency to a rule (such as a moral norm) should be an analytic process (Posner \& Snyder, 1975; Sloman, 1996; Kahneman, 2003). There is a corresponding debate, with some researchers arguing that deontological decisions are a confabulation of moral emotions (Greene, 2007; Haidt, 2001) and others rejecting this assumption (Kahane \& Shackel, 2010; Kahane, 2012; Mihailov, 2016). We propose progress this debate, using a novel lab-based moral dilemma, that we call The Refugees' Dilemma. We explore whether it is possible to discriminate between moral decisions based on the emotional content of a situation (emotional decisions) and decisions driven by a prerogative of consistency with a rule (rule-based decisions).

Moral decision-making has been dominated by the Trolley dilemma (Thomson, 1985). However, the footbridge version of this dilemma is ill-suited for the present purposes, because the deontological option (not to push the fat man) is confounded with the emotional choice. The novel Refugees' Dilemma addresses this problem. The Refugees' Dilemma is an adaptation of the Trolley dilemma, but involving three choices: Utilitarian (driven by consequences/outcomes) vs. Emotional (driven by emotions) vs. Rule-based (driven by an unemotional rule).

We employ three tools which may reveal differences between the three postulated routes to moral decisionmaking. First, we measured psychological distance. We assume that participants making rule-based or utilitarian decisions will evaluate a situation with greater psychological distance and conversely regarding emotional decisions. Psychological distance weakens the intensity of people's affective reactions, such as feelings of empathy (Williams et al., 2014). Furthermore, increasing psychological distance leads individuals to construe situations in more abstract terms, which sometimes aligns with more utilitarian decision-making (Trope \& Liberman, 2010) and, we hypothesize, with more rule-driven decisions too.

Second, we tested participants on the Cognitive Reflection Test (CRT) (Frederic, 2005), which distinguishes two modes of cognitive processing, one that is more reflective and slow versus one that is more immediate with little conscious deliberation. Differences in the CRT should align with a propensity to adopt utilitarian vs. rule-based vs. emotional decision making, whereby we assume that
utilitarian and rule-based decisions require greater reflection (since a person needs evaluate how the well-being of one group of individuals is balanced with that of another or consider the applicability of a rule and the consequences of violating it) than emotional ones.

Third, we implemented a time-manipulation, whereby participants would either be told they had unlimited time or that they should respond as quickly as possible (but even in the time pressure condition participants had ample time to respond). Finally, we included measures with a mindset for practical application. Is responding in The Refugees' Dilemma sensitive to religious or political characteristics?

## Method

## Participants

A total of 1508 participants, all of whom were US residents, were recruited on-line and received $\$ 0.80$ for doing the task ( 706 women, 801 men ; M age $=34.6$ years, $\mathrm{SD}=11.17$ ). As this is the first study with The Refugees' Dilemma, no prior power analyses were conducted and instead we decided a priori to limit recruitment to 1500 participants. The City, University of London Psychology Department Research Ethics Committee granted approval for this project (reference PSYETH (S/L) 15/16 238).

## Materials and Procedure

The study was designed in Qualtrics, run on Amazon Mechanical Turk and lasted 10 minutes approximately. We used frequency of Type of Judgment (Utilitarian vs. Emotional vs. Rule-based) as the dependent measure. Time (No Time vs. Unlimited Time vs. Time Pressure) was manipulated between participants and we used the scores from the CRT (Frederic, 2005) to measure thoughtful (high CRT scores) vs. unreflective (low CRT scores) cognitive processes.

After a few preliminary screens (consent form; some basic demographic information), all participants were presented with The Refugees' Dilemma (full text in Online Supplementary Material). They were instructed to read it carefully and had to spend at least 60 seconds reading it before the experiment advanced. The Refugees' Dilemma asks a participant to imagine himself/herself as a security guard in a border control of a hypothetical country, which neighbors three other countries. Participants are told they have to make one last decision before borders close (until further notice) and that there are instructions that entry into their country will be allowed from just one country.

Then, participants were presented with a reinforcementlearning task to ensure that they had been paying attention during the previous screen. Three basic multiple-choice questions regarding The Refugees' Dilemma were presented (e.g., "As a security guard, what is the name of your country?). Feedback was provided and participants had to keep responding until no mistakes were made.

Subsequently, the three moral scenarios were presented (Utilitarian: where ten refugees from another country need help; Emotional: where a refugee orphan child from another country needs medical attention immediately; and Rulebased: where a traveller from your own country wants to go back home and the law from your country specifies that travellers who are citizens from your own country have to take priority when returning). The text for each scenario was supplemented with an illustration (Figure 1). The moral choice was then presented to participants: "Who do you allow to your country? Remember, you can only allow traveller(s) from one neighbouring country". Participants had to choose between Choice 1 (Utilitarian; "The 10 refugees from Beta"), Choice 2 (Emotional; "The refugee orphan child from Gamma"), or Choice 3 (Rule-based; "The traveller who is an Alpha citizen coming from Delta").

Regarding the time manipulation, one third of participants was not provided with any indication of time for making their judgment (No Time). Participants in the Unlimited Time condition were instructed as follows: "You will have unlimited time to answer the question in the next page. Think carefully about your judgment before responding". Participants in the Time Pressure condition were presented with the following instructions: "The question in the next page should be answered as fast as possible. Use your first impression/ gut feeling in order to respond"; these participants had to make their moral choice while a timer (at the top of their screen) kept track of elapsed time.

Participants were next asked to complete a 4-items questionnaire (see Online Supplementary Material), which was intended as a measure of the basis of participants' judgments (e.g., "How much would you say that doing the greater good for the greatest number of people/ emotion/ a principle, norm or rule was the basis for your decision?"). The order of these three questions was presented randomly and participants had to respond moving a slider that went from 0 (not at all) to 7 (for the above question, completely based in doing the greater good for the greatest number of people/ emotion/ a principle, norm or rule). The fourth item of the questionnaire, following the same format, was a measure of psychological distance (Trope \& Liberman, 2010) (e.g., "How distant do you feel yourself from the scenario when making your decision?").

Participants were next presented with three "catch questions", to control for attention and basic comprehension during the task (e.g., "How many refugees there were in the group from Beta?").

Then, participants had to complete a CRT (Frederic, 2005) as a measure of two modes of cognitive processing, quick with little conscious deliberation versus slower and more reflective. The test consisted of three multiple-choice questions (e.g., "If it takes 5 machines 5 minutes to make 5 widgets, how long would it take 100 machines to make 100 widgets?").

Finally, participants were asked to complete demographic questions regarding their levels of Religiosity (using a 7-
point Likert scale) and Political Views (Liberal, Moderate, Conservative or Something else).

Figure 1: Illustrations and choices used in The Refugees'
Dilemma: (1) Utilitarian (judgment driven by consequences/ outcomes) vs. (2) Emotional (judgment driven by emotions) vs. (3) Rule-based (judgment driven by a rule, principle or norm).

## Results

## Validation of the Experimental Paradigm

We excluded those participants who did not answer the catch questions correctly (92/1508). No other sample trimming was conducted.

We first discuss results which aim to validate the assumptions in the design of The Refugees' Dilemma. We tested if the three different choices presented in the dilemma (Choice 1, Utilitarian, "The 10 refugees from Beta"; Choice 2, Emotional, "The refugee orphan child from Gamma"; and Choice 3, Rule-based, "The traveller who is an Alpha citizen coming from Delta") were indeed aligned with doing the greater good for the greatest number of people, with emotion or with a rule, as assumed (see Figure 2). As expected, participants making the utilitarian choice reported that their decision was mainly based on doing the greater good for the greatest number of people ( $\mathrm{M}=6, \mathrm{SD}=1.3$ ). Participants making the emotional choice reported that their decision was mainly based on emotions $(M=5.7$, $\mathrm{SD}=$ 1.4). Finally, participants making the rule-based choice reported that their decision was mainly based indeed on a rule, principle or norm $(\mathrm{M}=6, \mathrm{SD}=1.5)$. One-way ANOVAs for each group of participants were all significant: $\mathrm{F}(2,308)=56.93, \mathrm{p}<.001, \mathrm{w} 2=.27$ for the utilitarian respondents; $\mathrm{F}(2,1226)=337.787, \mathrm{p}<.001$, $\mathrm{w} 2=.35$ for the emotional respondents; $\mathrm{F}(2,2708)=2511.996, \mathrm{p}<.001$, $\mathrm{w} 2=.65$ for the rule-based respondents. A Tukey post-hoc test for each group revealed significant differences in the expected directions ( $\mathrm{p}<.001$ ). These results are all
consistent with expectation regarding the assumptions motivating the three options in The Refugees' Dilemma.

Figure 2: Mean scores for the basis of judgments, for participants making the utilitarian, emotional, or rule-based choice. Error bars represent standard errors.

As a manipulation check regarding time, we examined the amount of time that participants took to make their judgments. Participants spent more time responding in the Unlimited Time condition (18.74s) than in the No Time condition (14.47s) and than in the Time Pressure condition (8.11s). A one-way between subjects ANOVA for these means was significant $\left(\mathrm{F}(2,1414)=25.017, p<.001, w^{2}=\right.$ .03). A Tukey post-hoc test revealed that all pairwise comparisons between groups were significant $(p=.013)$.

## High vs. Low Cognitive Resources, Psychological

## Distance and Time

We first considered whether results from the CRT influence moral choice (entire sample; Figure 3). We selected participants who reported High vs. Low CRT scores (i.e. 3/3 points and $0 / 3$ points in the CRT, respectively). As expected, high CRT participants were more likely to opt for the utilitarian response $(59.38 \%)$ than low CRT ones ( $40.63 \%$ ). Likewise, emotional answers were more likely for low CRT participants (55.7\%) than otherwise (44.31\%). Importantly, the rule-based response was also more likely for high CRT participants ( $60.73 \%$ vs. $39.27 \%$ ), indicating the rule-based moral choices require a similar route as utilitarian ones. A $3 \times 2$ chi-square test on response counts, with the variables Type of Response (Utilitarian vs. Emotional vs. Rule-based) and CRT score (High vs. Low) was significant, $\chi 2(2, \mathrm{~N}=897)=19.66, \mathrm{p}<.001$.

Figure 3: Percentage of Utilitarian, Emotional and Rulebased responses for participants who followed a slow and more reflective cognitive process (High CRT) or a quicker with little conscious deliberation one (Low CRT). Error bars represent standard errors.

We next examined whether different moral changes reflected the expected differences regarding Psychological Distance (see Figure 4). Participants opting for the rulebased option reported the highest distance ( $\mathrm{M}=3.77$, $\mathrm{SD}=$ 2.1), followed by participants making the utilitarian selection ( $\mathrm{M}=3.18, \mathrm{SD}=2.1$ ), and finally the ones selecting the emotional answer $(\mathrm{M}=2.71, \mathrm{SD}=1.93)$. It is interesting that participants making the rule-based choice reported the highest distance, perhaps because the application of a rule to the dilemma requires a degree of detachment from the specifics of the situation more so than even for utilitarian respondents. A one-way between subjects ANOVA for these means was significant ( $\mathrm{F}(2$, $1414)=38.233, \mathrm{p}<.001, \mathrm{w} 2=.05)$. A Tukey post-hoc test revealed that psychological distance was significantly different between participants making the utilitarian and the rule-based selection ( $\mathrm{p}=.018$ ) and between participants making the emotional and rule-based selection ( $\mathrm{p}<.001$ ). There were no statistically significant differences between the utilitarian and emotional groups $(\mathrm{p}=.089)$.

Figure 4: Mean scores for psychological distance between the different moral choices presented in The Refugees’ Dilemma. Error bars represent standard errors.

Finally, we considered differences in Type of Response (Utilitarian vs. Emotional vs. Rule-based) depending on both the Time manipulation (No Time vs. Unlimited Time vs. Time Pressure) and the CRT score (High vs. Low). The three-way loglinear analysis produced a final model that retained the Type of Response x CRT score interaction, but not the three-way interaction. The likelihood ratio of this model was $\chi 2(12)=11.647, \mathrm{p}=.475$. The Type of Response $\times$ CRT score interaction was significant, $\chi 2$ (2) $=$ $20.225, \mathrm{p}<.001$. This interaction indicates that the relative frequencies of utilitarian, emotional and rule-based responses were different across high, low CRT scores. Of interest, the frequency of rule-based responses increased more dramatically between low, high CRT scores ( 225 to 351), than for utilitarian responses ( 25 to 38 ). As expected, the frequency of emotional responses followed the opposite direction (142-113 ratio of low to high CRT scores). Therefore, the analysis reveals a fundamental difference between the cognitive resources used to reach a specific type of judgment (as also concluded with the other analyses above), but these effects were not influenced by the time manipulation.

## Political Views and Religiosity

We first explored the differences in moral choice, depending on participants' stated Political Views (Figure 5a). Liberals were more likely to opt for the utilitarian response (10.11\%) compared to Moderates (5.3\%) and Conservatives (3.9\%). Liberals were also more likely to opt for the emotional answer (33.23\%) compared to Moderates (28.53\%) and Conservatives (21.19\%). Interestingly, Conservatives were more likely to opt for the rule-driven judgment (74.93\%) compared to Liberals (56.67\%) and Moderates (66.13\%). A corresponding $3 \times 3$ chi-square test of independence was highly significant, $\chi 2(4, \mathrm{~N}=1363)=37.62, \mathrm{p}<.001$. Individual $3 \times 2$ chi-square tests for each category of
respondents (utilitarian, emotional, rule-based) were also significant $\left(\chi^{2}(2, \mathrm{~N}=1363)=15.61, \mathrm{p}<.001 ; \chi^{2}(2\right.$, $\mathrm{N}=1363)=15.64, \mathrm{p}<.001 ; \chi 2(2, \mathrm{~N}=1363)=33.23, \mathrm{p}<$ .001; respectively).

Regarding religiosity, we selected only participants who reported Low vs. High levels of religiosity (i.e. $1 / 7$ points and $3 / 7$ or more points in the 7 point Likert scale, respectively; Figure 5b). Low-Religious participants were more likely to opt for the utilitarian response (8.1\%) compared to High-Religious ones (6.32\%). High-Religious participants were more likely to opt for the emotional answer ( $31.04 \%$ ) compared to Low-Religious ones (25.6\%). Finally, Low-Religious participants were more likely to opt for the rule-driven judgment ( $66.35 \%$ ) compared to HighReligious ones ( $62.64 \%$ ). A $3 \times 2$ chi-square test of independence on Type of Judgment (Utilitarian vs. Emotional vs. Rule-based) against participants' levels of Religiosity (Low vs. High) was significant $\chi 2$ (2, N=994) = 15.36, p $<.001$.

## Discussion

Established theory assumes that deontological moral choices involve a fast, gut-feeling process, driven by the emotional content of the situation (Greene, 2009). There is no doubt that this is sometimes the case, e.g., in cases of moral norms of high emotional content (Valdesolo \& DeSteno, 2006). However, it seems counterintuitive that all deontological moral choices are of this kind. We supported the hypothesis that there are deontological moral choices based on an unemotional rule, which can be distinguished from emotiondriven ones. We provided evidence for a route to moral choice, distinct from the emotional and utilitarian routes, and rather based on a prerogative to adhere by a given rule.

The characteristics of the rule-based influence in moral choice were explored with three manipulations. First, according to Construal Level Theory (CLT), greater psychological distance would go hand-in-hand with lower emotional involvement. We found that rule-based respondents reported the highest average distance, more so that even utilitarian respondents. Such a result is consistent with the nature of the rule provided in The Refugees' Dilemma, since application of the rule forces ignoring most characteristics of the different options. Second, high CRT participants were more likely to adopt utilitarian or rulebased responses, as opposed to emotional ones. This shows how emotional and rule-based influences can be separated and challenges the approach of assuming both can be combined into a single deontological route. Note, other work supports a view of utilitarian judgments as reflecting a greater "need for cognition" (Bartels, 2008), "cognitive reflection" (Hardman, 2008), and working memory capacity (Moore et al., 2008). Third, a time manipulation produced a complex interaction with CRT level. Future work should examine whether perhaps just tracking time might result in reduced cognitive resources for moral decisions, regardless of condition.

We developed a new paradigm for moral choice, The Refugees' Dilemma, which is based on a situation relevant for millions of citizens, especially in Europe and North America. We hope that future work will further explore moral decision situations informed by relevant current affairs or near-future social dilemmas (e.g., Bonnefon et al., 2016). With a mind to such applications, we reported some interesting correspondences between moral choice in The Refugees' Dilemma and participants' political affiliations and religious convictions.

#### Abstract

Natural pedagogy emerges early in development (Knudsen \& Liszkowski, 2012), but good teaching requires presenting evidence specific to learners' knowledge (Shafto, Goodman, \& Griffiths, 2014). How might the development of Theory of Mind (ToM) relate to the ability to select pedagogical evidence? We present a training study in which we investigated the link between preschool-aged children's false-belief understanding and their ability to select evidence for teaching. Our results suggest that children with more advanced ToM abilities were better evidence selectors, even when controlling for effects of age and numerical conservation abilities. We also found that children who improved more in false-belief understanding from pre- to post-test performed better on the pedagogical tasks over the course of the training. Finally, we report tentative evidence for a link between the pedagogical training and improvements in ToM. Our findings suggest important connections between ToM and evidential reasoning in natural pedagogy in early childhood.

Keywords: pedagogy, theory of mind, evidence selection

## Introduction

The ability to teach and be taught by others is an indispensable human capability. Social transmission of information is one of the key ways in which both children and adults learn about the world, and some have argued that the natural tendency to teach and to be ready to learn from others may be what sets human intelligence apart from other animals (e.g., Moll \& Tomasello, 2007). Indeed, teaching in children emerges at an early age: Three-year-olds spontaneously engage in teaching behavior with their peers (Ashley \& Tomasello, 1998), and infants as young as 12 months selectively point to convey information to naïve (as opposed to knowledgeable) adults (Knudsen \& Liszkowski, 2012). Investigating children's developing ability to teach others may shed insight into the cognitive mechanisms that support natural pedagogy. We will suggest that the factors that support this skill - reasoning about the knowledge states of others and reasoning about evidence - are intertwined.

## Teaching in Early Childhood and Theory of Mind

Children's teaching abilities improve considerably between the ages of three and five years. Davis-Unger and Carlson (2008) had three- to five-year-old children teach a confederate how to play a novel board game, and found that older children 1) taught for longer periods of time, 2) explained
more of the rules, and 3) used a more diverse range of teaching strategies. Similarly, Strauss, Ziv, and Stein (2002) found that five-year-olds taught others by providing verbal explanations, whereas three-year-olds used more demonstrationbased teaching strategies. There is also evidence that older children possess more declarative knowledge about pedagogy in general (Ziv \& Frye, 2004).

What are the fundamental cognitive underpinnings that support the development of children's pedagogical skills? Theory of Mind (the ability to represent others' mental states and to understand that others may experience mental states that are different from one's own) has been proposed as being critical for children's teaching. Intuitively, a relationship between Theory of Mind (ToM) and children's developing teaching skills makes sense: ToM involves monitoring the mental states of others, and effective teaching requires understanding what your student does and does not know. Additionally, ToM undergoes drastic qualitative change between the ages of three and five, the same period during which children's pedagogical skills are developing. Indeed, there is a wealth of empirical work that provides evidence for a link between ToM development and pedagogical skill (Davis-Unger \& Carlson, 2008; Strauss et al., 2002). ToM may thus be an important cognitive mechanism that drives the development of children's ability to teach others.

## Evidence Selection in Teaching

The past work on children's teaching and ToM ability has operationalized teaching ability in various ways, including by the length of the teaching interaction, the types of strategies used, and whether children recognize that some individuals need to be taught while others do not. An additional and perhaps more detailed way of conceptualizing pedagogical skill comes from the distinct but related body of literature on concept learning and pedagogical sampling. Research in this field emphasizes the importance of selecting and presenting a learner with specific evidence that will allow them to infer a particular conclusion (e.g., Gweon, Tenenbaum, \& Schulz, 2010; Shafto et al., 2014). According to this view, being a "good" teacher requires more than just recognizing whether or not someone needs to be taught, or even that some learners need to be taught more than others; rather, good teaching depends on having a deeper understanding of the precise ev-
idence that certain learners may or may not need in order to infer a particular conclusion.

Prior work has shown that children are sensitive to learning goals in pedagogical scenarios. Six-year-olds will select diverse samples to teach a novel concept to a peer, but not to learn a novel concept for themselves (Rhodes, Gelman, \& Brickman, 2010). Preschoolers are even capable of selectively presenting evidence to intentionally deceive learners. Rhodes, Bonawitz, Shafto, Chen, and Caglar (2015) showed three- to six-year-olds a novel toy that activated when any block was placed on it. They then asked children to pick two blocks to either 1) teach a naïve puppet how the toy really worked, or 2) trick her into thinking that only red blocks made it go. Children reliably selected blocks that would best communicate the pedagogical goal, regardless of whether the goal was to teach or to deceive (Rhodes et al., 2015).

There is also an abundance of work demonstrating that when learning from others, children use the evidence presented to them to make inferences about the knowledgeability of their teachers (see Kushnir and Koenig (in press) for a recent example). Pasquini, Corriveau, Koenig, and Harris (2007) showed children videos of adults naming familiar objects with varying rates of accuracy; children were then asked from whom they would prefer to learn the names of novel objects. Three- and four-year-olds preferred to learn from more accurate teachers, suggesting that children use presented evidence in pedagogical scenarios to update their beliefs about whether teachers are knowledgeable or not. Despite this robust preference for accurate teachers, there has also been work showing that children are able to exonerate previously inaccurate teachers whose past inaccuracies occurred for legitimate reasons (Nurmsoo \& Robinson, 2009). Children therefore additionally monitor teachers' epistemic states in conjunction with the evidence they've presented in order to make inferences about their competence.

Together, the works cited in this section suggest that children are developing the ability to reason about evidence in the service of teaching in the early childhood years. However, we are unaware of any work that has investigated the precise relationship between ToM development and children's ability to effectively select pedagogical evidence to teach others. ToM may play an especially important role in supporting this aspect of teaching, because effective evidence selection requires the on-line monitoring of a learner's epistemic state relative to a particular learning goal. The current paper presents a novel experiment that explores the relationship between children's pedagogical evidence selection and ToM development.

## Teaching Training and Theory of Mind Study

We investigated the relationship between children's Theory of Mind ability (as measured by a false-belief battery; Wimmer \& Perner, 1983; Gopnik \& Astington, 1988) and their ability to select evidence to teach another. Assuming this link, we predicted that children with more proficient Theories of Mind would be better at pedagogical evidence selection, and also
that training pedagogical skill might lead to improvements in ToM reasoning abilities. To explore this, we assessed children's false-belief understanding before and after training them on two pedagogical tasks. We also assessed children's understanding of numerical conservation; we wanted to be sure that any improvements we saw due to the pedagogical training was specific to ToM abilities and not to other unrelated domains of cognitive development.

We chose to use false-belief tasks to measure ToM ; between the ages of three and five, children reliably transition from predicting others' actions based on the veridical state of the world to understanding that others' actions are in fact guided by their (sometimes false) beliefs (Wellman, Cross, \& Watson, 2001). Some have argued that implicit falsebelief understanding emerges at much earlier ages (between 10 and 15 months), and that apparent developments in ToM between the ages of 3 and 5 years are actually reflections of task demands (Baillargeon, Scott, \& He, 2010). Nevertheless, there is ample evidence that the changes that occur in children's ToM understanding during the preschool years are critical: This is the time during which children gain the ability to provide explicit causal explanations for others' actions based on epistemic states (e.g., Bartsch \& Wellman, 1989); further, differences in preschoolers' false-belief understanding are predictive of numerous other capabilities, including children's tendency to talk about people in everyday conversation, and their social competence more broadly (see Astington \& Jenkins, 1995; Imuta, Henry, Slaughter, Selcuk, \& Ruffman, 2016), suggesting an important link between performance on these tasks in early childhood and real cognitive development. We therefore used false-belief tasks to measure ToM abilities.

## Methods

## Participants

Sixty-one children $\left(M_{\text {age }}=47\right.$ months, range $=39-55$ months) were recruited from and tested at local preschools.

## Tasks

False-Belief Children's ToM was assessed using two classic false-belief tasks. In the first task, children saw a storybook in which Sally put her cookie in a box and then left the room. While Sally was gone, Anne came in and moved Sally's cookie from the box to a bag. Children were then asked, "When Sally comes back, where will she look for her cookie?" Children earned a point if they correctly reported that Sally would look for her cookie in the box. In the second task, children were shown a crayon box that, it was soon revealed, actually contained some keys. Experimenters asked the children 1) what they thought was inside the box when they first saw it, and 2) what was really inside. Children earned one point if they correctly answered both of these questions. The experimenter then introduced a doll, and asked children the same two questions ("What will the doll think is inside this box? What's really inside?"). Children
again received one point for correctly answering both questions. False-belief scores could thus range from zero to three.
Numerical Conservation Control Task To assess children's understanding of numerical conservation, experimenters showed children two parallel rows of ten objects each, both of which were equal in length. Children were asked if row A or B had more objects, or if they were the same. Then, experimenters lengthened one of the rows, and again asked children if row A or B had more objects, or if they were the same. This process constituted one trial; children had to answer both questions correctly on a given trial to earn one point. Experimenters administered two trials; conservation scores could thus range from zero to two.
Pedagogical Training and Test The pedagogical training entailed a novel word learning task and a causal toy activation task. In the novel word learning task, children were told that a novel word (e.g., "Dax") represented the concept they were trying to learn. They were shown a picture of an object with two discrete features (e.g., a fork that is white), and were told that this picture represented the target concept ("This is a Dax!"). Given the inherent ambiguity in the word's extension, the experimenter explained what the novel word really meant ("Dax means fork."). The experimenter then presented two additional pictures, each of which contained an item that overlapped with exactly one of the original picture's two features (e.g., a white spoon, and a black fork). The experimenter then asked children to teach a confederate what the novel word meant by providing examples using the three pictures, without explicitly telling the confederate what the novel word meant. In order to provide a correct response, children had to present the necessary and sufficient examples to identify the correct rule while ruling out other hypotheses ${ }^{1}$.

In the causal toy activation task, children were presented with a novel toy with two distinct mechanisms (e.g., a wheel and a bell). The experimenter first showed children how to activate the toy, causing it to perform some desirable outcome such as lighting up or playing music ("You need to ring the bell and spin the wheel at the same time to make the toy go."). As in the novel word task, children were then instructed to teach a confederate about the toy by providing examples of which combinations of mechanisms did and did not make the toy go. In order to provide a correct response, children had to demonstrate both necessary and sufficient evidence for the confederate to rule out all alternative explanations and correctly infer which mechanism(s) activated the toy.

For both tasks, if children provided insufficient evidence, the confederate prompted the child by musing aloud about the remaining possible explanations. For example, if the child only showed the confederate that operating both mechanisms simultaneously made the toy go, the confederate might say:

[^19]"Oh, so you showed me both at the same time. It could be that you need to do both at the same time to make it go, or it could be that the wheel by itself could make it go, or that the bell by itself could make it go. Can you teach me?" Note that often children would need to present negative examples to rule out plausible hypotheses (e.g., showing that the wheel by itself did not make it go). The number of prompts children required before providing complete evidence was the primary DV for both pedagogical training tasks; these scores could range from a minimum of zero (i.e., children who provided necessary and sufficient evidence spontaneously) to a maximum of two (i.e., children who required prompting after each demonstration until all evidence had been provided).

There were six different versions of each task: The novel words were fep, dax, modi, toma, wug, and blicket; the causal toys were phone, gear toy, helicopter, shadowbox, red airplane, and purple. Some of the novel words represented just one of the two categories to which the example object belonged ("Dax means fork"), while others represented both categories ("Dax means white fork"). Likewise, some causal toys would activate any time one of the mechanisms was operated ("Any time you ring the bell, it makes the toy go"), while others would only activate if both mechanisms were operated simultaneously ("You need to ring the bell and spin the wheel at the same time to make the toy go"). Varying the stimuli in this way ensured that children would have distinct teaching goals on different trials, and would thus have to select evidence that corresponded to the particular teaching goal of a given trial in order to provide a correct response.

## Procedure

Children's understanding of false-belief and numerical conservation was assessed on a preliminary testing day. Children who scored fewer than two out of three points on the false-belief task were classified as copy theorists (i.e., those who think that beliefs are always consistent with the world), while children who scored two or more points were classified as perspective theorists (i.e., those who understand that beliefs may vary with perspective, and can thus be false; see Goodman et al., 2006). Copy theorist (CT) children ( $N=40$ ) were randomly assigned to either the control or the training condition. Over the course of the following six weeks (beginning on the preliminary testing day), children in the training condition ( $N=22 ; M_{\text {age }}=46$ months) received two training sessions per week on both pedagogical tasks. One version of each task was administered on a given testing session, with the novel word task always being presented first. As there were six versions of both the novel word task and the causal toy task, the experimenter administered the same version of each task across both sessions of a given week. The order in which the different versions of the tasks were presented was randomized across participants. At the end of this six week period, children's understanding of false-belief and numerical conservation were reassessed using the same measures with slightly different stimuli.

months) received no pedagogical training, and their falsebelief and conservation understanding was reassessed after a six-week delay. Perspective theorist (PT) children ( $N=21$; $M_{\text {age }}=49$ months) did not receive longitudinal pedagogical training, since they had little to no room for improvement on the false-belief tasks; instead, they received just one session of the pedagogical tasks on the preliminary testing day, allowing us to measure their initial teaching abilities. The versions of the pedagogical tasks used with PT children were randomized across participants. PT children's false-belief and conservation understanding was not reassessed. See Figure 1 for a schematic of our study design.

## Results

One CT child in the training condition did not complete one session of the causal toy task, another CT child did not complete one session of both tasks, and one PT child's numerical conservation abilities were not assessed; these individual data points were treated as missing in subsequent analyses. Otherwise, all children completed all training sessions and assessments. We created a composite pedagogical skill score for each training session by calculating the average number of prompts children required across both tasks in a given session. Lower scores indicated better task performance.

## Initial False-Belief \& Pedagogical Skill

We first investigated the effects of preliminary false-belief understanding on initial (i.e., non-trained) pedagogical skill. An independent-samples t-test compared CT children in the training condition to PT children on the average number of prompts required on the preliminary testing day. We found that PT children $(M=1.05, S D=.57)$ provided complete evidence with significantly fewer prompts than CT children $(M=1.45, S D=.55), t(41)=2.38, p=.022,95 \% \mathrm{CI}_{\text {diff }}=$ [.06, .75]; see Figure 2A. We also looked at the novel word and causal toy tasks separately: While PT children ( $M=.57$, $S D=.68$ ) significantly outperformed CT children ( $M=1.27$, $S D=.78)$ on the causal toy task $(t(41)=3.17, p=.003,95 \%$
$\left.\mathrm{CI}_{\text {diff }}=[.26,1.15]\right)$, there were no significant differences between the two groups on the novel word task (CT: $M=1.64$; PT: $\left.M=1.52 ; p=.584,95 \% \mathrm{CI}_{\text {diff }}=[-.30, .53]\right)$. This disparity may be explained by the seemingly increased difficulty of the novel word task relative to the causal toy task. Indeed, two paired-samples t-tests revealed that both CT and PT children performed better on the causal toy task than on the novel word task on the preliminary testing day (CT: $t(21)=5.05$, $p<.001,95 \% \mathrm{CI}_{\text {diff }}=[.56,1.35] ; \mathrm{PT}: t(20)=2.16, p=.042$, $\left.95 \% \mathrm{CI}_{\text {diff }}=[.01, .71]\right)$; additionally, more children required the maximum of two prompts on the novel word task $(N=29)$ than on the causal toy task $(N=12)$. The novel word task might have been more difficult for children than the causal toy task for several reasons; perhaps children are more generally familiar with toys, or have more experience teaching about toys than about words. Future work could explore the differences between these two tasks.

There are many possible reasons why PT children may have outperformed CT children on the causal toy task, including age or other cognitive factors. To control for this, we ran two between-subjects ANCOVAs, with theorist type (CT vs. PT) predicting performance on the causal toy task; we included preliminary conservation scores as a covariate in one analysis, and age at pre-test in the other. PT children still outperformed CT children on the causal toy task, even when controlling for effects of age $(F(1,40)=6.11, p=.018)$ and conservation scores $(F(1,39)=9.35, p=.004)$, providing stronger evidence for a direct link between false-belief understanding and teaching ability.

## False-Belief Improvement \& Pedagogical Skill

Next, we investigated the relationship between overall aggregate performance on the two pedagogical tasks and improvement on the false-belief task from pre- to post-test. Using data from CT children in the training condition, we ran a correlation between false-belief improvement (i.e., pre-test false-belief scores subtracted from post-test scores) and the

Figure 2: A. PT children provided the confederate with complete evidence after receiving significantly fewer prompts than CT children on the first day of pedagogical testing. B. Children required fewer prompts over the course of the pedagogical training. C. For children who answered all false-belief questions incorrectly at pre-test, those in the training condition significantly improved in false-belief understanding from pre- to post-test, whereas those in the control condition did not. Asterisks denote significance at the $p<.05$ level. All error bars represent two standard errors.
mean number of prompts required across all twelve training sessions. We found a statistically significant negative linear relationship between these two factors, $r(20)=-.43, p=$ .047. In other words, children who required fewer prompts over the course of the training generally improved more in false-belief understanding from pre- to post-test. Two partial correlations revealed that this finding qualitatively persisted when statistically controlling for average age $(r(19)=-.43$, $p=.054$ ) and improvement in conservation understanding $(r(19)=-.41, p=.063)$.

## Effect of Training on False-Belief Understanding

Finally, we evaluated the possible effects of pedagogical training on children's false-belief scores. Our first question was whether the training was actually effective in improving children's pedagogical skills. A repeated-measures ANOVA on the mean number of prompts children required on each of the twelve training sessions revealed a significant effect of session $(F(11,220)=4.96, p<.001)$, as well as a significant linear trend (i.e., a straight line fit the data at better than chance levels; $F(1,20)=20.85, p<.001)$. Children's performance on the pedagogical tasks thus did improve with training (see Figure 2B).

Next, we ran an independent-samples t-test comparing CT children in the training condition $(N=22)$ to those in the control condition ( $N=18$ ) on false-belief improvement. This direct comparison between training and control participants did not yield significant results ( $p=.65$ ). However, CT children who answered one false-belief question correctly at pre-test had less room for improvement. Indeed, looking only at CT children who answered zero false-belief questions correctly at pre-test, we did observe improved false-belief understanding for children in the training condition ( $N=12 ; M_{\text {improve }}=.19$, $S D=.26 ; t(11)=2.55, p=.027$ ), but not for those in the control condition ( $N=8 ; M_{\text {improve }}=.08 ; p=.170$ ); see Figure 2C. Importantly, conservation scores did not differ for either group between pre- and post-test (Training: $p=.551$; Control: $p=.197$ ), suggesting that the training targeted ToM
without necessarily leading to general improvement in cognitive reasoning. Note that this result does not directly compare training to control children, and should be interpreted with caution. However, coupled with our finding that initial false-belief understanding is related to non-trained pedagogical skill, this may suggest an important link between reasoning about others' minds and pedagogical evidence selection.

## Discussion

Past work has shown that children's developing ToM reasoning abilities are related to their pedagogical skill, but has not looked at the precise relationship between ToM development and the ability to select optimal evidence to teach others. Our results suggest that having a more developed ToM is broadly related to being better at evidence selection, even when controlling for age and more general cognitive abilities. Further, we found tentative supporting evidence for the idea that training pedagogical evidence selection may in turn improve children's ToM reasoning abilities. Taken together, our results are consistent with prior work on the relationship between ToM and teaching skills, and provide support for a strong link between pedagogical evidence selection and theory of mind.

Our results speak to existing models of ToM development that postulate genuine conceptual change during the preschool years. Specifically, we found evidence for a link between performance on a false-belief task and the discrete developmental capability of pedagogical evidence selection, suggesting that the changes in false-belief understanding that occur between the ages of 3 and 5 may reflect deeper qualitative changes in children's Theories of Mind. As we noted in the introduction, we recognize that there is a diverse range of perspectives on the course of children's ToM development, and we will not attempt to resolve that debate here. Rather, we simply suggest that our findings cannot be explained in their entirety by false-belief task demands (especially given that our results persist when controlling for effects of age), and may therefore be indicative of some type of conceptual change in ToM during the preschool years.

Our findings also have implications for current theories and models of natural pedagogy and epistemic trust. Shafto et al. (2014) propose a Bayesian model of pedagogical teaching and learning, according to which the evidence that teachers choose to present directly depends on the learner's prior knowledge and the learning goal that the teacher is trying to communicate. This pedagogical model is a special case of the broader model of epistemic trust (Shafto, Eaves, Navarro, \& Perfors, 2012; Eaves \& Shafto, 2012, in press), which explicitly connects developmental changes in reasoning about others' beliefs to interpretation of evidence selection by others. Our results support these models that link evidence selection and reasoning about other minds. We also extend their findings, showing that this link 1) exists even in young children who have not yet been exposed to formal schooling, and 2) is manifest in their selection of evidence for others.

Along with this prior work, our paper also speaks to broader theories of natural pedagogy, and supports a potential link between the uniquely human ability to teach others and the development of the ability to reason about others' minds; this raises questions about whether these skills may even be evolutionarily intertwined. Whatever the case may be, reasoning about other minds, as conceptualized in the field, is composed of multiple interrelated inference problems. Understanding the role of these social inferences in learning requires investigating how children approach several conjoined problems, as we have done. Our work exemplifies and shows the value of that approach.

#### Abstract

The ability to recognize and evaluate reliable informants is a critical skill for effective social learning. Building on prior work showing children's sensitivity to informants who omit relevant information, here we asked whether children's teacher evaluations incorporate information about 1) the epistemic state of the teacher, and 2) the amount and value of information taught. Preschool-aged children rated informants who taught learners about a novel toy with four functions; we systematically varied the number and value of functions the teachers knew and taught. Our results indicate that children exonerated unintentional omissions of teachers who had incomplete knowledge, and provided graded ratings based on the degree of omission. These findings are consistent with the predictions of prior computational work, and suggest that the ability to reason about others' knowledge plays an important role in children's inferences about others' efficacy as informants.

Keywords: cognitive development, pedagogy, social learning

## Introduction

Young children rely heavily on others for their learning. Although children readily explore and learn from their own experience (Schulz, 2012; Bonawitz, van Schijndel, Friel, \& Schulz, 2012; Stahl \& Feigenson, 2015), pedagogy is a powerful, effective way to learn about the world. Recent research suggests that children do more than simply absorb and accumulate information from others; they actively modulate their inferences depending on the social context (Bonawitz et al., 2011), and selectively approach others to request information when help is needed (Gweon \& Schulz, 2011; Goupil, Romand-Monnier, \& Kouider, 2016). However, learning from pedagogy comes with an inherent hazard: being misinformed. Informants may vary in quality - some may be wrong, ignorant, or even deceptive. Thus, the ability to detect and evaluate unhelpful informants is critical for accurate learning. How do young children face this challenge?

Prior research has found that children avoid learning from informants who provide inaccurate information (e.g., Birch, Vauthier, \& Bloom, 2008; Jaswal \& Neely, 2006; Koenig, Clément, \& Harris, 2004; Pasquini, Corriveau, Koenig, \& Harris, 2007). Recent studies further suggest that young children recognize and evaluate a more subtle form of misinformation: providing accurate yet insufficient evidence. Given a teacher who presented one function on a toy, children rated the teacher as more helpful when the toy only had one function than when it had four (i.e., when the teacher omitted 3 of the 4 functions; Gweon, Pelton, Konopka, \& Schulz, 2014a; Gweon \& Asaba, in press). Children as young as four show this sensitivity, although they successfully evaluate underinformative teachers only after observing a fully informative
teacher (Gweon \& Asaba, in press). Thus by the preschool years, children expect teachers to be accurate and fully informative, and penalize those who violate these expectations.

This early-emerging sensitivity to teacher informativeness raises important questions about how children make these evaluations: What are the representations and inferences that allow children to distinguish helpful and less helpful teachers? One possibility is that children learn sets of rules and exceptions that allow them to recognize and avoid undesirable teachers. Prior findings suggest that young children are biased towards trusting adult informants, and may even continue to trust them after discovering their unreliability (Jaswal, Croft, Setia, \& Cole, 2010). Children may also acquire a set of rules akin to Gricean Maxims (Grice, 1975), which prescribe that a helpful, cooperative communicator should provide accurate and relevant information in the right amount. If children are simply using learned heuristics or rules to evaluate informants, it may be difficult for them to make nuanced, context-specific judgments of informant quality, particularly in novel situations. However, another possibility is that these evaluations arise from sophisticated inferences about teacher informativeness; by understanding how unobservable mental states of others (e.g., informants' intent or knowledge) can influence their teaching behaviors, children can draw much more flexible and accurate informant evaluations even in novel contexts.

Previous work on Theory of Mind and moral reasoning suggests that young children readily interpret others' observable actions in light of their unobservable mental states: They evaluate others' actions based on their outcomes and on the actor's underlying intent, exonerating accidental harms (e.g., Cushman, Sheketoff, Wharton, \& Carey, 2013; Wellman, Cross, \& Watson, 2001; Nelson, 1980; Baird \& Astington, 2004). Furthermore, even toddlers exonerate an agent who refused to help another person when the agent was incompetent and thus unable to help the requester (Jara-Ettinger, Tenenbaum, \& Schulz, 2015). Given prior work on children's ability to consider others' mental states in evaluating others, here we ask whether children can consider informants' knowledge and their competence in evaluating their teaching.

Prior computational work describes teacher-learner interactions as based on a set of mutually constraining inferences. The teacher considers the learner's knowledge to select the evidence that would maximally increase the learner's belief in the correct hypothesis. The learner updates his beliefs with the assumption that the teacher is knowledgeable and intends
to provide the best information for the learner (Shafto, Goodman, \& Frank, 2012; Shafto, Goodman, \& Griffiths, 2014). In this framework, a teacher can be evaluated based on how she samples information for the learner, and what the learner can infer from the information.

This allows us to consider two key hypotheses about what might influence children's evaluations of teachers. Consider a teacher demonstrating a device with four functions (some interesting, some humdrum) to a naïve learner. How might a rational observer evaluate the teacher, based on what she demonstrates? First, we might predict that an evaluation of an informant is sensitive to the epistemic state of that informant. For example, consider two teachers, each of whom demonstrates just one of the four functions. One teacher knows that the device has four functions, but the other only knows about the one function she demonstrated. While the learner only learns about one of the four functions in both cases, we might be more inclined to pardon the teacher who didn't know about the additional functions: The ignorant teacher demonstrated everything she knew, and may thus be considered a better teacher than the knowledgeable informant who omitted information. We refer to this as the epistemic pardon hypothesis.

Our second hypothesis pertains to the quality of the taught information. A teacher who knows all four functions of a device will be most helpful if she demonstrates all four, and least helpful if she demonstrates none. Extending this reasoning to partial demonstrations, we would predict evaluations to be modulated by the degree of omission: Even when two teachers both omit information, a teacher who demonstrates two functions is still better than someone who showed just one. Further, if the functions differ in their value (e.g., how interesting they are), we might also expect an effect of the value of demonstrated functions: A teacher who demonstrates two high-value functions and omits two low-value functions would be better than someone who does the opposite. We refer to these predictions as the quality-of-omission hypothesis.

Recent computational work has formalized the two hypotheses posited above, and shown that adults' evaluations of various teachers are highly consistent with these hypotheses (Bass, Hawthorne-Madell, Goodman, \& Gweon, 2015). When adults evaluate informant quality, they readily incorporate information about a teacher's epistemic state, as well as the amount and the value of taught information. Adults' informant evaluations are thus likely based on abstract representations of others' minds rather than a set of rules that dictate what a teacher should or should not do.

Some prior work suggests that children's evaluations of teachers also depend on abstract representations of knowledge states rather than simple heuristics. For instance, children show increased exploration of a toy following a teacher's demonstration of that toy if the teacher had previously committed a sin of omission (Gweon et al., 2014a), suggesting that children use concrete demonstrations to infer abstract qualities of teachers' quality, and adjust their inferences accordingly. Children also understand that omission isn't al-
ways bad: Given a toy with 20 buttons but only 3 that are functional, children prefer a teacher who shows just the 3 functional buttons (as opposed to the one who additionally shows the 17 inert buttons), if the learner already expects only a few of the buttons to work (Gweon, Shafto, \& Schulz, 2014b). Children thus readily consider learners' epistemic states to evaluate teacher helpfulness, and even judge omission as beneficial when partial demonstration is sufficient. However, these studies leave open a critical question: Can children consider the teacher's epistemic state in evaluating the helpfulness of their teaching? Going beyond recognizing that teachers might not know everything (Jaswal \& Neely, 2006), can children actually use this information to exonerate under-informative pedagogy? Because children are surrounded by many adults who are much more knowledgeable than they are, this may be a particularly challenging inference for young children.

## Preschoolers' Evaluations of Teachers

In the current study, we investigate whether preschool-aged children's teacher evaluations reflect the underlying representations of teachers' knowledge and competence; in particular, we ask whether each of our two hypotheses (epistemic pardon, and quality-of-omission) - both of which are consistent with adults' teacher evaluations (Bass et al., 2015) are also consistent with children's ratings of teacher quality. We showed children videos of five different informants who taught learners about a novel toy with four functions. We systematically varied the number and value of functions that the teachers knew and taught, and randomized the order in which the five teachers were seen with one caveat: All children first saw the teacher who knew and taught all four of the toy's functions, and were told that this was an example of excellent teaching. Our decision to anchor children's responses in this way was motivated by prior findings: First, children reliably rate teachers highly when they provide true and complete information (e.g., Gweon et al., 2014a; Koenig \& Harris, 2005); second, although four- and five-year-olds' ability to evaluate under-informative teachers is limited, seeing an example of a fully informative teacher first allows them to successfully evaluate under-informative teachers (Gweon \& Asaba, in press). These results suggest that such contextual support helps children attend more closely to dimensions of teacher informativeness. Since we are interested in children's ratings of several under-informative teachers relative to each other (and not to the fully informative teacher), we anchored children's ratings of this ideal teacher at the top of the scale.

## Methods

## Participants

Thirty-four children $\left(M_{\text {age }}=60\right.$ months, range $=49-72$ months; 15 females) were tested at local preschools.

## Materials

Rating Scale Children used a 0 to 20 point rating scale to evaluate teachers. Children placed a small circular magnet on

Figure 1: All children saw and rated the KA_TA teacher first. The order of the remaining four test trials was counterbalanced across children. Memory cues were adhered to the rating scale as children provided their ratings.
the scale to indicate how good they thought a teacher was.
Novel Toy The novel toy was a square pyramid covered in blue felt with four colorful buttons, each corresponding to a different function. Two functions were low-value: The toy could beep, and it could make a static-like noise. The other two functions were high-value: The toy could play clips of two different children's songs. The relative value of these functions were validated in a separate group of 10 children $\left(M_{\text {age }}=66\right.$ months, range $=49-91$ months $)$, who were asked to rate "how cool" each of the four functions were using the rating scale described above. The two songs ( $M=15.3$, $S D=3.1$ ) were rated significantly higher than the beep and the noise ( $M=8.8, S D=3.7 ; t(9)=3.41, p=.008$ ), with no differences within the value pairs ( $p$ 's $>.33$ ).

Teaching Videos Teaching videos were presented on a 15inch MacBook Pro, and comprised two main phases. In the Exploration phase, the teacher sat down at a table on which the novel toy was placed and explored the toy's functions; then, a naïve learner suddenly entered the room, startling the teacher out of her exploration, and asked her to show him how the toy worked. In the Teaching phase, the teacher demonstrated to the learner some subset of the functions she had discovered during the exploration phase (details follow), after which she said, "That's how this toy works!" thereby clearly ending the demonstration.

There were five versions of the teaching videos, which varied based on the number and value of the functions that the teacher discovered and taught. In the Exploration phase, the teacher either discovered 1) all four functions, or 2) just the low-value "beep" function before the learner entered the room. In the Teaching phase, the teacher either taught: 1) all four functions, 2) both high-value functions, 3) both lowvalue functions, or 4) just one low-value function ("beep"). Crossing these two variables yielded five possible teaching scenarios: KA_TA, in which the teacher Knew All and Taught

All; KA_THH, where she Knew All and Taught 2 Highvalue functions; KA_TLL, in which she Knew All and Taught 2 Low-value functions; KA_TL, where she Knew All and Taught 1 Low-value function ("beep"); and KL_TL, where she Knew 1 Low-value function ("beep") and taught it.
Memory Cues To help children recall precisely what each teacher knew and taught, we created small cards that depicted screenshots of the Exploration and Teaching phases from the teaching videos. Small arrows with adhesive backs were attached to each memory cue (see Figure 1).

## Procedure

Frame Story \& Rating Scale Training Children were told that they would be meeting some people who were in teaching school; the experimenter needed the child's help to figure out how good the different teachers were so that she would know how much more school the teachers needed. The experimenter then introduced the rating scale, and children were briefly trained on how to use it to indicate teacher quality. Children who failed this training did not proceed to the main task and were dropped from analysis (see Results).
Novel Toy Next, the experimenter introduced the novel toy, and encouraged children to try to figure out how it worked. After the child successfully pressed all four buttons, the experimenter noted that they now knew all about the toy. Children were then told that the other day, the teachers from the school had taught some new students about how the novel toy worked, and it was the child's job to watch them teach about the toy and figure out how good each teacher was at teaching. Teacher Evaluations All children were first shown the KA_TA condition. Before watching the video, children were told that this teacher was all done with school, and was therefore already a good teacher. After watching the first video, children were shown the memory cue for the KA_TA teacher,
and were asked to provide a rating. Children who did not place the marker near the top of the rating scale were reminded that this teacher was already done with school. The experimenter adhered the memory cue's arrow to the rating scale where the child had placed the marker.

Children were then shown the remaining four teachers who, they were reminded, were still in teaching school; these constituted the four test trials. The order in which these four teaching scenarios were presented was completely counterbalanced, yielding 24 different orders. While the actors in the videos and the test conditions were fully counterbalanced with respect to each other, such that any potential effects of teaching condition could not be explained by personal characteristics of the actors, the order of the actors was always the same (e.g., "Liz" was always the first teacher, even though the first test condition varied between participants). After watching each video, children were shown the memory cue for the teacher they had just seen, and were asked to provide a rating. The experimenter adhered the memory cue's arrow to the rating scale where the child had placed the marker. Children who merely placed each teacher on the scale in the order of presentation (from most helpful to least helpful) were excluded from analysis. See Figure 1 for a schematic of the procedure for teacher evaluations.

## Results

Prior to analysis, we dropped children who did not pass the rating scale training $(N=1)$, placed teachers in descending order on the rating scale as they saw them $(N=7)$, or gave all teachers the same rating $(N=1)$. One additional child did not want to continue playing after the first KA_TA trial. Our final sample therefore consisted of 24 children ( $M_{\text {age }}=60$ months, range $=49-72$ months; 12 females).

We first asked whether children differentiated between the four teachers in the test trials. An omnibus repeated-measures ANOVA on children's ratings in these four trials revealed a significant main effect of condition $(F(3,69)=3.50, p=$ $.020, \eta_{\mathrm{p}}^{2}=.132$; see Figure 2). We therefore conducted followup analyses to investigate our two stated hypotheses.

## Epistemic Pardon Hypothesis

To investigate the effect of the teacher's epistemic state on children's ratings, we compared the KA_TL condition to the KL_TL condition, thereby holding constant what the teacher taught and only varying what she knew. A paired-samples t -test revealed significant differences between the ratings of these two teachers $\left(t(23)=2.58, p=.017, \eta_{\mathrm{p}}^{2}=.224\right)$, with children giving higher ratings to the teacher who knew only one function ( $M=11.5, S D=5.7$ ) than the teacher who knew all four functions but taught just one ( $M=7.8, S D=5.4$ ).

We also looked at the number of children who placed the KL_TL teacher higher than the KA_TL teacher on the rating scale. Seventy-one percent of participants rated the KL_TL teacher higher than the KA_TL teacher; this proportion differed significantly from chance ( $50 \%, p=.032$ one-tailed),

Figure 2: Average ratings for the KA_TA reference teacher and all four test conditions. Children rated the teacher who knew only one function (KL_TL) higher than the teacher who knew all but taught one (KA_TL), pardoning omission when it occurred for epistemic reasons. Children also showed sensitivity to the degree of omission, rating the teacher who demonstrated two low-value functions (KA_TLL) as better than the teacher who demonstrated one (KA_TL).
providing additional evidence that children considered teachers' epistemic states when making their evaluations, and were even able to exonerate bad teaching when it was explained by limited knowledge.

## Quality-of-Omission Hypothesis

We explored the effect of the degree of teachers' omission of information on children's ratings with a paired-samples ttest, comparing the KA_TLL condition to the KA_TL condition (varying the number of functions taught while holding epistemic state and value constant). We again found significant differences $\left(t(23)=2.54, p=.019, \eta_{\mathrm{p}}^{2}=.218\right)$ : Children gave higher ratings to the teacher who demonstrated two low-value functions ( $M=11.9, S D=6.4$ ) than the teacher who demonstrated just one low-value function ( $M=7.8$, $S D=5.4$ ). As before, we also compared the proportion of children who rated the KA_TLL teacher higher than the KA_TL teacher to chance. This binomial test neared significance ( $p=.076$ one-tailed), with $67 \%$ of children rating the KA_TLL teacher higher than the KA_TL teacher.

Finally, we compared the KA_TLL teacher to the KA_THH teacher to examine the effect of information value on children's ratings. This paired-samples t-test was not significant ( $p=.874$ ): Children did not differentiate between teachers who taught two high-value ( $M=12.1, S D=5.2$ ) versus two low-value ( $M=11.9, S D=6.4$ ) functions. Possible explanations for this null result follow in the discussion. ${ }^{1}$

## Discussion

Inspired by computational models of pedagogy and prior behavioral work with adults (e.g., Shafto et al., 2014; Bass et al., 2015), here we investigated how children make nuanced evaluations of helpful and unhelpful teachers; specifically, we asked whether children 1) exonerate partial teaching based on the teacher's epistemic state, and 2) provide graded evaluations based on the amount and value of information taught. We found that, like adults, preschoolers were sensitive to teachers' epistemic states, and accordingly pardoned informants who provided less information when teaching from limited knowledge. Children's ratings were also sensitive to the amount (but not the value) of information taught.

The results from our epistemic comparisons extend prior work showing that children prefer truthful teachers (Koenig et al., 2004; Koenig \& Harris, 2005; Jaswal \& Neely, 2006), and fully informative teachers (Gweon et al., 2014a; Gweon \& Asaba, in press). They are also consistent with more recent findings on children's ability to consider learners' epistemic states (Gweon et al., 2014b) in evaluating teachers. However, our findings are somewhat surprising in light of the idea that many explicit Theory of Mind (ToM) skills are just developing between the ages of three and five (Wellman et al., 2001). Without explicit information about what the teacher knew, preschoolers were able to 1) infer her epistemic state by observing her exploration, and 2) use this representation to pardon her "sin of omission".

This finding thus raises important questions about the relationship between the development of ToM reasoning and social evaluation in pedagogical contexts. If ToM does in fact modulate children's teacher evaluations, children may become more adept at selecting from whom to learn throughout their preschool years. Indeed, Jaswal et al. (2010) found that three-year-olds are almost indiscriminately trusting of informants, while older children are more wary of possible misinformation. It would be interesting to ask whether children who are better at ToM reasoning also consider teachers' epistemic states more readily, leading them to be more willing than children with less proficient ToM abilities to exonerate teachers who were unintentionally under-informative. Critically, given recent findings on the relationship between ToM and children's own teaching skills (Bass et al., in press), such results would support important links between theory of mind, pedagogical skill, and teacher evaluations.

Note that although children did exonerate the KL_TL teacher relative to the KA_TL teacher, no under-informative teacher was rated as favorably as the informant who knew and taught all four of the toy's functions. Intuitively, this makes sense: Children's ratings of an informant's helpfulness will reflect, among other things, how well a learner learned as a consequence of the informant's teaching. Thus while the KL_TL teacher did the best she could given what she knew, she was still not as good of a teacher as the KA_TA teacher because she failed to discover information that could have been useful for the learner. This intuition also naturally arises
in adults' teacher evaluations, and is consistent with Bayesian models of pedagogical reasoning (e.g., Bass et al., 2015). Are there circumstances under which under-informative teaching can be fully exonerated? In ongoing work, we are exploring whether the degree to which children exonerate underinformative teachers is modulated by contexts that explain away the teacher's failure to discover relevant functions and resultant lack of knowledge (e.g., a broken toy).

Our results also show that children did not penalize all omissions equally. Even though all teachers were underinformative, children were sensitive to the "degree of omission," giving lower evaluations to teachers who provided less information. This extends prior work showing that children distinguish fully informative teachers from those who were vastly under-informative (Gweon et al., 2014a; Gweon \& Asaba, in press), and further suggests that children's evaluations of under-informative teachers are based on a more nuanced understanding of teachers' behaviors than a simple binary judgment. This leaves open questions about the nature of the mechanisms that underlie sensitivity to informant quality more generally: How early do they emerge? What other factors can children incorporate into their informant evaluations, and how do these change as children develop?

Our work adds to the growing body of literature on children's ability to draw pragmatic inferences from others' behaviors in both verbal and nonverbal communication. Recent work has demonstrated intriguing parallels between children's evaluations of pedagogical informants and their ability to draw scalar implicature (Gweon \& Asaba, in press). Given prior work on scalar implicature that reveals children's ability to evaluate infelicitous uses of quantifiers (Barner, Brooks, \& Bale, 2011; Katsos \& Bishop, 2011), our results further suggest that children as young as four might have the necessary prerequisites for considering the "degree of sin" in infelicitous scalar expressions (e.g., it is worse to say that the boy drank "a bit" of milk than to say he drank "some" milk, when really he drank almost all the milk in the cup).

Finally, we note that children's ratings in the current study were not moderated by the value of the demonstrated functions: Children rated a teacher who chose to show the two lower-value functions just as highly as the teacher who showed two higher-value functions. These results differ from adults' sensitivity to information value in a highly similar paradigm (Bass et al., 2015). There are several possible explanations for this null finding. First, the relative value of the toy's functions in our study may not have been salient enough to elicit this difference. While we did validate the functions' values in a separate group of participants, those children were explicitly asked to compare and consider the functions' "coolness"; for children in the current study, these subtle value differences may not have been conspicuous enough to differentiate teachers who taught the songs versus the noises. A second possibility is that the ability to consider the value of information in service of making pedagogical evaluations does not emerge until later in development. This would suggest that
although children show remarkable ability in evaluating others, there may be other important factors that young children fail to consider. Third, it is possible that children are capable of considering information value (and that the functions' values were sufficiently salient in our task), but that children spontaneously attributed a reason for why the informant selected these functions; for instance, perhaps the low-value teacher really liked those functions, or thought they would be more important for the learner to know. Future work could tease apart these hypotheses to identify the role of information value in children's informant evaluations.

As we have discussed, there are many unanswered questions concerning the nature of children's reasoning about pedagogical informants that our results do not directly address. Nevertheless, along with prior work, our findings suggest that young children do have abstract representations of what it means to be a good teacher. Understanding the development of children's epistemic trust and its relationship to their growing ability to reason about others' minds will provide further insight into the cognitive mechanisms that support the uniquely human abilities to learn from and teach others.

# Modeling human categorization of natural images using deep feature representations 

Ruairidh Battleday<br>Helen Wills Neuroscience Institute; University of California, Berkeley, Berkeley, California, USA<br>Joshua Peterson<br>Department of Psychology, University of California, Berkeley, Berkeley, CA, USA<br>Tom Griffiths<br>Department of Psychology, University of California, Berkeley, Berkeley, CA, USA

#### Abstract

Over the last few decades, cognitive scientists have developed sophisticated formal models of human categorization, and computer vision researchers have achieved increasingly impressive performance in natural image classification. In this paper, we combine the strengths of these approaches, using representations from a convolutional neural network to evaluate cognitive models of categorization against $>300,000$ human judgments of natural images. We find that a prototype model performs best overall, and that an exemplar model performs best when the network's most abstract features are used. Altogether, our results demonstrate that the optimal categorization strategy over a set of stimuli is deeply linked to how they are represented, suggesting that any satisfying characterization of categorization behavior over naturalistic stimuli must consider it the result of a dual process of feature learning and strategy selection. The paradigm we present herein offers one avenue to begin this undertaking.

# Semantic Typology and Parallel Corpora: Something about Indefinite Pronouns 

Barend Beekhuizen<br>Department of Computer Science<br>University of Toronto<br>barend@cs.toronto.edu

Julia Watson<br>Department of Computer Science<br>University of Toronto<br>j.watson@mail.utoronto.ca

Suzanne Stevenson<br>Department of Computer Science<br>University of Toronto<br>suzanne@cs.toronto.edu

#### Abstract

Patterns of crosslinguistic variation in the expression of word meaning are informative about semantic organization, but most methods to study this are labor intensive and obscure the gradient nature of concepts. We propose an automatic method for extracting crosslinguistic co-categorization patterns from parallel texts, and explore the properties of the data as a potential source for automatically creating semantic representations for cognitive modeling. We focus on indefinite pronouns, comparing our findings against a study based on secondary sources (Haspelmath 1997). We show that using automatic methods on parallel texts contributes to more cognitively-plausible semantic representations for a domain.

Keywords: semantic typology; semantic representation; parallel corpora

## Introduction

An important goal of cognitive science is to determine valid semantic representations, e.g., for use in computational cognitive models of language acquisition and processing. Semantic typology - which studies the patterns of crosslinguistic variation in what words and other linguistic elements mean - reveals universal tendencies in how languages carve up the space of a semantic domain (Haspelmath, 2003; Regier, Kemp, \& Kay, 2015). In particular, Bowerman (1993) argues that (all else being equal) the greater the number of languages that label a pair of situations (objects, events, ...) with the same word (called co-categorization), the more conceptually similar these situations are. For instance, many languages co-categorize situations of 'stable support' (see Fig. 1) with those of 'tenuous support', but use a different term for 'containment', reflecting that the first two situations are more semantically similar than the last.

More generally, such crosslinguistic co-categorization patterns can define a geometric semantic similarity space (Levinson et al. 2003). To obtain such a space, we first represent a situation as a vector of terms used to express that situation across languages (cf. the row of terms in Fig. 1). These vectors are then projected into a lower-dimensional space (cf. the distances in the two-dimensional space of Fig. 1). This insight has informed cognitive modeling work on spatial relations (Beekhuizen, Fazly, \& Stevenson, 2014) and color (Beekhuizen \& Stevenson, 2016), where descriptions of situations, elicited from speakers of a number of languages, were used to create vector-based geometric semantic representations. A computational learning model trained on those representations successfully simulated developmental error patterns in word meaning acquisition.

In order to deploy such approaches to additional semantic domains, we need practical and robust methods for semantic typological analysis. Elicitation data (e.g., Berlin \& Kay,

Figure 1: Representing the conceptual distance between situations as the number of languages co-categorizing them.

1969; Bowerman \& Pederson, 1992) - terms describing nonlinguistic stimuli, obtained from informants - allows control in defining the set of stimuli for a domain, but is resource intensive and limited to concrete domains. Expert (Haspelmath, 1997) or automatic (Youn et al., 2016) analyses of secondary sources (such as dictionaries and grammars) don't rely on access to informants across many languages, but are focused on coarser-grained semantic distinctions than are found in elicitation stimuli. Both of these methods lack the frequencies and patterns of actual usages in natural communication.

A complementary source of data recently used in semantic typology is parallel text (e.g., Cysouw \& Wälchli, 2007) i.e., the same text translated into different languages. While parallel text has its own potential disadvantages, such as a risk of "translationese" or mistranslations (Levshina, 2017), it can be applied to abstract domains that are hard to obtain elicitation data for, and has actual usage tokens that can reveal nuances of meaning not captured in dictionaries. This latter point is especially relevant for creating semantic spaces for cognitive modeling, as semantic categories display prototype structures with more and less central members (Rosch, 1973). Deriving semantic representations from actual usages can yield a continuous semantic similarity space which potentially reflects such structures; training computational cognitive models on such representations thus has the potential to better match behavioural data. To exploit this potential of parallel text, we need automatic methods for extracting the co-categorization patterns - the terms used across multiple languages for the same situation (cf. Fig. 1) - that can form the basis for such vector-based representations.

In this paper we first propose an automatic method for extracting crosslinguistic co-categorization patterns from parallel texts, to complement elicitation data and secondary sources. Next, we explore the properties of the resulting data as a potential source for automatically creating semantic spaces for cognitive modeling. We focus on indefinite

| Acronym | Semantic function | Example |
| :--- | :--- | :--- |
| SP-K | specific, known | I want to tell you something. |
| SP-U | specific, unknown | Someone broke into our apartment. |
| NS | irrealis non-specific | I need someone strong for the job. |
| CD | conditional | Let me know if anybody shows up. |
| QU | question | Is anything bothering you? |
| IN | indirect negation | I don't think anything matters. |
| DN | direct negation | Nobody came. |
| CP | comparison | She can run faster than anybody. |
| FC | free choice | You can pick anything! |

Table 1: Haspelmath's 9 functions with examples.
pronouns as an abstract semantic domain for which elicitation would be a difficult method, but for which we have a good understanding of the typology from expert judgments and secondary sources (Haspelmath, 1997). By using parallel texts, we are able to get a fuller picture of the semantic structure of this domain, in particular seeing evidence for gradience in multiple ways: finer-grained semantic functions that show gradient patterns across languages, and gradient relationships (distances) among the semantic functions. We thus show that using automatic methods on this complementary data source can contribute to more cognitively-plausible semantic representations, by fleshing out expert analysis of secondary sources with usage data that reflects the discourse use and frequency of the semantic functions.

## Indefinite pronouns

Indefinite pronouns, such as somebody, anything, and nowhere, are used to express indefinite reference - i.e., introducing a discourse referent which the speaker typically does not intend the hearer to uniquely identify. Reference may be to an entity from any of the major ontological categories such as PEOPLE, THINGS, and Places. Haspelmath (1997) outlines 9 semantic functions that indefinite pronouns can express; see Table 1. To identify the set of functions, he draws on semantic motivation - whether a coherent functional definition can be established for each. Importantly, linguistic evidence is considered for deciding whether two related functions should be merged or split: specifically, if at least one language has a term that can be used for only one of the functions - i.e., if there is a language with a term that does not co-categorize the two - then the two functions are considered distinct.

The identified semantic functions are analogous to stimuli in an elicitation task, although at a coarser grain: each function represents a set of situations that are co-categorized. Like elicitation data, terms in each language are associated with each of the semantic functions they can express, and patterns of crosslinguistic co-categorization can be revealed. These patterns can be visualized in a graphical semantic map: functions (nodes) are connected by edges such that connected subgraphs correspond to sets of functions that can be cocategorized. The semantic map of Haspelmath (1997), in Fig. 2, shows that, in both example languages, the terms carve out different, but in both cases connected, partitionings of the graph.

Figure 2: Semantic map from Haspelmath (1997) with English and Nanay terms.

Despite the insight they provide, semantic maps do not capture certain properties of the underlying semantic space that are important to semantic representation. Two related issues in particular motivate our work here. First, there is no indication of the distance in semantic space that an edge in the map represents, although it is likely that some functions connected to a node may be closer or further semantically than others. For example, although IN connects to both DN and CP by a single edge in Fig. 2, it is likely more similar to DN. Second, the use of a single node for a function assumes (instrumentally) that functions are internally homogeneous. However, functions may display a gradient internal structure - e.g., some cases of DN may be 'better' instances than others. Both of these factors may contribute to the cognitive plausibility of a semantic space for use in computational modeling.

As discussed above, parallel usage data has the potential to address these issues by providing a more continuous representation than secondary data. Actual usage data may reveal how related Haspelmath's various functions are, and how homogeneous they are internally. Such insights are crucial for the use of semantic-typological analyses in cognitive science, e.g., in modeling the acquisition of such terms.

## Method: Translations from Parallel Text

Our goal is to construct geometric semantic spaces through the use of parallel (translated) usage data. We draw on the patterns of how terms are translated across many languages to find co-categorization patterns, which can then be used to derive a semantic space. We propose an automatic method that extracts the translations of each occurrence of a seed word (here, English indefinite pronouns) in every other language in our corpus. These extracted arrays of translations form a vector of terms across languages analogous to those obtained through elicitation data (cf. Fig. 1), and can be used to construct a geometric space.
Corpus and language sample. We extracted our data from a sentence-aligned parallel corpus of subtitles of films and TV series (Lison \& Tiedemann, 2016; www. opensubtitles.org). We selected the 30 (out of 65) languages across 9 language families for which the most

Figure 3: Extraction of situation vectors; see text.
parallel data was available, ${ }^{1}$ and extracted all utterances for which we found a translation into all languages.
Identifying translations across languages. We first obtained automatic alignments of translated words for each pair of languages in our corpus, using the HMM implementation of Liang, Taskar, and Klein (2006) with the default settings; see Fig. 3(a) for an example with four languages. From the pairwise alignments, we created a graph, per utterance, with edges between all words that are aligned with each other, (Fig. 3(b)). From this graph, we extracted the subgraphs that were densely connected (i.e., for which the words are often mutually aligned), ${ }^{2}$ and select those subgraphs that contain one of the indefinite pronouns in English (Fig. 3(c)). Each such subgraph is then linearized to form the vector representation of a situation (Fig. 3(d)). The Table in Fig. 3(d) illustrates the correspondence to semantic typology: Every row contains a 'stimulus', for which the various languages present elicited terms (cf. the table in Fig. 1). Note that sometimes responses are missing, or multiple words form the response.
Extraction of indefinite pronouns. We focus on the two ontological categories PEOPLE and THINGS; other categories (e.g., TIME and PLACE) were too infrequent. To identify indefinite pronoun usages in our corpus, we extracted utterances for which the English expression consists of any of the 9 words combining some-, any-, no- with -thing, -body, -one (cf. rows in bold in Fig. 3(d)). From among these situations, we selected only those that included an expression from each of at least 25 languages, to ensure sufficient linguistic variation for each situation. ${ }^{3}$ The resulting data consisted of 698

[^21]situations - i.e., exemplars of indefinite pronoun usage represented by vectors of terms in 25-30 languages.
Annotation. In order to compare the patterns in our usage data to Haspelmath's (1997) analysis, it was necessary to identify the semantic function (see Table 1) of the indefinite pronoun usages in each of our situations. To do so, three annotators (the authors) labelled the English indefinite pronoun in each situation with its Haspelmath function. Annotators were provided the sentence containing the pronoun, as well as some context before and after. We merged Specific Known and Specific Unknown into one function called Specific (SP), given the uncertainty in this task of judging whether something is known to the speaker. ${ }^{4} 152$ cases consisted of negative English indefinite pronouns like nothing and no one, which we automatically marked as DN. On the remaining 546 exemplars, inter-annotator agreement was satisfactory for a task of this difficulty (pairwise Cohen's $\kappa=[.84, .80, .79]$ ), and the majority annotation was used for each situation.
Further experimental set-up. Although the extracted situations are generally of a high quality, ${ }^{5}$ sometimes mistranslations are extracted. To reduce noise, we only use those terms that are statistically significantly associated with at least one of the annotated functions (using a Fisher Exact test). This way, low-frequency translations that are dispersed over functions are filtered out. To avoid the risk of overinterpreting patterns or overtuning models on the basis of a single sample, we split the data set into a development (dev) and test set. The examples and patterns reported below come from both the dev and test set, but quantitative results are provided for the test set only. We conduct all analyses on PEOPLE and things separately, because we found in exploratory data analysis that PEOPLE and THINGS showed differences in their patterns which have potentially interesting cognitive implications. The full data set, including stemming dictionary, annotation schemas, and all software used for the analyses, can be found at https://github.com/dnrb/indefinite-pronouns

## Results

With the extracted situation vectors, we can now study the semantic space derived from parallel usage data, and see how similar it is to Haspelmath's (1997) semantic typology based (primarily) on secondary sources. In particular, we are interested to see where the parallel usage data reveals characteristics of the semantic space not observed in Haspelmath's map.

## Are all semantic functions equally important?

Table 2 presents the frequency of the semantic functions. We see that most functions in the center of Haspelmath's

[^22]|  | SP | NS | CD | QU | IN | DN | CP | FC |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| PEOPLE | .16 | .20 | .07 | .16 | .05 | .28 | .01 | .08 |
| THINGS | .28 | .15 | .05 | .09 | .02 | .36 | .00 | .06 |
| Overall | .24 | .17 | .06 | .11 | .03 | .33 | .00 | .06 |

Table 2: Distribution of functions given ontological category.

|  | $k=$ | 2 | 3 | $\mathbf{4}$ | 5 | 6 | 7 | 8 | 9 |
| :--- | ---: | ---: | ---: | ---: | ---: | ---: | ---: | ---: | ---: |
| 10 |  |  |  |  |  |  |  |  |  |
| PEOPLE | .20 | .25 | .41 | .35 | .34 | .34 | .32 | .30 | .32 |
| THINGS | .30 | .38 | .47 | .36 | .35 | .35 | .33 | .39 | .33 |

Table 3: Adjusted Rand index score for PEOPLE and THings with $k$-means clustering, given various values of $k$.
(1997) semantic map are rather infrequent (CD, IN, CP). This may explain Haspelmath's observation that, across languages, there are no terms that solely apply to two functions in the middle of the map: Languages typically co-categorize infrequent functions with one of the more frequent neighboring functions (e.g., NS or DN). It also explains aspects of the graphical structure of the map: low-frequency functions are in the middle of the map because sometimes they share a term with the left side of the map, and sometimes with the right.

A notable exception is FC, located at the edge of the map despite its low frequency. This suggests FC is conceptually different from the other functions (except CP). Many languages co-categorize FC and universal quantification - unlike English, which generally uses any- vs. every- respectively. The use in many languages of a universal quantification term for the semantic function FC may account for its distinctive position in the map despite its low frequency.

## Are the functions at the right level of granularity?

A second issue worth investigating is whether Haspelmath's proposed functions constitute the best way of grouping the usage data into sets with related semantics: actual usage data may reveal that the functions are not well discriminable or have further coherent subdivisions. We explore this through automatic clustering of the parallel usage data. Each of our extracted situations is a vector of mutually-translated indefinite pronouns (see Fig. 3(d)); together they form a vector space within which we can measure situation (dis)similarity. Thus we can determine the optimal partitioning of the data into clusters and see how well those clusters correspond to the gold annotation. Here, we use $k$-means clustering (MacQueen, 1967), an unsupervised technique that partitions the data into $k$ clusters. The input for $k$-means is a distance matrix between all pairs of situations belonging to either PEOPLE or THINGS. The distance $d$ between a pair of situations $s$, $s^{\prime}$ is given by taking the Jaccard index over the sets of terms ${ }^{6}$ $T_{l}(s)$ and $T_{l}\left(s^{\prime}\right)$ used to express each of $s, s^{\prime}$ in each of the languages $l \in L$, and summing over all languages $l$ :

[^23]| Cluster | Function |  |  |  |  |  |  |  | Evaluation |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  | SP | NS | CD | QU |  |  | CP | FC | $P$ | $R$ | $F_{1}$ |
| 1 | 18 | 24 | 6 | 3 | 0 | 2 | 0 | 0 | . 91 | . 92 | . 91 |
| 2 | 1 | 0 | 2 | 15 | 1 | 4 | 0 | 2 | . 60 | . 83 | . 70 |
| 3 |  | 0 | 1 | 0 | 5 | 27 | 0 | 0 | . 97 | . 82 | . 89 |
| 4 | 0 | 0 | 0 | 0 | 0 | 0 | 1 | 7 | . 80 | 1.00 | . 89 |

Table 4: Correspondence table for the 8 functions with $k=4$ clusters for PEOPLE; rightmost columns present cluster precision $(P)$, recall $(R)$ and $F_{1}$ score for every cluster against function tuples (SP,NS,CD); (QU); (IN,DN); (CP,FC).

$$
\begin{equation*}
d\left(s, s^{\prime}\right)=\sum_{l \in L} \frac{\left|T_{l}(s) \cap T_{l}\left(s^{\prime}\right)\right|}{\left|T_{l}(s) \cup T_{l}\left(s^{\prime}\right)\right|} \tag{1}
\end{equation*}
$$

We assess the relative quality of different numbers of clusters by comparing their fit to the annotations using the adjusted Rand index (Rand, 1971). Table 3 presents the results.

If Haspelmath's set of functions is the best way of describing the data, $k$-means clustering with $k=8$ should be the $k$ with the highest correspondence to the annotated functions, partitioning the data into 8 clusters corresponding to the 8 functions. However, with $k=8$, a relatively poor Rand index score is achieved, and rather than aligning with the semantic functions, the inferred clusters mostly cross-cut them (e.g., there are 2 clusters containing many DN ). The fact that the optimal partitioning cross-cuts functions suggests that there are finer semantic distinctions within the functions that play out in the way languages label these.

Instead, we find that $k=4$ gives the highest correspondence with the manually annotated clusters. The 4 clusters correspond to 4 sets of related functions: (SP,NS,CD), (QU), (IN,DN), and (FC,CP); see Table 4. There is some leakage between the clusters (see the non-boldface numbers in Table 4), but the precision, recall, and $F$ scores using these sets of functions as the target labels for the 4 clusters are very high, showing these sets of related functions have a clear similarity structure. ${ }^{7}$

These results yield two distinct views of the data. On one hand, the typological usage data points to more fine-grained semantic distinctions within some of the 8 functions. On the other hand, we find semantic similarity between the functions that reveals a coarser grouping of the functions than is apparent from the semantic map structure of Haspelmath (1997). These findings point to a key role of gradience in understanding the semantic space of indefinite pronoun usage.

## The perspective of a similarity space

The clustering over the parallel usage data suggests more gradience in the semantic space underlying indefinite pronoun semantics, both within and between functions, than the semantic map of Haspelmath (1997) suggests. We take a more

[^24]

Figure 4: OC plots for indefinite pronouns (best viewed on screen).
direct way of obtaining insight into this space by representing the similarity between all situations in a low-dimensional space. Visualizing this space can also be informative about the use of such a space in a computational cognitive model.

We apply 2-dimensional Optimal Classification (OC), a dimensionality reduction technique useful for typological data (Croft \& Poole, 2008). The input for this algorithm is the list of individual situations, each represented as a set of terms (across all languages) used for that situation. For each term $w$ across all languages, OC creates a cutting line in the 2 dimensional plane, which divides the situations into those expressed with $w$ and those not expressed with it. This way, pairs of situations expressed with similar sets of terms will typically be located close together in the OC space. (In our data, we have $n=303$ cutting lines for PEOPLE and $n=435$ cutting lines for things.) Our data yields very high accuracy (proportion of situations being on the correct side of the cutting line, averaged over all cutting lines) of .94 (PEOPLE) and .95 (THINGS). Because each situation is represented by a set of terms across all languages, this result shows high agreement among the languages in how they carve up the situations into functions - although, as we see next, they exhibit gradience in the gradual shifting of terms for related situations.

The topology of the function annotations in the twodimensional space generally follows Haspelmath's map, despite working from different data and with different methods (see Figures 4 a and 4 b ): in the top-left corner, we find NS and SP followed by CD and QU towards the center; the top-right cluster contains DN and IN, whereas the bottom cluster consists of CP and FC. ${ }^{8}$ However, there are several aspects of the functions that are observable in this continuous space that are not apparent in the graphical semantic map.

First, we observe that not all functions that neighbor each

[^25]| bs | hr | en | $\underset{\text { sl }}{\substack{\text { guage }}}$ | pt | da | Functions |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| išta | išta | anything kaj |  | alguma coisa noget |  | QU |
| nešto nešto |  |  |  | QU, CD |
|  |  | QU, CD |  |  |
|  |  | something nekaj |  |  |  | QU, CD, NS |
|  |  | algo |  |  |  | NS, SP |

Table 5: A gradient for the (SP,NS,CD,QU) region.
other in Haspelmath's map are equidistant in the OC solution: QU has an edge to each of NS and IN in the map, but is closer to the former in the OC projection. The projection furthermore displays gradience among the functions: some QU-labeled situations are closer to NS, whereas others are closer to IN, DN, or FC, suggesting that the functions are more continuous than the graphical map suggests.

Second, the functions display internal gradience. Fig. 4c shows terms in four languages for THINGS annotated as DN. The gradient comes about because of languages whose terms form supersets of each other: Estonian keegi is a superset of Croatian nitko, which is a superset of English nobody, which is a superset of Slovene nihče. Across languages there thus seems to be agreement about a scale of subtypes of DN, but languages vary on the placement of the lexical boundaries.

Finally, we find gradients that cross-cut the function boundaries. Table 5 illustrates a gradient of terms standing in a superset-subset relation to each other that cross-cuts the functions SP, NS, CD, and QU. This gradient was obtained by running a one-dimensional OC on the situations in the (SP,NS,CD,QU) region, which lays out all situations on one line so as to obtain a maximal accuracy in placing cutting points for terms. This analysis yields an accuracy of .96 , which suggests that languages strongly agree on having a single dimension roughly cross-cutting the functions SP, NS, CD , and QU on which they locate their term boundaries.

Visualizing crosslinguistic usages in a continuous space gives further insight into the structure of the underlying semantic domain. The observed gradients call for further analysis and provide predictions for behavioural experiments. In
particular, if the patterns of crosslinguistic variation are indicative of cognitive distinctions in semantic space, we expect to see evidence in both adult behaviour and developmental patterns in children.

## Conclusions

Crosslinguistic patterns of co-categorization yield insight into the semantic space underlying linguistic usages. We deploy parallel usage data in the form of movie subtitles to study the patterns of crosslinguistic variation in the categorization of indefinite pronouns. We find the cross-linguistic usages display a more fine-grained pattern than suggested by a study on the basis of (primarily) secondary data (Haspelmath, 1997). In particular, the frequencies of the identified semantic functions vary, the distances between the functions are not uniform, and within functions, coherent subgroupings could be established. Our findings suggest the parallel usage data captures something about the semantic space that is not represented in the more static secondary sources.

The current method can easily be applied to other domains, but also involves several restrictions. Using pairwise alignments on parallel texts makes the approach computationally intractable beyond 30-50 languages, as a set of alignments has to be extracted for every language pair. We are looking into methods to circumvent this aspect of the method. The inability of the model to go 'below' the word level is also limiting, as many well-established patterns of cross-linguistic semantic variation involve morphology (e.g., case marking, nominalization patterns).

Furthermore, it is crucial to establish the cognitive plausibility of the semantic similarity space independently by seeing if it can predict behavioral experiments such as word usage similarity judgments, or developmental patterns. For example, we must explore whether, as for space and color, the semantic space for indefinite pronouns predicts aspects of the acquisitional pattern of these words: Is English any-, for instance, hard to acquire because it covers a large, rather disjunct region of the semantic space? Are indefinite pronoun systems in languages that follow the typologically more common patterns easier to acquire for first and/or second language learners? We hope these automatic methods for using parallel text in semantic typology can help us further understand patterns of learning and usage in abstract domains of meaning.

## Acknowledgments

We would like to thank Martin Haspelmath for sharing his indefinite pronoun data, and support from NSERC of Canada.

# How Relative is the Relative Frame of Reference? Front and back in Norwegian, Farsi, German, and Japanese 

Sieghard Beller (sieghard.beller@uib.no)<br>Andrea Bender (andrea.bender@uib.no)<br>Department of Psychosocial Science, University of Bergen<br>N-5020 Bergen, Norway

#### Abstract

Across languages, people differ in which of the three basic frames of reference (FoRs) they prefer when describing spatial relations: absolute, intrinsic, or relative. But how much variation is there with regard to the relative FoR, which is anchored in the observer and occurs as one of three variants? Is the reflection variant canonical, as assumed by many scholars? And how are objects in a person's back referred to: by turning towards the objects? Results from two studies, one with speakers of Norwegian and Farsi, the other with speakers of German and Japanese, reveal that reflection is not canonical, but that translation and even rotation are used as well. In addition, turning towards objects arranged in a person's back is very rare; what people use instead is a backward projection strategy that goes without rotation.

Keywords: Spatial cognition, frames of reference (FoR), relative FoR, cross-linguistic study.

## Introduction

"Where is the ball in relation to the box?" In order to answer questions like this, we have to establish a coordinate system-a frame of reference (FoR)-that allows us to derive a specific response such as "The ball is in front and to the right of the box." Across languages, people differ in the frame of reference they preferentially adopt. Variation has been documented especially with regard to which of the three basic FoRs is used: the absolute FoR anchored in a superordinate field like the cardinal directions, the intrinsic FoR anchored in a reference object like an arrow, or the relative FoR anchored in an observer (Levinson, 2003; Majid et al., 2004; Senft, 1997). Less attention has been devoted to the variants of the relative FoR, despite the fact that variation in relative referencing has been known since Hill's (1982) comparison of English and Hausa speakers.
This paper adds to a survey exploring variation in the use of the relative FoR in different languages (for results on German, English, Mandarin Chinese, and Tongan, see Beller et al., 2015), by extending the set of sampled languages. In two studies, one with speakers of Norwegian and Farsi, and another with speakers of German and Japanese, we inspected which variant of the relative FoR speakers of these languages apply in frontal and dorsal tasks with objects laid out in front of or behind an observer.

## Variants of the Relative Frame of Reference

Frames of reference are used to describe the position of a figure object F in reference to a ground object G . In contrast to the absolute and intrinsic FoR, the relative FoR requires
to do so from an observer's viewpoint V. As objects can be in front of or behind the observer, the distinction between frontal and dorsal is indispensable.

## FoRs in Frontal Settings

Constructing a relative frame of reference requires the coordinate system that is originally anchored in the observer-his or her FRONT/BACK and LEFT/RIGHT-to be projected onto the ground object G. In frontal settings, this can be done in three ways (Levinson, 2003): The coordinate system can be translated into G so that FRONT is assigned in gaze direction of the observer to the space beyond $G$ (see Figure 1A). It can be reflected in G so that FRONT is assigned to the space between the observer and G (Figure 1B). In both cases, assignment of LEFT and RIGHT remain unaffected. Finally, it can be rotated in G by $180^{\circ}$; in this case, FRONT is, again, assigned to the space between the observer and G, but assignment of LEFT and RIGHT are swapped (Figure 1C).

Of these variants, reflection is often assumed to be the canonical one (Clark, 1973; Grabowski \& Miller, 2000; Janzen et al., 2012). In our cross-linguistic survey (Beller et al., 2015, cf. Table 3, p. 11), such a preference for reflection was found most strongly among speakers of German (89\%) and English (73\%), whereas speakers of Mandarin Chinese and Tongan clearly preferred translation (64\%) over reflection (24\%). The rotation variant was chosen rarely in

Figure 1: Variants of the relative FoR for frontal settings (according to Levinson, 2003); L/R: left/right; F/G: figure/ground; V : viewpoint of the observer.
all four languages. Extending our survey to other languages so as to broaden our knowledge with regard to intra- and cross-linguistic variation in the use of these variants of the relative FoR is the first aim of the current paper.

## FoRs in Dorsal Settings

Research on the relative FoR has focused nearly exclusively on how people describe relations of objects that are laid out in front of an observer-for obvious reasons the most natural situation-although adopting someone's perspective already includes the distinction between what is in front of and what is behind that person. But how, if at all, would objects laid out behind that person be referred to?
One hypothesis put forward by Grabowski and Miller (2000) is that people refrain from referring to objects in their back. Rather, they turn around toward the objects, thereby converting the dorsal into a frontal setting, and then employ the FoR they prefer for frontal settings. However, the first studies on dorsal references (Beller et al., 2015, 2016) provided only weak evidence for this turn hypothesis. Despite participants' preferences for reflection or translation in frontal tasks, only a few responses in dorsal tasks were in accordance with the corresponding strategies turn-reflection and turn-translation. What most participants seemed to do instead was a kind of backward projection of the observer's coordinate system (without rotating the observer's perspective) either in a back translation version (Figure2A) or a reflection "with eyes in the back of one's head" (Figure 2B).
For logical reasons, both of these backward projection strategies lead to the same responses as the turn-rotation strategy (turn the perspective and apply the rotation variant to the resulting frontal setting; see Figure 2C). The reasons for why we assumed that the participants applied backward projection were twofold: First, these strategies do not necessitate two laborious (mental) rotations, and second, participants applied the rotation variant (Figure 1C) only rarely in frontal tasks-why should they do so in dorsal

"The ball is in front and to the right of the box."

Figure 3: Four example items (Beller et al., 2015, p. 6).
tasks? Exploring backward projection further, as compared to the turn-hypothesis, is the second aim of the current paper.

## Study 1

The first study was implemented as a paper-and-pencil survey that followed the design described in Beller et al. (2015) and included two languages from the Indo-European language family: Norwegian from the Germanic branch and Farsi from the Indo-Iranian branch.

## Methods

Materials. The materials were the same as in Beller et al. (2015): twelve items in each of two conditions (frontal and dorsal), six with a non-oriented ground object (three depicting inanimate objects, three depicting living beings) and six with an oriented ground object (again three depicting inanimate objects and three depicting living beings). Participants were asked to indicate for each item the relation between figure F and ground G from the viewpoint V of a depicted observer, by choosing one of eight options (in front of, behind, to the left of, to the right $o f$, and combinations of in front of/behind and to the left/right of). Four example items are shown in Figure 3. All materials were translated into Norwegian and Farsi by bilinguals.

Participants. The Norwegian sample consisted of 64 students from the University of Bergen ( 51 female; age $M=$ 23.3 years, $S D=5.3$ ), and the Farsi sample of 130 participants, most of them students from the Universities of Teheran, Schiraz, and Ghazwin, but also some non-students ( 88 female; age $M=26.8$ years, $S D=15.9$ ).

Design and Procedure. For each of the two conditions (frontal vs. dorsal), two item orders were prepared: The first one started with the six non-oriented items (in a random order) and then proceeded with the six oriented items (also in a random order); the second order was the exact reversal and thus started with the six oriented items. The eight response options were always presented in the same order. A between-subjects design was used. Participants were assigned randomly (but equally) either to the frontal or to the dorsal condition; the two item orders per condition were balanced in each subgroup. Participants were tested individually or in small groups, and were instructed to work on all tasks in the given order.

## Results and Discussion

In the frontal condition, we distinguished between the three variants of the relative FoR: translation, reflection, and rotation (Figure 1). In the dorsal condition, we distinguished between three variants according to the turn-hypothesis: turn-translation, turn-reflection, and turn-rotation, the latter one being equivalent to two backward projection strategies, translation ${ }_{\text {BP }}$ and reflection ${ }_{\text {BP }}$ (Figure 2). For items with an oriented ground object, we also considered the intrinsic FoR.
In a first step, we checked the two samples for differences in the mean number of responses that are not covered by one of these FoRs. Overall, this number of "unexplained responses" was fairly low ( $M=8.6 \%$; Table 1 ). An analysis of variance with two between-subjects factors, language (Norwegian vs. Farsi) and perspective (frontal vs. dorsal), and one within-subject factor ground object (non-oriented vs. oriented) indicated no significant effects (all $F(1,190)$ < $1.53 ; p \geq .218 ; \eta^{2} \leq .008$ ), suggesting that neither the

|  | Dorsal, oriented | 91.2 | 83.9 |

unusual dorsal perspective nor the type of ground object influenced the coverage of responses by the FoRs under scrutiny in the two samples alike.

In the next step, we determined whether the individual participants adopted one FoR consistently and, if so, which one. To this end, we counted for each participant how often each FoR variant could be coded in each of the four blocks of six items (frontal non-oriented, frontal oriented, dorsal non-oriented, and dorsal oriented). For example, if reflection could be coded on 6 out of the 6 frontal oriented items, consistency would be $100 \%$ for reflection; if reflection could be coded on 5 items and translation on 1 item, consistency would be $83.3 \%$ for reflection and $16.7 \%$ for translation; etc. We then used the maximum of these values (among the different FoR variants) as estimate of a participant's consistency in FoR adoption across the items of the respective block ( $100 \%$ and $83.3 \%$ in the examples). Mean consistency values are displayed in Table 2.

Overall, FoRs were adopted with a mean consistency of $80.1 \%$ across the two samples. In other words: Participants adopted their individually preferred FoR in 4.81 of 6 items of a block. An analysis of variance with two betweensubjects factors, language (Norwegian vs. Farsi) and perspective (frontal vs. dorsal), and one within-subject factor ground object (non-oriented vs. oriented) indicated three significant effects: Consistency was generally higher for the Norwegian speakers than for the Farsi speakers ( $84.9 \%$ vs. $\left.75.3 \% ; F(1,190)=11.3 ; p=.001 ; \eta^{2}=.056\right)$; it was higher for non-oriented items than for oriented items ( $85.1 \%$ vs. $75.2 \% ; F(1,190)=31.8 ; p<.001 ; \eta^{2}=.144$ ); and there was an interaction of the two factors language $\times$ ground object $\left(F(1,190)=5.6 ; p=.019 ; \eta^{2}=.029\right)$. Thus, the possibility of applying an additional FoR (here: intrinsic) was a source of inconsistency, but to a different extent in the two languages. Interestingly, the unusual dorsal perspective per se did not matter: Consistency did not differ significantly between the frontal and the dorsal condition ( $84.4 \%$ vs. $79.8 \% ; F(1,190)=0.045 ; p=.832 ; \eta^{2}<.001$ ).

Finally, we identified each participant's preferred FoR as the one FoR variant that was coded (a) more often than all others and (b) in at least 4 out of the 6 items of a block (i.e.,

Table 3: Preferred FoR (in \%), adopted in at least 4 out of 6 items of a block (frontal non-oriented, frontal oriented, dorsal non-oriented, and dorsal oriented) in Study 1 and Study 2.

| No preference | 12.5 | 17.2 | 21.9 | 40.6 | 5.7 | 6.4 | 4.3 | 9.2 |

Note. BP: backward projection; n.a.: not applicable; modal response printed in bold face.
with a consistency of $\geq 66.7 \%$ ). Participants' preferred FoRs are presented in Table 3. Log-linear analyses of FoR preferences revealed differences between the two languages for the two blocks of frontal items (non-oriented: $G^{2}=12.7$; $d f=3 ; p=.005$; oriented: $G^{2}=33.7 ; d f=4 ; p<.001$ ), and for the block of oriented dorsal items ( $G^{2}=8.9$; $d f=2$; $p=.012)$, but not for the block of non-oriented dorsal items ( $G^{2}=4.7 ; d f=3 ; p=.194$ ).

If adopting the intrinsic FoR was possible, some participants preferred this $\mathrm{FoR}^{1}$, particularly in the Farsi sample (mean percentage across all items with an oriented G for Norwegian: 4.7\%; Farsi: 19.2\%). Other participants seemed to change their referencing strategy itemspecifically, as indicated by the increased number of participants with no clear preference for any FoR variant as compared to the items with a non-oriented ground object.
Among the variants of the relative FoR for frontal tasks, both translation and reflection were adopted, but to a different extent in the two samples. The reflection variant prevailed most strongly among the Norwegian speakers (mean percentage across all frontal items for Norwegian: $71.9 \%$; Farsi: $28.8 \%$ ), while translation was preferred by a substantial proportion of speakers in both samples (Norwegian: $18.8 \%$; Farsi: $23.5 \%$ ); the rotation variant, in contrast, was confined to some Farsi speakers (7.6\%).
Among the variants of the relative FoR for dorsal tasks, one variant clearly stood out, namely the one that is indicative of the application of backward projection and turnrotation (Figure 2). Its frequency (mean percentage across

[^26]all dorsal items for Norwegian: 76.6\%; Farsi: 61.7\%) approximates the sum of translation, reflection, and rotation from the frontal tasks. But since the factor perspective was implemented between-subjects, the frontal and dorsal data cannot be related to one another on an individual basis, which would have provided a stronger argument in favor of this correspondence. In either case, the two FoR variants predicted by the turn-hypothesis-turn the view towards the objects and then apply the FoR preferred for frontal settings (i.e., reflection or translation)-were adopted very rarely.

In sum, Study 1 demonstrated that the reflection variant of the relative FoR is not canonical. While being the most frequent FoR in frontal tasks, the translation variant is adopted as well, and some participants even adopted the rotation variant. Participants' dorsal references suggested backward projection as the main strategy, but the data are not fully conclusive due to the between-subjects design.

## Study 2

In order to allow us to relate a participant's referencing preference in dorsal tasks to that in frontal tasks, the second study included perspective (frontal vs. dorsal) as a withinsubject factor. The study was implemented as an online survey and compared two languages from different language families: German, another Germanic language, and Japanese from the Japonic language family.

## Methods

Materials. The items were the same as in Study 1. The materials were translated from German into Japanese by bilinguals and were implemented as a web-based online questionnaire.

Participants. The German sample consisted of 140 student and non-student participants ( 105 female; age $M=27.3$ years, $S D=10.9$ ), and the Japanese sample of 109 student and non-student participants ( 64 female; age $M=28.5$ years, $S D=10.4$, with 15 not indicating their age).

Design and Procedure. The two perspectives (frontal vs. dorsal) were implemented within-subject. Which came first was assigned randomly for each participant. Within each perspective, non-oriented and oriented items were presented in blocks, and within each block in random order.

## Results and Discussion

The data were analyzed in the same way as in Study 1. In the first step, we checked the two samples for differences in the mean number of responses that are not covered by one of the FoRs under scrutiny. Overall, this number of "unexplained responses" was very low ( $M=3.7 \%$; Table 1) and lower still than for Norwegian and Farsi. An analysis of variance with the between-subjects factor language (German vs. Japanese) and two within-subject factors, perspective (frontal vs. dorsal) and ground object (nonoriented vs. oriented), indicated no significant effects (all $\left.F(1,247)<1.9 ; p \geq .171 ; \eta^{2} \leq .008\right)$. Neither the unusual dorsal perspective nor the type of ground object influenced the coverage of responses by the FoRs under scrutiny in the two samples alike.
Then, we checked how consistently each FoR variant was adopted. Overall, FoRs were adopted with a mean consistency of $88.9 \%$ across the two samples (Table 2). In other words: Participants adopted their individually preferred FoR in 5.33 of 6 items of a block. An analysis of variance with the between-subjects factor language (German vs. Japanese) and two within-subject factors, perspective (frontal vs. dorsal) and ground object (nonoriented vs. oriented), detected the same three effects as in Study 1: main effects of language and ground object, and an interaction of the two factors. Consistency was higher for the German speakers than for the Japanese speakers ( $91.8 \%$ vs. $\left.86.0 \% ; F(1,247)=15.2 ; p<.001 ; \eta^{2}=.058\right)$. It was also higher for non-oriented items than for oriented items ( $91.0 \%$ vs. $\left.86.8 \% ; F(1,247)=32.2 ; p<.001 ; \eta^{2}=.115\right)$, indicating again that the possibility of applying the intrinsic FoR was a source of inconsistency, but to a different extent in the two languages (as reflected in the interaction; $F(1,247)=5.1$; $p=.024 ; \eta^{2}=.020$ ). And, as in Study 1, the unusual dorsal perspective per se did not matter: Consistency was nearly the same for the frontal items as for the dorsal items ( $88.2 \%$ vs. $\left.89.6 \% ; F(1,247)=2.258 ; p=.134 ; \eta^{2}=.009\right)$.

Participants' preferred FoRs are shown in Table 3. Loglinear analyses of FoR preferences indicated differences between the two languages for the same three item blocks as in Study 1: for the two blocks of frontal items (non-oriented: $G^{2}=78.3 ; d f=3 ; p<.001$; oriented: $G^{2}=96.0 ; d f=4$; $p<.001$ ), and for the block of oriented dorsal items ( $G^{2}=10.4 ; d f=4 ; p=.034$ ), but not for the block of nonoriented dorsal items ( $G^{2}=4.6 ; d f=3 ; p=.201$ ).

Table 4: Preferred FoR in dorsal item blocks depending on the preferred FoR in frontal item blocks in Study 2.

| Dorsal <br> preference | Frontal preference |  |  |  |
| :--- | :---: | :---: | :---: | :---: |
|  | Translation | Reflection | Rotation | Other |
| Turn-translation | 3 | - | - | 2 |
| Turn-reflection | 2 | 20 | - | 1 |
| BP/turn-rotation | $106_{\mathrm{BP}}$ | $278_{\mathrm{BP}}$ | 3 | 40 |
| Other | 8 | 16 | 1 | 18 |
| $N=498$ | 119 | 314 | 4 | 61 |

Note. Data are summed over non-oriented and oriented item blocks and the two samples. BP: backward projection (translation ${ }_{B P}$ or reflection ${ }_{B P}$ ); the category other includes participants with no preference (from all tasks) and with a preference for the intrinsic FoR (from tasks with an oriented G). Grey cells: Responses according to the turn-hypothesis.

If adopting the intrinsic FoR was possible, again some participants preferred this FoR (mean percentage across all items with an oriented G for German: $3.2 \%$; Japanese: $5.5 \%$ ), but less so than in the Farsi sample. Some participants also seemed to change their referencing strategy item-specifically, as indicated by the increased number of participants with no clear preference for any FoR variant as compared to the items with a non-oriented ground object.

Among the variants of the relative FoR for frontal tasks, translation and reflection were preferred most often, but again to a different extent in the two samples. The reflection variant prevailed most strongly among the German speakers (mean percentage across all frontal items for German: $86.8 \%$; Japanese: $32.6 \%$ ). This finding replicates data from a German sample collected with a paper-and-pencil questionnaire (Beller et al., 2015), thereby validating the methodological change to an online assessment (see Beller et al., 2015, 2016, for a broader discussion of the paperpencil assessment and other methodological issues). In contrast, the translation variant prevailed among the Japanese speakers (German: 5.7\%; Japanese: 48.6\%). The rotation variant was adopted only by very few participants (German: 0.4\%; Japanese: $1.4 \%$ ).

Among the variants of the relative FoR for dorsal tasks, the variant indicating the application of backward projection and turn-rotation strongly dominated in the two samples alike (mean percentage across all dorsal items for German: $87.1 \%$; Japanese: $83.9 \%$ ).

The implementation of perspective as a within-subject factor in this study allows us to relate each participant's preference in dorsal tasks to his or her preference in frontal tasks and thereby to disambiguate the dorsal response (cf., Beller et al., 2016). To this end, we cross-tabulated participants' preferred FoRs for frontal and dorsal tasks (summed over non-oriented and oriented item blocks and the two samples). The results are reported in Table 4. Of the 498 preference pairs, $26(5.2 \%)$ were indicative of the turnhypothesis (grey cells). Most of these participants adopted the turn-reflection variant in line with the overall higher
prevalence for reflection. This provides some support for the turn-hypothesis. However, the vast majority of pairings (384 or $77.1 \%$ ) pointed at backward projection as the prevailing strategy (translation $_{\mathrm{BP}}$ : $21.3 \%$; reflection ${ }_{\mathrm{BP}}$ : $55.8 \%$ ).

In sum, Study 2 corroborated further that the reflection variant of the relative FoR is not universally adopted. While being the most frequent FoR used for frontal tasks in the German sample, the translation variant predominated in the Japanese sample. In line with the results from Beller and colleagues (2016), participants' dorsal references indicated backward projection as the main strategy.

## General Discussion

The goal of this paper was to broaden our knowledge regarding intra- and cross-linguistic variation in the use of different variants of the relative FoR for spatial references in frontal and dorsal settings. In particular, we asked two questions: Do people have a canonical preference for the reflection variant of the relative FoR in frontal settings, as assumed by some scholars? And do people (mentally) turn around to an object configuration in their back and apply the FoR they prefer for frontal settings (turn-hypothesis)? Our findings indicate that neither is the case.
With regard to the first question, we detected a great deal of intra- and cross-linguistic variation in people's use of the relative FoR in frontal settings. The speakers of Norwegian, German, and Japanese exhibited high intra-individual consistency. Almost all participants applied the same variant of the relative FoR repeatedly for a whole set of tasks. Among the speakers of Farsi, consistency was lower, indicating more task-specific references, particularly in cases where the intrinsic FoR was also possible. With regard to the inter-individual consensus within the samples, we observed high consensus among the German speakers (i.e., most speakers adopted the same FoR variant as everybody else: reflection), moderate consensus among the Norwegian and Japanese speakers (some of which preferred the reflection variant, others the translation variant), and an even weaker consensus among the Farsi speakers (for which the data also indicate a rare but consistent use of the rotation variant). All in all, reflection and translation were the dominant variants of the relative FoR for frontal settings, replicating the general pattern found for German, English, Mandarin Chinese, and Tongan (Beller et al., 2015).
In spite of this diversity in frontal tasks, most participants converged on the very same response in the dorsal tasks. In most cases, this response could be attributed to backward projection strategies that are in line with people's frontal preference for translation or reflection, but get by without (mental) rotation, and are thus quite adaptive given the fact that mental rotation comes with substantial cognitive costs (Duran, Dale, \& Kreuz, 2011; Shepard \& Cooper, 1982).

Finally, the degree of linguistic variation is revealing in yet another regard. The intra-linguistic variation we found reflects the fact that spatial prepositions like "in front of" or "behind" are inherently underspecified. Nothing in these words tells us where exactly FRONT or BACK is. This can
only be established after having adopted a specific point of view, or frame of reference. Yet, which FoR a speaker adopts is either due to his or her individual preference or to conventions within his or her speech community. Viewed in this way, the variation we found is a cultural rather than a purely linguistic phenomenon.

# Quantifying Infants' Statistical Word Segmentation: A Meta-Analysis 

Alexis Black (akblack2g@gmail.com)<br>Department of Linguistics, 2613 West Mall<br>Vancouver, BC, Canada V6T 1Z4

Christina Bergmann (chbergma@gmail.com)<br>Laboratoire des Sciences Cognitives, Ecole Normale Supérieure, 29, rue d'Ulm 75005 Paris, France

#### Abstract

Theories of language acquisition and perceptual learning increasingly rely on statistical learning mechanisms. The current meta-analysis aims to clarify the robustness of this capacity in infancy within the word segmentation literature. Our analysis reveals a significant, small effect size for conceptual replications of Saffran, Aslin, \& Newport (1996), and a nonsignificant effect across all studies that incorporate transitional probabilities to segment words. In both conceptual replications and the broader literature, however, statistical learning is moderated by whether stimuli are naturally produced or synthesized. These findings invite deeper questions about the complex factors that influence statistical learning, and the role of statistical learning in language acquisition.

Keywords: language acquisition; statistical learning; word segmentation; meta-analysis

## Introduction

Statistical learning (SL), the ability to extract statistical patterns from a continuous stream of perceptual experiences, is of fundamental theoretical importance. The first evidence that infants can extract statistical information from speech and use it to group syllables was provided by Saffran, Aslin, and Newport in 1996. This seminal paper has since accrued thousands of citations, and spurred a rich literature invoking SL as one foundation for language acquisition (see Newport, 2016) as well as perceptual learning more broadly (see Aslin, 2017). SL mechanisms have furthermore been successfully implemented in a range of computational models (e.g., Pearl, Goldwater, \& Steyvers, 2010; Lloyd-Kelly, Gobet, \& Lane, 2016). In short, statistical learning abilities are of fundamental, crossdisciplinary importance to better understand the computational foundations of cognition.

While many would accept some role for SL mechanisms, the nature and extent of this role remains contested. The more abstract the level of analysis, the more vigorous the debate (e.g., can SL yield syntactic 'rules'?) - but inconsistencies emerge even at the level of tracking transitional probabilities (TPs) as a means of word segmentation. For example, the original effect has failed to replicate under certain conditions (e.g., variable word length: Johnson \& Tyler, 2010; Lew-Williams \& Saffran, 2012) or showed a developmental shift in cue-weighting (e.g., Thiessen \& Saffran, 2003). Finally, a recent meta-
analysis that examined natural speech word segmentation (not determined by TPs) revealed a significant, but small effect (Bergmann \& Cristia, 2016), leading to concerns about the robustness of infants' word segmentation in the absence of TPs.

In the current paper, we use meta-analysis to quantify and contextualize infants' ability to detect regularities in a continuous speech stream. To this end, we have aggregated all available evidence from the published record and present a meta-analysis of infant SL word segmentation studies. A meta-analytic approach helps establish the magnitude of an underlying effect, something single experiments are not equipped to do - and thus has the potential to impact future theory- and model-building. On the practical side, effect sizes are crucial for determining power of future studies, thus increasing the replicability of a line of inquiry and reducing the cost (failed studies, or testing too many participants) for single researchers.

We also take several steps beyond quantifying the underlying effect: Aggregating over studies allows for the identification of moderator variables, which also contributes to theory building and may guide future research. We examine three potential moderators that are relevant to the intersection of theories of infant cognition and statistical learning: (1) age, (2) stimulus naturalness, and (3) non-TP cues. The justification for investigating these particular moderators is described in brief. (1) All studies in the current meta-analysis use looking-time preferences. The direction of preference (to novel or familiar items) is commonly thought to relate to infant age and/or stimulus complexity (e.g., Hunter \& Ames, 1988). We therefore predicted that developmental change might be reflected in a shift of preference (e.g., from a preference for words to one for non-words), or in a stronger effect over time. (2) Given the familiarity preference found in a previous meta-analysis on natural speech (Bergmann \& Cristia, 2016), we hypothesized that it might be that the predominant novelty preference established for SL studies since Saffran et al. (1996) is grounded in methodological choices. The primary difference between these two datasets is in the nature of the stimuli: naturally produced vs highly artificial speech stimuli. Even within the literature of the current dataset, however, stimuli differ along this dimension. We therefore compare SL studies with natural and artificial stimuli. (3) Finally, a number of studies pitted alternative cues (e.g., word-level stress) against TPs. It is therefore important to
examine the impact of these conflicting cues on SL performance compared to no conflict.

We also assess publication bias in the literature; a current topic that is especially important for infant research, considering the high cost of testing participants and the consequent use of small samples (Frank et al., 2017).

## Methods

To collect data, we complemented expert lists with two google scholar searches. We first surveyed papers citing Saffran, Aslin, \& Newport (1996) with the word "infant/infancy", but not "visual" in the title. The second search aimed to cast a wider net; search terms were now "month/s" and not "infant/infancy" or "visual". These two strategies yielded a total of 314 unique papers, which were then screened for inclusion. The criteria were: (1) contains data on infants from (2) behavioral experiments which exposed infants to a familiarization phase of continuous, artificial speech and which measured (3) reactions (typically looking times to unrelated visual stimuli) to both statistical words and non-words (this definition includes part-words).

The final sample encompassed 20 papers ( 10 containing conceptual replications ${ }^{1}$ ) yielding 68 ( 17 replication) effect sizes. Note that one paper often contains several experiments (henceforth: samples) that can yield effect sizes, for example when testing different age groups. In total, we are reporting on experiments testing 1,454 infants between 4.5 and 11.1 months. Children were tested in the headturn preference procedure (Kemler Nelson, et al., 1995; 59 samples) or the central fixation paradigm (Graf-Estes \& Lew-Williams, 2015; 9 samples).

## Effect Size Calculation

All scripts and raw data are available on github. ${ }^{2}$ The effect size we report here is a standardized mean difference of infants' looking behavior when listening to statistical words versus non-words. Since a preference for non-words (novelty preference) is dominant in the literature, positive values reflect this direction of the effect. The larger the effect size, the bigger the observed standardized mean difference between the two types of test trials. In turn, negative values indicate that infants demonstrated a familiarity preference, i.e. they listened longer to statistical words over non-words ${ }^{3}$.

[^27]We computed Hedges' $g$ (Morris, 2010), a variant of Cohen's $d$ (Cohen, 1988) that is preferred in the case of small sample sizes. Effect sizes were calculated based on reported test statistics: for 50 samples we could use means and standard deviations of test trials; for 17 samples $t$-values for the main comparison were available. To ensure consistency in the direction of the effect, we re-coded $t$ values as positive when infants listened longer to statistical non-words and as negative otherwise. We used standard formulae for effect size calculation in within-participant designs (Lipsey \& Wilson, 2001, when means and standard deviations were available; Dunlap et al., 1996, for effect sizes based on $t$-values). One paper reported betweenparticipant results and we computed effect sizes and variances from means and standard deviations accordingly (Lipsey \& Wilson, 2001). When the same infants contributed to multiple effect sizes, we computed the median of all critical values to ensure independent samples (here, 4 effect sizes were derived from 8 non-independent samples). We could not compute effect sizes for 6 additional experiments, due to lack of information.

Only one of the 20 papers included reported correlations between test trials, which capture the dependency between the two data points stemming from the same participants and are necessary for $t$-value based effect size and general effect size variance calculation. We imputed random values based on the distribution of correlations reported in a similar meta-analysis (Bergmann \& Cristia, 2016; updated data available via metalab.stanford.edu). ${ }^{4}$

## Meta-Analysis

To establish the size and variance of the effect, we fitted a multivariate random effects model using the R ( R core team, 2016) package metafor (Viechtbauer, 2010). Random effects models assume that all effect sizes are sampled from a distribution of effect sizes and try to estimate the mean and variance of this distribution. In the multivariate model, the interdependence between effect sizes from the same paper is taken into account, yielding a more robust measure

[^28]of the true effect. To investigate the impact of additional variables, we introduce moderators to this model.

## Bias

We tested for bias in the published literature by assessing funnel plot asymmetry, which is significant when a portion of the expected distribution of effect sizes around the weighted mean is missing, yielding an over-representation of a part of the underlying effect size distribution. We test for asymmetry using the rank correlation test (implemented in metafor; Viechtbauer, 2010).
To further investigate biases, we make use of p-curves to test whether there is an excess in $p$-values just below the significance threshold of .05 and if the distribution of $p$ values indicates an underlying real effect (Simonsohn, Nelson, \& Simmons, 2014). To this end, we enter all exact $t$-values that were reported ( $\mathrm{n}=48$ for the whole dataset).

## Results

## Original Paper

We first calculated the effect size and its variance for the two experiments reported by Saffran, Aslin, and Newport (1996). Hedges' $g$ was $0.4(\mathrm{SE}=0.040)$ for experiment 1 and 0.38 ( $\mathrm{SE}=0.041$ ) for experiment 2. According to Cohen's (1988) criteria this is a small to medium effect.

If experimenters base their sample size decisions on this effect size, they would have to test 53 infants in a paired samples design to achieve $80 \%$ power (computed with the R package pwr; Champely, 2016). The median sample size in our dataset is 22 participants, which would mean a $42 \%$ probability of obtaining a significant result, assuming the effect is of the size reported in the initial study; inversely, $58 \%$ of attempts to replicate this finding should fail.

## Conceptual Replications

First, we report on the experiments that were identified as replications of the original report (Saffran et al., 1996). Seventeen experiments could be included in these analyses.

Meta-Analytic Effect The variance-weighted effect size Hedges' $g$ is $0.21(\mathrm{SE}=0.1)$, which is significantly different from zero ( $95 \%$ CI $[0.02,0.4], p=.03$ ) and indicates a preference for statistical non-words. Note that this effect is smaller than the original report, and typical power is thus only $16 \%$ with 22 participants. Heterogeneity is significant, indicating variance in the data that is not explained by random measurement error $(\mathrm{Q}(16)=71, p<.001)$.

Moderator Analysis: Age We find no significant effect of the moderator centered age in days $(\mathrm{Q}(1)=0.6, \beta=-0.001$, $\mathrm{SE}=0.0015,95 \% \mathrm{CI}[-0.004,0.018], p=.5)$.

Moderator Analysis: Stimuli Naturalness Studies on SL differ in the stimuli; in this dataset, 11 effect sizes came from experiments with synthetically generated speech, 6 were based on experiments with naturally produced speech.

Figure 1: Funnel plot (code adapted from Sakaluk, 2016) showing standard error of the effect size as a function of effect size for 17 conceptual replications. The solid line marks zero, the dashed line the effect estimate, and the grey line indicates the funnel plot asymmetry.

Overall, the moderator test is significant $(\mathrm{Q}(1)=5, p=$ .023 ) with a negative estimate $(\beta=-0.35, \mathrm{SE}=0.16,95 \%$ CI $[-0.66,-0.05]$ ), indicating that infants tend to show less of a novelty preference with stimuli produced by human speakers.

Follow-up analyses focusing on subsets revealed that synthetically produced stimuli lead to a significant positive effect (Hedges' $g=0.32, \mathrm{SE}=0.05,95 \%$ CI [0.2, 0.4$], p<$ .001 ), while those replications relying on naturally-produced speech yield an effect size not different from zero (Hedges’ $g=0.02, \mathrm{SE}=0.2,95 \% \mathrm{CI}[-0.36,0.41], p=.9)$.

Publication Bias The funnel plot shown in Figure 1 displays a greater density of large effect sizes that are of low-precision (lower right quadrant) and some effect sizes that are of high precision but outside the expected distribution (upper left quadrant), which is illustrated further by the linear regression line in grey. This line should be horizontal in the case of an even distribution around the median effect. Nonetheless, asymmetry is not significant with Kendall's $\tau=.26, p=.15$.

The p-curve analysis based on the 6 significant $t$-values available in this dataset indicates a flat distribution of $p$ values, as would be expected when there is no underlying effect ( $\mathrm{Z}=-0.43 ; p=.33$ ). However, these $6 t$-values might not be representative of the 17 studies analyzed here.

## Complete Literature

Meta-Analytic Effect When taking into account all 68 independent effect sizes, the meta-analytic effect size Hedges' $g$ is 0.09 ( $\mathrm{SE}=0.05$ ), which is not significantly different from zero (CI [-0.02, 0.19], $p=.1$ ). This dataset, however, includes a number of samples that explicitly pit TPs against other segmentation cues, and thus may be expected to lead to different effects represented within the same data. Indeed, heterogeneity is significant $(Q(67)=$ $334, p<.001$ ). We thus analyze each of our moderators.

Figure 2: Effect size by participant age for all samples; point size is inverse variance. Black refers to synthetic, grey to natural speech. The dashed line indicates zero.

Moderator Analysis: Age As described in the introduction, more mature infants might show a different direction of preference or larger effect. However, we find no (linear) effect of age $(\mathrm{Q}(1)=0.3, p=.6)$. Follow-up analyses introducing a quadratic term for age confirmed this finding.

Moderator Analysis: Stimuli Naturalness In the full dataset, the use of artificial and natural speech is fairly balanced, with 38 instances of computer-generated stimuli and 30 of human speakers. The moderator test is significant $(\mathrm{Q}(1)=11, p<.001)$, and the results mirror our findings in the conceptual replication dataset. Figure 2 displays all samples, with color encoding natural (grey) vs artificial (black) stimuli. The meta-analytic effect for experiments with artificial stimuli is significantly above zero (Hedges' $g$ $=0.23, \mathrm{SE}=0.06,95 \%$ CI $[0.11,0.35], p<.001)$. In contrast, natural speech yields an effect not different from zero (Hedges' $g=-0.05,95 \%$ CI $[-0.2,0.06], p=.4$ ).

Moderator Analysis: Cue conflict Cues can either be absent ( $\mathrm{n}=20$ ), congruent with TPs (32), or in conflict with statistical information (16). Those cues encompass word stress (8), sentence level prosody (3), duration (2), intensity (2), and co-articulation (1). We predicted that cues that coincide with TPs might strengthen the effect, while those that conflict with TPs may reveal a different, possibly even opposing effect. We therefore introduced a three-leveled moderator. This analysis revealed no significant moderator effect $(\mathrm{Q}(2)=1.9, p=.4)$.

Of the 48 samples that involve additional cues, 24 are based on the effect of a correlate of word-level stress on segmentation. These studies propose that infants will be driven to segment speech using a trochaic stress pattern, in line with their native language. Artificial languages with trochaic stress are therefore congruent with TP cues, and are predicted to lead (as a whole) to novelty preferences; those with iambic stress conflict with TPs, and are predicted to lead (as a whole) to null or familiarity preferences.

Figure 3: Funnel plot of all samples. For details see Figure 1.

A moderator analysis restricted to samples with additional stress-based segmentation cues fails to confirm this prediction $(Q(1)=0.7, p=.4$; Cue conflict [iambic stress]: $\beta$ $=-0.07, \mathrm{SE}=0.08,95 \% \mathrm{CI}[-0.23,0.09])$.

Publication Bias Figure 3 shows an even distribution of effect sizes around the estimated median, the large spread illustrating the unexplained heterogeneity. The ranktest indicates no significant asymmetry (Kendall's $\tau=-.01, p=$ .9; see also grey linear regression line in Figure 3).

The p-curve based on 34 significant $t$-values indicates that the data contain evidential value $(\mathrm{Z}=-2.47 ; p=.007$ for the full p-curve) and there is no excess of "just significant" pvalues. Power based on the p-curve is estimated to be $25 \%$.

## Discussion

In the present paper, we examine infants' ability to track transitional probabilities (TPs) in continuous streams of speech. Experiments replicating the original Saffran et al. (1996) paradigm reveal a significant and reliable effect (Hedges' $g=.21$ ) that is on par with the effect found in the meta-analysis of natural speech segmentation (Hedges' $g=$ .22; Bergmann \& Cristia, 2016), albeit in the opposite direction of preference. An analysis of the whole literature fails to find a significant aggregated effect, but is reliably influenced by naturally vs. synthetically produced speech. There was no evidence for a developmental shift in or strengthening/weakening of preference, nor for a consistent and reliable role of additional cues. Finally, there is no clear evidence for publication bias. Taken together, these results invite deeper consideration of several issues in the future study of SL and theories of language acquisition, discussed in turns below.

## One Mechanism Among Many

The data presented here confirm that infants can track statistically defined patterns and use that information to segment a stream of speech into word-like units. The strength of this capacity, however, may be more fragile than expected. How are we to understand these findings, as we
continue to examine the import of statistical learning in language acquisition?

When aggregating across different studies, we put to the test the idea that researchers can predict the direction of infant looking-time preferences. Most popular theories of infant preference (e.g. Hunter \& Ames, 1988; Kidd, Aslin \& Piantadosi, 2012; 2014) predict an interplay between stimulus complexity and infant readiness to encode this complexity. In the case of TP-based word segmentation, we therefore expected a linear (or quadratic) shift from familiarity to novelty preferences as infants age. We instead find a consistent novelty preference. On the other hand, there is a significant effect of stimuli naturalness: While studies using synthesized speech yield reliable novelty preferences, studies using naturally produced speech fail to find reliable effects. It is likely that natural speech, even when altered to be largely monotonic and lacking syllable co-articulation, is more acoustically complex than synthetic speech. This is supported by the consistent familiarity preference across age groups found by Bergmann \& Cristia (2016). Infants may thus be more likely to show a familiarity preference to natural speech because it may take more time to process (and hence habituate to/learn from) this complex signal. There is some evidence in the SL literature to support this idea: some studies find alternating patterns of looking preference by block (e.g. Graf-Estes \& Lew-Williams, 2015). This, however, is rarely reported. Future investigations based on the meta-analytic data presented here might pursue the role of stimulus complexity by assessing the possible interactions between stimulus type, familiarization duration, age, and direction of lookingtime preference.

Several of the studies in the dataset were designed to test the limits of SL. They have been included because in all cases infants might have opted to segment the language based on TPs alone; we hypothesized that, once taken in sum, these studies might have revealed evidence that TPs drive segmentation even in the face of alternative cues. This did not turn out to be the case - there is no reliable effect for segmentation when all studies are considered together. Moreover, and surprisingly, there is no pattern that unites samples in which cues are congruent with TPs vs those in conflict with TPs. These results, in fact, suggest that infants only succeed at tracking TPs when presented with artificial speech sounds. Given the results of the Bergmann \& Cristia (2016) meta-analysis, we find this unlikely to reflect the true state of the world; rather, we believe it suggests that what does drive performance in the relatively simple paradigm of TP-based word segmentation remains underspecified and requires further theoretical, experimental, and metaanalytical consideration. Future work extending from the current dataset will aim to contribute to this discussion by accruing enough data to be able to examine additional moderators (e.g. familiarization duration) and outcome variables (i.e. effect sizes based on proportions of infants showing the effect, as opposed to standardized means of looking-time differences).

## Practical Implications

There are several points to take into account when planning future SL word segmentation studies. First, assuming an effect size of Hedges' $g=.21$, the power of a typical 22 sample design is a meagre $16 \%$ (note that the pcurve analysis indicates an overall power level of $25 \%$ in the significant portion of the studies). A well-powered study ( $80 \%$ ) would require a sample of 180 infants ( 142 if the direction of the preference can be predicted). This is impractical in the current state of infant research which relies on single labs conducting such studies (but see the alternative collaborative approach outlined by Frank et al., 2017). We do not intend to suggest that SL is not worth investigating - but it does call into question the methods with which we choose to investigate it. Power might, for example, be increased with more robust methods, calling for infant researchers to improve extant paradigms. At this point, we are only beginning to have sufficient power to fully understand the role of methods, stimuli, and test set-up (see e.g., Frank et al., 2017). One possibility lies in adopting more implicit measures of SL such as through neuroimaging, which may be less susceptible to factors affecting the direction of infant looking-preference.

## Limitations

Any meta-analysis is limited by a number of factors, one of which is that the analysis is only as good as the data it contains. In other words, the studies reported here are those that have been published (or made available online) and were findable through our search criteria (see supplementary material for a full list of included studies). Since the effect is small, we expect that a number of failures to replicate the original finding are confined to the file-drawer, simply because they were underpowered. Further, studies showing a familiarity preference might not be published as those are not expected in replications of Saffran et al., (1996). Including such (presumed) file-drawer studies would make our estimates much more reliable and we strongly encourage researchers with unpublished work to contact the authors and contribute these findings (or any published data that may have been regrettably missed).

A second limitation is missing information. For example, in order to compute effect sizes and their variance for within-participant designs, it is necessary to know the correlation between infants' preferences for each test-item type. We have temporarily imputed these figures based on similar data (Bergmann \& Cristia, 2016), and ran additional analyses to confirm that different values result in similar outcomes. However, we hope that authors who can retrieve this data will be willing to enrich our dataset, and recommend to all to include this information in future publications

## Conclusion

This meta-analytic analysis of statistical learning as applied to word segmentation has revealed a reliable but small
effect. We hope that this paper promotes future research that will seek to better characterize infant performance on SL tasks, and will thus contribute to stronger theories and models of infant cognition and behaviour.

## Acknowledgments

The authors thank the Cognitive Science Society for hosting a meta-analysis tutorial in 2016 and for participants of this tutorial, who pre-coded some of the included papers. Department of Psychological Sciences, Birkbeck, University of London

#### Abstract

The Cone of Direct Gaze (CoD) is described as the range of eye gaze deviations over which an observer reports gaze as being directed towards them. The CoD has been found to narrow with age across childhood (Mareschal et al. 2016). We investigated whether reinforcement learning, so critical in shaping eye gaze responses in infancy, was able to account for the emergence of a CoD and its narrowing in childhood. To this end, we adapted Triesch et al.'s (2006) reinforcement learning model by (1) defining a topology over object locations, and (2) introducing opponent non-linear reward profiles for looking at objects and caregivers. In Simulation 1 we show that these modifications give rise to a functional CoD in which there is reduced eye gaze following and increased fixation on the caregiver for locations with a small caregiver eye gaze eccentricity. In Simulation 2 we show that the width of this effect reduces with learning, suggesting that developmental decreases in the CoD may be driven by reinforcement learning. In Simulation 3 we explore how changes in model parameters can explain the CoD in high anxiety populations. Finally, the model provides one way of unifying the developmental gaze-following and CoD literatures, until now considered largely independent.

Keywords: Reinforcement Learning; Cone of Direct Gaze; Gaze Following; Development; Social Anxiety; Autism;

## Background

The eyes are a key aspect of social intelligence. From the eyes one can infer an individual's emotions or desires, which can help guide social behavior, and also learn about the surrounding environment (Shepherd et al., 2010). Through joint attention, individuals can alert others to interesting objects in the environment by guiding their attention to that object. Eye gaze following is one form (Scaife and Bruner, 1975). In this seminal study the authors showed that infants were able to interpret the direction of another individual's eye gaze could and use that as a cue to look in the perceived direction. This allows infants to find objects of interest in the environment and learn from experienced caregivers in a non-verbal manner. Indeed, infants have been shown to be sensitive to eye gaze from a very young age, appearing to show a preference for eyes over other parts of the face (Hains \& Muir, 1996).

Infants with autism have a reduced ability to follow eye gaze (Leekam et al., 1997). A recent study by Thorup et al. (2016) found that infants at high risk of developing autism rely disproportionally on directional information from the head as compared to the eyes. This reduced ability to follow eye gaze may be a contributing factor to the deficits in social cognition and communication associated with autism.

While joint attention via eye gaze following appears to be a crucial tool for the developing infant, the perception of
eye gaze direction is not uniform across eye gaze deviations. The Cone-of-Direct gaze (CoD), is defined as the range of gaze deviations that we perceive to be looking directly at us (Gamer and Hecht., 2007). The CoD, therefore, has implications for how we perceive social situations and our interpretation of eye gaze. For example, if a gaze deviation falls inside our CoD then we may perceive it as looking directly at us and not engage in any eye gaze following behavior.

The perception of whether an individual is looking directly at you or not is also of particular interest to those investigating social anxiety disorders (Schulze et al., 2013). For example, a study by Jun et al. (2013) reported a wider CoD for high socially anxious males compared to low socially anxious males. Similarly, Gamer et al. (2011) conducted a study where participants had their CoD measured in response to a virtual head. They found that participants with social phobia had a wider CoD in the presence of a second virtual head that was directed at them. Such studies suggest that a wider CoD is associated with social anxiety and may play a role in the disorder.

Both eye gaze following and the CoD undergo changes during development. Eye gaze following emerges and improves during infant development (Brooks and Meltzoff., 2005, Deak., 2015), while the CoD becomes narrower during childhood (Mareschal et al., 2016). This equates to older children being more reliable at following eye gaze and more accurate at interpreting small eye gaze deviations as not being directed at them. It is possible that these developmental timelines for eye gaze following and the CoD are crucial for infant and child development and may be altered in clinical disorders such as autism and social anxiety. It is therefore important to understand their emergence and developmental trajectory.

Reinforcement learning (Sutton and Barto, 1998) has received much interest in recent years and there is now good evidence of the neurocomputational basis of reinforcement learning (Schultz et al., 1997). It has been proposed as a possible mechanism for the emergence and improvement of eye gaze following in infants. Triesch et al. (2006), describe a reinforcement learning model in which rewards obtained by following a caregiver's gaze led to the reinforcement of eye gaze following behavior. According to this account, infants associates the rewarding object that the caregiver is looking at with the act of following the caregiver's gaze, thereby building a predisposition to follow gaze as a consequence of experience rather than an innate behavior.

While reinforcement learning may account for the emergence of eye gaze following, the mechanism behind the emergence of a CoD is yet to be elucidated. To what extent is the CoD and its development the result of an innate prior
and to what extent is it the result of learning and the external environment? To investigate such a question, we explored whether the reinforcement learning framework could also account for the CoD and its changes through development. If reinforcement learning where to play a role in the emergence of a CoD then it may provide a link between eye gaze following and the CoD. It would also highlight reinforcement learning as a promising target for the therapeutic investigation of disorders such as autism and social anxiety.

## Triesch et al.'s (2016) Model

Triesch et al.'s (2006) model serves as a spring board for this study. The model consists of an infant, a caregiver and an object (Figure 1). Both the infant and caregiver remain in fixed positions while the object is able to move around N discrete locations. Two parameters, T_min and p_shift are responsible for the movement of the object around these locations. T_min specifies the minimum amount of time an object must spend in a location, while $p_{-}$shift specifies the probability of shifting to a new location per time step after T_min. This shifting of the object also determines the shifting of the caregiver's gaze.

Figure 1. Diagram of the gaze following reinforcement learning model proposed by Triesch at al. (2006).

When the object moves to a new location the caregivers gaze is shifted to a new location. The caregiver can look at $\mathrm{N}+1$ potential locations; the N locations the object can reside in plus the location of the infant. The parameter p_valid determines the probability that the new location of the caregiver's gaze is the same as the new location of the object. This probability effectively models two scenarios. The first scenario is when the caregiver's gaze may not be a $100 \%$ predictive of where the object is and the second scenario is when the infant's interpretation of the caregiver's gaze may not be a $100 \%$ accurate. The p_valid parameter accounts for both of these scenarios because both an inaccurate caregiver gaze or a poor interpretation of the caregiver gaze will lead to the infant following the caregivers gaze to an incorrect location.

The infant's behavior is modelled using a reinforcement learning framework whereby it is essentially driven to maximize rewards in the environment. The infant is broken up into two agents, a 'when' agent and a 'where' agent. The when agent is responsible for deciding whether it is time to shift gaze on a time step and the where agent is responsible
for deciding where to shift the gaze. These decisions are driven by the rewards encountered in the environment by the infant. In this environment the infant has four possible views, each of which having an associated reward:

1. An empty location ( $\mathrm{R}_{\text {nothing }}$ )
2. A location containing the object $\left(\mathrm{R}_{\text {object }}\right)$
3. A profile view of the caregiver $\left(\mathrm{R}_{\text {profile }}\right)$
4. A frontal view of the caregiver as they look directly at the infant ( $\mathrm{R}_{\text {frontal }}$ )
For each of these views the infant receives the associated reward $\left(R_{x}\right)$ multiplied by a habituation value. This habituation value exponentially decreases as the infant fixates on a location. The degree of this decrease is controlled by the habituation parameter beta ( $\beta$ ). Equally, the reward value for locations that have been habituated to, but the infant is no longer looking at, recover at the same rate. Habituation is important in a reinforcement learning framework such as this because otherwise the infant could just fixate on a single reward (e.g. the caregiver), and never have the motivation to shift gaze.

Taking the reward structure and habituation into account, the state-space of the when agent becomes two dimensional. The first dimension is how long has the infant been looking at the same location and the second dimension is the reward received by the infant. Representing the state-space with these two dimensions allows the when agent to decide whether to carry on looking at the same location or look somewhere else. If the decision is made to look somewhere else, then the where agent then specifies the location of the new gaze. The state-space of the where agent varies along a single dimension, which represents the gaze of the caregiver. This corresponds to $\mathrm{N}+2$ states. There are N number of states for when the caregiver is looking at each of the N object locations. It is these states that the infant uses to interpret where the caregiver is looking. Another state is for when the caregiver is looking directly at the infant and a final state is for when the gaze of the caregiver is unknown to the infant. While the action-space of the when agent is simply stay or move, the action-space of the where agent is of size $\mathrm{N}+1$. The where agent can decide to shift gaze to one of the N object locations or to look directly at the caregiver.

Both the when and where agents learn using temporal difference (TD) learning and the SARSA algorithm (Rummery and Niranjan, 1994; Equation. 1).

```
\(\delta_{t}=r_{t}+\gamma Q_{t}\left(s_{t+1}, a_{t+1}\right)-Q_{t}\left(s_{t}, a_{t}\right)\)
    \(Q_{t+1}\left(s_{t}, a_{t}\right)=Q_{t}\left(s_{t}, a_{t}\right)+\alpha \delta_{t}\)
    \(s_{t}=\) state at time \(t\)
    \(a_{t}=\) action at time \(t\)
    \(r_{t}=\) reward at time \(t\)
    \(\delta_{t}=\) temporal difference error at time \(t\)
    \(Q_{t}\left(s_{t}, a_{t}\right)=\) state - action value at time \(t\)
    \(\alpha=\) learning rate
    \(\gamma=\) discount factor for future rewards
```

In this framework the temporal difference error is calculated and the parameter gamma $(\gamma)$ is used as the discount factor
for future rewards. This temporal difference error is then used to update the appropriate state-action value and the size of this update is controlled by the learning parameter alpha $(\alpha)$. A softmax function was used to mapped the state-action values to actions. This allowed for a balance between exploration and exploitation, determined by the parameter tau was responsible for this balance. A larger value of tau results in more exploration and less exploitation of the stateaction values.

## Simulation 1 - Emergence of the Cone of Direct Gaze

To investigate whether reinforcement learning could also account for the emergence of a CoD , the reward structure of Triesch et al.'s model was modified to include a spatial topology in the reward space

## Methods

A CoD is inherently a spatial phenomenon that is assessed by having an individual look further and further away from a participant until the participant judges the gaze to no longer be directed at them. For this reason, the N object locations in Triesch et al.'s model were first given a spatial location identity based on the gaze deviation required from the caregiver to look at them (Figure 2). Values stepped four degrees at a time and the N locations were arranged in a linear manner. This alteration to Triesch et al.'s model allowed for the analysis of gaze following behaviour based on the spatial location of the caregiver's gaze.

Figure 2. Layout of the object locations in the model.
Next, the model's reward structure was modified. Specifically, the caregiver profile reward ( $\mathrm{R}_{\text {profile }}$ ) and object reward ( $\mathrm{R}_{\text {object }}$ ) were changed in an opposing manner using Gaussian functions (Figure 3).

Various studies have shown that infants prefer direct gaze over averted gaze (e.g., Farroni et al., 2002), which in the model equates to $\mathrm{R}_{\text {frontal }}>\mathrm{R}_{\text {profile. }}$. In terms of a CoD, small eye gaze deviations are likely to be interpreted as being direct and so $\mathrm{R}_{\text {profile }}$ should have a higher reward value for small eye gaze deviations compared to large eye gaze deviations. A Gaussian function was therefore applied to $\mathrm{R}_{\text {profile }}$ so that it increased in value as the caregiver looked at locations which required smaller eye gaze deviations.

The opposite transformation was applied to $\mathrm{R}_{\text {object }}$ so that it decreased in value as the caregiver looked at locations which required smaller eye gaze deviations. This aimed to represent the fact that objects outside of the infant's current
visual field are more likely to be unexpected ( so informative) and therefore more rewarding than objects that currently reside in the visual field. These two modifications to the reward structure had the net effect of increasing the caregiver's relative reward at smaller eye gaze deviations and increasing the object's relative reward at large eye gaze deviations.

Figure 3. The modified reward structure for the object and the profile view of the caregiver.

To evaluate the effect of these modifications 500 simulations were run for 100,000 learning iterations to establish gaze following. After learning, each simulation was run for 10,000 iterations without any learning to gather stable gaze following measurements, which were then averaged across simulations. The model parameters were as follows: Number of locations ( N ) $=10$; Degree step per location (D) $=4$; Reward for looking at empty location $\left(\mathrm{R}_{\text {nothing }}\right)=1$; Reward for looking at the frontal view of the caregiver $\left(\mathrm{R}_{\text {profile }}\right)=1$; Peak Reward for looking at the object $\left(\mathrm{R}_{\text {object }}\right)=1$; Sigma of the Gaussian applied to the object reward $\left(\mathrm{S}_{\text {object }}\right)=9$; Sigma of the Gaussian applied to the caregiver $\left(\mathrm{S}_{\text {profile }}\right)=9$; Habituation rate $(\beta)=0.5$; Learning Rate $(\alpha)=0.0025$; Discount Factor $(\gamma)=0.8$; Exploration vs. exploitation $(\tau)=0.095$; Minimum fixation time $\left(T_{\min }\right)=4$; Probability of shifting $\left(\mathrm{p}_{\text {shift }}\right)=0.5$; Predictiveness of caregiver gaze $\left(p_{\text {valid }}\right)=0.75$. Unless otherwise stated, these values were used in all simulations

## Results

Two measurements were used to assess the effect of the modified reward structure. The first measurement was the mean time spent by the infant fixating on the caregiver. This represented how long the infant looked at the caregiver before shifting gaze and served as an indirect measure of the probability of shifting gaze. The second measurement was the total number of gaze follows made by the infant. This was a direct measure of eye gaze following behaviour. Both of these measurements were examined as a function of object location.

After implementing the reward structure in Figure 3, the mean time spent fixating on the caregiver was larger when the caregiver was looking at locations that required small eye gaze deviations (Figure 4, left panel). This contrasted with the model's performance when endowed with a flat reward profile. In addition, the total number of gaze follows
was smaller when the caregiver was looking at locations that required small eye gaze deviations (Figure 4, right panel). These findings are consistent with the concept of a CoD . By fixating on the caregiver for longer during small eye gaze deviations the infant acts as if the caregiver is looking directly at them and is unable to follow their gaze to another location. Similarly, the increased number of eye gaze follows for large eye gaze deviations indicates that the infant is correctly classifying them as indirect and can therefore follow them to the object. These findings suggest that a CoD can emerge under a reinforcement learning framework where the caregiver and object rewards act in an opposing manner.

Figure 4. (Left panel) Mean time spent by the infant fixating on the caregiver as a function of the caregiver's gaze. The dotted magenta line represents the results when the object reward and caregiver profile reward are not modified, as in the original Triesch et al. (2006) model. (Right pane) Total Number of gaze follows made by the infant as a function of the caregiver's gaze. The dotted magenta line represents the results when the object reward and caregiver profile reward are not modified.

## Simulation 2 - Developmental Trajectory of the Cone of Direct Gaze

After confirming that reinforcement learning could lead to the emergence of a CoD, we investigated the effect of reinforcement learning on the CoD over time to see if it could also explain known developmental changes.

## Methods

In order to get a measure of the width of the induced CoD , the mean fixation duration and the number of gaze follows were overlaid and their intersects calculated. To achieve this, it was first necessary to rescale the feature so that both measurements were operating on the same scale (Equation 2). Each value had the minimum value subtracted and this was then divided by the range of the values. This produced a final value that ranged between 0 and 1 . Gaussian curves were then fit to both feature scaled measures, with the mean fixation time requiring a single term and the number of gaze follows requiring two terms. Finally, the two intersection points of the fitted Gaussian curves were calculated and the width between the two points
was taken as a proxy for the width of the CoD in the model (Figure 5).

Equation 2

$$
x^{\prime}=\frac{x-\min (x)}{\max (x)-\min (x)}
$$

To observe the change in this width over time, 500 simulations were run for $1,000,000$ learning iterations. At 100,000 learning iteration intervals, learning was halted and 10,000 iterations were run to gather stable gaze following measurements. These results were averaged across all simulations for each break in the learning process.

Figure 5. Quantification of the width of the CoD effect. After feature scaling each measure, Gaussians were fit to both of them. The intersect points of these Gaussians were then calculated and the horizontal distance between the intersection points was taken as a proxy for the width of the CoD effect.

## Results

The CoD width was found to decrease as the number of learning iterations increased (Figure 6). This is consistent with the finding that the CoD decreases during child development (Mareschal et al., 2016) and suggests that reinforcement learning may be one explanation for these changes.

Figure 6. Change in the width of the CoD effect as a function of the number of learning iterations.

## Simulation 3 -High Anxiety Populations

In this simulation, we explore different parameter values in an attempt to capture known differences in the CoD for individuals with social anxiety.

## Methods

The peak reward value for both the frontal and caregiver rewards ( $\mathrm{R}_{\text {frontal }}, \mathrm{R}_{\text {profile }}$ ) were systematically decreased. For each set of $R_{\text {frontal }}$ and $R_{\text {profile }}$ values 500 simulations were run for $1,000,000$ learning iterations. At 200,000 learning iteration intervals, learning was halted and 10,000 iterations were run to gather stable measurements. These results were averaged across all simulations for each break in the learning process. The same method was used for decreasing values of $\beta$ (habituation rate) but results were taken at 100,00 learning iteration intervals. The $\beta$ values allowed for a finer temporal resolution than adjusting the $\mathrm{R}_{\text {frontal }}$ and $\mathrm{R}_{\text {profile }}$ values because when $\mathrm{R}_{\text {frontal }}$ and $\mathrm{R}_{\text {profile }}$ were set to a value of 0.5 the CoD effect broke down at 100,000 iterations.

## Results

Socially anxious individuals have a wider CoD than control individuals (Jun et al., 2013; Gamer et al., 2011). One possible explanation for this is that they are avoiding eye contact (Schneier et al., 2011; Schulze et al., 2013) and therefore may have a reduced 'caregiver' reward compared to non-socially anxious individuals. To test this hypothesis, we reduced the rewards associated with the caregiver ( $\mathrm{R}_{\text {frontal }}, \mathrm{R}_{\text {profile }}$ ) and looked at the effect on the width of the CoD . Simulations were run for longer than previous simulations because the wider CoD for highly anxious individuals should be present during adulthood (Jun et al., 2013; Gamer et al., 2011). Reducing $\mathrm{R}_{\text {frontal }}$ and $\mathrm{R}_{\text {profile }}$ did not result in a wider CoD (Figure 7). On the contrary, the simulations suggest that after 600000 iterations, there is a trend towards a narrower CoD when $\mathrm{R}_{\text {frontal }}$ and $\mathrm{R}_{\text {profile }}$ were reduced.

Figure 7. Change in the width of the CoD effect for different values of $R_{\text {profile }}$ and $R_{\text {frontal }}$ as a function of the number of learning iterations.

Another common theory relating to social anxiety is the hyper-vigilance-avoidance hypothesis (Horley et al., 2004) (Wieser et al., 2009). This hypothesis states that socially anxious individuals are hyper-vigilant towards anxiety provoking stimuli and tend to engage in avoidance by looking away. To investigate whether such a hypothesis could account for the wider CoD in socially anxious individuals we increased the value of the habituation parameter $\beta$. The goal of this modification was to reduce the
infant's gaze fixation time on the caregiver, as would be expected from avoidance. Increasing the value of $\beta$ resulted in a progressively narrower CoD effect (Figure 8). This effect was evident after around 200,000 learning iterations.

Figure 8. Change in the width of the CoD effect for different values of $\beta$ as a function of the number of learning iterations. Larger values of $\beta$ resulted in a narrower CoD effect.

## Discussion

We have demonstrated that a reinforcement learning account of eye gaze following behavior can be extended to account for the emergence and development of a CoD. In addition, the model also captured the developmental narrowing of the CoD (Mareschal et al., 2016). While a preference for direct gaze may be present from birth for example (Farroni et al., 2002), the fact that the CoD appears to narrow under the influence of reinforcement learning, as seen in developing children, suggests that at least some aspects of the CoD are experience dependent.

The fact that the CoD appears to be influenced by experience and learning poses interesting questions for researchers investigating clinical populations of socially anxious individuals. Importantly it suggests that a critical developmental period may exist that could act as a therapeutic window to reduce the occurrence of behaviors such as social anxiety. We used the model to investigate which aspects of the reinforcement learning framework could influence the developmental trajectory of the CoD. One theory for why socially anxious people may have a wider cone than control individuals is because of their aversion to direct eye contact (Schneier et al., 2011; Schulze et al., 2013). To probe this further, we reduced the rewards associated with the caregiver ( $\mathrm{R}_{\text {frontal }}$ and $\mathrm{R}_{\text {profile }}$ ) and looked at the effect on the width of the CoD. Reducing $R_{\text {frontal }}$ and $\mathrm{R}_{\text {profile }}$ resulted in a trend towards a narrower CoD , the opposite of what is seen in highly anxious individuals.

As an alternative to reducing $\mathrm{R}_{\text {frontal }}$ and $\mathrm{R}_{\text {profile }}$, we also investigated the effect of increasing the value of the habituation parameter $\beta$. This was done in an attempt to capture the hyper-vigilance-avoidance hypothesis, which states that socially anxious individuals are quicker to engage and then avoid anxiety provoking stimuli. An increase in the value of $\beta$ however, did not lead to a wider CoD. That said, care must be taken when making conclusions from this result. We used mean the infant's fixation time on the
caregiver as a functional measure of COD. This measure was used because under a CoD an infant should fixate for longer at small eye gaze deviations because it judges the gaze to be direct. However, this poses a problem when we want to model hyper-vigilance and avoidance by increasing $\beta$. An individual exhibiting hyper-vigilance and avoidance will have a reduced mean fixation time on the 'caregiver' even if they perceive the gaze to be directed at them because they would rather shift their gaze to nothing than hold direct gaze. So while increasing the value of $\beta$ may capture this behaviour, the measure of mean fixation duration will be lower for these cases causing the width of the CoD effect to be smaller even if the CoD is actually wider. Therefore, in order to accurately assess the effect of hyper-vigilance and avoidance on the width of the CoD effect, a different measure that captures when the infant perceives the gaze as being direct is needed.

Our findings (and Triesch et al's) have potential implications for several disorders other than social anxiety. The fact that both eye gaze following and the CoD appear linked by reinforcement learning could provide novel opportunities to investigate disorders that produce both characteristic eye gaze following and CoD behavior. One example of this is autism spectrum disorder. Triesch et al. (2006) put forth multiple candidates under the reinforcement learning framework that could produce the reduced eye gaze following described in individuals with autism. These candidates included a reduced learning rate, reduced caregiver reward and increased shifting latency. The fact that reinforcement learning can account for both eye gaze following and the CoD allows us to explore these candidates further. For example, studies have suggested that individuals with autism have a narrower CoD (Matsuyoshi et al., 2014) and so these candidates should be able to account for that. Indeed, in this study we demonstrated that reducing the caregiver rewards resulted in a slightly narrower cone in the later stages of a simulation. This finding lends weight to reduced caregiver rewards being present in autism. A similar approach should be taken for the other candidates to see if they too can account for both the eye gaze following and CoD differences described in autism, thereby either confirming or rejecting their validity.

#### Abstract

Preferential activation to faces in the brain's fusiform gyrus has led to the proposed existence of a face module termed the Fusiform Face Area (FFA) (Kanwisher et. al, 1997). However, arguments for distributed, topographical object-form representations in FFA and across visual cortex have been proposed to explain data showing that FFA activation patterns contain decodable information about non-face categories (Haxby et. al, 2001; Hanson \& Schmidt, 2011). Using two deep convolutional neural network models able to perform humanlevel object and facial recognition, respectively, we demonstrate that both localized category representations (LCRs) and high-level face-specific representations allow for similar decoding accuracy between non-preferred visual categories as between a preferred and non-preferred category. Our results suggest that neuroimaging of a cortical "module" optimized for face processing should yield significant decodable information for non-face categories so long as representations within the module are activated by non-face stimuli.

Keywords: module, localized categorical representation, distributed object-form topography, deep convolutional neural network, virtual electrophysiology

## Introduction

How are mental representations organized in the brain? Do certain brain regions contain functional modules, dedicated to representing and processing a very specific type of information? Or is neural real estate more generally involved in the processing of many different types of stimuli? Evidence from fMRI has been used to propose the existence of functional modules for the processing of certain classes of visual information within the brain. Cortical modularity was proposed first for the visual processing of faces in the socalled Fusiform Face Area (FFA) (Kanwisher et. al, 1997), then for the visual processing of scenes/places in the so-called Parahippocampal Place Area (PPA) (Epstein \& Kanwisher, 1998), and then for the visual processing of body parts in the so-called Extrastriate Body Area (EBA) (Downing et. al, 2001). In each of these studies, preferential activation of a certain class of visual stimuli (e.g. faces) in a certain region of the brain (e.g. fusiform gyrus) was used as evidence for
modular processing within that region, leading to the authors renaming the region in terms of the modular processing (e.g. Fusiform Face Area). Not all authors agreed that preferential activation of a cortical region by a certain stimulus class was convincing evidence of underlying modular processing. Haxby et. al (2001) used multi-variate pattern analysis (MVPA) to demonstrate that putative functional modules for processing of scenes in the PPA and faces in the FFA contain patterns of activation useful for decoding whether a subject is viewing one of two categories not thought to be processed within the module. These authors interpreted their findings in the context of an "object-form topography" model, in which the ventral temporal cortex possesses a distributed, topographical representation of object-form features which underlie all forms of visual recognition. In their account, the large responses found in proposed functional modules are complemented by small responses throughout ventral temporal cortex in computations underlying visual categorization and other aspects of visual cognition.

Later, Spiridon \& Kanwisher (2002) ran a similar fMRI study incorporating greater variability across images within a category (e.g. different viewpoints, exemplars, and image formats) in order to determine whether decodable abstract category information was truly distributed equally throughout ventral temporal cortex, as was argued by Haxby et. al (2001), or whether there might be localized decoding advantages corresponding to the locations of proposed functional modules. This study demonstrated that some abstract categorical information was present for certain categories outside their region of maximal activation (i.e. the location of a proposed module), replicating a main finding of Haxby et. al (2001). However, controlling for the number of voxels used in decoding analysis, this study demonstrated strong advantages in decodable information relating to discrimination between a preferred category (e.g. faces) and a non-preferred category (e.g. houses) in the region of proposed modularity (e.g. FFA). Additionally, in PPA and FFA, distinct disadvantages were found for the decoding of two non-preferred categories (e.g. faces vs. objects and objects vs. houses, respectively). Thus, while abstract
categorical information of certain categories may exist outside the region where modular processing is proposed, such abstract categorical information is by no means equally distributed throughout ventral temporal cortex. The authors thus argued for a more modular account of PPA and FFA, whereby these regions are primarily involved in the processing of a single category of information (scenes/houses and faces, respectively).

To account for both sets of findings, Cowell \& Cottrell (2013) performed multi-variate pattern analysis (MVPA) on a neurocomputational model capable of discriminating between the 6 visual categories used in the analyses of Haxby et. al (2001). The neurocomputational model first applies Gabor filtering of input images to obtain a perceptual representation; it then feeds the activations of many Gabor filters into a self-organizing Kohonen map, which utilizes unsupervised learning to cluster its inputs into a twodimensional representation. While the neurocomputational model contained no modular mechanisms, through unsupervised learning it developed the types of functionally localized stimulus representations used to argue in favor of modular processing, whereby certain patches of the Kohonen grid contained both preferential activation and enhanced decodable information about some categories. The effects were greatest for faces. Because they were able to simulate the data used to argue both for localized and distributed topographical representation with a neurocomputational model of distributed topographical representations that is more parsimonious than one postulating the existence of functional modules, the authors rejected the interpretation of a functional module for face processing based on the data of Spiridon \& Kanwisher (2002).

The result of Cowell \& Cottrell (2013) demonstrates that the evidence used to postulate functional modules may be accounted for by a model employing a distributed representation. However, the model is unable to account for human-level behavioral performance, and rather was constrained only to perform 6-way visual categorization. In the age of biologically-inspired computational systems capable of human-level object categorization (e.g. Krizhevsky et. al, 2012) and face individuation (e.g. Parki, Vedaldi, and Zimmerman, 2015), such behavioral constraints should become standard practice for models of neural representation. The decision not to constrain the computational model to perform human level face individuation, for example, belies the need for a functional module for face processing. Thus, we examine two deep, convolutional neural networks (DCNNs), one trained for large-scale object categorization and one trained for expert face individuation. In these networks, we focus on two types of category-specific representations for analysis. The first type of representation is the localized categorical representation (LCR), found in the final hidden layer of AlexNet (Krizhevsky et. al, 2012), whereby a single unit represents the likelihood of a given category in an image shown to the network. Such a localized categorical representation differs from the topographical object-form
representations proposed by Haxby et. al (2001), in that a single value represents the abstract category information. However, localized category representations receive input from a processing layer which is well-described as a topographical object-form representation; thus, they are not true "modules". The second type of representation is taken as a deep layer of face-specific representations within the faceindividuation network of Parki, Vedaldi, and Zimmerman (2015), VGG-Face, which is optimized for facial recognition only. In our view, VGG-Face in toto is a face-dedicated module; that is, a system optimized on and dedicated to to the processing of faces, only. The deep layer was chosen as a layer with high-level, complex face-specific features useful for recognition, but not explicitly representing individuals. We think that such representations are a reasonable model for what is proposed to be encoded in FFA (see Kanwisher \& Yovel, 2006). We perform "virtual electrophysiology," (Yamins \& DiCarlo, 2016) on both systems in order to determine whether these two types of category-specific representations produce the characteristic signal used to argue for distributed category-general representations: decodable information for non-preferred categories.

## Method

Model simulations were run in the MATLAB programming environment, using the MatConvNet toolbox (Vedaldi \& Lenc, 2015). Both models used in this study are examples of deep convolutional neural networks (DCNNs). Such networks were developed by computer vision researchers as engineering solutions for problems of visual recognition (e.g. LeCun et. al, 1998; Krizhevsky et. al, 2012). DCNNs contain several layers of processing, each of which contains a set of mathematical filtering operations (units or filters) which are convolved across the input, usually followed by a set of fully-connected layers which contain units which apply simple weighted summations of the units at the layer before. In all DCNNs for visual categorization, there exists a final layer of processing containing a set of units whose size is equal to the number of categories to be tested from, where each unit's activation corresponds to the likelihood that a certain category is present in the image; this vector of information is typically transformed via a softmax operation into explicit probabilities that the image may be categorized into each possible category.

The first DCNN model used is AlexNet (Krizhevsky et. al, 2012), pre-trained and uploaded to MatConvNet by Vedaldi \& Lenc (2015). AlexNet was trained to perform 1000-way categorization of visual images on the 2011 ImageNet training set, which contains 1.2 million images evenly distributed across 1000 categories. For simulations, a different set of images not used in training, the 2011 ImageNet validation set, was used as stimuli, containing 50 images for each of 1000 categories. First, we recorded the activation patterns of each unit within AlexNet to each image of the validation set. While the network is said to contain 5 convolutional layers and 3 fully-connected layers, additional intermediate operations (rectification, pooling,
normalization) result in 22 stages of processing with activation values, where the first stage is defined by the RGB coordinates of the image. Full details on AlexNet can be found in the original paper (Krizhevsky et. al, 2012).

In our initial analyses, we consider four representative layers within AlexNet (Conv1, Conv5, FC6, and FC8) to demonstrate how informational content changes with depth in the network (Figure 1). The activation patterns of Conv1 are those which are input directly to Conv2, thus occurring after rectification, max-pooling, and response normalization. The activation patterns of Conv5 are taken after the fifth convolution and rectification, and are the inputs to FC6. The patterns of fully-connected layers FC6 and FC8 are taken after rectification. For each unit of each layer considered, we compute a set of "categorical signal-to-noise ratios" (cSNRs), for each category of ImageNet. For a given unit and category, the cSNR is computed as the signal-to-noise ratio of the unit's activation across all exemplars of the category. To create populations of units sorted by their cSNR for a given discrimination task on a subset of categories, we first create a vector containing the maximum unit cSNRs across all categories in the subset. This vector is then sorted in three ways, keeping the indices of units available: increasing cSNR, decreasing cSNR, and random. For each layer and discrimination task, three populations of size $n$ are created by selecting the first $n$ units from each of these vectors, for several values of $n$, and bootstrapping is performed across random samples of categories. The activation patterns of each population serve as the set of predictors for the classification of the ImageNet validation set images for each category in the discrimination task. Multi-class classification is achieved with a classification-tree based system, using the fitctree function in the MATLAB Statistics and Machine-Learning toolbox. The classifier is cross-validated using 10 -folds of $80 \%$ training, $20 \%$ testing samples (crossval function). Finally, the loss is computed across the several folds of the cross-validated model (kfoldLoss function). Across bootrsapped camples of category, accuracy is reported as $1-$ mean loss, and error bars are the standard error of accuracy.

Next, AlexNet FC8 is examined in more detail (Figure 2). In analyses similar to those conducted by Haxby et. al (2001), we compare the 2 -way classification of preferred and nonpreferred categories. For a given unit, the preferred category is the category which is explicitly represented; all other categories are potential non-preferred categories. Starting with 20 randomly-drawn ImageNet categories, we generate 100 pairs of preferred/non-preferred categories, and 100 pairs of non-preferred/non-preferred categories, with 5 pairs of each type for every category. For 2-way classification, we use a support-vector machine classifier (fitcsvm function, MATLAB Statistics and Machine-Learning toolbox). The same cross-validation and bootstrapping methods described in preceding analyses are used to generate an estimate of mean and standard error of classification accuracy for each pair type.

We perform similar analyses on VGG-Face, a DCNN trained for face-individuation on over 2000 faces (Parki,

Vedaldi, and Zimmerman, 2015). To achieve a representation to serve as a model of FFA representations, we examine the activations in layer 35 , the final layer before activations are condensed to individual face-specific representations. Layer 35 contains 4096 nodes representing high-level, complex information optimized for face individuation. In performing virtual electrophysiology on VGG-Face, we use as stimuli the fMRI localizer stimulus sets for faces, body-parts, objects, and scenes, in addition to the 2011 ImageNet validation set. These localizer sets are used by TarrLab and many other laboratories in the Center for the Neural Basis of Cognition, Pittsburgh PA, for fMRI research in order to localize functionally-defined regions such as the Fusiform Face Area (FFA), Extrastriate Body Area (EBA), Lateral Occipital area (LO), and Parahippocampal Place Area (PPA). Each localizer set contains 80 images of the category used to localize a corresponding functional brain area. 2-way classification tasks are created using pairs of the categories defining each localizer set. Additionally, a sample of 45 pairs taken from 10 randomly drawn ImageNet categories are used to bootstrap an estimate of the ability to predict all pairs of ImageNet categories. All units in VGG-Face layer 35 are used as predictors in a 2 -way SVM classification system akin to that used in Figure 2 and the results are shown in Figure 3.

## Results

The results of initial system-wide analyses of AlexNet representations are shown in Figure 1. In nearly all cases, decoding accuracy increases with the number of units used as predictors in the classifier, and decreases with the number of categories required for discrimination. In Conv1, Conv5, and FC6, for all discrimination tasks, sorting units by their categorical signal-to-noise ratio (cSNR; see methods) allows for improvements in decoding accuracy given the same number of units. However, in FC8, for all discrimination tasks, sorting units by cSNR has no effect on decoding accuracy, suggesting that localized categorical representations in FC8 possess information relevant to decoding between non-preferred categories.

The results of detailed analyses of AlexNet fully-connected layer 8 (FC8) are shown in Figure 2, where categories are organized by whether they are preferred (explicitly represented) or non-preferred (not represented) by a given unit in FC8. The decoding accuracy between the preferred category and a randomly chosen non-preferred category (see Methods) is not significantly greater than the decoding accuracy between randomly-generated pairs of non-preferred categories ( $\mathrm{p}=0.57$ ); both values are significantly greater than chance ( $\mathrm{p}<0.001$ ).

The results of all analyses of VGG-Face are shown in Figure 3. All discriminations involving face as one of two categories yield perfect discrimination accuracy. 2 out of 4 discriminations involving pairs of non-face categories (scene vs. body part; scene vs. object) yield perfect discrimination accuracy. The remaining 2 discrimination tasks (body part vs. object; pairs of ImageNet categories) yield non-perfect but greater than chance discrimination accuracy ( $\mathrm{p}<0.001$ ).

## Figures

Figure 1: Population decoding from specified layers of the DCNN. Populations are selected in three ordering schemes, choosing the units with the highest cSNR (blue), the lowest cSNR (red), or at random (yellow). A large separation between curves indicates a local code, whereas a small separation indicates a distributed code.

Figure 2: Single-unit decoding of FC8 in AlexNet. Each unit has a "preferred" category - the category it represents. All other categories are non-preferred categories. Bootstrapping was performed as described in Methods. Mean accuracies and standard errors across bootstrapping are shown. Accuracy for preferred/non-preferred is not significantly greater than accuracy for non-preferred only $(p=0.57)$. Both values are significantly greater than chance ( $\mathrm{p}<0.001$ ).

Figure 3: Support-vector machine (SVM) classification of layer 35 activations of VGG-Face network, shown for different pairs of categories. Each SVM is cross-validated with 10 folds of $80 \%$ training $/ 20 \%$ test data, and the accuracy is reported as 1 - mean loss across folds. Error bars are shown as 1 - standard error of loss across folds. For ImageNet, standard error is computed across 45 bootstrapped pairs of 10 randomly chosen categories. All accuracies are significantly greater than chance ( $\mathrm{p}<0.001$ ).

## Discussion

First, using AlexNet, an arbitrary deep convolutional neural network (DCNN) for visual object categorization, we demonstrated that units explicitly representing a single visual category, what we deem localized categorical representations (LCRs), provide information allowing for the decoding of non-preferred categories, at a level equal to that for decoding between the represented category and a non-preferred category. Demonstrating that these localized categorical representations contain distributed information related to non-preferred categories suggests that the presence of domain-general decodable information in a putative domain-specific cortical region is not grounds to reject domain-specificity, as was done by Haxby et. al (2001), and Hanson \& Schmidt (2011), in favor of distributed objectform topographical representations. While LCRs differ from distributed object-form topographical representations in that they represent abstract category information in a single value, the LCRs in AlexNet receive their input from a distributed object-form representation of the sort proposed by Haxby et. al (2001), and are by no means well-described as the sort of functional modules rejected by this study and proposed by the likes of Kanwisher et. al, (1997) for visual face processing, Epstein \& Kanwisher (1998) for visual place/scene processing, or Downing et. al (2001), for visual body-part processing, whereby functional modules likely contain several processing stages for fine-grained analysis of exemplars of the preferred category. To ask whether such functional modules might also give rise to decodable information about stimuli outside the domain of modularity, we relied on a second DCNN specialized for face individuation, VGG-Face.

To acquire a representation of maximal similarity to the high-level face-optimized representations thought to be housed in the Fusiform Face Area, we took the layer 35 activations of VGG-Face, a set of 4096 nodes which project to the individual face probability nodes one layer later. We model these layer 35 nodes as a face module akin to the domain-specific interpretation of the Fusiform Face Area (e.g. Kanwisher et. al, 1997; Kanwisher et. al, 2006). We demonstrated that this "face module" contains patterns of activation capable of perfect discrimination between pairs of categories containing a face, and two of four pairs of categories not containing a face; the other two pairs yielded high discrimination significantly above chance. Thus, we find that domain-specific, face-optimized representations yield domain-general decodable information. This result provides support for the idea that activations within a cortical "module" might contain information relevant to decoding between categories for which that module is not specialized to process. This result strengthens our earlier result, demonstrating that it is improper to reject the possibility of a functional module associated with a given brain region on the grounds that the region's activation patterns allow for decoding between stimuli unrelated to the module's proposed primary function.

An important conceptual point is that the interpretation of our results - that modules should not be rejected on the grounds of producing domain-external information - rests on the assumption that a cortical module would be activated by domain-external information. In the case of localized categorical representations for object categories, it seems likely that all categories would be processed and that some activation might reach LCRs not representing the category of viewing. However, in the case of a cortical module for face processing, this point is less clear. Evidence of subcortical face detection mechanisms (for review, see Johnson, 2005) suggest that the brain may be capable of filtering out non-face information from higher processing (i.e., in FFA), via a fast detection process. Though, as we sometimes perceive faces on trees and in other places in which there are not faces, it is likely that non-face information does, on occasion, pass through the face-detector for further processing. It is possible that all information that arises for domain-external stimuli in FFA, for example, comes from images or image parts which contain something that looks enough like a face to pass through an early detection process, into higher regions of the face processing network. Once the visual information is allowed to pass, our results demonstrate that its processing within a face-optimized processor should give rise to decodable information.

Some authors have argued that the Fusiform Face Area (FFA) is better described as a mechanism for expert-level, fine-grained visual discriminations rather than a faceprocessing module, suggesting that neural substrate within FFA is specialized for visual categorization requiring repeated subordinate-level identification, a task which happens to occur most frequently in the context of face processing, thus resulting in the large preference for faces (e.g. Gauthier et. al, 1999; Tarr \& Gauthier, 2000). Indeed, our results add an interesting point to this theoretical framework. Regardless of whether FFA is specialized for faces or expertise, if it develops representations useful for discriminating between individual faces, these representations are also likely to be useful for discriminating other visual objects. Thus, learning a new category of expertise (e.g. birds) might recruit a previously face-specific cortical region, on the basis of that region containing the most useful representations for the expert task, especially if exemplars of these categories have sufficient visual similarity to faces to pass through an early face-detection gate (if one exists). In this sense, FFA would not be a face module, but rather a brain area optimized most strongly for facerecognition, but also recruited for expert subordinate-level visual recognition.

Whether cortical modules exist in the sense motivated most strongly by Kanwisher (2010) remains an open debate. However, should such cortical modules exist, if their representations are activated by non-preferred categories, these "modules" are likely to produce activation patterns which allow for decoding between non-preferred categories, the characteristic result of studies which sometimes claim evidence of distributed, non-modular processing. As such, it
behooves the field to develop more sensitive and diagnostic measures to assess these critical questions regarding the fundamental nature of representation in the brain.

## Acknowledgments

NB is grateful to his family, and especially to his parents Lisa and James, for their endless support; to the summer Undergraduate Program in Neural Computation at CNBC, Pittsburgh, where the majority of this research was performed; to Ying Yang for mentorship on machine learning techniques, and for helpful discussions of early pieces of this work throughout the summer; and finally to Rosie Cowell for introducing him to the modular debate, which spawned the theoretical interpretation of earlier results, as well as for helpful comments on an early version of this manuscript.

# Inferential Role Semantics for Natural Language 

Peter Blouw (pblouw@uwaterloo.ca) Chris Eliasmith (celiasmith@uwaterloo.ca)<br>Centre for Theoretical Neuroscience, University of Waterloo<br>Waterloo, ON, Canada N2L 3G1

#### Abstract

Cognitive models have long been used to study linguistic phenomena spanning the domains of phonology, syntax, and semantics. Of these domains, semantics is somewhat unique in that there is little clarity concerning what a model needs to be able to do in order to provide an account of how the meanings of complex linguistic expressions, such as sentences, are understood. To help address this problem, we introduce a treestructured neural model that is trained to generate further sentences that follow from an input sentence. These further sentences chart out the "inferential role" of the input sentence, which we argue constitutes an important part of its meaning. The model is trained using the Stanford Natural Language Inference (SNLI) dataset, and to evaluate its performance, we report entailment prediction accuracies on a set of test sentences not present in the training data. We also report the results of a simple study that compares human plausibility ratings for both ground-truth and model-generated entailments for a random selection of sentences in this test set. Finally, we examine a number of qualitative features of the model's ability to generalize. Taken together, these analyses indicate that our model is able to accurately account for important inferential relationships amongst linguistic expressions.

Keywords: natural language inference; recursive neural networks; language comprehension; semantics

## Introduction

By most accounts, linguistic comprehension is the result of cognitive processes that map between sounds and mental representations of meaning (Christiansen \& Chater, 2016; Pickering \& Garrod, 2013; Smolensky \& Legendre, 2006). An obvious challenge for these accounts is to provide a good theoretical characterization of the relevant representations. Numerous proposals can be found in the literature, but there is no obvious consensus regarding their relative merits.

Arguably, the reason for this lack of consensus is that linguistic comprehension is itself a somewhat vague and illdefined phenomenon. In the context of efforts to model linguistic comprehension, for instance, it is not entirely obvious what a model needs to be able to do in order to provide an account of how people understand complex linguistic expressions such as phrases and sentences.

In this paper, we argue that one thing models of linguistic comprehension need to be able to do is generate predictions about what follows from a given sentence during a conversation. For example, to understand the statement "The dancers parade down the street", one must be able recognize that the dancers are outside, that they are not standing still, that there is likely a surrounding audience, along with various other things. Comprehending a sentence therefore involves drawing inferences that identify the expected consequences of the occurrence of the sentence in the linguistic environment. And since comprehending a sentence involves

Figure 1: Sentence encoding with a dependency tree recursive neural network (DT-RNN). A dependency parser is used to produce the computational graph for a neural network, which is then used to produce a distributed representation of sentence by merging distributed representations of individual words. Figure adapted from Socher et al. (2014).
comprehending its meaning, it follows that meaning of an expression is at least partly determined by the inferences it licenses (Brandom, 1994)

To motivate this inferential approach to semantics, we introduce a neural network model that learns to generate sentences that are the inferential consequences of its inputs. The model functions by first encoding a sentence into a distributed representation, and then decoding this representation to produce a new sentence. The encoding procedure involves dynamically generating a tree-structured network layout of the sort depicted in Figure 1. Once a sentence encoding is produced using this network, it is fed through an "inverse" treestructured network to produce a predicted sentence. Interestingly, different inverse or decoding networks can be used to generate different sentences from a single encoding. To train the model parameters (i.e. the network weights shared across different tree structures) we use the Stanford Natural Language Inference dataset (Bowman et al., 2015).

In what follows, we first describe the model and then empirically evaluate its ability to produce plausible entailments for sentences unseen in the training data. We present experimentally produced plausibility ratings for a random collection of generated sentences, and from these ratings conclude that the model captures something important about the inferential roles of ordinary linguistic expressions. We further contend that the model motivates the view that understanding a linguistic expression is not (as is typically thought) a matter of mapping it onto a representation that somehow constitutes its meaning. Rather, understanding a linguistic expression is a
matter of inferring the expected consequences of its occurrence in the linguistic environment. The reason for drawing this conclusion is that the expected consequences of a sentence cannot be "read off" of any single representation in the model. Instead, these consequences are derived from the global behavior of the model and the processes that it implements.

## Tree-Structured Neural Networks

To build our model, we take advantage of recently developed techniques for using neural networks to define composition functions that merge distributed representations of words into distributed representations of phrases and sentences (Socher et al., 2012, 2014). The core idea behind these techniques is to produce a parse tree for a sentence, and then transform the tree into a neural network by replacing its edges with weights and its nodes with layers of artificial neurons. Activation is then propagated up the tree by providing input to layers that correspond to certain nodes, as shown in Figure 1. The input at each node is typically a distributed representation or "embedding" corresponding to a single word (see Mikolov et al., 2013).

This general method can be applied using arbitrary tree structures, and we adopt a dependency-based syntax in the experiments described below. There are three reasons for this choice (Socher et al., 2014). First, the assignment of different network weights to different dependency relations allows for the creation of networks that are more sensitive to syntactic information. Second, the semantic role of an individual word can often be read off of the dependency relation it bears to a head word, which allows for the creation of networks that are also sensitive to semantic information. Finally, dependency trees are less sensitive to arbitrary differences in word order, which helps to ensure that simple variations of a sentence get mapped to similar distributed representations. The model we adapt - the dependency tree recursive neural network (DTRNN) - is introduced in Socher et al. (2014)

Some formal details concerning the behavior of DT-RNNs are helpful at this point. First, an input sentence $s$ is converted into a list of pairs, such that $s=\left[\left(w_{1}, x_{1}\right),\left(w_{2}, x_{2}\right), \ldots\left(w_{n}, x_{n}\right)\right]$, where $w$ is a word and $x$ is the corresponding word embedding. Next, a dependency parser is used to produce a tree that orders the words in the sentence in terms of parent-child relations. Each node in this tree is then assigned an embedding in a two-step manner. First, all of the leaf nodes in the tree (i.e. nodes that do not depend on other nodes) are assigned embeddings by applying a simple transformation to their underlying word embeddings:

$$
\begin{equation*}
h_{i}=f\left(W_{v} x_{i}+b\right) \tag{1}
\end{equation*}
$$

where $h_{i}$ is the embedding for some leaf node $i$ in the tree, $x_{i}$ is the embedding for the word corresponding to this node, $W_{v}$ is a matrix that transforms word representations, $b$ is a bias term, and $f$ is an element-wise nonlinearity. Second, embed-
dings are recursively assigned to all of the non-leaf nodes by composing the embeddings of their children as follows:

$$
\begin{equation*}
h_{i}=f\left(W_{v} x_{i}+\sum_{j \in C(i)} W_{R(i, j)} \cdot h_{j}+b\right) \tag{2}
\end{equation*}
$$

where $h_{i}$ is again the embedding for some node $i$ in the tree, $x_{i}$ is the embedding for the word corresponding to this node, $j$ is an index that ranges over the children, $C(i)$, of the node $i$, and $W_{R(i, j)}$ is a matrix associated with the specific dependency relation between node $i$ and its $j^{t h}$ child. $h_{j}$ is the embedding corresponding to this child. So, in the example tree in Figure 1, the embeddings for nodes 1,4 , and 6 would be computed first, since these nodes have no children. Then, embeddings will be computed for any nodes whose children now all have assigned embeddings (in this case, nodes 2 and 7). And so on, until an embedding is computed for every node.

Model training is done via backpropogation and requires that a cost function be defined for the sentence embeddings produced at the root of each tree. The free parameters are the weights $W_{v}$ and $W_{r \in R}$, along with the bias term $b$. Word embeddings can also be fine-tuned over the course of training.

## Generating Entailments

Choosing an appropriate cost function for a recursive neural network can be difficult, since it is not always clear what makes for a "good" sentence embedding. It is accordingly common to see these networks applied to narrow classification tasks such as the prediction of sentiment ratings (e.g. Socher et al., 2012). Our goal is define an optimization objective that accounts for the principle that understanding a linguistic expression involves drawing inferences about what follows from it.

To accomplish this goal, we define a model composed of two DT-RNNs, one that encodes an input sentence into a distributed representation, and another that decodes this representation into a new sentence that is entailed by the input sentence. This model is inspired by Iyyer et al.'s (2014) work using DT-RNNs analogously to autoencoders, but introduces a decoding procedure that computes an appropriate response to the input sentence, rather than merely reconstructing it. Other related work is described in (Kolesnyk et al., 2016).

The model is trained on pairs of sentences standing in entailment relations. A dependency parser ${ }^{1}$ is again used to produce a tree-structured network for each sentence, but the network associated with the second sentence is run in reverse, as shown in Figure 2. A word prediction is generated at each node in this second tree using a softmax classifier, which allows us to define a cross-entropy loss function over nodes and trees as follows:

$$
\begin{equation*}
J(\theta)=-\sum_{i} \sum_{j} t_{j}^{(i)} \log p\left(c_{j}^{(i)} \mid s_{i}\right) \tag{3}
\end{equation*}
$$

[^29]

Figure 2: Generating entailments with paired encoder and decoder DT-RNNs. The decoder network computes a probability distribution over words at each node, conditioned on the sentence representation produced by the encoder. The parameters of both the encoder and decoder are trained via backpropogation through structure using error derivatives supplied at each node in the decoding tree. The encoder and decoder trees are dynamically generated for each pair of sentences in the training data.
where $t_{j}^{(i)}$ is the target probability (i.e. 1) for the correct word at the $j^{\text {th }}$ node in the $i^{\text {th }}$ training example, $p\left(c_{j}^{(i)} \mid s_{i}\right)$ is the computed probability for this word given the input sentence $s_{i}$, and $\theta$ is the set of combined parameters for the encoder and decoder DT-RNNs.

We train the model via stochastic gradient descent by backpropogating through both the decoder and encoder tree for each training example. The result of training is a set of weights associated with dependencies for both encoding and decoding, a set of weights for predicting a distribution over words from a node embedding for each dependency, a set of biases (we allow dependency-specific biases), and the input transformation matrix $W_{v}$. When the trained model is used to perform inference using a novel input sentence, the encoder DT-RNN is assembled into a tree using the learned encoding weights. The decoder DT-RNN is then also assembled into a tree using the learned decoding weights, and activation is propagated through the encoder and into the decoder to produce a probability distribution over words at each tree node. The words with the highest probability at each node are then used to construct the predicted entailment for the input sentence. The tree structure for the decoder can either be selected randomly or stipulated ahead of time.

## Experiments

In the remainder of the paper, we describe a number of basic experiments that illustrate how this general modeling framework can be used to illuminate the phenomenon of language comprehension. We first perform a basic evaluation of how well the decoder model is able to generate entailments by measuring the percentage of correct word predictions over all decoding tree nodes in both the training set and an unseen test set. We then present the results of an experiment designed to evaluate the quality of the entailments generated by our model. Next, following Kolesnyk et al. (2016), we iterate the encoding-decoding procedure to generate chains of
entailments from a given input sentence that delineate simple inferential roles. Finally, we analyze the effect of substituting individual words in an input sentence. The goal of this analysis is to evaluate the extent to which the model is able to learn indirect inferential roles for words and appropriately generalize to a wide range of novel sentences that can be substitutionally derived from a single familiar sentence.

## Training Data

To train encoder and decoder networks, we use a subset of the Stanford Natural Language Inference dataset introduced in Bowman et al. (2015). This dataset consists of approximately 570,000 sentence pairs with labeled inferential relationships. Specifically, the first sentence in each pair can either entail, contradict, or be neutral with respect to the second sentence, and since our interest is generating entailments, we restrict our attention to pairs labeled with the entailment relation.

To reduce the amount of noise and complexity in the dataset, we also perform some simple pre-processing steps. First, we screen for misspelled words, ${ }^{2}$ and eliminate all sentence pairs containing a misspelling. Second, we eliminate all sentence pairs containing a sentence longer than 15 words in order to avoid fitting model parameters to a small number of very long sentences that produce highly complex dependency trees. After preprocessing, the data consists of 106,288-pair training set, a 1701-pair development set, and 1666 pair test set. We train on the training set and use the development set for tuning hyperparameters such as the learning rate and the number of training epochs. The vocabulary used during training and testing consists of 22,555 words.

## Quantitative Evaluations

To evaluate the ability of the model to generate plausible entailments, we first measure the proportion of correct wordlevel predictions during decoding in both the training set and

[^30]Table 1: Examples of Entailments Generated From Novel Test Sentences.

Sentence A boy and girl child swing together on a swing set. Entailment Two kids swing on a swing.

A young blond boy is eating cake with a spoon.
A boy is eating a cake.
A surfer is performing a jump stunt in the ocean. A surfer and a surfboard is outside.

Table 2: Word-Level Accuracy for Entailment Generation

| Model | Training Set (\%) | Test Set (\%) |
| :---: | :---: | :---: |
| Chance | 6.0 | 5.9 |
| DT-RNN | 66.7 | 61.8 |

the test set. We provide the tree structure of each entailed sentence during decoding, so inference involves propagating activities through paired trees of the sort depicted in Figure 2 to generate a set of word predictions. Some example entailments produced from sentences drawn from the test set are listed in Table 1. The decoding tree used to produce each entailment is chosen randomly in these examples.

The word vectors that provide input to the encoder are initialized using 300-dimensional Word2Vec embeddings (Mikolov et al., 2013), while biases are initialized as the zero vector. Each set of weights associated with a syntactic dependency is initialized as a $300 \times 300$ identity matrix with mean-zero Gaussian noise for both the encoder and decoder. The word transformation matrix, $W_{v}$, is initialized in the same way. During learning, all of these matrices are updated using stochastic gradient descent, along with the Word2Vec embeddings and the biases. We perform approximately 5 epochs of training using an initial learning rate of $6 \times 10^{-4}$, and we progressively anneal this rate over the course of training.

To collect accuracy measures, we simply tally the proportion of nodes in the decoding trees for which the predicted word is the same as the actual word given in the relevant test set; the decoding tree is determined by a parse of the correct entailment in every case. We compare against a baseline accuracy of chance. As shown in Table 2, The DT-RNN model performs considerably better. It is worth noting that generated sentences containing words not present in the correct entailment may still be appropriate, given that no entailment is uniquely correct. It is also worth noting that prior work involving SNLI has almost uniformly focused on the problem of classifying sentence pairs. Given that our interest is in generation rather than classification, we cannot easily draw comparisons to earlier work, and therefore use novel methods of evaluation.

## Empirical Evaluations

Next, we conduct a simple study in which human subjects are asked to evaluate the plausibility of model-generated sentences. During the study, participants are shown a series of

Table 3: Plausibility Ratings for Inferential Relations.

| Source | Status | Mean Likert Rating (1-5) |
| :---: | :---: | :---: |
| Human | Entailment | $4.05 \pm 0.09$ |
| Model | Entailment | $3.53 \pm 0.12$ |
| Human | Contradiction | $2.05 \pm 0.12$ |

* Margins are bootstrapped $95 \%$ confidence intervals.
sentences introduced as true captions for unseen images. ${ }^{3}$ For each caption, the participants are shown an alternate caption and asked to evaluate the likelihood that it is also true of the corresponding image. Evaluations are recorded using a five point Likert scale that ranges from "Extremely Unlikely" (1) to "Extremely Likely" (5). The original caption in each case is the first sentence in a pair randomly chosen from the SNLI test set, while the alternate captions are either (a) model-generated entailments, (b) human generated entailments drawn from the test set, or (c) human generated contradictions also drawn from the test set. This betweensubjects experimental design is similar to the method used by Bowman et al. (2015) to validate human-generated sentence pairs during the creation of SNLI. The main difference is that we evaluate model-generated sentences in addition to humangenerated sentences.

Seventy-five participants from the United States were recruited through Amazon's Mechanical Turk and split evenly into the three conditions. The main captions were identical across conditions, and each participant was asked to rate 20 caption pairs. ${ }^{4}$ Participants were paid $\$ 1.00$ for their time. Two of the seventy-five participants failed to complete the study and did not have their responses included in the results. Repeat participation was blocked by screening Mechanical Turk worker IDs.

The Likert ratings collected during the study are assessments of the plausibility of the inferential transition from one sentence (the main caption) to another (the alternate caption).

[^31]

Figure 3: A model-generated inferential network around the sentence "A man is outside". Each inferential transition is the result of generating a predicted entailment after encoding the sentence at the beginning of each arrow. The entire network is generated starting with only the four outermost sentences, which are drawn from the SNLI test set.

The transitions involving sentence pairs drawn directly from SNLI offer a kind of gold standard for both good and bad transitions. The results shown in Table 2 indicate that modelgenerated transitions are seen to be almost as plausible as the gold-standard transitions drawn from SNLI. We take this to be preliminary evidence that model is able to capture certain tacit inferential relationships between natural language expressions.

## Qualitative Extensions

In order to further analyze the model's behavior, we examine a number of qualitative features of the inferential relationships it is able to learn. First, we examine iterative applications of the model to its own predictions, following similar work by Kolesnyk, Rocktäschel, and Reidel (2016) that makes use of a sequential LSTM. Next, we examine the model's ability to disciminate the inferential significance of lexical items by performing simple word-by-word substitutions in an input sentence. The point of these analyses is to demonstrate that models of the general class we are proposing are useful tools for both formalizing and learning the inferential roles of a wide variety of linguistic expressions.

## Iterative Inferences

Once an input sentence has been passed through the model to generate an entailment, it is possible to use this entailment as a new input to the model. Repeated applications of the model accordingly make it possible to chart out an "inferential network" around a particular starting sentence. Figure 3 offers a simple model-generated example of an inferential network in which numerous sentences describing men doing things outdoors are eventually mapped to the sentence "A man is outside".

In general, predicted entailments that are shorter than an input sentence tend to be more abstract and general, while predicted entailments that are longer than an input sentence tend to introduce plausible elaborations (Kolesnyk et al., 2016). For instance, the sentence "A bird is in a pond." can be used to generate the sentence "A little bird is outside in a small pond." by using a decoding tree with nodes for two additional adjectives and an additional adverb.

## Substitutional Analysis

If individual words in an input sentence are replaced, it becomes possible to identify the impact of particular words on
the inferences that are licensed by a particular sentence. In Figure 4, for instance, the replacement of a subject noun or the main verb can be seen to have significant effects on the kinds of entailments that are generated. The model is impressively sensitive to sophisticated linguistic cues concerning agreement. For instance, the model correctly infers that "boy" should be paired with the male possessive "his", while "girl" should be paired with the female possessive "her". It is worth emphasizing that all of the sentences that result from substitution are completely novel from the model's perspective. The fact that the model is able to generate reasonable entailments for many of these sentences suggests that it is able generalize beyond the training data quite successfully.

A further application of substitutional analysis involves examining a model's ability to learn about theoretically interesting constructions involving negations, quantifiers, and numerals. For instance, the model exhibits a rudimentary ability to handle numerals appropriately, as is shown by the inference from "A boy and a girl..." to "Two kids..." Negations are a bit more troublesome: the model correctly infers "not outside" from "in a car", but incorrectly infers "not indoors" from "in a store". Quantifiers, finally, are an open question: the model correctly infers "The women" from "Many women", but it is not clear that this is the result of learning a relation between "Many" and the plural forms of nouns. Examining specific linguistic constructions in this substitutional manner is a promising avenue for future research.

## Discussion

Overall, the point of this work is to motivate an approach to semantics based on inferential relationships amongst linguistic expressions (Brandom, 1994). Our use of the encoderdecoder DT-RNN model is designed to illustrate how generalized inferential roles can be learned for arbitrary linguistic expressions from examples of how sentences are distributed as tacit "premises" and "conclusions" in a space of inferences. It is accordingly possible to characterize this work as an extension to the well-known distributional approach to semantics (Turney \& Pantel, 2010), wherein we replace the generic notion of a linguistic context with the more fine-grained notion of an inferential context.

As with most natural language generation systems, many of the sentences produced by our model are defective in some way. As can be seen in the examples in Table 1, our generated entailments are almost always thematically appropriate,

Figure 4: Substitutional analysis using the sentence "A boy in a beige shirt is sleeping in a car". The model is able to predict appropriate entailments for a range of sentences that are similar to this initial sentence shown at the top left. The fact that these substitutionally-derived sentences are not present in SNLI dataset indicates that our model is able to generalize by interpolating between the example inferential transitions found in the training data.
but sometimes contain agreement errors or misplaced words that render the entailment as a whole ill-formed. And, not infrequently, the model produces entailments that are more or less incomprehensible. There are two ways to address these problems. The first involves the use of increased amounts of training data to provide the model with a more points in the "space of inferences" to interpolate between. The second involves the use of more sophisticated network architectures that help the model to learn to more selectively make use of only the input information that is most relevant to generating a good entailment. LSTM network architectures, such as the Tree LSTM (Tai et al., 2015), are likely to provide improvements on this second front.

Finally, an important limitation of our work is that we do not consider the relationship between linguistic expressions and the non-linguistic world. A natural way to account for this relationship is to suppose that a sentence's occurrence in the linguistic environment licenses certain expectations about what can be seen, heard, or otherwise perceived. To return to our initial example, if one understands the statement "The dancers parade down the street", one will expect to see and hear dancers upon going to the relevant street. We accordingly suggest that if an individual can adequately infer all that follows from a given linguistic expression, both linguistically and non-linguistically, then there is nothing further they need to be able to do to count as understanding what the expression means. The main consequence of this view is that inference should be at the core of any theory of semantic cognition.

# Split-Second Detection of Cooperativeness from Faces in the Trust Game 

Jean-Francois Bonnefon<br>University of Toulouse, Toulouse, France<br>Astrid Hopfensitz<br>University of Toulouse, Toulouse, France<br>Wim De Neys<br>Université Paris Descartes, Paris, France

#### Abstract

Economic interactions often imply to gauge the trustworthiness of others. Recent studies showed that when making trust decisions in economic games, people have some accuracy in detecting trustworthiness from the facial features of unknown partners. Here we provide evidence that this face-based trustworthiness detection is a fast and intuitive process by testing its performance at split-second levels of exposure. Participants played a Trust game, in which they made decisions whether to trust another player based on their picture. In two studies, we manipulated the exposure time of the picture. We observed that trustworthiness detection remained better than chance for exposure times as short as 100 ms , although it disappeared with an exposure time of 33 ms . We discuss implications for ongoing debates on the use of facial inferences for social and economic decisions.

# Diversity in a Contrast Set Increases Generalization from a Single-Item Target 

David Bosch<br>New York University<br>David Kalkstein<br>New York University<br>Tali Kleiman<br>The Hebrew University of Jerusalem

#### Abstract

Four experiments explored the effect of diversity of contrasting negative evidence on inductive inferences drawn from a single-item target. In Experiments 1 and 2, we found that increasing the diversity of a contrast set led people to infer that a target exemplar corresponded to a higher level category and led to greater generalization of a novel property associated with the target. Further, we demonstrated two boundary conditions in which the effect only occurred when the contrast set was consistent with a higher level category that both united the contrast exemplars and distinguished them from the target (Experiment 4) and when contrast and target shared an obvious parent category (Experiment 5). Taken together, these findings demonstrate that increasing the diversity of a contrast increases generalization from a target, but only if the contrast set is drawn from a single category that excludes, but shares a common parent with, the target.

# Causal learning from interventions and dynamics in continuous time

#### Abstract

Event timing and interventions are important and intertwined cues to causal structure, yet they have typically been studied separately. We bring them together for the first time in an experiment where participants learn causal structure by performing interventions in continuous time. We contrast learning in acyclic and cyclic devices, with reliable and unreliable causeeffect delays. We show that successful learners use interventions to structure and simplify their interactions with the devices and that we can capture judgment patterns with heuristics based on online construction and testing of a single structural hypothesis.

Keywords: causal learning; intervention; time; causal cycles; structure induction; dynamics.

In a dynamically unfolding world, using actions to uncover causal relationships requires good timing. It is hard to tell whether a new medication is effective if you take it with others, or just as you start to feel better. Likewise, it is hard to tell whether a new law lowers crime if it is introduced just after other reforms or before a major election. Such inferences, having to do with delayed effects and an evolving causal background, can be particularly tough in cyclic systems in which feedback loops make prediction difficult even with complete knowledge (Brehmer, 1992). Thus, for interventions to be effective tools for unearthing causal structure it is important to time and locate them carefully, paying close attention to the temporal dynamics of surrounding events and the possibility of feedback loops.

Previous work has shown that people make systematic use of temporal information, taking event order as a strong cue to causal order (Bramley, Gerstenberg, \& Lagnado, 2014), and making stronger attributions when putative cause-effect delays are in line with expectations (Buehner \& McGregor, 2006) and have low variance across instances (Greville \& Buehner, 2010). Recent work has also developed frameworks for probabilistic causal inference from event timings based on parametric assumptions about cause-effect delays (Bramley, Gerstenberg, Mayrhofer, \& Lagnado, submitted; Pacer \& Griffiths, 2015).

A distinct line of work has shown that people are adept at inferring causal structure from interventions - idealized actions that set variables in a system (e.g., Bramley, Dayan, Griffiths, \& Lagnado, 2017; Coenen, Rehder, \& Gureckis, 2015). This work has not explored the role of temporal information however. While researchers have speculated about the close relationship between temporal and interventional inference (e.g., Lagnado \& Sloman, 2004), our paper is the first to explore interventional causal learning in continuous time.

## The learning problem

We explore the general problem of how people learn about a causal system by interacting with it in continuous time. We focus on abstract causal "devices" made up of 3-4 components (cf. Figure 1). For causally related components, we assume each activation of a cause will tend to bring about a single subsequent activation of its effect after a parametric delay (described below). For example, Figure 1a shows a learner's interactions with a $B \leftarrow A \rightarrow C$ Fork during which time they perform four interventions. Activations of both $B$ and $C$ succeed the interventions on $A$ but with some variability in delays.

We focus on situations where components never spontaneously activate, but where causal relations work stochastically (e.g., are successful with probability $w_{S}$ ). Any pair of components can be connected in either, neither or both directions resulting in a hypothesis space $S$ of 64 possible structures for devices made up of three components, and 4096 for four components. Learners can intervene on the devices by directly activating any component at any moment of their choosing. Interventions are always successful in that they instantaneously activate the targeted component. The downstream causal effects of intervened-on components are the same as those of components that were activated by other components. Thus, we model the consequences of interventions in analogy to the $\operatorname{Do}($.$) operator introduced by Pearl$ (2000), such that interventions provide no information about the causes of the intervened-on component.

## Choosing interventions

Seeing the effects of one's interventions in continuous time provides rich information for causal inference. On the flip side, there are also no completely independent trials. For instance, in Figure 1a, the early interventions on $C$ and $B$ might, in principle, be responsible for the observed effects that happen shortly after the intervention on $A$. In general, one cannot rule out the possibility something that happened earlier is still exerting its influence, or that an effect is yet to reveal itself. Fortunately, interventions provide anchor points. We know that events due to interventions weren't caused by anything else, and that these events only affect the future but not the past (Lagnado \& Sloman, 2004). This means that by intervening, learners can recreate some of the advantages that come with a discrete trial structure. For example, by waiting long enough between interventions to be confident prior effects have dissipated, an otherwise confusing event stream

Figure 1: Examples of using real-time interventions to infer causal structure. Left: True generative causal model with subplots showing delay distributions. Right: Timelines showing an active learners' interactions with each system with a row for each component $A$ (top), $B$ (middle) and $C$ (bottom), and white circles indicating their activations over 45 seconds (x-axis). " + " symbol and incoming hand icon indicate interventions. Dashed gray lines indicate the actual cause-effect relationships.
becomes more palatable and informative about the underlying structure. Figure 1 b gives an example of interventions that are not well chosen. The learner performs four interventions in the same locations as Figure 1a but does so in close succession. It is hard to attribute causal responsibility for these activations, since there are so many similarly plausible candidates. Consequentially, this data is considerably less informative.

In discrete-trial interventional learning, participants exhibit a positive testing strategy - they prefer to intervene on root variables that bring about many effects (Coenen et al., 2015). While often not leading to the most globally informative choice, a positive testing strategy is an effective way of assessing the adequacy of one's current working hypothesis, making it a manifestation of confirmatory testing (Nickerson, 1998). Many other components will be affected if one's hypothesis is right, and few if it is wrong. Repeated positive testing might be more justifiable in the continuous time context because cause-effect delays may play out differently each time, and potential temporal reversals between variable activations will help to rule out candidate structures (Bramley et al., 2014). For example, in Figure 1a the second intervention on $A$ leads to $B$ and $C$ occurring in reversed order, allowing the learner to rule out a $A \rightarrow B \rightarrow C$ Chain structure.

## Causal cycles

The vast majority of causal learning studies have focused on acyclic causal systems in which causal influences flow only in one direction, never revisiting the same component. However, many natural processes are cyclic and people frequently report cyclic relationships when allowed to do so (e.g.

Sloman, Love, \& Ahn, 1998). While there are ways of adapting the causal Bayes net formalism to capture cycles (Rehder, 2016), these generally simplify the problem to influences between fixed time steps (e.g. Rottman \& Keil, 2012), or just to the long-run equilibrium distribution (e.g. Lauritzen \& Richardson, 2002). However, by focusing on continuous time and developing a representation capable of modeling causal dynamics, we are able to directly compare learning in acyclic and cyclic causal systems.

Dynamic systems can be hard to predict even with perfect knowledge. Positive feedback loops can lead to sensitive dependence on initial conditions with very different behavior resulting from small perturbations in starting conditions (e.g., Gleick, 1997). Figure 1c gives an example of interventions on a cyclic causal system (assuming that the connections work $90 \%$ of the time). Interventions initialize looping behavior because of the bidirectional relationship $A \leftrightarrow B$ (e.g., $A \rightarrow B \rightarrow A \rightarrow B \ldots$ ) leading to many subsequent activations of both the loop components and the output component $C$, continuing until either the $A \rightarrow B$ or $B \rightarrow A$ connection fails. Based on simply looking at the timeline, it seems likely that it will be easier to identify which components are either directly involved in cycles, or outputs from cyclic components (due to their recurrent activations), but harder to identify the exact causal relationships (e.g. whether it is $A$ or $C$ that causes $B$ in this example since both tend to recur shortly before $B$ ).

## Normative inference

As a benchmark, we developed a Bayesian model of causal structure inference. We consider the data $\mathbf{d}_{\tau}\left\{d_{X}^{(1)}, \ldots, d_{X}^{(n)}\right\}$ to be made up of all activations (with events indexed in chronological order and $X$ indicating the activated component) conditioned upon the set of interventions $\mathbf{i}_{\tau}=$ $\left\{i_{X}^{(1)}, \ldots, i_{X}^{(m)}\right\}$. Both $\mathbf{d}_{\tau}$ and $\mathbf{i}_{\tau}$ are restricted to the interval between the beginning of the clip and time $\tau$, which we assume to be the moment at which the learner makes the inference. For instance, one might interact with a causal device for 5000 ms , performing interventions on components $A$ and $B$ at 100 ms and 1200 ms respectively: $\mathbf{i}_{5000}=\left\{i_{A}^{(1)}=100, i_{B}^{(2)}=\right.$ $1200\}$, and observing two activations of $C: \mathbf{d}_{5000}=\left\{d_{C}^{(1)}=\right.$ $\left.1500, d_{C}^{(2)}=2800\right\}$.

Normative Bayesian structure inference involves updating a prior over structure hypotheses $P(S)$ with the likelihood $p\left(\mathbf{d}_{\tau} \mid S ; \mathbf{i}_{\tau}, \mathbf{w}\right)$ to get a posterior belief over structures $P\left(S \mid \mathbf{d}_{\tau} ; \mathbf{i}_{\tau}, \mathbf{w}\right)$ given the set of parameters $\mathbf{w}:{ }^{1}$

$$
\begin{equation*}
P\left(S \mid \mathbf{d}_{\tau} ; \mathbf{i}_{\tau}, \mathbf{w}\right) \propto p\left(\mathbf{d}_{\tau} \mid S ; \mathbf{i}_{\tau}, \mathbf{w}\right) \cdot P(S) \tag{1}
\end{equation*}
$$

An immediate issue with calculating the likelihood of an observed set of activations given a candidate model is that there are likely to be multiple potential paths of actual causation that could have produced the data (Halpern, 2016), each

[^32]

Figure 2: Devices tested and results from experiment in a) reliable and b) unreliable delay conditions. Node shading: Intervention choice prevalence by component. Edge shading: accuracy. Note: Ints = average number of interventions performed; Acc = mean accuracy.
of which implying a different likelihood. For example, if the true structure is a $A \rightarrow C \leftarrow B$ Collider, the data above might be produced in two ways. $A$ could have caused the first activation of $C$ and $B$ the later $\left(i_{A}^{(1)} \rightarrow d_{C}^{(1)}, i_{B}^{(1)} \rightarrow d_{C}^{(2)}\right)$. Alternatively, $A$ could have caused the later activation of $C$ and $B$ the earlier $\left(i_{A}^{(1)} \rightarrow d_{C}^{(2)}, i_{B}^{(1)} \rightarrow d_{C}^{(1)}\right)$.

However, as there can only be one true path of actual causation in the set of possible paths $\mathbf{Z}_{s}$, we can sum over these to get the likelihood of the data given a candidate model $s \in S$ :

$$
\begin{equation*}
p\left(\mathbf{d}_{\tau} \mid s ; \mathbf{i}_{\tau}, \mathbf{w}\right)=\sum_{\mathbf{z}^{\prime} \in \mathbf{Z}_{s}} p\left(\mathbf{d}_{\tau} \mid \mathbf{z}^{\prime} ; \mathbf{i}_{\tau}, \mathbf{w}\right) \tag{2}
\end{equation*}
$$

We assume that the actual causal delays (in $\mathbf{Z}_{s}$ ) are Gamma distributed (see also Bramley et al., submitted) with a known expected duration $\mu$ and shape $\alpha$ (i.e., variability). The likelihood of the data given a specific path $\mathbf{z}^{\prime}$, then, is the product of the (Gamma) likelihoods of the observed delays and causal strength $w_{S}$ combined with the likelihoods of (non-)events, the occurrence of which failed either due to the $1-w_{S}$ causal failure rate or due to the effect potentially occurring after $\tau$ (i.e., some time in the future).

With these ingredients the posterior belief over causal structure hypotheses can be determined. However, it is only feasible to enumerate all possible paths of actual causation for a sufficiently small number of events. While for a large number of events the calculations become intractable, we were able to compute the posteriors in the described manner for the data from the current experiment, resorting only in rare cases to an approximation. ${ }^{2}$

## Experiment

Participants' task was to discover the causal connections between the components of several devices in limited time

[^33](see Figure 2). Half of the devices were acyclic (top; no feedback loops) and half were cyclic (bottom; contained a feedback loop). Participants were able to activate any of the components by clicking on them. We were interested in how participants chose where to intervene and when. We examined two delay conditions between subjects, one in which the true cause-effect delays were reliable (Gamma distributed with $\alpha=200, M \pm S D 1.5 \pm 0.1$ seconds) and one where they were unreliable ( $\alpha=5, M \pm S D 1.5 \pm 0.7$ seconds). Following Greville and Buehner (2010), we expected that performance would be better when causal delays were reliable. We also predicted that complex dynamics would lead to worse performance when the true structure was cyclic, and that successful participants would spread their interventions widely over time, thus minimizing the ambiguity of resulting patterns of effects.

## Methods

Participants Forty participants (14 female, aged $32 \pm 9.0$ ) were recruited from Amazon Mechanical Turk (yielding 20 subjects in each delay-reliability condition) and were paid between $\$ 0.50$ and $\$ 3.20(\$ 2.06 \pm 0.39)$ depending on performance (see Methods section). The task took around 20 minutes.
Materials and procedure Each device was represented with a circle for each component and boxes marking the locations of the potential connections (see Figure 3a). ${ }^{3}$ Trials lasted for 45 seconds during which components activated if clicked on or if caused by the activation of another component, with delay and probability governed by the true underlying network (Figure 3b). Causal relationships worked $90 \%$ of the time (i.e., causal strength $w_{S}=0.9$ ) and there were no spontaneous activations. Activated components turned yellow for 200 ms , and intervened-on components were additionally marked by a "+" symbol. Initially, all components were inactive and no

[^34]

Figure 3: Experimental procedure. a) Up to 6 interventions could be performed by clicking on the components during the 45 second trial. b) This would lead to subsequent activations determined by causal connections and delays in the true model. c) Participants marked their beliefs about the structure during the trials by clicking on the edges. d) At the end of each trial they received feedback. Broad gray arrows: ground truth, Green $=$ correct, Red $=$ incorrect.
connections were marked between them.
Prior to the inference tasks, participants were trained on the delays in their condition and how to register structure judgments through interaction with an an example device. They then had to correctly answer comprehension check questions and complete a practice problem, before facing the 12 test devices in random order with randomly orientated and unlabeled components.

In the test phase, participants could perform up to 6 interventions on each trial and register/update their judgments about the causal structure as often as they liked until the 45 seconds for a device ran out (for details see Figure 3). At the end of each trial, they were given feedback showing the true relationships and which of them they had correctly identified. To incentivize proper judgments, bonuses were paid based on connections participants had registered at a randomly chosen point during each trial.

## Results

We analyze participants' judgments by first comparing their accuracy by delay-reliability condition (between subjects: reliable vs. unreliable) and device type (within subject: acyclic vs. cyclic). We then analyze the timing and spacing of participants' interventions and how these relate to the evidence and judgments.
Accuracy Participants updated and confirmed their judgment about the structure $\mathrm{M} \pm \mathrm{SD} 1.6 \pm 1.2$ times per trial on average. Judgment time was not significantly related to accuracy, but within trials, final judgments were slightly more accurate than initial judgments, with participants correctly identifying $69 \% \pm 30 \%$ (chance performance would be $25 \%$ ) compared to $65 \% \pm 28 \%$ of the connections, $t(479)=$ $5.2, p<.001$ (remember that bonuses incentivised making judgments early). Only $4 \%$ of judgment updates decreased the number of connections, $24 \%$ resulting in the same number as before, and $72 \%$ increasing the number of connections.

Focusing on final judgments, participants correctly identified [reliable,acyclic]: $82 \% \pm 29 \%$, [reliable,cyclic]: $68 \% \pm$ $28 \%$, [unreliable,cyclic]: $69 \% \pm 29 \%$, [unreliable,cyclic]: $56 \% \pm 29 \%$ of the connections. A repeated measures analysis revealed a significant effect of delay-reliability condition, $F(1,38)=4.6, p=.04$, and cyclicity, $F(1,38)=39, p<$ .001, but no interaction, with unreliable delays and cyclic structures associated with lower accuracy. Figure 2 shows that participants found the Cyclic 3, 5 and 6 structures hardest to identify on average, struggling in particular with distin-
guishing looping from output components.
Ideal Bayesian inference based on the evidence generated by participants predicts a different pattern. While reliable delays allow greater accuracy than unreliable ones, $F(1,38)=$ $24.3, p<.001$, there is no predicted difference in accuracy between acyclic and cyclic devices, $F(1,38)=0.43, p=.5$. In fact, posterior uncertainty over all possible models, measured by Shannon entropy, was generally lower for evidence generated by a cyclic $.74 \pm 1.26$ than an acyclic $1.95 \pm 1.29$ devices, $F(1,38)=109, p<.001$.
Timing of interventions We hypothesized that spacing interventions out in time would be important for successful learning. Participants waited $7.3 \pm 2.8$ seconds between interventions on average. In a regression including delay condition and total number of interventions as covariates, leaving longer intervals between interventions was positively associated with accuracy, $F(1,36)=14.0, \beta=0.04, \eta_{p}^{2}=$ $.26, p=.001$, with no interaction with condition. The variability of these gaps - measured by their coefficient of variation $C V=\frac{\sigma}{\mu}$ - was also inversely related to accuracy, $F(1,36)=7.9, \beta=-0.5, \eta_{p}^{2}=.18, p=.008$ and this effect was stronger in the unreliable delay condition, $F(1,35)=4.5, \eta_{p}^{2}=.11, p=.04$. We also assessed the intervals participants left after the most recently preceding event (whether this was an intervention or an effect) before performing their next intervention. Again larger intervals, $F(1,36)=7.7, \beta=0.06, \eta_{p}^{2}=.18, p=.008$, and less variation, $\beta=-.25, F(1,36)=5.0, \eta_{p}^{2}=.12, p=.03$, was associated with accuracy with neither measure interacting with delay condition. Both larger intervals between interventions, and between interventions and the most recently preceding effect were also associated with lower posterior entropy, with $\beta=0.05, F(1,36)=9.9, \eta_{p}^{2}=.22, p=0.003$ and $\beta=0.09, F(1,36)=8.1, \eta_{p}^{2}=.18, p=0.007$, respectively. However, there was no evidence for a relationship between entropy and the variability of either interval type.
Positive testing We found evidence of a preference for positive testing, with participants performing $1.2 \pm 0.5$ times as many interventions per root component than per non-root component $t(59)=3.9, p<.001$. This preference was associated with higher accuracy after accounting for condition, $F(1,37)=21, \eta_{p}^{2}=0.37, p<.001$, and did not interact with condition. Degree of root preference, however, was not significantly related to posterior uncertainty from the perspective of an ideal Bayesian learner.

Adaptation to cycles While participants performed fewer interventions on cyclic $(4.1 \pm 1.1)$ compared to acyclic ( $5.4 \pm$ 0.7 ) devices, $t(39)=8.7, p<.001$ (see Figure 2), they still experienced far more effects in the cyclic systems $(29.3 \pm 10)$ compared to the acyclic ones $(4.7 \pm 1.1), t(39)=15.5, p<$ .001. This was due to the reciprocal relationships sustaining activations until one of the links failed. Thus while there was normatively more evidence available in the cyclic trials - as reflected by the generally lower posterior uncertainty - the large number of events resulted in more ambiguous evidence, with many candidate causes per effect and a large number of potential actual causal pathways.
Summary Participants were better at identifying causal relations from interventions when delays were reliable and the true structure was acyclic. Meanwhile, ideal learner accuracy was affected by reliability by not cyclicity. Successful participants spread their interventions out more in time, waited longer after previous events, distributed them more evenly and favored root components. Participants frequently updated their models by adding additional connections but rarely removed connections.

## Modeling heuristic inferences

Participants' deviations from the prediction of an ideal Bayesian learner suggests that they relied on simpler learning strategies. In this section we compare judgment patterns to several heuristic models inspired by work on order-driven (e.g., Bramley et al., 2014) and incremental causal structure learning (e.g., Bonawitz, Denison, Gopnik, \& Griffiths, 2014; Bramley et al., 2017).

Several papers have proposed that human causal learning is based on the adaptation of a single global hypothesis (Bonawitz et al., 2014), which might be achieved incrementally through making local changes as data is observed (Bramley et al., 2017). This seems particularly applicable in a continuous-time context, where normative inference is tough and the evidence arrives continuously. People may learn locally, ignoring dependence on beliefs about surrounding relationships (e.g. Fernbach \& Sloman, 2009), or use their current model as a basis, comparing observations against predictions, only adding new connections to explain events that cannot easily be accommodated by their existing model (Bramley et al., 2017).

The idea that learners might construct their causal hypotheses incrementally can be combined with different degrees of sensitivity to timing as well as the predictions of their current structure hypothesis. This suggests several potential heuristics that adapt a single model belief $b$ as events are experienced. The result in each case is a single structural belief that evolves as events occur (we write $\mathbf{b}=\left\{b^{(0)}, \ldots, b^{(n)}\right\}$, where the sequence of belief indices correspond to the event indices in $\mathbf{d}_{\tau}$ ):

1. Order Only (OO) Heuristic OO attributes each new effect to the most recently preceding event at any different component (either the most recent intervention in $\mathbf{i}_{\tau}$ or activa-
tion in $\mathbf{d}_{\tau}$ ). If the currently held model hypothesis $b^{(t-1)}$ does not contain a respective edge, $b^{(t-1)}$ is augmented with an edge to make $b^{(t)}$. Figure 4 a gives an example of this. Starting from $b^{(t-1)}$ with a single $D \rightarrow B$ connection, the heuristic connects $A$ to $B$ upon observing $B$ 's activation straight after activating $A$, and then $B$ to $C$ when $C$ activates shortly after.
2. Time Sensitive (TS) TS is like OO but with sensitivity to the expected cause-effect delays. It attributes activations to the (previous) event such that the respective delay would be most likely given the knowledge of the true causal delay distribution, and augments $b^{(t-1)}$ with an edge, if there is none yet, to form $b^{(t)}$. In the example (Figure 4 b ), $C^{\prime}$ s activation time is most consistent with $C$ being caused by the intervention on $A$, thus the model adds an $A \rightarrow C$ connection, rather than a $B \rightarrow C$ connection, going into $b^{(t+1)}$.
3. Structure + Time Sensitive (STS) STS is like TS, but it first checks if there is already an adequate explanation in the current model $b^{(t-1)}$. Concretely, it compares the likelihood of the most likely explanation that is already a cause in $b^{(t-1)}$ to the most likely explanation overall (i.e., the one selected by TS). Where these differ, it only adds an edge if the respective delay is substantially more likely than the delay implied by the best existing explanation in $b^{(t-1)}$, where we assume that "substantially more likely" means a likelihood ratio $>\frac{20}{1}$. Figure 4 c gives an example. Unlike TS, this heuristic does not add an $A \rightarrow C$ connection going into $b^{(t+1)}$ because $C$ 's activation can be explained well enough by the existing connection $D \rightarrow C$. While an $\mathbf{i}_{A}^{(2)} \rightarrow \mathbf{d}_{B}^{(1)}$ delay is slightly more probable than a $\mathbf{i}_{D}^{(1)} \rightarrow \mathbf{d}_{B}^{(1)}$ delay, the difference is not substantial enough to warrant the addition of another connection.

## Model comparison procedure

To compare the heuristics to participants' judgments, we simulated belief trajectories bs for all the heuristics based on the evidence generated by all participants, starting each trial with an unconnected model at $t=0$. For TS and STS, we assumed knowledge of true $\mu, \alpha$ and $w_{S}$ as participants had been trained on these during the instructions. We predicted participants' judgments based on what the simulated belief trajectories looked like at judgment time. We then assessed their accuracy in the task (e.g. the proportion of connections marked correctly) and accordance rate (the proportion of connections marked the same as the matched participant's). Additionally, we also compared participants to a Random baseline that marked a new random causal structure on every judgment, and an Ideal learner that always selects the max $P\left(M \mid \mathbf{d}_{\tau} ; \mathbf{i}_{\tau}, \mathbf{w}\right)$ according to the Bayesian inference model.

## Modeling results

The results of these simulations are reported in Table 1. Overall, STS was the most closely accordant with participants but individually participants were almost evenly split between STS and OO, both for all judgments and restricted to the final

Figure 4: Example where proposed heuristics' predictions diverge. $b^{(t-1)}$ : the learner's belief at the start of the period depicted in the timeline. After observing $d_{B}^{(t)}$ the models update $b^{(t-1)}$ to form $b^{(t)}$. Then after observing $d_{C}^{(t+1)}$, they update to form $b^{(t+1)}$. Blue lines indicate probability density for cause-effect delays starting from each event, used to determine the most likely cause of each event (TS), and whether it is sufficiently more likely than any existing causes (STS).
judgments. Participants accuracy $(0.65 \pm 0.19)$ was closest to that of the simplest heuristic OO. Mean participant accuracy by trial was correlated with that of all three heuristics $r_{\mathrm{OO}}=$ $.83, r_{\mathrm{TS}}=0.92, r_{\mathrm{STS}}=0.61$, but negatively correlated with Ideal judgments $r_{\text {Ideal }}=-.45$. Like participants but unlike the Ideal learner, all three heuristics were less accurate at cyclic than acyclic structures OO: $t(39)=9.5, p<.001$, TS: $t(39)=$ $10.6, p<.001$, STS: $t(39)=4.5, p<.001$.

## General Discussion

In our experiment, people used interventions to learn about the causal structure of devices whose dynamics unfolded in continuous time. As we predicted, cyclic structures were harder to learn than acyclic ones even though this was not reflected in the evidence available for an ideal learner, suggesting that the evidence produced by cyclic devices, involving many activations and potential causal paths, was harder for human learners to process. We found that the observed determinants of successful learning - equal spacing of interventions in time and a preference to intervene on root variables - made structure inference easier for a heuristic and

Table 1: Model comparison

| Model | Accuracy (\%) |  | Accordance (\%) |  | N best (/40) |  |
| :--- | :--- | :--- | :--- | :--- | :--- | :--- |
|  | All | Final | All | Final | All | Final |
| Random | 25.0 | 25.0 | 25.0 | 25.0 | 0 | 0 |
| OO | 66.2 | 64.7 | 67.2 | 64.9 | 16 | 17 |
| TS | 79.7 | 78.9 | 67.3 | 65.5 | 4 | 5 |
| STS | 87.9 | 90.9 | 69.3 | 69.2 | 15 | 13 |
| Ideal | 91.0 | 95.3 | 66.1 | 68.9 | 5 | 5 |

bounded learning system.
In light of this, we considered several heuristic learning models. Participants' judgments were best explained by assuming that they added connections to a single evolving candidate hypothesis as they observed events. Some subjects appeared to rely on a simple order heuristic (OO) whereas others displayed sensitivity to the delays between events (TS) and whether events were predicted by existing structure beliefs (STS). Participants rarely removed connections during the trials. Given more time to learn, however, it seems likely that they would also sometimes prune connections from their models - e.g., when events predicted by their current model repeatedly fail to occur. In general, positive testing of one's current hypothesis is an effective way for learners that are limited to a single global hypothesis to test its predictions against reality, and tune, refine, or or even abandon it, if necessary.

In sum, rather than grappling with an unmanageable space of possible structures and causal paths, participants seem to naturally follow Yogi Berra's advice: "You don't have to swing hard [to hit a home run]. If you got the timing, it'll go."

# Harmony in a non-harmonic language: word order learning in French children 

Guillaume Braquet (s1577900@sms.ed.ac.uk)<br>Department of Linguistics and English Language, 3 Charles Street<br>Edinburgh, EH8 9AD UK

Jennifer Culbertson (jennifer.culbertson@ed.ac.uk)
Centre for Language Evolution, 3 Charles Street
Edinburgh, EH8 9AD UK

#### Abstract

Recent studies using artificial language learning have argued that the cross-linguistic frequency of harmonic word order patterns-in which heads are ordered consistently before or after dependents across syntactic categories-reflects a cognitive bias (Culbertson, Smolensky, \& Legendre, 2012; Culbertson \& Newport, 2015a). These studies suggest that English speaking adults and children favor harmonic orders of nouns and different nominal modifiers (adjectives, numerals). However, because they target English learners, whose native language is harmonic in the nominal domain (Num-Adj-N), this preference may be based on transfer rather than a universal bias for harmony. We present new evidence from French-speaking children, whose native language is non-harmonic in this domain (Num-N-Adj). Our results reveal clear effects of native language transfer, but also evidence that a harmonic pattern is favored even in this population of learners.

Keywords: cognitive biases; artificial language learning; typology; syntax; word order; French

## Introduction

Cross-category harmony (Greenberg, 1963; Hawkins, 1983) is perhaps the most well-known typological generalization of syntax: while it has been revised many times over the years (Dryer, 1992; Biberauer, Holmberg, \& Roberts, 2014), most linguists continue to assume that it reflects some underlying "law of human behavior" (Greenberg, 1966). Nevertheless, like most typological generalizations, harmony is a statistical tendency, and researchers have pointed to the possibility that correlations in word order across categories may largely reflect the effects of language contact and shared inheritance rather than universal properties of human cognition (Dunn, Greenhill, Levinson, \& Gray, 2011; Ladd, Roberts, \& Dediu, 2014).

To provide evidence of a link to cognition, a number of recent studies have investigated word order harmony using artificial language learning experiments. Culbertson et al. (2012) taught English-speaking adults a miniature artificial language in which simple noun phrases, including a noun and either an adjective or a numeral word, are used to describe a set of pictures. The languages feature variable patterns of nominal word order that tend toward either harmonic or non-harmonic. Learners tended to regularize harmonic input patterns-using the input harmonic order more frequently than it appeared in the input. By contrast, they tended to shift non-harmonic patterns toward harmonic ones rather than regularizing. Culbertson and Newport (2015a) found an even stronger effect in English-speaking children, who almost across the board altered non-harmonic input patterns to
make them harmonic (e.g., by changing the order of one of the modifiers to match the other). Indeed, even when children were taught a completely regular non-harmonic pattern (e.g., adjectives always follow and numerals always precede the noun), they still produced a harmonic output (Culbertson \& Newport, 2015b).

## Cognitive bias or native language influence?

These studies suggest the possibility that learners may preferentially change non-harmonic patterns to harmonic ones, rather than the reverse, offering a potential explanation for a similar typological asymmetry. Frequencies of the relevant nominal word order patterns are reported in the World Atlas of Language Structures Online, shown in Table 1. Harmonic patterns (both modifiers either pre-nominal or post-nominal) outnumber non-harmonic patterns. Note in addition, that within both harmonic and non-harmonic pattern types, the one with post-nominal adjectives is more frequent (i.e., N Adj with N-Num; N-Adj with Num-N).

Table 1: Frequency of harmonic and non-harmonic combinations of noun with adjective and numeral (Dryer, 2013a, 2013b).

|  | Adj-N | N-Adj |
| :--- | :--- | :--- |
| Num-N | 251 | 168 |
| N-Num | 37 | 509 |

Data from English-speaking learners reflects both a harmony bias and a bias for post-nominal adjectives to some extent. For example, English-speaking adults were equally likely to regularize pre- and the post-nominal harmonic patterns, despite the latter having less surface-level overlap with English than either non-harmonic pattern. They were also least likely to regularize the non-harmonic pattern with pre-nominal adjectives (Culbertson et al., 2012). Englishspeaking children did not exhibit any differences among nonharmonic patterns, however, their overall preference for harmonic patterns was in fact skewed toward the post-nominal N-Adj with N-Num (Culbertson \& Newport, 2015a).

Nevertheless, evidence of a harmony preference in English speakers does not unequivocally suggest an explanation for the typological asymmetry seen here. This is of course because English itself exemplifies one of the two harmonic
patterns-Adj-N with Num-N. Thus a preference for harmony in this population may be due to transfer at a more abstract level. In other words, English speakers may find the postnominal harmonic pattern easy to learn because they are used to treating numerals and adjectives similarly in terms of their relative order with the noun. If abstract transfer is responsible for the harmony bias in English speakers, then French speaking learners should behave quite differently. The default nominal word order in French exemplifies the more common non-harmonic pattern, N-Adj with Num-N. Numeral order is strictly pre-nominal, while adjectives are typically postnominal but exhibit some flexibility. Most importantly, there is a small lexically-specified set of adjectives which precede the noun. Examples of default order are shown in (1). ${ }^{1}$
(1)

> a. maison bleue house blue
> 'blue house'
> b. deux maisons
> two houses
> 'two houses'

French speakers could therefore be reasonably expected to prefer non-harmonic patterns over harmonic ones, since their prior language experience provides evidence that these two types of modifiers behave differently with respect to order. On the other hand, if the preference for harmony reflects a universal cognitive bias, then even French speakers-whose native language violates it-may exhibit its effects.

## Experiment 1

Here we explore the potential effects of native language influence and cognitive biases on nominal word order learning in French-speaking children. We follow the general design and procedure of Culbertson and Newport (2015a) and Culbertson and Newport (2015b). Children are taught a variable version of one of four patterns corresponding to those in Table 1. They are trained on simple phrases comprising a noun with an adjective or a noun with a numeral, and are then tested on their production of those phrases. The extent to which learners accurately reproduce and regularize these variable patterns is used to infer their relative preferences.

## Participants

Participants were 48 children ( 24 females), 6-7 years of age (mean $=6 ; 7$, matched with participants in Culbertson and Newport (2015a)). They were recruited from elementary schools in Southwest France, and were native speakers of French, who were either monolingual, or bilingual in French and Occitan (a Romance language spoken in this region, which uses the same nominal word order as French). Parental consent was obtained for all participants. Three additional children were excluded from the analysis due to failure to

[^35]complete the experimental session (2), or extremely low score on vocabulary learning (1).

## Materials

The artificial language consisted of 10 words: 4 nouns corresponding to novel objects, 3 adjectives, and 3 numeral words. Following Culbertson and Newport (2015a), nouns were nonce words which were phonotactically plausible in the participants' native language, and modifiers were pseudononce words resembling the corresponding native language words. This lexicon was used to describe pictures like those shown in Figure 1. Importantly, all of the adjectival modifiers used here appear in the default post-nominal order in French, they are not in the set of pre-nominally ordered adjectives.

Table 2: Artificial language lexicon.

| Nouns | Adjective | Numerals |
| :--- | :--- | :--- |
| [bogi] | [bly] (bleu 'blue') | [doks] (deux, 'two') |
| [sefi] | [tachu] (tacheté, 'spotted') | [tra] (trois, 'three') |
| [voli] | [pølu] (poilu, 'furry') | [kits] (quatre, 'four') |
| [kani] |  |  |

Figure 1: Example visual stimuli.

## Design \& Procedure

Participants were randomly assigned to one of four input word order conditions. Each condition featured a dominant pattern for each modifier type, used in $75 \%$ of utterances. The remaining $25 \%$ used the alternative order. The variation present in the input was unpredictable; it was not conditioned on any particular lexical items. These conditions are illustrated in Table 3.

Table 3: Conditions, according to dominant pattern type (shaded cells are non-dominant.

|  | Adj-N | N-Adj | Num-N | N-Num |
| :--- | :---: | :---: | :---: | :---: |
| Harmonic dominant |  |  |  |  |
| Pre-N | $75 \%$ | $25 \%$ | $75 \%$ | $25 \%$ |
| Post-N | $25 \%$ | $75 \%$ | $25 \%$ | $75 \%$ |
| Non-harmonic dominant |  |  |  |  |
| N-Adj, Num-N | $25 \%$ | $75 \%$ | $75 \%$ | $25 \%$ |
| Adj-N, N-Num | $75 \%$ | $25 \%$ | $25 \%$ | $75 \%$ |

Following Culbertson and Newport (2015b), the experiment consisted of a single session, lasting approximately 30 minutes. During this session participants were trained and
tested on the language with an experimenter present. The experiment was presented using PsychoPy software (Peirce, 2009) on a Macintosh laptop in a quiet corner of the child's classroom. Children were told they would be playing a game to learn an alien language with the help of a friendly alien named Clémy.

The experiment began with a series of games designed to teach children the novel nouns and their meanings. The first game ( 20 trials) involved seeing a grayscale picture of a single object, listening to the label provided by the alien speaker, and repeating the label aloud. The second game ( 20 trials) involved listening to a label and clicking on whichever of the four novel objects it corresponded to. Feedback highlighting the correct picture was given on all trials. A sound indicated whether the child's choice was correct or incorrect. The third game ( 20 trials) tested children's ability to provide the correct label for an object shown on the screen. Feedback in the form of the correct noun label was provided on all trials.

The second part of the experiment consisted of a series of similar games designed to teach children simple phrases in the language. Recall that each phrase consisted of either a noun with an adjective or a noun with a numeral, but never both. Half of all trials featured an adjective, and half a numeral. The first game (48 trials) involved seeing pictures as in Figure 1 above, and hearing a phrase to describe it provided by the alien speaker. Participants were told to repeat the phrase. The second game ( 48 trials) involved hearing a phrase and choosing the corresponding picture from an array of four choices. Feedback was given as described above. Finally, children were shown a picture, and were asked to provide a description for it ( 48 trials). No feedback was given, however if the child had trouble with one of the words, the experimenter would help.

## Results

Here we report results from the final phrase production task. Comprehension of phrases was uniformly high across conditions ( $>85 \%$ ). Figure 2 shows the average proportion of trials in which children used the dominant word order in each of the four word order input conditions. Children used the dominant order almost exclusively in the post-nominal harmonic condition, however dominant order use in the other three conditions was much lower. Children roughly matched the input proportions in the non-harmonic N -Adj, Num- N condition, which is most similar to their native language pattern.

Figure 3 shows use of the dominant pattern broken down by the type of modifier, illustrating more clearly what learners are producing when they don't match the input. While in the post-nominal harmonic condition both modifier types are regularized equally often, there is a clear difference between modifier types for the other three conditions. In the pre-nominal harmonic condition, children tended to use the numeral in the dominant input order more often, however neither modifier type reproduces the input pattern closely. In the two non-harmonic conditions, children were more likely to match the dominant input order for whichever modifier

Figure 2: Average proportion use of dominant input order by condition. The dotted line is the proportion of the dominant order used in the input (75\%). Error bars represent 95\% CIs.
tended to appear post-nominally: the adjective in the Frenchlike N -Adj, Num-N condition, and the numeral in the Adj$\mathrm{N}, \mathrm{N}$-Num condition. In other words, learners' productions in these three conditions tended to move the language away from the input pattern and toward a post-nominal harmonic pattern.

Figure 3: Average proportion use of dominant input order for each modifier type by condition. The dotted line is the proportion of the dominant order used in the input (75\%). Error bars represent 95\% CIs.

These data were analyzed using mixed-effects logistic regression as implemented in the lme 4 R package (Bates, 2010), with condition (input pattern type) and modifier type (adjective or numeral) as fixed effects and participants and items (stimulus picture) as random effects. Modifier type was sum coded; condition was treatment coded with the most French-like pattern ( $\mathrm{N}-\mathrm{Adj}$, Num-N) as the baseline
level. This model revealed a significant difference between the French-like ( $\mathrm{N}-\mathrm{Adj}, \mathrm{Num}-\mathrm{N}$ ) condition and each of the other three conditions: compared to this condition there was significantly less use of the input order in the pre-nominal harmonic condition $(\beta=-3.99 \pm 0.56, p<0.001)$ and the nonharmonic Adj-N, N-Num condition ( $\beta=-3.60 \pm 0.54, p<$ 0.001 ), but significantly more use of the input order in the post-nominal harmonic condition ( $\beta=17.88 \pm 17.03, p=$ 0.03 ). A significant main effect of modifier type was also present, indicating less matching of numeral order overall ( $\beta=-2.28 \pm 0.22, p<0.001$ ). Finally, significant interactions between condition and modifier type were found. As suggested by Figure 3, the main difference between the French-like and post-nominal harmonic conditions is in use of the dominant order for the numeral ( $\beta=-12.50 \pm$ $17.04, p=0.04)$. By contrast the opposite was true for both the pre-nominal harmonic $(\beta=4.45 \pm 0.33, p<0.001)$ and non-harmonic Adj-N, N-Num ( $\beta=4.89 \pm 0.31, p<0.001$ ) conditions where the bigger difference with the French-like condition was in use of the dominant adjective order. ${ }^{2}$

A visualization of the general direction of change from the input in each condition can be seen in Figure 4. This shows the proportion of pre-nominal adjectives and numerals each individual child produced, colored by their input condition. Learners generally cluster in the harmonic post-nominal area of the space, no learners for whom this was the input condition shifted away from this pattern. A smaller cluster appears around the non-harmonic French-like ( $\mathrm{N}-\mathrm{Adj}$, Num-N) area, with children in that input condition plus some from the prenominal harmonic input condition who have switched only the adjective order to post-nominal. Figure 5 summarizes this picture by calculating each child's preferred pattern, determined by the order used in the majority of utterances (greater than $50 \%$ ) for each modifier type. For example, one child in the French-like N-Adj, Num-N condition produced adjectives post-nominally $100 \%$ of the time, and numerals postnominally $88 \%$ of the time. This child was thus classified as having the post-nominal harmonic pattern.

## Discussion

French-speaking children learning variable patterns of harmonic or non-harmonic nominal word order showed a striking pattern of behavior in their productions. When their input featured the post-nominal harmonic pattern $\mathrm{N}-\mathrm{Adj}$, $\mathrm{N}-\mathrm{Num}$ as the dominant order, they regularized this pattern, producing nearly deterministic output. When their input featured a dominant pattern similar to their own native language, N - Adj , Num-N, they matched or regularized the adjective order, but not the numeral order. To the extent that children were fail-

[^36]

Figure 4: Output patterns for each individual participant, colored by condition, defined as proportion pre-nominal order for each modifier type. Points are jittered to prevent overplotting. Larger points outlined in black represent input proportions for each condition. Dashed lines provide a visualization of rough pattern types.

Figure 5: Number of participants in each condition whose preferred pattern (used in $>50 \%$ of utterances) corresponds to each pattern type.
ing to match the pre-nominal numeral order, they were necessarily switching it to post-nominal, in harmony with the adjectives. This same behavioral pattern, of switching the predominantly pre-nominal modifier to match the post-nominal one, is seen to a more extreme degree in the non-harmonic Adj-N, N-Num condition. Children in that condition generally matched the post-nominal numeral order, and showed a very strong tendency to switch the adjective to follow as well. In the pre-nominal harmonic condition, a similar pattern is again found: children generally produced more postnominal phrases than were present in the input for both modifier types, but particularly the adjective. Overall then, most
of the children in this experiment produced a pattern corresponding most closely to the post-nominal harmonic N -Adj, N -Num.

Recall that above we suggested two competing hypotheses which generated different predictions about the behavior of French-speaking learners in our experiment. Under the first hypothesis, influence from the native language is the primary driver of behavior. Previous results with English speaking learners were consistent with abstract level transfer (i.e., a general preference for harmonic patterns). Thus French speakers would be predicted to prefer non-harmonic patterns, though a preference for the specific native language pattern (here N -Adj, Num-N) is also possible. The second hypothesis is that a cognitive bias favoring harmonic patterns is present universally across learners, even learners whose native language actively violates it. This predicts that French-speaking learners will, like English speakers, prefer harmonic patterns. The results reported here are not fully consistent with either hypothesis. Most obviously, learners did not show a preference for the pattern, or pattern type, most similar to their native language. Neither did they prefer harmonic patterns across the board. However, a combination of native language transfer effects and a universal harmony bias provides a coherent explanation. French-speaking children in our experiment exhibited a strong preference for post-nominal adjective order, in accord with their native language. This preference was generalized to numerals under a pressure for harmony.

In order for this explanation to work, we need to rule out a potential alternative: that French-speaking children age 67 years do not distinguish numerals from adjectives, or have not fully mastered the order of numerals in their native language. This could lead to the over-use of post-nominal ordering if children have, by contrast, mastered the default adjective order. There is relatively little work on the acquisition of nominal word order in monolingual French children. Indeed, we are not aware of corresponding work on the acquisition of numeral-noun order. We therefore extracted all instances of noun phrases including one of the numeral words 'two' through 'ten' in the Lyon corpus (Demuth \& Tremblay, 2008). ${ }^{3}$ This is a publicly available corpus of naturalistic parent-child interactions including 5 children, recorded for 1 hour every 1-2 weeks from age 1 to 3 years ( 185 hours of speech total). Children's first noun phrases with a numeral word occurred as early as $1 ; 9$. Out of a total of 258 instances, no word order errors were found. Based on this evidence, it appears likely that by 6-7 years of age, French-speaking children have long since mastered the pre-nominal order of numerals words in their language. Given the variation in adjective ordering in French, it would seem plausible that children may take longer to acquire this aspect of the syntax of their native language. However, evidence from spontaneous speech suggests that French-English bilingual children have

[^37]mastered French adjective order very early as well, by $2 ; 5$ at least (Nicoladis, 2002). This may be accomplished earlier in monolinguals, in line with the early documented acquisition of adjective order in English by the age of 2 (Brown, 1973). In our study then, it does not seem likely that French-learning children's preference for post-nominal order in both adjectives and numerals is the result of a lack of knowledge about the syntax of these categories in their native language.

What remains then, is to understand how the results of this study fit with with the previous findings from Englishspeaking adults and children. As mentioned above, Englishspeaking child learners did not generalize their native prenominal order preferentially, but rather readily produce both harmonic patterns. If anything, there was somewhat stronger preference for the post-nominal harmonic pattern (Culbertson \& Newport, 2015a, 2015b). For English-speaking adults, both harmonic patterns were regularized, and among nonharmonic patterns the one with pre-nominal adjectives (Adj$\mathrm{N}, \mathrm{N}-\mathrm{Num}$ ), was particularly dispreferred (Culbertson et al., 2012). Recall that the typological distribution in Table 1 suggests both a preference for harmonic patterns, and a general preference for post-nominal adjectives. Thus among the harmonic patterns, the post-nominal one is more common, and within the non-harmonic patterns, N -Adj, Num-N is the most common. If these two pressures are at work across both learner populations, English and French, then we expect to see behavior mirror the typology. However, if these two biases are, as suggested above, influenced by learners' native language experience, then a more complex picture emerges. For English-speaking children (and adults), the harmony bias is strengthened by native language experience, while the preference for post-nominal adjectives is weakened. As a result, learners strongly prefer harmonic languages, and only weakly prefer post-nominal over pre-nominal order. For Frenchspeaking children, the opposite holds. The harmony bias is weakened, while the preference for post-nominal adjectives is strengthened. This results in a strong preference for the post-nominal harmonic pattern only, and changes to the input in each other condition which move the language toward that pattern via the adjective. Based on differences found between English-speaking adults and children, we would predict that French adults should show a similar but less dramatic pattern of preferences to children in our study.

## Why these biases?

Both of the biases we have argued to be at work here reflect potentially quite general cognitive mechanisms. Harmonic patterns are simpler, in the sense that they involve fewer, more general rules, which can be generalized across categories. For extensive discussion of this idea, see Culbertson and Kirby (2016). The preference for post-nominal adjectives may reflect a pressure to establish the object of modification first, particularly in cases where the meaning of the noun is predictive in determining the meaning of the adjective, e.g., for gradable adjectives like 'tall' (Kamp \& Partee, 1995; Ramscar, Yarlett, Dye, Denny, \& Thorpe, 2010). Interestingly,

Nicoladis (2006) shows that French-English bilingual children ( $2 ; 11-5 ; 3$ ) produce more reversals of adjective order than their monolingual counterparts in both French and English. These reversal errors were more likely to involve adjectives incorrectly in the post-nominal position than the reverse. In French, this corresponded to placing a typically pre-nominal adjective like grand 'big' after the noun. In English, this corresponded to placing adjectives in an incorrect post-nominal position when they were post-nominal in French (e.g., 'a monkey purple'). This is in line with our findings in the sense that post-nominal adjective order seems to be more readily generalized than pre-nominal order. Overall then, the preference for post-nominal adjective ordering found among languages of the world and reflected in both English and French learners, may be related to general properties of learning and processing.

## Conclusion

This study tested a classic hypothesis in linguistics: that harmonic word order patterns, which maintain a consistent order of syntactic heads relative to modifiers, are preferred to non-harmonic alternatives. Previous studies have shown that English-speaking learners prefer harmony in the nominal domain, however this could reflect abstract transfer since English exemplifies a pre-nominal harmonic pattern. Here, we targeted French-speaking child learners, whose native language is non-harmonic. If a harmony bias is present in this population it would provide a strong indication that this is indeed a universal pressure. By contrast, if transfer is the main driver of learning behavior, then no harmony bias is expected in this population-instead, non-harmonic patterns may be preferred. Our results revealed a strong preference for post-nominal harmonic order, which we argue reflects the effects of a harmony bias in conjunction with a preference for post-nominal adjectives.

## Acknowledgments

We thank the schools, parents and children who participated in this study and the developmental linguistics reading group at the University of Edinburgh for comments on this work.

# How can I help? 24- to 48-month-olds provide help specific to the cause of others' failed actions 

Sophie Bridgers (sbridge), Sara Altman (skaltman), and Hyowon Gweon (hyo@stanford.edu)<br>Department of Psychology, Stanford University

#### Abstract

When young children see others fail to achieve a goal, they spontaneously help. But there are many reasons why someone might fail, and consequently, many ways to help. In order to help effectively, we need to understand why someone is failing, so we can address the cause. One important distinction is whether the failure is due to the agent's own actions or something external to her in the world. Here we show that 24 - to 48 -month-olds can use their past experience to reason about the probable cause of another person's failure and provide help appropriate for that cause. Children's help targeted the world when their prior knowledge suggested that the source of failure was external to the agent, and targeted the person's actions when this source appeared to be internal to the agent.

## Introduction

Imagine a frustrated traveler at a train station, fumbling with a ticket machine. Chances are someone will offer help, but how this person helps might depend on the situation. If the helper sees that the traveler is inserting the bill in the wrong direction, she might kindly re-orient the bill; however, if the helper knows that the ticket machine is out of order, she might direct the traveler to another machine nearby.

Humans are remarkably helpful creatures from an early age (Tomasello, 2009). Although preverbal infants may not yet be able to offer help with ticket machines, they will pick up objects others have dropped and pass them back, and show someone struggling to reach inside a box an easier way to get in (Warneken \& Tomasello, 2006). As in the ticket machine example, however, helping others is not only a decision of whether to help, but also a decision of how to help.

The decision of how to help is sometimes straightforward. When someone is struggling to hold open a door, there is typically only one way to help. In many contexts, however, it is not so clear what kind of help is needed. In order to figure out how to help others, we need to understand why someone is struggling. Critically, more often than not, it is up to the helper, rather than the helpee, to determine exactly what kind of help is needed. If the traveler knew the reason why she was failing to insert her bill, she might have already solved the problem. When deciding how to help, therefore, it is critical to determine the source of an actor's failure: whether the failure is due to the actor herself, or due to the external world.

We routinely make these judgments about our own failed actions. If everyone else bought a ticket from the machine but somehow you cannot, you are likely using the machine incorrectly. However, if everyone experienced occasional failure, perhaps the machine is not reliable. Furthermore, these inferred reasons inform our decisions about what to do next: if
you are the source of your failure, you might seek help; if the machine is broken, you might try a different one.

Previous work suggests that even infants can infer the causes of their own failed actions, and respond appropriately to achieve their goals (Gweon \& Schulz, 2011). In this study, children were given covariation evidence indicating either that a toy sometimes worked and sometimes did not (regardless of the agent), or worked for some agents but not others. In the former case, when children failed to activate the toy, they reached for a new toy, suggesting they attributed their failures to the toy and not to their own actions. In the latter case, they were more likely to hand the toy to their mother, suggesting they inferred that their failures were due to something about their own actions and not the toy. In this case, infants were able to determine the source of their failures because they had observed others' interactions with the toy. Without such information, they would not have been able to determine why they had failed; they might not know what to do without a knowledgeable agent's help. Critically, this agent's help would be most effective is she could directly address the cause of the child's failure.

Here, we ask whether young children can reason about the cause of others' failures to inform their decisions of how to help. There are reasons to believe that even very young children may be able to do this. Studies with toddlers and preschoolers suggest that young children can provide help not only when the helpee's needs are straightforward and observable (e.g., picking up dropped objects, Warneken \& Tomasello, 2007), but also when her needs are more internal and abstract (e.g., beliefs, goals, competence). For instance, 12-month-olds are more likely to point out the location of a dropped object if their social partner has not seen it fall than when she has seen it (Liszkowski, Carpenter, \& Tomasello, 2008); 18-month-olds can use their social partner's prior experience to infer different goals from the same failed action and help her achieve that goal (Buttelmann, Carpenter, \& Tomasello, 2009). Preschoolers (42-month-olds) can reason about other peoples' action capabilities to predict from whom someone else will ask for help (Paulus \& Moore, 2011), and even anticipate that their social partner needs help before she does and pre-emptively intervene to help her achieve her ultimate goal (Bridgers, Jara-Ettinger, \& Gweon, 2016; Martin \& Olson, 2013).

However, inferring the possible causes of others' failed goal-directed actions might be more challenging than reasoning about the goals themselves, as the child must decide between (at least) two competing hypotheses which may or may not be observable in the failed action itself. Furthermore, us-
ing this inferred cause to generate the appropriate helpful behavior is also a nontrivial task, and arguably more difficult than helping in contexts in which there is one clear way to help. Even though prior work suggests that preverbal infants can make these inferences about their own failures and decide what to do to achieve their own goals, applying the same inferences to others' actions and providing the most effective help may be more challenging. Indeed, there is a body of research suggesting that reasoning about one's own actions may precede, and is a necessary precursor to, reasoning about others (e.g., Sommerville \& Woodward, 2005; Sommerville, Woodward, \& Needham, 2005).

The current study investigates 24 - to 48-month-olds' abilities to reason about the causes of others' failed actions and offer help accordingly. Children observed an adult fail to activate a toy because she either (a) used the toy incorrectly, or (b) chose a faulty toy. We then gave children the choice to help by either handing the person a working toy or by demonstrating the correct way to use the toy. Individually, both options were perfectly reasonable ways to help, and within the repertoire of behaviors children have exhibited in prior work (e.g., Warneken \& Tomasello, 2006). The critical question here, however, is whether children will provide help that best addresses the likely cause of this person's failure (i.e., the toy or her own actions).

## Experiment

In our experiment, we created a situation in which children were faced with two ways to help. We manipulated the cause of the helpee's failure, which made one way more effective than the other. We recruited 24- to 48-month-olds, who were slightly older than children in other studies that reported spontaneous helping behaviors (e.g., Warneken \& Tomasello, 2006; Cortes Barragan \& Dweck, 2014), as the ability to help others appropriately based on the cause of their failure might require richer representations about others' goal-directed actions and more sophisticated inferential abilities.

## Methods

Participants Fifty-two 24- to 48-month-olds $(M(S D)=$ $2.78(.48) \mathrm{yrs}, 44 \%$ female) from a museum in Palo Alto, CA participated. An additional 15 children were excluded from analysis due to parental interference ( $n=9$ ), experimenter error $(\mathrm{n}=1)$, shyness ( $\mathrm{n}=3$ ), or lack of video recording $(\mathrm{n}=2)$. We randomly assigned children to one of two conditions: the Broken Toy condition ( $\mathrm{n}=26 ; M(S D)=2.78(.54) \mathrm{yrs}$ ) or the Wrong Action condition ( $\mathrm{n}=26 ; M(S D)=2.78(.43) \mathrm{yrs}$ ).
Stimuli We constructed 3 identical-looking toys. One side of each toy was covered in yellow felt and had a yellow button in the center. The opposite side was covered in red felt and had a red button in the center. The yellow button on two toys played music, while the yellow button on the third toy was inert. On all 3 toys, the red buttons were always inert. The toys were placed on a white-plastic tray and covered with grey felt. See Figure 1 for a schematic of the toys and procedure.

Procedure The experiment began with a warm-up phase in which a confederate and experimenter engaged the child in reciprocal games (e.g., rolling a ball back and forth through a tube) in order to help the child feel comfortable with the researchers, and promote general helping behavior (see Cortes Barragan \& Dweck, 2014). After approximately 5 minutes of warm-up, the confederate excused herself from the room, explaining that she had work to do.

Next came the play phase in which the child gained experience with the toys. The experimenter did not pedagogically demonstrate how the toys worked, but instead behaved as if she were exploring the toys and discovering what they did. She took one toy out at a time and showed it to the child. In the Broken Toy condition, the toys were oriented such that the yellow side was on top. She noticed the yellow button, pressed it, and reacted positively to the music that played. She also encouraged the child to press the yellow button and again reacted positively, saying, "Music! The yellow side plays music!". She then turned the toy around in her hands until she discovered the red button on the opposite side, and expressed mild surprise, as if she did not expect it to be there. She pressed the red button and also encouraged the child to do so, acting perplexed and disappointed that it did not play music. The experimenter then took the second toy out, which she and the child explored in the same way (i.e., the experimenter pressed each button, and then encouraged the child to do so). This second toy was always the broken toy, so neither button played music. This process was repeated with the third toy, which functioned the same as the first (i.e., the yellow button played music, but the red button did nothing). The child and experimenter then explored each toy again, taking turns pressing the buttons. In the Wrong Action condition, everything was the same except that the toys were placed with the red side up, such that the red button was discovered first, and then the yellow. By the end of this phase, all children experienced that pressing the yellow buttons on two of the toys played music (and one was inert), and that none of the red buttons played music.

In the helping phase, the experimenter placed toys back on the tray and covered them with the felt. The toys were placed as they were during the play phase: yellow-side-up in the Broken Toy condition, and red-side-up in the Wrong Action condition. The child sat approximately 6 ft away from the tray, either by him-/herself or with a parent. The experimenter then called the confederate back into the room and explained that she and the child were playing with toys that played music. The confederate said, "I love music!" and knelt down behind the tray, facing the child. She appeared to select a toy at random from behind the felt; the child could not see which toy was chosen.

The confederate then moved the tray (which contained 2 of the 3 toys, covered by the felt) off to one side (counterbalanced) and placed her chosen toy in front of her. She pressed the button on top (the yellow button in the Broken Toy condition; the red button in the Wrong Action condition), and the

Figure 1: Schematic of the play phase and the helping phase and the toys used in both conditions.
toy did not play music. The confederate remarked, "Hmm, no music!" and pressed the button again, expressing disappointment and saying, "Still no music! I really want to play music!" She then put one hand on the tray, and at the same time, slid her toy with the other hand such that it was parallel with the tray but on her opposite side. Once the toy and tray were equidistant from the confederate, she removed her hand from the toy and removed the felt from the tray to reveal the two other toys. She then gestured to both the toy and the tray and asked, "Can you help me play music?" The toy and tray were far enough apart (approx. 2 ft ) and from the child (approx. 5 ft ) that $\mathrm{s} /$ he could not approach both simultaneously.

If the child did not respond, the confederate and experimenter provided planned prompts, waiting 5 seconds in between, until the child responded. The last of these prompts involved the confederate moving closer to the child (approx. 2 ft .) and placing the tray and the toy within the child's reach but still far enough apart that the child could only reach to one location at a time.

In summary, the only difference across conditions was whether the non-obvious button (i.e., the button on the bottom of the toy) that the experimenter revealed to the child during the course of the play phase was non-functional (Broken Toy condition) or functional (Wrong Action condition). In both conditions, the confederate pressed the obvious button (i.e., the button on top) and the toy did nothing.
Coding We were interested in children's first helping response after the confederate's failure to activate the toy (i.e., her first button press). The key dependent measure was the target toy of this behavior, coded as either the "confederate's toy" or the "toys on the tray". All children who responded fell into one of these two categories.

Additionally, we looked at the consequence of children's first helping responses. We coded whether their behavior was "successful or "unsuccessful" in achieving the confederate's goal of playing music. In the Broken Toy condition, a child's first response was coded as "successful" if the child pressed the yellow button on a toy from the tray or directed
the confederate to press it (e.g., telling her to do so; handing or pointing to a toy yellow side up); "unsuccessful" responses included pressing or directing the confederate to press the red button on any toy or the yellow button on the confederate's toy. In the Wrong Action condition, a behavior was coded as "successful" if a child flipped and pressed the yellow button or directed the confederate to do so (e.g., telling her to press it, flipping a toy and handing or pointing to it yellow-sideup). Thus, in the Wrong Action condition, a behavior could be successful regardless of which toy a child's first response targeted, whereas in the Broken Toy condition, only behavior directed toward the toys on the tray could be successful. The first and second author transcribed and coded children's behavior and a researcher blind to the hypotheses coded these transcriptions for reliability; agreement was $100 \%$.

## Predictions and Results

Children in both conditions saw the same set of toys and a confederate fail in the same way (she pressed an obvious button on top of a toy and it did not play music). Furthermore, in response, all children could approach either the confederate's toy or a toy on the tray. What differed across conditions was the likely cause of the confederate's failure. We manipulated the source of failure by varying whether the obvious button on top of the toy was functional on 2 of the 3 toys (i.e., yellow button; Broken Toy condition) or non-functional on all 3 toys (i.e., red button; Wrong Action condition).

We predicted responses to vary across conditions depending on the source of the confederate's failure. In the Broken Toy condition, the likely reason for her failure was the toy and not her own action. Thus, it was more helpful to get a new toy (a toy on the tray) than to act on the confederate's toy. In the Wrong Action condition, however, the likely reason was the confederate's action and not the toy, suggesting that children could help by approaching the confederate's toy to correct her action (there was less need to get a new toy). Thus, we predicted that more children would approach the "toys on the tray" in the Broken Toy condition than in the Wrong Action condition. As predicted, children were significantly more

Figure 2: Proportion of children whose first response was directed to the confederate's toy (blue) or the toys on the tray (red) in the helping phase. Error bars: bootstrapped 95\% CI.
likely to direct their help toward a toy on the tray in the Broken Toy condition than in the Wrong Action condition (73\% vs. $27 \%$; two-tailed Fisher's Exact Test, $p=0.002$ ).

We then looked at children's responses within each condition. In the Broken Toy condition, it was clear that the confederate was acting on the broken toy, and that children could offer help only by approaching a toy on the tray. No action on the confederate's toy could yield music. We thus predicted that children in this condition would preferentially direct their help toward a toy on the tray. Indeed, children were more likely to approach the "toys on the tray" than the "confederate's toy" (19/26; two-tailed binomial test, $p=0.029$ ).

In the Wrong Action condition, children could, in principle, help the confederate by showing the yellow button on either the confederate's toy or a toy on the tray. In fact, unlike in the Broken Toy condition, the outcome of their help was probabilistic, as there was a $33 \%$ chance that any toy children chose to flip over would be broken. However, there were reasons to expect a preference for the confederate's toy in the Wrong Action condition. First, children might have been inclined to approach the toy on which the confederate had just acted. Second, by acting on the object with which she failed, children can guarantee that they are offering help to achieve her specific goal to activate that toy. Finally, while approaching a toy on the tray changes two variables (both the object and the agent), by acting on the confederate's toy, children can more clearly disambiguate the cause of her failure. Thus, we expected that children might show a mild preference for the confederate's toy, although we did not have a strong a priori prediction. The results showed that the majority of children in the Wrong Action condition did approach the "confederate's toy" (19/26, two-tailed binomial test, $p=0.029$ ). See Figure 2 for a summary of children's first responses.

Our secondary measure of interest was the success of children's helping responses (i.e., did their help enable the confederate to achieve her goal of playing music?). Successful behavior in the Wrong Action condition was arguably more
complex than in the Broken Toy condition, as children had to reveal the non-obvious button on the bottom of a toy. In the Broken Toy condition, children simply had to point out another obvious button on a different toy. Despite this difference, children's help did not differ across conditions (twotailed, Fisher's exact test, $p=0.01$ ) and was remarkably successful overall. The majority of children engaged in successful helping behavior ( $44 / 52,85 \%$ ), and this trend was consistent within each condition (Broken Toy: 19/26, 73\%; Wrong Action: 25/25, 100\%). In the Broken Toy condition, children's help could only be successful if they approached the "toys on the tray". Of the children who did this, $100 \%$ of them were successful. In the Wrong Action condition, children's help could be successful if they approached either the "toys on the tray" or the "confederate's toy". One child was dropped from this analysis because the camera angle prevented clear visual access to the nature of her helping behavior, but all children included provided successful help.

Finally, as an exploratory analysis, we re-coded children's first responses as "correct" (Broken Toy: "toys on tray"; Wrong Action: "confederate's toy") or "incorrect". We fit a generalized linear model with correctness as the outcome variable, condition as a categorical predictor variable, and age as a continuous predictor variable. This analysis revealed no difference in children's tendency to behave "correctly" by condition or age (condition: $\beta=-.364, z=-.471, p=.638$; age: $\beta=1.533, z=1.614, p=0.107$ ).

## Discussion

Our results suggest that 2- and 3-year-old children were able to infer the likely cause of another person's failure and offer help that appropriately addressed this cause. Rather than simply helping the confederate with the toy she previously tried but failed to activate, or offering her a new toy across the board, children selectively approached the confederate's toy or a new toy depending on the source of the confederate's failure. More specifically, when children's prior knowledge suggested that the confederate was failing due to something about the world (e.g., a faulty toy), they provided help that changed this external variable (i.e., acting on a new toy in the same way). But when her own action was the likely culprit, children helped by keeping the world constant and showing her the correct action to take (i.e., acting on the same toy but in a different way). Moreover, beyond simply directing their help toward the likely cause, they provided assistance that successfully fulfilled the confederate's goal.

These results support the idea that young children are not just motivated to help (Tomasello, 2009); they are also motivated (and able) to provide help that is appropriate and effective. From a brief training with the causal structure of simple toys, children as young as 2 years of age were able to use their prior experience to infer the cause of the actor's failure, and intervene in a way that specifically targeted this cause.

In the Broken Toy condition, the toy was clearly the cause of the confederate's failure, and the only way to help was
to get her a new toy. In the Wrong Action condition, the confederate's action was clearly the cause of her failure, but there was more than one way to help: you could show her the right action on her toy or another toy. Children in this condition appeared sensitive to this response ambiguity. Although most children approached the confederate's toy (19/26; 73\%) and revealed the functional button on the bottom, some (7/26; $27 \%$ ) approached the toys on the tray and flipped one of these toys over instead. Therefore, although the children who approached the tray may have thought the confederate's toy was broken, their behavior suggests they still attributed the confederate's failure to her action.

Though children in the Wrong Action condition could have helped the confederate by revealing the functional button on the confederate's toy or on a toy from the tray, children still preferentially approached the confederate's toy. While this tendency could be a simple inclination to approach a toy that someone else has chosen before, it could also reflect more sophisticated reasoning about how best to help the confederate. First, showing the confederate the correct action on the same toy directly helps her achieve her specific goal of making that toy play music. Second, by acting on the confederate's toy, children can effectively hold the "toy" variable constant and vary just the "action" variable. Thus, even though the probability of providing effective help is the same (67\%) for any of the toys, the outcome of the action is more informative when the child acts on the confederate's toy. If this action is successful (i.e., the toy plays music), then the confederate's action was wrong; if this action is unsuccessful, the confederate has a broken toy. By contrast, acting in a new way on a different toy can only be informative for the confederate if the action is successful. The exact reasoning underlying children's preference for the confederate's toy remains unclear and is an avenue for future work.

The content of children's helping behavior provides a more nuanced picture of their reasoning about the confederate. Children not only seemed to reason about the confederate's observable, failed action but also her internal mental states. In the Broken Toy condition, all of the children who successfully helped indicated that the confederate should try to press the yellow button on one of the toys on the tray. However, none of these children provided exhaustive information about the functionality of the toys (i.e., they did not reveal the nonfunctional red button on the bottom). This suggests that the children were sensitive to the fact that the confederate's goal was to play music, rather than to learn how the toys worked. This finding is consistent with prior research showing that 4- to 5-year-olds adjust the amount of information they provide depending on whether their social partner wants to know how a toy works or simply wants to see what the toy does: children were more likely to provide information that fully disambiguated the causal system for the former than for the latter goal (Gweon, Chu, \& Schulz, 2014). Would children in our current age range similarly demonstrate the other side of the toy if the confederate expressed a desire to learn how the
toy works? This is an interesting question we might explore in future studies.

In addition to reasoning about the confederate's goal, it is possible that children were reasoning about her knowledge and beliefs. This possibility is particularly salient in the Wrong Action condition. The confederate held the incorrect expectation that the red button played music and expressed frustration upon failure. Thus, a rich interpretation of children's helping behavior (in this case, flipping over the toy) is that they acted on the toy to correct the confederate's false belief. Although considerable evidence from the literature on Theory-of-mind development suggests children are unable to represent others' mistaken beliefs until around age 4 (e.g., Gopnik \& Slaughter, 1991; Wellman, Cross, \& Watson, 2001), some work suggests children the age of our participants might be capable of such belief reasoning, especially in contexts in which they are motivated to help others (Buttelmann et al., 2009; Southgate, Chevallier, \& Csibra, 2010).

Although this is an interesting possibility, it is important to note that it was not necessary to attribute a mistaken belief to the confederate in order to provide appropriate help in our task. Children could have selected the appropriate action by simply attributing ignorance about the functionality of the toys instead of a false belief. Thus, understanding the exact nature of the representation that motivated children's behavior remains an important question for future research.

The absence of age-related trends raises the question of when children might be able to offer help that addresses the cause of others' failed actions. As previously discussed, 16-month-olds are capable of distinguishing between external and internal sources of their own failed actions and will intervene accordingly (Gweon \& Schulz, 2011). Our current work extends these findings in an important direction, suggesting that the causal inference that supports how we respond to our own failed actions may also support how we help others remedy theirs. Thus one might naturally ask: Would 16-montholds also use this reasoning to choose how to help?

In order to succeed in our task, children must (1) have the ability to infer the cause of failure for others' goal-directed actions, (2) have the knowledge to figure out how best to help, and (3) select and execute the more effective action. One possibility is that even though preverbal infants can reason about the cause of agents' failures, they may fail to recruit this reasoning in helping decisions due to constraints in their working memory or executive function. Additionally, prior work suggests that although one-year-olds can provide help when the helping action is constrained, they struggle when the situation is more open-ended (Svetlova, Nichols, \& Brownell, 2010). However, it is possible that we may find similar abilities in infants in a simple paradigm that minimizes such demands. We are currently exploring this possibility.

Finally, our findings have implications for understanding the nature of early instrumental helping. Much of the prior work on the development of helping behavior has focused
on whether and why young children help (e.g., Warneken \& Tomasello, 2006; Cortes Barragan \& Dweck, 2014; Svetlova et al., 2010). Though our experiment instead focuses on the how of early helping, it is still reasonable to ask whether children in our task were really offering help to the confederate or if they responded for another reason, such as a desire to socially interact, or a personal desire to hear the music (see Paulus \& Moore, 2012). Although the selectivity in children's helping responses in our study provides suggestive evidence that children were not simply motivated to interact with the confederate, our experimental design does not allow us to completely disentangle the different possible motivations behind their helping behavior. However, this distinction is not critical for our current purposes. Our main interest in this study was whether children can infer the likely cause of others' failures, and whether such causal reasoning can lead to behaviors that are consequentially effective in helping others achieve their goals.

In fact, children's behaviors in our study suggest that another important motivator for our prosocial behaviors may be our curiosity and desire to understand causal relationships (Gopnik, 1998). When we see someone struggling at the ticket machine, we might want to help not only because we want to help her but also because we want to know why she is failing. Children in our study might have been motivated by similar reasons; such actions would not only help others achieve their goals but also help children themselves learn about the world.

By using what we know, we can better help others. Although deciding how to help in the real-world can be a challenging, open-ended problem, humans can figure out why others fail and the best way to help. Our work suggests that even toddlers are able to solve this problem using their own experience as a guide. While young children are constantly helped and taught by others, the ability to harness this knowledge to figure out how to effectively help others themselves is present early in life.

#### Abstract

This study investigates whether making and observing (human) gestures facilitates learning about non-human biological movements and whether correspondence between gesture and to-be-learned movement is superior to noncorrespondence. Functional near-infrared spectroscopy was used to address whether gestures activate the human mirrorneuron system (hMNS) and whether this activation mediates the facilitation of learning. During learning, participants viewed the animations of the to-be-learned movements twice. Depending on the condition, the second viewing was supplemented with either a self-gesturing instruction (Y/N) and/or a gesture video (corresponding/non-corresponding/no). Results showed that high-visuospatial-ability learners showed better learning outcomes with non-corresponding gestures, whereas those gestures were detrimental for low-visuospatialability learners. Furthermore, the activation of the inferiorparietal cortex (part of the hMNS) tended to predict better learning outcomes. Unexpectedly, making gestures did not influence learning, but cortical activation differed for learners who self-gestured depending on which gesture they observed. Results and implications are discussed.

Keywords: Learning about movements; dynamic visualizations; human mirror-neuron system; gestures; functional near-infrared spectroscopy.

## Learning from Dynamic Visualizations

In recent years, dynamic visualizations such as animations and videos have become a popular instructional tool to visualize processes and phenomena that are dynamic in nature (e.g., cardiovascular system, lightning formation, fish movements). Obviously, dynamic visualizations are wellsuited for this purpose given that they explicitly depict visuospatial information over time. Nevertheless, research thus far indicates that dynamic visualizations are often not superior to learning from static visualizations (e.g., CastroAlonso et al., 2016; Mayer et al., 2005). It appears that dynamic visualizations are particularly effective for learning about movements when biological movement is involved (Hoffler \& Leutner, 2007) like when learning to tie knots
with the hands (Marcus et al., 2013) or learning to classify fish movements (Brucker et al., 2015). However, so far (1) there is only a handful of studies investigating the instructional potential of dynamic visualizations addressing biological movement and most of them focus on handmanipulative tasks, and (2) it is yet unexplored to what extent learning about biological movements from dynamic visualizations can be enhanced by additional instructional support. These aspects provided the basis for the present study wherein we investigated the value of observing and making gestures for learning to classify fish movement patterns from dynamic visualizations.

## Gestures and Learning

It is by now relatively well-established that making and observing gestures is beneficial for acquiring knowledge about different scientific topics and spatial problem solving (e.g., Chu \& Kita, 2011; Cook \& Goldin-Meadow, 2006). In learning about movements from dynamic visualizations, there is also increasing evidence that showing hands in manual tasks (e.g. origami folding, Marcus et al., 2013) or observing gestures in addition to the learning material improves learning outcomes (Brucker et al., 2015; De Koning \& Tabbers, 2013). It is assumed that this is due to the activation of brain regions (i.e., the human mirrorneuron system [hMNS]; Fogassi \& Ferrari, 2011; Rizzolatti \& Craighero, 2004) involved in the observation, understanding and imitation of other persons' actions. This is in line with the current hypothesis that the stimulation and involvement of this hMNS might be beneficial for learning about complex continuous aspects with dynamic visualizations (Ayres et al., 2009; Van Gog et al., 2009).

Initial evidence for this comes from a study by Brucker et al. (2015) wherein low- and high-visuospatial-ability learners had to learn fish movement patterns from dynamic visualizations whilst observing additional gestures that did or did not correspond to the depicted movements. Results showed better learning outcomes and higher cortical
activation in the inferior-frontal cortex (part of the hMNS) for low-visuospatial-ability learners after watching gestures that corresponded to the to-be-learned fish movements compared to watching non-corresponding gestures. High-visuospatial-ability learners achieved high learning outcomes with both gestures. Unexpectedly, low-visuospatial-ability learners who watched the noncorresponding gestures could also achieve high learning outcomes if they activated their inferior-parietal cortex (also part of the hMNS). These findings provide the first indication that the hMNS is also involved in representing non-human biological or even non-biological movements, if the observer is able to anthropomorphize these movements (cf. De Koning \& Tabbers, 2011). So, drawing on the hMNS by showing learners gestures associated with the learning content seems an effective instructional strategy to improve learning about biological movements from dynamic visualizations.

Based on the notion that learner-generated gestures, as compared to just observing other's gestures, have a more direct and stronger influence on the degree to which the hMNS is activated (e.g., Montgomery, Isenberg, \& Haxby, 2007), asking learners to make gestures related to the movements depicted in a dynamic visualization themselves may be a way to further enhance learning (cf. De Koning \& Tabbers, 2011). Additional advantages of self-performed gestures relate to the manner (e.g., speed, amplitude) in which the gestures are made and the possibility to draw on one's personal experiences (with fish movement) in order to perform the gestures. By embodying the learning content in one's sensory and motor systems based on physical movements (i.e., gestures), the information is coded in a distinct, visuospatial representational format that enriches the way the information is represented, thereby creating a higher-quality mental representation (Paas \& Sweller, 2012). Higher-quality mental representations are associated with better learning (Goldin-Meadow et al., 2001), yielding faster and more accurate performance on learning tests. It is important to note that these anticipated benefits only arise as long as the act of making gestures is not too demanding, complex or distracting (De Koning \& Tabbers, 2013; Skulmowski et al., 2014). Together, by focusing on selfperformed gestures whilst learning about biological movements from dynamic visualizations, we move into a promising but yet unexplored field of research (for an exception see De Koning \& Tabbers, 2013).

## Visuospatial Ability, Gestures, and Learning

As processing continuous changes requires visuospatial ability (cf. Hegarty, 1992), it is likely that learners' visuospatial ability will determine how much they benefit from dynamic visualizations and additional gestures (cf. Hegarty \& Waller, 2005). According to previous research (e.g., Höffler, 2010) learners with higher visuospatial ability outperform learners with lower visuospatial ability during learning with visualizations, and visuospatial ability may moderate the effectiveness of learning with different
instructions and visualization formats. Higher visuospatial ability may compensate for "poor" instructions (i.e., in our case unrelated non-corresponding gestures, cf. Methods section), whereas learners with lower visuospatial ability suffer from such instructions (cf. ability-as-compensator hypothesis; Höffler, 2010). For example, relating this to the Brucker et al. (2015) study, high-visuospatial-ability learners likely possess the skills and resources to see when gestures are in conflict with the depicted content and come up with an own strategy to elaborate on the relevant movements, whereas low-visuospatial-ability learners do not possess these skills and therefore are less able to deal with situations where gestures are in conflict with the dynamic visualizations resulting in lower learning outcomes. Thus, taking into account learners' visuospatial ability is relevant when studying the value of gestures in learning about movements from dynamic visualizations.

## Present Study

This study addresses the question to what extent learning about biological movements from dynamic visualizations can be enhanced by adding information in the form of gestures. We implemented gesture-information in two ways: By making gestures of the learners themselves and by observing gestures displayed on a video. We investigated making gestures (by the learner) by contrasting (1) studying the dynamic visualizations whilst making gestures to (2) studying the visualizations without making gestures. Moreover, we examined observing gestures (that do or do not correspond to the depicted non-human biological movements) by contrasting studying the dynamic visualization whilst (1) observing corresponding versus (2) observing non-corresponding versus (3) not observing additional gestures. Furthermore, functional near-infrared spectroscopy (fNIRS), which is a non-intrusive neurophysiological method to gather data about cortical activation of humans, is used to investigate whether the hMNS is activated during viewing gestures and learning about biological movements from dynamic visualizations. We hypothesize that studying the dynamic visualization with additionally making gestures yields higher learning outcomes than studying without making gestures. Additionally, we hypothesize that studying the dynamic visualizations with additionally observing gestures yields higher learning outcomes than studying without observing gestures. In accordance with Brucker et al. (2015), this pattern is expected to vary as a function of level of gesture correspondence and learner's visuospatial ability: low-visuospatial-ability learners are expected to show higher learning outcomes only on corresponding gestures, whereas high-visuospatial-ability learners are expected to show improved learning outcomes for corresponding and noncorresponding gestures. Furthermore, we hypothesize that the hMNS is more strongly activated with self-performed gestures than with observed gestures, which in turn is more strongly activated than studying without gestures. Moreover, we hypothesize that higher hMNS activation is
associated with higher learning outcomes. This is expected to be particularly true for low-visuospatial learners.

## Methods

## Participants and Design

One hundred and eighteen university students ( $M=24.37$ years, $S D=3.99$; 84 females; 109 right handed) were recruited via an online system (http://www.orsee.org/) and compensated with 10 Euro. They had to learn to discriminate different fish according to their movements based on dynamic visualizations. There were four different to-be-learned movement patterns of fish. The participants saw each movement pattern twice: Firstly, they saw an animation of the specific movement pattern. Secondly, they saw the animation of the specific movement pattern again. But this time depending on the experimental condition, the animation could have been complemented with two additional sources: either a written instruction to self-gesture (making gestures) and/or a video of a person performing gestures with his hands and arms (observing gestures). Depending on this 2-by-3-between subjects design of the study with the two independent factors making gesture and observing gesture there were six conditions in total. Making gesture was varied in two variants: Participants either did or did not get the instruction "Please make your own gestures, that help you to better understand the movement." Observing gesture was varied in three variants: Participants either saw gestures that did correspond or that did not correspond (i.e., were unrelated) to the fish movement patterns or they saw no gesture at all (see Figure 1).

For the observing gestures conditions we used the gestures from Brucker et al. (2015). For the corresponding gestures, an expert regarding fish movements displayed with his hands and arms representations of the respective movements as clearly as possible, whereas for the noncorresponding gestures the (same) expert performed gestures with his hands and arms that were unrelated to the fish movement patterns (i.e., waving, circulating the forearms around each other, drumming, and pointing.

Participants saw the animation of the first fish movement for 30 s . Then a pause of 30 s (black screen) followed before they saw the animation of the first fish movement with its additions (depending on the experimental condition) for 30 s again. Then again a pause of 30 s (black screen) followed before the presentation of the next fish movement started in the same manner. The learners were instructed to relax in the pauses with the intention that the activations of the brain areas of interest were supposed to return to baseline level before the next visualization was displayed.

## Materials

Participants were asked to learn to classify four different fish movement patterns. These fish movement patterns differ in terms of the parts of the body that generate propulsion (i.e., several fins or the body itself) and also in the manner of how these body parts move in the three-
dimensional space (i.e. different paddle-like or wave-like movements). The four different movement patterns were: 1. oscillation of the pectoral fins; 2 . undulation of the body; 3 . undulation of the dorsal and anal fins; and 4. oscillation of the dorsal and anal fins (and undulation of the pectoral fins). During identifying these movement patterns it is very challenging that fish may deploy other movements in addition (e.g., to navigate) and these additional movements can easily be mistaken for movements used for propulsion in another movement pattern. We used the fish animations and gesture videos from Brucker et al. (2015). The movement cycles of the movement patterns were presented in loops in the animations ( 30 s per movement pattern, 25 fps, size: $480 \times 360$ pixels). The gestures were presented in the respective conditions in loops in the videos ( 30 s per movement pattern, 25 frames per s, size: $480 \times 360$ pixels). The presentation of all visualizations was system-controlled.

Figure 1: Six conditions in the 2-by-3-design of the study.

## Measures

Learning Outcomes To assess learning outcomes, we administered a movement pattern classification test comprising 45 dynamic multiple-choice items. These items consisted of underwater videos of real fish performing one of the four to-be-learned movement patterns or a distractor movement pattern. Learners had to identify the body parts relevant for propulsion and their way of moving to choose for each item the kind of movement pattern that was depicted. Each item was visible for 7 s and immediately afterwards participants had 3 s time to choose the correct answer by pressing a corresponding button. Each item was awarded one point for the correct answer ( 0 to max. 45 points). The test items were presented in blocks of 30 s so that 3 items were grouped together. Pauses of 30 s (black screen) followed each block.

Learners' Visuospatial Ability To assess learners' visuospatial ability we used a short version of the paper folding test (PFT, Ekstrom et al., 1976; ten multiple-choice items; total processing time: three minutes). In this task, participants see five options from which they have to choose the correct answer. The stimuli are depictions of papers that are folded stepwise and then were punched in the folded state. The answer options depict unfolded papers with punches being either in the correct or incorrect positions. Each correct answer is worth one point (max. 10 points).

Cortical Activation During viewing the fish animation for the second time in the learning phase, cortical activation was assessed via fNIRS measurements with an ETG-4000 (Hitachi Medical Co.). We used a $2 \times 22$ channel array as probe set that was placed over fronto-temporo-parietal regions and was centered at the T3-T4 and C3-C4 positions (not exactly terminating on these positions because of the fixed interoptode distances) according to the standard locations of the 10-20 system for electrode placement (Jasper, 1958). The fNIRS system measures the change in the product of hemoglobin $(\mathrm{Hb})$ concentration and effective optical path length in human brain tissue. The unit of Hb change is molar concentration ( $\mathrm{mM}=\mathrm{mmol} / \mathrm{l}$ ) multiplied by optical path length (mm). Local increases of Hb are indicators of cortical activity (Obrig \& Villringer, 2003).

## Procedure

Participants were tested individually. After reading a printed overview with information about the procedure of the study, they had to answer the demographics and the PFT. Then, the experimenter placed and adjusted the fNIRS probe set on the scalp of the participants. Subsequently, the computerbased learning materials were presented (learning phase). For each of the four to-be-learned movement patterns, learners were presented with the two presentations of the fish animations (1. fish animation and 2. fish animation plus additional gesture video and/or self-gesturing instruction depending on the experimental condition). Following the learning phase ( 8 min ) learners performed a filler task (about 8 min ), in which they answered some questions on object positions of depicted objects. Subsequently, learners completed the movement classification test ( 15 min ). Participants were instructed to put both their forefingers and both their middle fingers on predefined keys as well as one of their thumbs on the space bar to answer the test items. The predefined keys were labeled on the screen with static screenshots from the learning animations of the four movement patterns and the spacebar was labeled with a grey bar indicating movements that were not part of the learning phase (i.e. distractor items). In total, one experimental session lasted approximately 50 minutes.

## Results

## Learning Outcomes

To analyze learning outcomes, we conducted an ANCOVA (univariate analysis of covariance) with the factors making gesture, observing gesture, and the continuous factor learners' visuospatial ability as a covariate. We inserted all interaction terms in the analysis to investigate the possible interactions. For learning outcomes, results showed no main effect of making gestures ( $F<1$, ns), no main effect of observing gestures $(F(2,106)=1.65, M S E=119.63, p=$ $.20, \eta_{p}^{2}=.03$, ns), but there was a significant main effect for learners' visuospatial ability $(F(1,106)=11.58, M S E=$ 119.63, $p=.001, \eta_{p}^{2}=.10$ ). This effect has to be interpreted in terms of the significant interaction between observing
gestures and learners' visuospatial ability on learning outcomes $\left(F(2,106)=7.93, M S E=119.63, p=.001, \eta_{p}^{2}=\right.$ .13 ; see means and standard errors in Figure 2). There were no other significant interactions or three-way-interactions (all $p \mathrm{~s}>.35$, ns). The significant interaction between observing gestures and learners' visuospatial ability on learning outcomes showed that for participants with high visuospatial ability (defined as one standard deviation above the sample mean) the non-corresponding gesture led to better learning outcomes than the corresponding gesture ( $p$ $=.001$ ) and no gesture $(p=.02)$. For participants with low visuospatial ability (defined as one standard deviation below the sample mean) non-corresponding gestures were worse for learning than no gesture ( $p<.01$ ), whereas there was no significant difference between the corresponding gesture condition and the no gesture condition ( $p=.23$, ns). Thus, the non-corresponding gestures are beneficial for high-, but detrimental for low-visuospatial-ability learners.

Figure 2. Interaction between learners' visuospatial ability and observing gestures on learning outcomes.

## Cortical Activation

To analyze the cortical activation, we defined two regions of interest (ROIs) on the left hemisphere for the hMNS among the respective channels (cf. Rizzolatti \& Craighero, 2004). The two ROIs were the left inferior-frontal cortex (IFC) and the left inferior-parietal cortex (IPC, cf. Figure 3). Cortical activation in these areas was analyzed with two ANCOVAs with the factors making gestures, observing gestures, and learners' visuospatial ability as a covariate. We had to exclude five participants from these analyses because of poor data quality resulting in a total number of 113 participants in these analyses. Even though making gestures did not influence results on learning outcomes, analyses on cortical activation showed tendencies for an interaction between making gestures and observing gestures for both IFC activation $\left(F(2,100)=2.94, M S E=.001, p=.06, \eta_{p}^{2}=\right.$ $.06)$ and IPC activation $(F(2,100)=2.42, M S E=.001, p=$ $.06, \eta_{p}^{2}=.05$ ). There were no other significant main effects or interactions in these analyses (all $p \mathrm{~s}>.104$, ns). Pairwise comparisons revealed that participants observing corresponding gestures showed higher IFC activation if they self-gestured than when they did not self-gesture ( $p=.005$ ). However, participants observing non-corresponding gestures showed higher IPC activation if they self-gestured than when they did not self-gesture $(p=.02)$. This might be an indicator that during watching corresponding gestures the

IFC is more important, whereas during processing noncorresponding gestures the IPC becomes more important at least when the participants were instructed to self-gesture.

Figure 3. Spatial arrangement of the left probe set.

## Effects of Cortical Activation on Learning

To address the question whether higher hMNS activation is directly associated with better learning outcomes, we conducted two ANCOVAs with the factors making gestures, observing gestures, learners' visuospatial ability and cortical activation in terms of IFC activation or IPC activation, respectively. There was a tendency that higher IFC activation lead to higher learning outcomes $(F(1,88)=$ $3.22, M S E=124.85, p=.08, \eta_{p}^{2}=.04$ ). This analysis on IFC activation did also show the main effect for visuospatial ability $\left(F(1,88)=7.58, M S E=124.85, p<.01, \eta_{p}^{2}=.08\right)$ as well as the interaction between observing gesture and visuospatial ability $(F(2,88)=3.93, M S E=124.85, p=.02$, $\eta_{p}^{2}=.08$; both effects reported for learning outcomes, see Figure 2). For IFC activation there were no other significant main effects or interactions (all $p \mathrm{~s}>.27$, ns). The analysis on IPC activation did also show the main effect for visuospatial ability $(F(1,88)=7.18, M S E=128.56, p<.01$, $\left.\eta_{p}^{2}=.08\right)$ and the interaction between observing gesture and visuospatial ability $(F(2,88)=5.18, M S E=128.56, p<.01$, $\eta_{p}^{2}=.11$; both effects reported for learning outcomes, see Figure 2). For IPC activation there were no other significant main effects or interactions (all $p \mathrm{~s}>.189$, ns).

## Discussion

This study investigated whether making and observing additional gestures improves learning about biological movements from dynamic visualizations and to what extent this is related with the cortical activation in areas associated with the hMNS. Regarding learning outcomes, our results indicate that the observation of gestures has different effects for high- and low-visuospatial-ability learners, particularly when dealing with non-corresponding gestures. For high-visuospatial-ability learners, non-corresponding gestures improved learning (even beyond corresponding gestures), whereas for low-visuospatial-ability learners the observation of non-corresponding gestures had detrimental effects on learning. These findings are largely in line with those reported by Brucker et al. (2015) and indicate that particularly when high-visuospatial-ability learners are challenged by a desirable difficulty (cf. Schüler, 2017), in this case by creating a conflict between the visualized fish movements and the (mismatching) gestures, they are stimulated to put more effort in reducing the conflict and come up with a strategy to more elaborately process the relevant movements. This in turn increases the chance that
they properly understand the depicted movement. In contrast, low-visuospatial-ability learners presumably are insufficiently equipped for managing such a situation of conflicting information (e.g., they do not have the resources to identify the mismatch or do not know how to cope with that), and are not able to accurately process the movements and to avoid reduced performance.

In this study, IFC activation tended to predict better learning outcomes. However, compared to the Brucker et al. (2015) study, we did not find the result pattern that IPC activation compensates for missing support of visuospatial ability or non-conflicting gestures. This might be explained by the fact that in the present study participants who neither have visuospatial ability nor non-conflicting gestures at their disposal (i.e. the group of low-visuospatial-ability learners who saw non-corresponding gestures) still could focus on the fish animation. This was possible because in this study the gestures were presented at the same time as the fish, whereas in our prior study the gestures were presented separated in time from the fish animations. However, further research should investigate direct comparisons of sequential and simultaneous presentations of additional gestures.

Another interesting result of this study is that, in contrast to our hypothesis, self-performed gestures did not improve learning outcomes. In line with this, several recent attempts to augment learning about non-human movement (e.g., lightning formation, grammar rules) by instructing learners to make gestures while studying an animation also failed to improve learning performance (e.g. De Koning \& Tabbers, 2013; Post et al., 2013). Collectively, the conclusion from this and other studies is that independent from timing of gestures (during or after learning from dynamic visualizations) and instructional approach (instruct specific ways to perform gestures or let learners decide how to perform gestures) making gestures does not seem to benefit learning from dynamic visualizations involving non-human movement. Importantly, however, making gestures did activate the hMNS. Participants who were instructed to selfgesture activated different parts of the hMNS depending on which gesture they simultaneously observed: with the corresponding gestures there was higher IFC activation, whereas with the non-corresponding gestures there was higher IPC activation. This can be brought in line with our previous findings (Brucker et al., 2015), in which we also found evidence that the IFC plays a role during watching corresponding gestures, whereas the IPC comes into the picture when (conflicting) non-corresponding gestures have to be processed. The IPC is associated with processes of motion analysis and motor imagery, which may both be helpful in the context of identifying the mismatch between the to-be-learned movements and the non-corresponding gestures. However, future research is needed to explore these processes in more detail. Future research should also address one limitation of this study - namely the lack of insight into learners' strategies - by replicating it with think-aloud protocols so that it is possible to discover the strategies learners use when observing and making (non-
corresponding) gestures in learning from dynamic visualizations. Furthermore, it is important to further identify potential neural correlates of (gesture-supported) learning with dynamic visualizations and to further unravel the relations between activation in different parts of the brain and learning outcomes. The present study provides a starting point from which future research endeavors within this emerging field of research can be explored with the goal to incorporate (observing and making) gestures in a way that learning about non-human movements from dynamic visualizations is enhanced. In conclusion, this study shows that observing additional gestures is helpful for learning about movements, but learners need different types of gestures depending on their amount of visuospatial ability. Thus, different types of gestures should be applied: High-visuospatial-ability learners should be challenged with noncorresponding gestures, whereas low-visuospatial-ability learners might be supported with corresponding gestures.

# Learning on Multi-Touch Devices: The influence of the distance between information in pop-ups and the hands of the users 

Birgit Brucker (b.brucker@iwm-tuebingen.de)<br>Lara Scatturin (scalara@gmx.de)<br>Peter Gerjets (p.gerjets@iwm-tuebingen.de)<br>Leibniz-Institut für Wissensmedien, Schleichstrasse 6, 72076 Tuebingen, Germany

#### Abstract

Prior research indicated that information processing is influenced by the proximity of the hands to information: visuospatial processing is fostered near the hands, whereas textual processing might not be affected or even inhibited near the hands. This study investigated how the proximity of the hands to digital information in pop-ups influences learning outcomes on multi-touch devices. Depending on the distance between the information in the pop-ups and the hands of the users there were three conditions: (1) all pop-ups opened near the hands, (2) all pop-ups opened far from the hands, and (3) pop-ups with visuospatial information opened near the hands, whereas pop-ups with textual information opened far from the hands (mixed condition). Results showed better learning outcomes when visuospatial pop-ups are presented near the hands, whereas there was no difference in learning outcomes between near and far presented textual pop-ups. Results and implications for multi-touch designs are discussed.

Keywords: Learning; Information in Pop-Ups; Near-HandAttention; Hand Proximity; Multi-Touch Devices; Design Implementations

## Learning with Multi-Touch Devices

Our hands are the perfect interface of our body to get in contact with the world we live in. They allow us to grasp objects or defend us from potentially harmful things. In our daily life not only real objects, but also digital objects on multi-touch devices become more and more present due to the rapid technological development. One general question that arises, is, how such interaction devices should be designed and implemented to support users during acquiring knowledge with digital objects, such as digital pictures and texts (cf. North et al., 2009). Particularly, the conditions under which interactive multi-touch displays are able to facilitate learning are important. This study investigated how the distance between the hands and fingers of the users to additional digital information in pop-ups influences learning on multi-touch devices. Additionally, this was addressed for different types of information in the pop-ups, namely visuospatial and textual information.

## Near Hand Attention

A few studies investigate the directness of manipulation in terms of hand proximity on multi-touch-tables. For
example, Schmidt, Block, and Gellersen (2009) compared direct input on a multi-touch table display with indirect input where the input is made on the table but the surface on which the action was visible was a separate vertical display. Schmidt et al. (2009) showed that the direct condition led to better results than the indirect version. Moreover, Brucker et al. (2014) and Brucker, Ehrmann, \& Gerjets (2016) showed that direct interaction with visuospatial elements (i.e., pictures of art pieces) was beneficial for learning compared to indirect interaction. This leads to the assumption that hand proximity is particularly beneficial for learning about visuospatial information.

Indeed, prior research on information processing near the hands on computers without multi-touch interaction indicated that the processing of visuospatial information is positively influenced when the hands are near the to-beprocessed stimuli. For example, Reed, Grubb, and Steele (2006) showed that visuospatial processing is enhanced near the hands, because objects that are located near the hands receive higher visual attention than objects that are distant to the hands. There is a large amount of studies pointing in the same direction that visuospatial processing is fostered near the hands (e.g., Abrams et al., 2008; Cosman \& Vecera, 2010; Tseng \& Bridgeman, 2011; Vishton et al., 2007). Tseng and Bridgeman (2011) found evidence that the proximity of the hands lead to deeper and more detailed processing of visual information. Cosman and Vecera (2010) showed facilitated figure-ground-distinctions near the hands. Vishton et al. (2012) showed higher visual precision near the hands (lower Ebbinghaus-illusion).

However, Davoli et al. (2010) showed that not only visuospatial processing is fostered, but that also semantic processing might be impaired near the hands. In their first experiment, participants judged sentences classified by the experimenters as meaningless (e.g., "Tim typed his suitcase to the car" instead of a sentence classified as meaningful, such as "Tim carried his suitcase to the car") more often as meaningful in the near-hand conditions than when the sentences were presented far from the hands (cf. Figure 1). In their second experiment, Davoli et al. (2010) found a reduced stroop-interference in the near-hand condition on a classical stroop-task (naming the color of a word instead of reading it: for example the word "RED" could be written in red [congruent condition] or in green [incongruent
condition]). Thus, participants could better suppress reading the word when their hands were near the stimuli. Davoli et al. (2010) interpreted the results of both studies as impaired semantic processing. According to Graziano and Gross (1994) stimuli that appear outside the border of 20 cm around the hands do not activate bimodal neurons sensitive to both touch and sight and thus, these stimuli can be considered as presented far from the hands. Furthermore, Adam et al. (2012) demonstrated that the proximity of the hands to the stimuli plays also a role while the hands are moving. This is particularly of interest, because during interaction gestures on multi-touch devices the hands have to be moved almost all the time.

Figure 1: Experimental setting in the near-hand (left) and the far-hand condition (right; cf. Abrams et al., 2008).

## Design Implementations of Information in Pop-Ups

During interacting with digital information on mutli-touch devices it is common that touching on the information activates a certain functionality. We address one specific functionality of information depiction on multi-touch devices - namely pop-ups displaying additional information - by addressing how the information processing of the additional information is influenced by the proximity of the hands to the pop-ups. If pop-ups are used on multi-touch devices the question arises where these pop-ups should open on the display in relation to the position of the hands and fingers that activate it. We will shortly introduce three possible distances: near, far, or mixed.

Near distances between the pop-ups and the fingers of the users have the advantage that users easily find the additional information and do not have to run with their eyes over the display to search for it. However, near distances might also lead to coverings because information that is beforehand near to the finger of the user has to be superimposed by the new additional information in the popups. Regarding far distances between the pop-ups and the fingers of the users exactly the opposite advantages and disadvantages occur: Coverings can be prevented, but learners might have to use cognitive resources to find the additional information with their eyes (even though the information might be connected to the position of the finger with a line or an arrow or something similar). This might cause a type of split attention effect (cf. Ayres \& Sweller, 2005) between the users previous focus, where her/his hands and fingers are, and the new additional information in the pop-ups. The third way of presenting additional information in pop-ups - the mixed distances - depends upon the information that is entailed in the pop-up: As abovementioned there is a large amount of studies showing that visuospatial information processing is fostered near the hands. Thus it might be advantageous to depict pop-ups
entailing visuospatial information near the hands (even though coverings might occur). For textual information the result pattern is not that clear: there is one study indicating that it might be better to process textual information further away from the hands (cf. Davoli et al., 2010), but this is not enough evidence to make a strong assumption about the best position for pop-ups entailing textual information.

## Hypotheses

We assumed that information in pop-ups entailing visuospatial information should be learned better when the visuospatial pop-ups are presented near to the hands of the users. For information in pop-ups entailing textual information we did not expect such a difference, although it might be even advantageous if these textual pop-ups are presented far from the hands of the users.

## Methods

## Participants and Design

Fifty-six university students (average age: 24.39 years, SD = 4.58 years; 43 female) from a German university were randomly assigned to one out of three conditions in a between-subjects-design with the factor "pop-up distance" (near versus far versus mixed). Each student received 12 Euro for participating in the study. Art history majors were excluded from the study.

## Materials and Domain

Learning Materials and Multi-Touch Table As instructional domain, art history was chosen. The learning materials consisted of five paintings (cf. Figure 2) from the Herzog Anton Ulrich-Museum in Braunschweig, Germany.

Figure 2: Pictures of the five paintings used in this study.
High quality photographs of the paintings (in the following termed pictures) were displayed on a multi-touch table:

1) "Selbstbildnis" (1547) - Ludger tom Ring d. J. (1522-1584),
2) "Porträt des Reinhard Reiners und seiner Ehefrau Gese" (1569) Ludger tom Ring d. J. (1522-1584),
3) "Frühstücksstillleben" (1642) - Willem Claesz. Heda (1594-168/82),
4) "Die Hochzeit des Peleus und Thetis" (1602) - Joachim Anthonisz. Wtewael (1566-1638), and
5) "Die Heilige Katharina" (around 1620/24) - Bernardo Strozzi (1581/82-1644).

The size of the display of the multi-touch table was $128 \times 135$ cm with a resolution of $1920 \mathrm{px} \times 2160 \mathrm{px}$ via $2-\mathrm{x}-$ Full-HDprojection. We implemented the following interaction
possibilities with the pictures on the multi-touch table. For all five pictures additional information was accessible by touching a " i "-symbol on the bottom right corner. By pressing the " i " the picture turned around and a menu appeared. The menu entailed on the top left a small version of the painting in the middle on the top a short introduction text to the painting, and moreover four thematic index cards with teaser sentences (see Figure 3 for an example).

Figure 3: Menu of "Die Hochzeit von Peleus und Thetis" (1602) with the four thematic index cards.

Each index card could be opened via the " $i$ "-symbol and gave additional information about a certain aspect concerning the painting (e.g., the artist, the story of the painting, details and imagery, space and composition, light and color; see Figure 4 for an example). By touching the " $x$ "-symbol the index card could be closed again to get back to the menu, which could then be itself closed again by touching the respective "x"-symbol on it to go back to the picture. This structure with its three layers (painting - menu - index card) was developed in cooperation with the curators from the museum as well as the computer scientists that implemented the information on the multi-touch table in the context of developing an informal visitor-informationsystem for the museum (Gerjets et al., 2013).

Figure 4: Example of an opened thematic index cars. The arrows mark the pop-ups within the text and the picture.

We decided to stick to three layers at the maximum, however for some aspects there was more additional information that would not have fit the limited space of the respective index card. For this additional information we decided not to open another layer to avoid the user of getting lost (e.g., Conklin, 1987), but instead used pop-ups. These pop-ups appeared by touching highlighted words or
parts of the pictures. The distance in which the pop-ups opened when participants touched them was subject to experimental manipulation (see next subsection).

Hand Proximity of Pop-Up Distance According to the factor "pop-up distance" we compared experimental conditions in which all pop-ups opened near the touching hand/finger of the users (see Figure 5) with conditions in which all pop-ups opened far from the touching hand/finger of the users (at least 25 cm ; this distance was chosen to definitely exceed the peripersonal space of 20 cm around the hands, cf. Graziano \& Gross, 1994; see Figure 6) with conditions in which pop-ups containing visuospatial information opened near, whereas pop-ups containing textual information opened far (at least 25 cm ) away from the touching hand/finger of the users (mixed, see Figure 7).

Figure 5: Near pop-ups condition.

Figure 6: Far pop-ups condition.

Figure 7: Mixed pop-ups condition.

## Measures

The measures comprised a questionnaire on demographics and on participants' familiarity with the domain, a visuospatial ability test, and learning outcome measures.

Demographic Data and Familiarity with the Domain The demographic questionnaire assessed age, gender, body size, need of glasses or contact lenses, major, and study progress. Moreover, this questionnaire assessed participants' familiarity with the domain to determine participants' familiarity with the content domain of this study (i.e., art) and to ensure that all students were novices with respect to this domain. Questions comprised details of the participants' school education in art (e.g., number of courses taken, grades) and their familiarity with and interest in art, for instance, indicated by their visits in museums or galleries within the last year. Participants received points for answers that indicated at least some familiarity with the domain. Depending on the question they could receive only positive points (e.g., 0 to +4 points), whereas for some questions they could also receive negative points (e.g., -2 to +2 points). Depending on these calculations, a participant could receive points within the range of -28 to +40 points.

Learners' Visuospatial Abilities Visuospatial abilities of the participants were assessed with a short version of the paper folding test (PFT, Ekstrom, French, Harman, \& Dermen, 1976). This short version consists of ten multiplechoice items. Participants have to choose the correct answer out of five options for each item. The stimuli are depictions of stepwise folded sheets of paper that were perforated in their folded state. The answer options depict the holes of various unfolded sheets of paper with the holes being either in the correct or incorrect positions. A maximum of three minutes is assigned to work on the items. For each correct answer participants received one point (max. 10 points).

Learning outcome measures Learning outcomes were measured by means of 60 multiple-choice items about the contents entailed in the pop-ups. For each of the 60 implemented pop-ups, there was one multiple-choice item. Most of the items ( $88 \%$ ) had four answer possibilities of which always only one was correct. The remaining items had two answer possibilities. Depending upon the content of the pop-up (visuospatial versus textual), the respective item asked for visuospatial or textual information. Visuospatial items asked for certain details (e.g., depicted objects or parts) from the picture, showed different versions due to color filters or mirroring (see Figure 8 for an example). Textual items asked for specific information that was only given in the texts of the corresponding pop-up (see Figure 9 for an example). For each correct answer participants received one point (max. 60 points).

## Procedure

Participants were tested individually. Subsequently to reading a short overview on the study, they worked on the demographics, the questionnaire on participants' familiarity with the domain, and the PFT. Afterwards, participants were instructed to stand at a fixed position in front of the multitouch table to control the distance from the table. Then, they started with a practicing task on the multi-touch table to get

- depending on the experimental condition - used to manipulating the digital objects and the way they could interact with the depicted information (about four minutes). Subsequently, participants started with the learning phase in which they could - again depending on the experimental condition - freely explore the five pictures of the paintings with the corresponding menus, index cards, and pop-ups (maximal 45 Minutes to explore the five paintings; participants took on average 35.84 Minutes [SD = 7.47]). During the learning phase participants were allowed to zoom and move the digital objects and freely switch between the paintings, their menus, index cards and popups. They were instructed to focus on the information in the pop-ups to ensure that they open preferably all of them to extract the relevant information. Subsequently to the learning phase, the participants answered the 60 multiplechoice items. One session lasted approximately 80 Minutes.

Figure 8: Example of a visuospatial test item.

Figure 9: Example of a textual test item.

## Results

## Learner Prerequisites

To investigate the comparability of the experimental conditions we conducted several analyses of variance (ANOVAs) with the between-subjects-factor "pop-up distance" and the dependent variables participants' familiarity with the domain, age, and visuospatial abilities and a chi-squared-test for gender. There were no differences between the three experimental conditions regarding participants' familiarity with the domain $(F(2,53)=2.00$, $\left.M S E=118.66, p=.15, \eta_{p}^{2}=.07, \mathrm{~ns}\right)$ and participants' age, ( $F<1$, ns). In general, the means indicated that participants' familiarity with the domain was rather low and that it varied a lot across participants (cf. large standard deviations; for means and standard deviations see Table 1). Furthermore, there were no significant associations between the three experimental conditions and participants' gender $\left(\chi^{2}(2,56)\right.$ $=1.58, p=.45$, ns; see Table 1 for the number of females in each condition). Thus, the conditions are comparable with
regard to learners' prerequisites in terms of familiarity with the domain, age and gender.

However, for participants' visuospatial abilities there was a significant difference between the three experimental conditions $\left(F(2,53)=3.76, M S E=5.81, p=.03, \eta_{p}^{2}=.12\right)$. Bonferroni-adjusted post-hoc comparisons showed that only participants in the mixed condition had higher visuospatial abilities than participants in the far condition ( $p=.04$ ). Thus, we calculated an analysis of covariance (ANCOVA) with the between-subjects factor "pop-up distance" and learning outcomes as dependent variable, in which we included visuospatial abilities as a covariate and moreover the interaction term pop-up distance * visuospatial abilities to test whether there was an interaction between pop-up distance and visuospatial abilities. Because this interaction term did not reach statistical significance, we report for reasons of simplicity the ANCOVA with visuospatial abilities included as covariate, but without incorporating the interaction term (pop-up distance * visuospatial abilities).

Table 1: Means and standard deviations (in parentheses) of learner prerequisites and learning outcomes ( $\%$ correct) as a function of hand proximity.

|  | pop-ups <br> near <br> $(n=18)$ | pop-ups <br> far <br> $(n=18)$ | pop-ups <br> mixed <br> $(n=20)$ |

## Learning Outcomes

An ANCOVA with the between-subjects factor pop-up distance and visuospatial abilities as covariate revealed a significant main effect of pop-up distance for learning outcomes $\left(F(2,52)=3.17, M S E=92.77, p=.05, \eta_{p}^{2}=.11\right.$, achieved power $=0.62$ ), whereas there was no effect of visuospatial abilities on learning $(F(1,52)=1.08$, MSE $=$ 92.77, $p=.30, \eta_{p}^{2}=.02, \mathrm{~ns}$ ). To disentangle the main effect of pop-up distance for the three groups, we calculated contrast analyses in which we compared on the one hand the two conditions with near pictures (pop-ups near and pop-ups mixed) to the condition with far pictures (pop-ups far) and on the other hand the two conditions with far texts (pop-ups far and pop-ups mixed) to the condition with near texts (pop-ups near). These contrast analyses revealed that near pictures lead to better learning outcomes than far pictures $\left(F(1,52)=6.10, M S E=92.77, p=.02, \eta_{p}^{2}=.11\right)$, whereas there were no differences in learning outcomes for near and far texts $(F<1$, ns). This result pattern is in line with our hypothesis (for means and standard deviations see Table 1).

## Discussion

This study addressed how the position of pop-ups in relation to the hands and fingers of the users on multi-touch devices influences learning about the information entailed in the pop-ups. Results showed that learning outcomes are better if pop-ups that contain pictures are presented near the hands, whereas there was no difference for learning outcomes between near-presented and far-presented pop-ups that contain texts. This result pattern is in line with prior findings that visuospatial information is better processed near the hands (e.g., Reed et al., 2006). Moreover it is in line with our hypothesis that visuospatial contents should be presented near the hands of users on multi-touch displays.

Both alternative explanations of split-attention (cf. Ayres \& Sweller, 2005) or possible coverings of important information were not solely valid. A split-attention effect would have favored the near condition because in the far hand conditions the attention of the learners would have been split between the origin of the pop-up where the finger activates it and the location where the pop-up really opens (at least 25 cm distance). A prevent-coverings explanation would have favored the far hand condition, in which the pop-ups open at least 25 cm away from the users fingers, because this implementation prevents coverings of the relevant contents that might have been caused by the opening pop-ups or the fingers, hands or arms of the users.

For textual contents it seems to be indifferent of how near or far these information is presented to the hands of the users. Maybe we were not able to find any differences for near and far texts because we measured recognition of specific details from semantically correct sentences. In contrast to this measure, the only paper that found evidence for differences regarding textual information so far, addressed semantic processing and contrasted meaningful with meaningless sentences (Davoli et al., 2010). However, we did not investigate this more basal type of semantics, but rather a more complex type of semantics. Weidler and Abrams (2014) showed enhanced cognitive control near the hands. Admittedly, they did not address textual processing directly in their studies, but their results indicate that tasks that highly focus on cognitive control should be enhanced near the hands. This result pattern might also explain parts of the Davoli et al. (2010) study, namely the reduced Stroop-inference-effect that can be also explained by higher cognitive control near the hands and not by worse semantic processing. Hence, particularly the complexity of the textual materials might have influenced the information processing. Thus, one might have also assumed that textual information should also be better processed near the hands. However, our results showed neither better nor worse performance for pop-ups containing textual information near the hands. We cannot preclude that both processes - the worse processing of semantic stimuli (cf. Davoli et al., 2010) and the enhanced processing due to higher cognitive control (cf. Weidler \& Abrams, 2014) - might have influenced learning about textual information in this study. Further research is needed to disentangle these concurring explanations.

Another important difference from our study compared to prior research in this field is the direct interaction with the materials. Participants directly manipulated the pop-ups during learning, instead of only holding their hands next to the stimuli as in many prior studies. Thus, in the present study the participants were involved by their active manipulation of the given materials (e.g., freely choosing with which object they want to interact, moving and zooming of objects). Under the evolutionary assumption visuospatial stimuli are potential candidates for manipulation, because grasping of desirable objects or withdrawing the hands in case of dangerous or harmful objects was important in the evolution of human beings. Thus visuospatial stimuli are much more likely to be interacted with than textual stimuli for which no such evolutionary assumption exists. This might also give some hints for the result pattern that we found differences for popups with pictures, but not for pop-ups with texts. Future studies should investigate the importance of the direct manipulation for our result patterns by comparing interactive with non-interactive conditions.

Moreover, in this study the hands and the fingers of the participants, with which they opened the pop-ups, was visible for both the near pop-ups, as well as the far pop-ups, whereas in prior research the hands of the participants were often not visible in the far hand conditions as the hands are for example positioned in the lab of the participants. The visibility of the hands and fingers might have influenced the result pattern even though the far pop-ups opened at least 25 cm away from the finger of the participants.

Further research is needed to replicate our findings. In future studies the exact distance of the pop-ups in the different conditions should be assessed. Moreover, the popup attendance should be gathered as a manipulation check whether all participants really accessed all relevant information by opening all pop-ups. Additionally, eyetracking data would deliver more insights in the question which information the participants really processed during learning. Furthermore, assessing verbal and visual memory skills in addition to visuospatial abilities might contribute to the understanding of the different result patterns for visuospatial and textual contents in the pop-ups.

In sum, the results from this study yield direct implications for designing multi-touch environments: Let pop-ups containing visuospatial information open near the hands, but let pop-ups containing textual information open further away to prevent coverings if the size of the display and the number of users allow for such a far presentation.

#### Abstract

While research on emotions has become one of the most productive areas at the intersection of cognitive science, artificial intelligence and natural language processing, the diversity and incommensurability of emotion models seriously hampers progress in the field. We here propose kNN regression as a simple, yet effective method for computationally mapping between two major strands of emotion representations, namely dimensional and discrete emotion models. In a series of machine learning experiments on data sets of textual stimuli we gather evidence that this approach reaches a human level of reliability using a relatively small number of data points only.

Keywords: Models of Human Emotion; Representation Mapping; Machine Learning; Natural Language Processing

## Introduction

In the past decades, a multitude of different models have been devised to elucidate the nature of human emotion (Scherer, 2000). A common distinction at the representational level of emotions sets dimensional models apart from discrete or categorical models (Stevenson, Mikels, \& James, 2007).

Dimensional models consider affective states to be best described relative to a small number of independent emotional dimensions (often two or three). Substantial contributions to this line of research are often attributed to Osgood, Suci, and Tannenbaum (1957) as well as Mehrabian and Russell (1974) (Scherer, 2000). Although different labels have been proposed by major proponents of this approach, we here refer to these fundamental dimensions as Valence (the positiveness or negativeness of an emotion), Arousal (a calm-excited scale) and Dominance (the perceived degree of control over a (social) situation) - $V A D$, in short. ${ }^{1}$

Discrete models, on the other hand, often refer to emotions as evolutionary derived response pattern to major environmental events-each with its specific elicitation conditions (Scherer, 2000). Thus, in contrast to dimensional models which tend to focus on the subjective feeling aspect of emotion (and its associated verbal expression) researchers who adhere to the discrete approach rather tend to focus on motor (especially facial) expression and adaptive behavior. Among others, Plutchik (1980), Izard (1994) and Ekman (1992) are most influential for the development of this line of research.

[^38]Although many different sets of such basic emotions have been proposed (typically ranging between 7 and 14 categories), up until now, no consensus has been reached on their exact and complete number (Scherer, 2000). However, most researchers seem to agree on at least five basic categories, namely Joy, Anger, Sadness, Fear, and Disgust.

For dimensional models, a broad variety of stimulus data bases have been developed, predominantly covering lexical stimuli. The Affective Norms for English Words (ANEW) (Bradley \& Lang, 1999a) have been one of the first and probably most important data sets which comprise affective norms for Valence, Arousal and Dominance for 1,034 English words. Complementary lexical affective norms have also been developed for a wide range of other languages, such as German, Spanish or Polish (Võ et al., 2009; Redondo, Fraga, Padrón, \& Comesaña, 2007; Riegel et al., 2015). In addition, larger linguistic units have been considered for emotion assessment moving ratings from lexical items up to sentence and text level (Pinheiro, Dias, Pedrosa, \& Soares, 2017; Bradley \& Lang, 2007), on the one hand, and considering alternative modalities, such as pictures and sounds, on the other hand (Lang, Bradley, \& Cuthbert, 2008; Bradley \& Lang, 1999b). Although these stimulus sets were primarily created for dimensional representations, research activities increasingly covered discrete emotion representations, as well (for all modalities). Consequently, many of the stimuli which have formerly been rated according to affective dimensions only, in the meantime, have also received discrete categorical norm ratings in terms of double encodings (e.g., Stevenson and James (2008), Stevenson et al. (2007) and Libkuman, Otani, Kern, Viger, and Novak (2007); see Table 1 for a list of resources with both dimensional and discrete ratings).

These resources have been highly influential for artificial intelligence (AI) research: Within the broader context of affective computing (Picard, 1997), they have specifically fostered the prediction of affective states from textual stimuli which is-as a subtask of natural language processing (NLP)—most commonly referred to as sentiment analysis (Pang \& Lee, 2008; Liu, 2015; Mohammad, 2016). At the outset, NLP researchers focused on the Valence dimension only, typically trying to assign a piece of text to either a positive or a negative class (Pang, Lee, \& Vaithyanathan, 2002). In the meantime, the interest in more advanced
models of emotions (going beyond positive-negative polarity judgments) has increased considerably. At first, this development was centered around discrete models (Ovesdotter Alm, Roth, \& Sproat, 2005; Strapparava \& Mihalcea, 2007), whereas only very recently the interest in dimensional models rapidly began to rise, as well (Buechel \& Hahn, 2016; Wang, Yu, Lai, \& Zhang, 2016; Sedoc, Preoţiuc-Pietro, \& Ungar, 2017)—a focal change that profoundly benefited from the availability of affective norms developed in psychology labs. Ironically, in NLP, we now face a situation where the enormous interest in analyzing affectively loaded language has led to a proliferation of competing formal representation schemes for affective states whose motivation can be traced in various branches of psychological emotion theory (Valence-only, Valence-Arousal-Dominance, different sets of basic emotions, etc.). Consequently, it has become increasingly difficult to reliably compare the performance of different emotion recognition algorithms (Buechel \& Hahn, 2016).

A possible solution to this dilemma is to elaborate explicit mappings between different representation formats, i.e., to predict the affective norm of a stimulus according to one representation format when the norm is already known in another format (e.g., dimensional and discrete representations; see Figure 1 for a graphical illustration). Not only would this affect formerly incommensurable algorithms but also widely ease the reusability of text collections annotated with different emotional ratings-one of the most important factors for advances given the predominance of training data-dependent supervised machine learning in NLP. In fact, not only computationally focused research would benefit from such mappings but also empirical research in psychology and cognitive science (Stevenson et al., 2007). By that, both the dimensional and the discrete view on emotion would be further integrated so that empirical findings from one view (e.g., regarding priming or memory) could be more directly compared to findings from the other view. Furthermore, existing stimulus sets originally based on one of these approaches could be easily enriched by norms employing other encoding schemes so that researchers could choose from a number of alternative, though mutually translatable emotion representation formats when designing experiments. This outlook becomes even more promising when we take into account the vast number of stimuli sets which bear ratings according to dimensional and discrete formats (see Table 1).

Despite the benefits of transferability, previous work on automatically translating between those formats (in contrast to manual re-annotation) has been relatively rare in the fields of psychology and AI. Stevenson et al. (2007) collected discrete ratings in addition to the dimensional ratings of ANEW. They repeated this effort in a follow-up study for the International Affective Digitized Sounds (IADS) stimulus set (Stevenson \& James, 2008; Bradley \& Lang, 1999b). Performing multiple linear regression between the categories/dimensions of both formats they evaluated the predictive power of the elements of the source representation (dimensions or categories) by the

Figure 1: Affective space spanned by the Valence-ArousalDominance model, together with the position of six basic emotions (as determined by Russell and Mehrabian (1977); figure adapted from Buechel and Hahn (2016)).
statistical significance of their $\beta$-coefficients. They conclude that neither any of the affective dimensions consistently predict (one of the) discrete categories nor can predictions be made the other way round. The findings of Pinheiro et al. (2017) on their own data set of Portuguese sentences, in principle, support this conclusion. The present study differs from these precursors by concentrating on the combined model performance (and not on the contribution of the individual independent variables to $i t$ ).

In contrast with these rather negative interpretations, in AI research, such emotion mappings have already been implemented with quite promising results. Calvo and Kim (2013) presented an algorithm that determines the emotional category of a text based on dimensional word ratings from psychology, using VAD as an interim representation before mapping onto discrete categories. Similarly, Buechel and Hahn (2016) presented a tool for predicting VAD scores from texts which maps their output onto basic emotions using support vector machines. Not only did they achieve highly competitive results regarding their emotion predictions, but they also report on a surprisingly high mapping performance (up to $R^{2}=.944$ when predicting Valence given numerical scores for five basic emotions).

In this contribution, we follow up on this line of research by presenting a series of machine learning experiments that scrutinize the capability of such mapping schemes for textual stimuli. We restrict ourselves to well-known data sets of relatively small size so that the implications of our work can be put into practice without further restrictions (e.g., data limitations in a specific domain). For modeling, we decided to rely on $k$ Nearest Neighbor (kNN) regression because of its simplicity, thus demonstrating that even elementary machine learning methods are sufficient here.

Our experiments fall into three steps. First, we generally demonstrate the feasibility of our approach by examining
the mapping performance between discrete and dimensional emotion formats on two different data sets, an English and a Spanish one. Second, we investigate how well these models generalize over different data sets and languages. In a third step, we examine how well this approach can be ported from psychology to NLP.

## Study A: Mapping within a Stimulus Set

In the first experiment, we examine the capability of machine learning techniques to map dimensional and discrete emotion formats onto each other when training and test data are derived from the same data set.

## Method

Material. We compose two different stimulus sets each receiving dimensional and discrete ratings from individual contributions. The first data set is ANEW which carries norms for Valence, Arousal and Dominance as supplied by Bradley and Lang (1999a); later on Stevenson et al. (2007) added discrete norms for Joy, Anger, Sadness, Fear and Disgust to it. The first half of the second set was originally presented by Redondo et al. (2007) as the Spanish adaptation of ANEW, thus including direct Spanish translations from the original English items. 1,012 of these words overlap with the ones rated by Ferré et al. (2016) according to basic emotions (together forming the second stimulus set). For both the English and the Spanish stimulus set, dimensional ratings were assigned using a 9-point SAM (a set of human-like pictograms displaying different levels of Valence, Arousal and Dominance (Bradley \& Lang, 1994)). For the emotional categories, 5-point scales ranging from not at all to extremely were used. We use mean ratings by all subjects as supplied by the respective authors without performing any further transformation of the data (e.g., re-scaling).
Procedure. We used the R package CARET ${ }^{2}$ to train kNN models in order to map between dimensional and discrete emotion representation schemes. For each dimension/category of the target representation, an individual model was trained given all the dimensions/categories of the source representation as features (e.g., there is one model to predict Anger given Valence, Arousal and Dominance ratings as input). We ran a 10 -fold cross-validation ( $90 \%$ of the data were used for training and hyper-parameter tuning and the remaining $10 \%$ were made available for testing; the process was repeated ten times averaging the results). For the hyper-parameter $k$ a grid search was performed repeating the procedure for each integer in the interval [ 1,100 ]. Consequently, the $k$-values may vary across the individual models. For comparability between different contributions, Pearson's $r$ was used to assess the goodness of the fit.

## Results

Table 2, section "Study A", depicts the results of the crossvalidation (data sets in rows, target dimension/category in

[^39]columns). As can be seen, the results range roughly between $r \approx .73$ up to .97 (both for mapping onto VAD on the English data set). We consider these figures to be surprisingly high, given the small amount of data points we have (from a machine learning point of view) and the elementary model we chose. Henceforth, for comparing correlation coefficients, we use two-tailed $Z$-tests for independent samples (tests for dependent samples are not eligible due to our crossvalidation methodology). We find that mapping from dimensional to discrete ratings performs significantly better on the English data set than mapping the other way round ( $z=2.42$, $p<.05$ ), while the difference in mapping accuracy is not significant regarding the Spanish data $(z=0.74, p \geq .05)$.

Next we compare our model's fit against human reliability. Warriner et al. (2013) replicated the ratings of ANEW finding a correlation of their novel data with the original norms of $r=.953, .759$ and .795 for Valence, Arousal and Dominance, respectively. Thus, on the English data set, computationally mapping discrete emotion norms to dimensional ratings results in a significantly higher correlation with the original values than this replication study regarding Valence and Dominance (Valence: $z=4.1, p<.001$; Dominance: $z=3.1$, $p<.001$ ). For Arousal, the results are not significantly different ( $z=1.72, p \geq .05$ ).

## Study B: Crosslingual Mapping

In our second experiment, we examine in how far the above models generalize over different studies and languages.

## Method

We use the same English and Spanish data sets as for the previous experiments (with both dimensional and discrete ratings). In line with Study A, we train an individual model for each target category/dimension using all dimensions or categories of the source format (discrete or dimensional) as features. The $k$-parameter was chosen according to the highest performance in the 10 -fold cross-validation set-up from the prior experiment. This time, the models were trained on the whole of one data set and then mutually tested on the other one (so that eight models are trained on the English data-one for each dimension/category-and then tested on the Spanish data, and the other way round). Therefore, no cross-validation is necessary. Performance is measured as correlation between predicted and actual values.

## Results

Overall, we find that the models trained on the English data generalize well over the Spanish data and vice versa (see Table 2, Study B). The drops in performance (compared to Study A) regarding the individual dimensions/categories range well below $10 \%$ points. In fact, regarding the average performance of mapping basic emotions onto VAD dimensions, for neither of the two data sets the correlation decreases significantly (comparison relative to the target data; mapping to English: $z=1.46, p \geq .05$, to Spanish: $z=1.6, p \geq .05)$. Regarding the mapping from the dimensional to the discrete

|  | Spanish $\rightarrow$ Spanish | 0.959 | 0.848 | 0.826 | 0.872 | 0.743 | 0.849 | 0.971 | 0.743 | 0.860 | 0.858 |
| B | English $\rightarrow$ Spanish | 0.948 | 0.791 | 0.807 | 0.829 | 0.698 | 0.815 | 0.966 | 0.740 | 0.808 | 0.838 |
|  | Spanish $\rightarrow$ English | 0.948 | 0.831 | 0.855 | 0.841 | 0.772 | 0.850 | 0.963 | 0.715 | 0.795 | 0.825 |
| C | EmoB. $\rightarrow$ EmoB. | 0.738 | 0.481 | 0.674 | 0.559 | 0.348 | 0.560 | 0.788 | 0.227 | 0.412 | 0.476 |
|  | English $\rightarrow$ EmoB. | 0.643 | 0.411 | 0.637 | 0.518 | 0.301 | 0.502 | 0.682 | 0.156 | 0.360 | 0.400 |
|  | Inter-Rater Reliab. EmoB. | 0.599 | 0.495 | 0.682 | 0.638 | 0.445 | 0.572 | - | - | - | - |

format, losses in performance are significant, however, only by a small margin when mapping from Spanish to English ( $z=1.98, p<.05$; to Spanish: $z=2.52, p<.05$ ). Comparing our models to human reliability (see above), we find that, for Valence, the predictions by the models trained on the Spanish data have still a significantly higher correlation with the original norms by Bradley and Lang (1999a) than the reproduced norms by Warriner et al. (2013) $(z=2.81, p<.001)$. For Arousal, the reproduction yields a significantly higher correlation ( $z=2.19, p<.5$ ) while for Dominance the difference is not significant $(z=0.03, p \geq .05)$.

## Study C: Application to NLP Data Set

In the third experiment, we examine whether the mapping approach from the previous two studies translates to a concrete NLP scenario, given the task to automatically enrich existing emotion data sets with complementary emotion formats.

## Method

We here rely on the recently developed EmoBank data set ${ }^{3}$ (Buechel \& Hahn, 2017) which comprises 10k sentences together with their VAD ratings. To the best of our knowledge, EmoBank is the only NLP resource annotated for multiple emotion formats: A subset of 1,192 sentences (English news headlines) has formerly been annotated for six emotion categories on a $[0,100]$ scale by Strapparava and Mihalcea

[^40](2007). We use this subset, first, to train kNN models in a cross-validation set-up (as in study A), and second, to evaluate the performance of the models previously trained on the English stimulus set on these novel ratings (as in Study B).

## Results

This set-up yields three main results. First, the overall mapping performance drops sharply compared to the former two studies. Comparing the cross-validation performance of our models from the English stimulus set (Study A) with those of the EmoBank data (Table 2, Study C), we find a considerable decrease in correlation of about 35 percentage points (comparing average correlation coefficients for basic emotions and VAD; $z=15.99$ and 16.21, respectively, $p<.001$ ).

In contrast to these mediocre results, the second main finding can be summarized such that our performance does only decrease by a small margin when the models are not trained on EmoBank but on the English stimuli from Study A (comprising words instead of headlines and gathered with a dissimilar methodology; first $v s$. second line of Table 2, Study C). For mapping onto VAD, the drop is still statistically significant ( $z=2.11, p<.05$ ) while for mapping onto BE it is not ( $z=1.82, p \geq .05$ ). This suggests that, although our approach works better for lexical data gathered in psychological settings than for headlines annotated in NLP frameworks, the models still generalize well in the sense that one can apply models trained on the former to the latter without sacrificing a lot of performance.

Even more surprisingly, our third main finding is that our approach still performs very well compared to human reliability (see bottom row of Table 2). Inter-rater reliability is reported by Strapparava and Mihalcea (2007) as the correlation of one rater with the mean judgment of the remaining raters averaged over all raters. Therefore, the output of our models can be cautiously compared against these reliability values. In this setting, we find no significant difference regarding the average over the basic emotions ( $z=0.4, p \geq .05$ ). We carefully interpret this observation to indicate that our output correlates with the aggregated rating of several subjects about as good as an average human does. Thus, consistent with our findings from Study A and B, our approach appears to perform comparably to human subjects and, in fact, even predicts normative Joy ratings significantly better $(z=6.02, p<.001)$. This suggests that the performance drop highlighted as the first main finding might point at different levels of data quality rather than taking this as evidence that our approach might be unsuitable for NLP data (we will get back to this issue in the subsequent discussion section).

## General Discussion

We presented a series of experiments in which we examined the level of performance that can be achieved for mapping emotion ratings onto each other following the dimensional or the discrete representation format for the case of textual stimuli. To make our work more informative in terms of immediate reusability, we limited ourselves to employing relatively small and commonly used data sets, as well as elementary machine learning techniques.

In study A, we took into account two data sets from psychology, an English and a Spanish word stimulus set, each one bearing dimensional and discrete emotion ratings. On both sets, the mapping performance was surprisingly high. When comparing our prediction accuracy to a reassessment study of the English norms with human subjects, we found that our predicted values yielded significantly higher correlation with the original ratings than the novel reproduction regarding two of the three VAD dimension. This astonishing result suggests that given affective ratings in one format, ratings for the complementary emotion format can be computationally induced at a human level of reliability.

Study B goes beyond these considerations by asking how well these models generalize over different data sets with focus on different languages. The observation that the decrease in average mapping performance is only statistically significant in half of the cases suggests that the models generalize well over different (European) languages. However, it must be taken into account that the English and Spanish data sets are direct translations of each other regarding their raw data, possibly boosting the pairwise reusability of the models.

In Study C, we investigated a realistic usage scenario for our approach. Instead of lab data sets typically used in psychology, we here focused on a recently developed corpus of real-world news headlines, again annotated for both emo-
tional dimensions and categories. This set-up yielded three results. First, compared to the former studies, we found a strong decrease in overall mapping performance. Second, the difference between the models directly trained on these data and the ones transfered from Study A were quite small (not even significant for mapping onto BEs). And third, our data suggest that our approach is on par with human annotation performance, despite the overall drop in mapping accuracy.

A possible explanation for this somewhat inconsistent behavior could be that, while the psychological data sets consist of word stimuli with explicit selection criteria, EmoBank comprises "real-world" language data (news headlines instead of individual words). Thus, subjects can interpret these stimuli in a greater number of ways and may also be more strongly affected by biases from, e.g., political orientation or personal biography. In addition, the stimuli from Studies A and $B$ have typically received a greater number of individual ratings which makes their aggregation potentially more reliable (i.e., less noisy in terms of training data).

Besides the above considerations, the results from Study C actually support the flexibility of the approach outlined here. Especially the observation that our models for mapping existing annotations operate about as accurately as a single human rater freshly annotating new raw data suggests that soon we may be able to fully automatically translate affective norms in terms of VAD to basic emotions and vice versa.

In conclusion, the experiments we presented here clearly demonstrate the power as well as the possible impact of our (still rather simple) set-up. The perspective of being reliably able to map back and forth between those popular emotion formats could not only lead to an improved availability of emotionally rated data sets in psychology and NLP. In addition, it may promote the integration of both views on emotion in psychological theory. Despite only presenting evidence from textual stimuli, we suggest that our approach may work for other modalities (and possibly across modalities) as well because no linguistic information was used for the prediction. We will address this conjecture in future work.

## Acknowledgments

We would like to thank the anonymous reviewers for their thoughtful suggestions and comments.

# Maintenance of Perceptual Information in Speech Perception 

Wednesday Bushong (wbushong@ur.rochester.edu)<br>Department of Brain and Cognitive Sciences, University of Rochester<br>T. Florian Jaeger (fjaeger@ur.rochester.edu)<br>Department of Brain and Cognitive Sciences, University of Rochester

#### Abstract

Acoustic and contextual cues to linguistic categories (e.g., phonemes or words) tend to be temporally distributed across the speech signal. Optimal cue integration thus requires maintenance of subcategorical information over time. At the same time, previous work suggests that finite sensory memory or processing capacity strongly limits how much subcategorical information can be maintained (or for how long). We argue that previous work might have over-interpreted the role of these limitations. In two perception experiments, we find no limit in the ability to maintain subcategorical information. We also find that maintenance seems to be the default, neither limited to perceptually particularly ambiguous signals, nor a learned strategy specific to our experiment. In contrast, listeners' decision for how long to delay categorization, we find, is a function of perceptual ambiguity. It is therefore crucial to distinguish between in-principle abilities (even when they reflect default processing), and decisions made within the bounds of those abilities.

Keywords: linguistics; cognitive science; speech recognition; language comprehension

## Introduction

One of the most fundamental problems of auditory processing is the transient nature of the acoustic signal; the systems underlying speech perception receive large amounts of information every second. The bounds of sensory memories thus create a pressure to incrementally infer abstract linguistic categories (e.g., phonemes and words) from the auditory signal before that information becomes unavailable.

However, much of the information relevant to inferring a particular part of the auditory signal, for example a segment (phoneme), is not contained on the segment itself. For example, one of the main cues to coda stop voicing is duration of the previous vowel (Klatt, 1976). Thus, in order to successfully resolve the voicing of a coda stop, listeners must maintain information about the previous vowel and integrate it with the evidence they receive later. This is opposed to a scheme where the listener removes information about the previous vowel and only maintains some abstract categorical representation that does not include duration information.

Previous work suggests that listeners can indeed maintain and use subcategorical information at least at short timescales. In a classic study, Ganong (1980) found that lexical constraints can influence the perception of a word-initial sound: sounds varying on the $/ \mathrm{d} /-/ \mathrm{t} /$ continuum are perceived to be more /d/-like when presented before "ash" (dash is a word while tash is not). More evidence that subcategorical information is maintained within a word comes from eyetracking studies: McMurray, Tanenhaus, and Aslin (2002) found that listeners looked to competitor items like "bear"
and "pear" gradiently according to voice onset time (VOT), the cue that distinguishes $/ \mathrm{b} /$ and $/ \mathrm{p} /$, suggesting that subphonemic information is maintained and used in higher-level processes (for a review of related work, see Dahan, 2010).

However, there are other possible sources of information that follow a target segment or word that occur much later downstream. For example, persevatory co-articulation might spread information over following syllables (Magen, 1997). The identity of later segments might also contain information about earlier segements because of phonotactic dependencies within and across syllables. Even context beyond word boundaries regularly contains information that can help to resolve uncertainty about the input.

A small literature has investigated the extent to which listeners can maintain subcategorical information at longer distances across the word boundary. In a classic study, Connine, Blasko, and Hall (1991) tested whether listeners could maintain subcategorical information about a segment 3 syllables or 6-8 syllables downstream. Participants listened to sentences like "When the ?ent in the fender was well camouflaged, we sold the car." and judged whether the word they heard was tent or dent. The ? represents a sound that varied along VOT, the primary cue distinguishing between $/ \mathrm{t} /$ and $/ \mathrm{d} /$. In this example, the later word fender semantically biases interpretation of the target word to be dent. If listeners can maintain information about the identity of the ?-segment, they should integrate the biasing context into their decisions. Connine and colleagues reported two important findings, both of which have recently been revisited.

First, participants maintained subcategorical information about the ?-segment for 3 syllables: responses reflected both the specific VOT of the segment and the contextual bias. After 6-8 syllables responses reflected only VOT, but not biasing context. This finding is often interpreted to demonstrate the limits of subcategorical information maintenance. However, participants were allowed to respond at any point during the sentence; in fact, in the 6-8 syllables condition, participants responded before even hearing biasing context $84 \%$ of the time. This leaves open whether participants could not maintain subcategorical information for longer periods of time, or chose to respond early for other reasons.

Secondly, Connine and colleagues report that the context effect was only reliably present at ambiguous VOTs: sounds that were perceptually unambiguously /t/ or /d/ were not integrated with later context. This has been taken to mean that even information maintenance of up to 3 syllables is limited to the special case of perceptually highly ambiguous per-
cepts. This second conclusion, too, however, has to be interpreted with caution. Connine and colleagues measured the context effect in proportion of $/ \mathrm{t} / \mathrm{vs}$. /d/ responses. This is problematic (see also Jaeger, 2008): a context effect that is identical across all VOTs when measured in log-odds-i.e., equally large for perceptually clear and perceptually ambiguous VOTs-will results in smaller or insignificant context effects for perceptually clear VOTs when measured in proportions. Crucially, there are a priori reasons to believe that the effect should be constant in log-odds (Bicknell, Jaeger, \& Tanenhaus, 2016). The analysis conducted by Connine and colleagues thus leaves open whether subcategorical information maintenance is limited to special cases.

A recent study, Bicknell et al. (2016), revisited both of these problems. Bicknell and colleagues replicated Connine et al. (1991) with one minor change to procedure. Participants were required to wait until the end of the sentence to respond, ensuring that they heard the biasing context. Unlike in the original study, Bicknell et al. (2016) analyzed the log-odds of responding /t/ vs. /d/ and found that listeners maintained subcategorical information for both the 3 and 6-8 syllable conditions (see also Szostak \& Pitt, 2013 for similar results in a different phonetic contrast). This suggests that there may be an important distinction between listeners' ability to maintain subcategorical information and when listeners decide to respond.

The idea of a distinction between in-principle abilities and the decision process motivates the present experiments. Our first goal is to replicate the between-experiment comparison across Bicknell et al. (2016) and Connine et al. (1991) within the same paradigm. Anticipating our result, we indeed replicate the contrast, showing that it is important to distinguish between the ability to maintain information and the decision to provide a categorization response. Given that listeners sometimes choose to make a response before receiving additional semantic information, we ask whether subcategorical information maintenance is a default strategy employed by listeners or is specific to experience in our task. Finally, we ask what influences the decision process by investigating the role of perceptual ambiguity on when participants choose to make a response.

In order to answer these questions, we conducted a webbased experiment that closely followed the paradigm of Connine et al. (1991) and Bicknell et al. (2016). Betweenparticipants we manipulated only one aspect of the procedure, holding everything else constant. In the forced-response group of participants, they were required to wait until the end of the sentence before making a response. In the freeresponse group, they could make a response whenever they wanted during the sentence. The forced-response group gives us insight into the ability to maintain subcategorical information. The free-response group allows us to ask what drives listeners' decisions to categorize.

| Context | Distance | Sentence |
| :--- | :--- | :--- |
| Tent-biasing | Near (3 syllables) | When the $[\mathrm{t} / \mathrm{d}]$ ent in the <br> forest was .. |
| Dent-biasing | Near (3 syllables) | When the $[\mathrm{t} / \mathrm{d}]$ ent in the <br> fender was ... |
| Tent-biasing | Far (6-8 syllables) | When the $[\mathrm{t} / \mathrm{d}]$ fent was <br> noticed in the forest, ... |
| Dent-biasing | Far (6-8 syllables) | When the $[\mathrm{t} / \mathrm{d}]$ ent was <br> noticed in the fender, ... |

Table 1: Example stimuli from the experiment in each biasing context and distance condition.

## Experiment

## Participants

We recruited a total of 96 participants from Amazon Mechanical Turk ( 48 for the forced-response group, 48 for the freeresponse group). Participants were awarded $\$ 3.00$ for their participation in a 30 -minute experiment.

## Materials

Materials were identical across the two participant groups and were modeled on Connine et al. (1991). Table 1 shows example sentences in each context and distance condition. We manipulated context (tent-biasing vs. dent-biasing), distance (near, 3 syllables vs. far, 6-8 syllables), and VOT (10, 40, 50, 60,70 , and 85 ms ). We chose our range of VOTs based on simulation-based power analyses so as to maximize statistical power to assess the size of the context effect across the VOT continuum, while also ensuring that there were a range of perceptually ambiguous and unambiguous sounds (based on the VOT distributions of our recording speaker). Seven different sentence frames were constructed. Each participant heard each sentence frame in each of the context, distance, and VOT condition combinations, resulting in a total of 168 sentences in the experiment.

## Procedure

Participants were instructed to listen to the sentence and report whether they heard tent or dent. In the forced-response group, participants were instructed to wait until the end of the sentence to make a response. In the free-response group, participants were instructed that they could respond whenever they wish during the sentence after hearing the critical word.

## Data Exclusions

We excluded participants who showed no main effect of VOT on their responses from further analysis. That is, these were participants who did not increase their /t/ responses as VOT increased, suggesting that they had faulty audio equipment, did not understand the task, or were otherwise not paying attention. In the forced-response group, this resulted in the removal of nine participants (18.75\%) from analysis. In the free-response group, eleven participants ( $22.92 \%$ ) were removed. These exclusions hold across all analyses below.

Figure 1: Proportion /t/ responses by biasing context condition for both groups of participants. Error bars are 95\% confidence intervals over subject means. See text for discussion of subset vs. all trials.

Figure 2: Size of context effect in log-odds space at each VOT for each group as estimated by our simple effects mixed models. Error bars are $95 \%$ confidence intervals.

## Analysis 1: Limits of Subcategorical Information Maintenance

## Analysis

Analyses 1 and 2 are based on the same mixed-effects regression, analyzing the proportion of $/ \mathrm{t} /$ responses as a function of VOT (a continuous variable), context, distance, trial number, and their interactions. We included random slopes for context and distance by participants and items (due to data sparsity and the consistency of the VOT effect across participants and items, we did not use the maximal random effects structure; see Bates, Kliegl, Vasishth, \& Baayen, 2015). Different predictors in this model answer different questions. In Analysis 1, we focus on the overall effect of context and its interactions with VOT and distance.

In addition to the model described above, in Analysis 1 we also fit a second model which assessed the relative magnitudes of the effect of context at each VOT while removing the potentially problematic assumption that VOTs are related linearly to the log-odds of /t/responses. This was achieved by recoding the model so as to assess the simple effects of context at each level of VOT. This analysis does thus not a priori assume any specific relation between VOTs and /t/ responses.

For each model of the free-response group, we present two analyses. First, we analyzed only the trials on which participants responded at least 200 ms after offset of the biasing context. This allows a direct comparison with the forced-
response group, where participants always responded after hearing the biasing context by design. Second, we also conducted the same analyses using all of the data in the freeresponse group in case these data are more comparable.

## Results

Figures 1 and 2 summarize the context effect results of both groups. We found a main effect of VOT on /t/ responses (forced-response: $\hat{\beta}=0.18, p<0.001$, free-response subset: $\hat{\beta}=0.13, p<0.001$, free-response all trials: $\hat{\beta}=0.16, p<$ 0.001 ). We also found a context main effect (forced-response: $\hat{\beta}=1.11, p<0.001$, free-response subset: $\hat{\beta}=2.08, p<$ 0.001 , free-response all trials: $\hat{\beta}=1.62, p<0.001$ ). In the forced-response group and the subset of trials in the freeresponse group where participants responded after biasing context, there was no interaction between context and distance (forced-response: $\hat{\beta}=-0.09, p=0.57$, free-response: $\hat{\beta}=0.18, p=0.38$ ). When we analyzed all trials of the freeresponse group, there was a context x distance interaction such that the context effect was smaller in the far condition ( $\hat{\beta}=-0.39, p=0.02$ ).

A simple effects analysis revealed that the effect of context was significantly positive at $50 \mathrm{~ms}, 70 \mathrm{~ms}$, and 85 ms VOT in both groups ( $\hat{\beta} s=0.58-1.95, p \mathrm{~s}<0.05$ ). In the freeresponse group, the context effect was also significant at all other VOTs (subset: $\hat{\beta} s=0.93-2.23, p s<0.01$, all trials: $\hat{\beta} s=0.61-1.97, p s<0.05)$. In the forced-response

Figure 3: Interaction between context effect over trial for both groups of participants.
group, the context effect was marginal at 40 ms and 60 ms VOT ( $\hat{\beta} s=0.87,0.47, p s=0.06,0.08$ ), and not significant at $10 \mathrm{~ms} \operatorname{VOT}(\hat{\beta}=-0.42, p=0.5)$.

## Discussion

Replicating both Connine et al. (1991) and Bicknell et al. (2016), we found that listeners have the ability to maintain subcategorical information well beyond the word boundary. When forced to wait, participants' responses reflected both the VOT and the contextual bias even at the longest delay tested (replicating Bicknell et al., 2016; Szostak \& Pitt, 2013). Interestingly, the effect of context seemed more or less constant across the entire range of VOTs tested in both groups. This is exactly as expected by an ideal observer that integrates the perceptual signal with context (Bicknell, Bushong, Tanenhaus, \& Jaeger, in preparation). It also suggests that listeners do not necessarily limit the maintenance of subcategorical information to perceptual inputs that are perfectly ambiguous. Instead, it seems listeners maintain subcategorical information even when the perceptual input is already rather unambiguous ${ }^{1}$.

When participants were free to choose when to respond, however, we found an interaction between context and distance, such that the context effect was smaller at longer timescales. This would suggest that participants were deciding to respond before hearing biasing context: indeed, the free-response group responded before biasing context on $32 \%$ of far trials and $0.5 \%$ of near trials (a point we return to in Analysis 3).

Analysis 1 leaves open whether this tendency to maintain subcategorical information is a strategy participants adopt specifically for this experiment, rather than reflecting a more general property of speech perception. Analysis 2 begins to address this question by investigating the context effect across trials.

[^41]
## Analysis 2: Subcategorial Information Maintenance: Experimental Artifact or Default Behavior?

We analyze changes in the effect of context over the course of the experiment in both groups. If we observe an effect of context from the very beginning of the experiment, this suggests that listeners maintain subcategorical information by default. On the other hand, if we observe no context effect until later in the experiment, this suggests that listeners have learned to maintain subcategorical information.

## Analysis

We used the same logistic regression model from Analysis 1 and focus on the effects of context, trial, and their interaction. Trial was coded so that the coefficient estimate for context reflects the context effect at the very first trial (by subtracting 1).

## Results

Figure 3 shows the context effect over trials in both groups of participants. The context effect was significant from the very first trial of the experiment (forced-response: $\hat{\beta}=$ $1.11, p<0.001$, free-response subset: $\hat{\beta}=2.08, p<0.001$, free-response all trials: $\hat{\beta}=1.62, p<0.001$ ). We found a significant negative interaction between context and trial for both groups of participants (forced-response: $\hat{\beta}=-0.004, p<$ 0.001 , free-response subset: $\hat{\beta}=-0.009, p<0.001$, freereponse all trials: $\hat{\beta}=-0.004, p<0.001$ ).

## Discussion

Particpants in both experiments exhibited clear context effects right from the beginning of the experiment. This suggests that participants have the ability to maintain subcategorical information without requiring extensive exposure to a particular task. We also found a negative context by trial interaction, such that the context effect got smaller over the course of the experiment. This could mean that participants maintain subcategorical information to a lesser extent as time goes on (e.g., because of fatigue or boredom with the task). Alternatively, participants may still be maintaining subcategorical information but may rely less on context during their
decision making process, and use VOT more (e.g., because participants become more certain of the talker-specific VOT distribution, cf. Kleinschmidt \& Jaeger, 2015).

## Analysis 3: Strength of Perceptual Evidence and Decision to Categorize

Although maintenance of subcategorical information seems to be a default strategy among participants, the context by distance interaction in the free-response group in Analysis 1 suggests that participants did not necessarily wait for biasing context to make their responses.

This raises questions about what determines when listeners provide a categorization response. If listeners have enough perceptual evidence to confidently make a categorization, they may tend to respond early rather than waiting for the biasing context that provides additional information about the identity of the segment (note that this leaves open whether listeners maintain subcategorical information beyond this point; we return to this below). To answer this question, we analyze when participants in the free-response group made responses, and whether this was dependent on the perceptual ambiguity of the stimulus.

## Analysis

We used mixed-effects logistic regression to analyze the proportion of responses before biasing context as a function of perceptual ambiguity and distance. For each trial, we coded whether the participant responded before or after having heard biasing context (defined as 200 ms after biasing word offset to account for motor planning). To estimate (subjective) perceptual ambiguity, we compute the distance (in probability space) of each VOT from the maximally unambiguous point based on average response probabilities ${ }^{2}$. If strength of perceptual evidence affects when listeners make a decision before obtaining more information (provided by the biasing context), we should see more responses before biasing context for less ambiguous stimuli.

## Results

Figure 4 shows proportion of responses before biasing context by perceptual ambiguity of the stimulus. We found a significant effect of ambiguity ( $\hat{\beta}=-4.06, p=0.006$ ), such that participants were less likely to respond before biasing context when the perceptual stimulus was more ambiguous. We also found a main effect of distance ( $\hat{\beta}=6.93, p<0.001$ ) such that participants were more likely to respond before biasing context when it occurred 6-8 syllables away from the target word than when it occurred 3 syllables away. We additionally found a main effect of VOT such that participants were less likely to respond before biasing context as VOTs became longer ( $\hat{\beta}=-0.007, p<0.001$ ). There were no other main effects or interactions.

[^42]

Figure 4: Proportion of responses before biasing context by perceptual ambiguity. Error bars are $95 \%$ confidence intervals.

## Discussion

We found that participants were more likely to respond before hearing biasing context when the perceptual signal was less ambiguous, and when biasing context appeared farther away from the target word. We also found a main effect of distance: participants were more likely to respond before biasing context when it occurred farther away from the target word. These results suggest that while listeners have the ability to maintain subcategorical information for unambiguous stimuli over long distances, when given a choice listeners decide to respond earlier when they have stronger perceptual evidence for categorization.

## General Discussion

Together, our results suggest that in principle, listeners can maintain subcategorical information well beyond word boundaries. Listeners seem to do so by default, and both for ambiguous and unambiguous percepts. This suggests that the limits of listeners ability to maintain subcategorical information are less strict than previously assumed (Connine et al., 1991; Christiansen \& Chater, 2016). At the same time, listeners do not wait arbitrarily long for additional informative context. When given the opportunity, listeners responded on $16 \%$ of all trials before additional context could aid recognition. Critically, listeners' decisions to respond early were not arbitrary, but rather systematically conditioned on the ambiguity of the perceptual input: listeners were more likely to respond before biasing context when the perceptual signal was less ambiguous. This strategy seems to vary little across participants.

Three questions stand out to us as requiring further attention. First, importantly, little is known about what kind of information is being maintained. It is possible that listeners retain a rich representation of the original percept, some more abstract representation of their certainty in the identity of the segment, or something in between.

Second, it is unclear what becomes of these representations after listeners make a perceptual decision. It could be the case that the maintenance process and decision-making process are dependent on or independent of each other. The large literature on exemplar-based approach to speech perception suggests that exemplars are stored and used later in speech perception (Hay \& Drager, 2010; Strand \& Johnson, 1996; Goldinger, 1997). The apparent storage of this low-level information in long-term memory is puzzling if there are strict limitations on the amount of information that can be maintained during speech perception-a paradox that has, to the best of our knowledge, received surprisingly little attention.

Third, we found evidence that the maintenance of subcategorical information in the present experiments does not seem to be learned over time in a task-specific manner. It is, however, an open question whether listeners can flexibly adapt the degree to which (or duration for which) they maintain subcategorical information, depending on their goals or the structure of the current task. Such flexibility would suggest that listeners' decisions about at which point to categorize input might more often be constrained by the goal to quickly infer the meaning-bearing message, rather than being constrained by strong limits of perceptual memory. For example, it is possible that the limits (or lack thereof) of maintenance observed in experiments like ours (and a large body of previous work; for review, see Dahan, 2010) reflect participants' beliefs based on previous experience about the expected utility of delaying categorization. In that case, listeners might adapt these beliefs after exposure to stimuli that contain or do not contain helpful contextual information.

#### Abstract

The estimation of duration has been shown to follow Bayesian inference, where people use their prior belief to calibrate the estimation. This explains timing biases such as the range bias where a duration is reproduced as longer when previously encountered durations were longer than shorter. However, it is unclear whether prior belief is based on previously perceived or reproduced durations. In 4 experiments, we show that the range bias occurs between short and long reproduction ranges but not between short and long perception ranges. Further analyses also show that the prior is updated by the most recent reproduced (but not perceived) duration. Together these results support a task-oriented Bayesian inference account of time reproduction, where people use the perceived duration and their past reproduction experience to make an inference about how much time to reproduce.

Keywords: time perception; Bayesian inference; memory; psychophysics

## Introduction

The mind is good at estimating quantitative dimensions of the physical world: we are able to estimate how much time has elapsed, how much distance has been traveled, how large an area is, etc. Indeed, our superb capacity to quantify things enables us to better adapt to the environment. However, these quantitative intuitions are not without errors. Systematic biases in human magnitude estimation have been identified (for reviews see Poulton, 1979, and Petzschner, Glasauer, \& Stephan, 2015). Of these, the most robust is probably the bias of central tendency (Hollingworth, 1910), a phenomenon which has also been known by a variety of other names (e.g., contraction, regression effect, regression toward the mean). Central tendency refers to the observation that people tend to make estimates closer to the mean of the magnitudes to be estimated, leading to the (relative) overestimation of lower magnitudes in the stimulus set and underestimation of higher magnitudes. A central tendency bias has been observed in the estimation of distance (Jou et al., 2004; Radvansky et al., 1995), brightness (Fotios \& Cheal, 2007), weight (Jones \& Hunter, 1982), and loudness (Algom \& Marks, 1990), to mention a few. In particular, the central tendency bias has been most often observed in the estimation of time intervals, with the tendency for people to relatively overestimate shorter durations and underestimate longer durations (Bausenhart, Dyjas, \& Ulrich 2014; Gu \& Meck, 2011;

Jazayeri \& Shadlen, 2010; Lejeune \& Wearden, 2009; Moon \& Anderson 2013). More interestingly, as a result of the central tendency bias, a stimulus duration tends to be reproduced as longer if it occurs as a member of a longer range (e.g., 1000 ms in the range of $847-1200 \mathrm{~ms}$ ) than as a member of a shorter range ( 1000 ms in the range of 671 1023 ms ) (Jazayeri \& Shadlen, 2010), a phenomenon which we refer to as the range bias.

Jazayeri and Shadlen (2010) argue that the central tendency and the range bias occur because time estimation follows Bayesian inference: as memories of durations (indeed magnitudes in general) are inherently noisy (Gallistel \& Gelman, 2000), people resort to their prior belief about how likely a duration is in order to calibrate their estimate of the magnitude of a perceived duration. In Bayesian inference, a posterior belief is the product of the "likelihood" (reflecting the variability of perceptions of a given duration) and the prior, and this posterior (the estimated duration) is necessarily pulled toward the mean of the prior distribution (e.g., the midpoint of experienced durations), hence the central tendency and the range bias. Such a Bayesian inference account of timing has been endorsed in many subsequent related research on timing behaviour, e.g., animal timing ( Li \& Dudman, 2014), time prediction (Griffiths \& Tenenbaum, 2011; Di Luca \& Rhodes, 2016) and delay discounting (McGuire \& Kable, 2012) (see Shi, Church \& Meck, 2014, for a review). Indeed, Petzschner et al. (2015) argue that Bayesian inference is used in estimating all kinds of physical magnitudes and can accommodate a wide range of behavioural effects in magnitude estimation, central tendency included.

A common assumption in Bayesian accounts of timing (and indeed magnitude estimation in general) is that people make an optimal estimate about how long the perceived duration is by incorporating their belief about how likely a duration is as a function of previously presented magnitudes; in a time reproduction task, they then reproduce an amount of time to match this estimate (Cicchini et al., 2012; Jazayeri \& Shadlen, 2010; Di Luca \& Rhodes, 2016). These accounts thus assume that the estimation of a perceived duration makes reference to the previously perceived durations.

However, these accounts ignore another source of information that participants can rely upon when trying to optimally reproduce durations, i.e. their past experience with
reproduced durations．According to this alternative account， instead of making an estimate of a perceived duration and then use this estimate to guide time reproduction，people directly make an estimate about how long the reproduced duration should be．In this task－oriented inference，people make use of their past reproduction experience rather than their past perception experience；after all，when one is to reproduce a duration，the history of the reproduced durations may provide a better constraint for optimally determining how much time to reproduce．

The current study investigates whether people resort to previous perception or reproduction experience as the prior in their inferences．To do so，we take advantage of the range bias（a duration is reproduced as longer if it is placed in a context of long than short stimulus durations）．If people use their perception experience to calibrate their time estimation， then we should expect the range bias to occur between contexts of long vs．short perceived durations，even when the context of reproduced durations is kept constant．If instead people use their reproduction experience in their inference， we should expect the range bias to occur between contexts of long vs．short reproduced durations，even when the context of perceived durations is kept constant．

## Experiment 1

## Methods

Participants． 32 volunteers（ 24 females， $20.3 \pm 1.6$ in age） from the South China Normal University community volunteered for a small monetary reward．Participants in this experiment（and indeed in each experiment reported here）did not take part in any other experiment，though participants for all the experiments came from the same participant pool． These participants（and also those in other experiments）had normal or corrected－to－normal vision and received a small monetary reward for their participation

Design．We manipulated the reproduction context while keeping the perception context constant．To do this，we used an alternative－task paradigm where participants perceived a duration and then，upon a cue，either reproduced the stimulus duration or compared it to a new duration．Participants were presented with a set of short durations（ $600-2200$ in steps of 200 ms ）a set of long durations（ $1800-3400$ in steps of 200 ms ），all interleaved．Half of the participants reproduced the short durations and compared the long durations；the other half did the opposite（i．e．reproducing long durations and comparing short durations）．Note that，in such a design，while the two groups of participants differed in their reproduction contexts，they had identical perception contexts．Critically， the two reproduction contexts overlapped in three stimulus durations（ $1800,2000,2200 \mathrm{~ms}$ ），which allowed us to determine whether different reproduction contexts lead to a range bias，even when the perception context was kept constant．

Materials．For each of the 18 durations，a shorter（ 0.1 log shorter）and a longer（ 0.1 log longer）comparison duration was created．Each participant completed 5 blocks of trials．In
each block，every stimulus duration was presented twice， either both as reproduction or comparison trial．Half of the comparison trials used a shorter comparison duration and the other half had a longer one．Trials in each block were presented in an individually randomized order．In total，there were 180 experimental trials．

Procedure．The experiment was run on a desktop using E－ Prime 2．0．Participants sat about 50 cm away from the monitor．The experiment began with a practice session of 4 trials（ 2 reproduction and 2 comparison trials）followed by the main experiment．In a trial，a black cross（Courier New 48）was presented for a stimulus duration，followed by a blank screen of 300 ms ．Then，a cue（an asterisk＂＊＂or the phrase＂第二段时间＂，meaning＂second duration＂）was presented．An asterisk informed participants to reproduce the stimulus duration by holding down the spacebar for the same duration．At the press of the spacebar，the asterisk turned into three asterisks which remained on screen until the release of the spacebar．The phrase＂第二段时间＂informed participants to compare the first（stimulus）duration with an upcoming（comparison）duration．The text cue stayed on screen for 1 s and was replaced by a blank screen of 300 ms ． The comparison duration was then presented with a blue cross（Courier New 48），followed by a blank screen of 300 ms．Then a judgment screen was displayed asking participants to decide whether the first（stimulus）or second （comparison）duration was longer by pressing the＂ F ＂or＂ J ＂ key．

Fig．1．Results of Experiment 1．Each dash represents a participant＇s averaged reproduction for each stimulus duration in the long（red）or short（blue）reproduction context； the squares represent the averaged reproductions at the group level．

## Results and discussion

As the comparison data does not address our theoretical interest，to save space，we only report analyses on the reproductions．We first excluded as outliers reproductions that were $1 / 3$ or 3 times the stimulus duration，leading to the loss of $2 \%$（ 65 reproductions）of the data（this trimming
criterion was adopted for all experiments reported in this study). For the remaining data, a participant's mean reproduction for each stimulus duration was computed. We compared reproductions for the three overlapping stimulus durations ( 1800,2000 , and 2200 ms ) between the two reproduction contexts. An ANOVA with reproduction context as a between-participant factor and stimulus duration as a within-participant continuous variable revealed a significant main effect of reproduction context $\left(F_{(1,30)}=\right.$ 12.41, $p=.001, \eta^{2}=.29$ ): durations were reproduced for longer in the long than the short reproduction context (see Fig. 1). Reproduced durations increased as a function of the stimulus duration $\left(F_{(1,30)}=72.03, p<.001, \eta^{2}=.71\right)$ and did not significantly interact with reproduction context $\left(F_{(1,30)}=\right.$ $\left.1.44, p=.240, \eta^{2}=.05\right)$.

The main effect of reproduction context suggested a range bias in the reproduction of the overlapping durations: even when the perception context was kept constant, durations were reproduced as longer when prior reproductions were longer. Such a reproduction range bias is inconsistent with previous Bayesian inference accounts which posit that, to estimate a duration, people use their memory of the perceived duration and experience of previously perceived durations. Instead, the results suggest that people make use of their experience of previously reproduced durations in order to calibrate their reproductions.

In Experiment 2, we aimed to replicate the reproduction range bias using a within-participant design. In particular, we distinguished the long and short reproduction contexts using different modalities of reproduction: for half of the participants, people reproduce long durations with motor reproduction and short durations with an auditory reproduction (see below); for the other half, the paring was reversed. If reproduction experience calibrates duration reproduction, we should again expect a range bias for overlapping durations between the two reproduction contexts.

## Experiment 2

## Methods

Participants. 20 volunteers ( 10 females, $20.8 \pm 2.5$ in age) took part in the experiment.

Design. This experiment was similar to Experiment 1 except that we replaced the comparison task in Experiment 1 with an auditory reproduction task (and we manipulated reproduction task within-participants). As in Experiment 1, there were two duration ranges (short range: $600-2200$ in steps of 200 ms ; long range: $1800-3400$ in steps of 200 ms ). Two experimental versions were created such that one version had the short range paired with motor reproduction and the long range with auditory reproduction and the other version had the reverse. As in Experiment 1, we were interested whether people would be susceptible to the reproduction range bias when reproducing the overlapping durations (i.e. 1800,2000 and 2200 ms ) under different reproduction contexts.

Materials. As in Experiment 1, there were 5 blocks of trials and each block contained two occurrences of each of the 18 stimulus durations (i.e. 36 trials in each block). Trials in each block were presented in an individually randomized order. For auditory reproduction, a 10 s sine-wave pure tone sampled at a rate of 44100 Hz was created using Audacity.

Procedure. The experimental setting and overall experimental procedure were the same as those in Experiment 1, except that participants always reproduced a stimulus duration. After a cross was presented for a stimulus duration, followed by a blank, an image of a keyboard (as a cue for motor reproduction) or a mouse (as a cue for auditory reproduction) was displayed. For motor reproduction, as in Experiment 1, participants held down the spacebar to reproduce the stimulus duration. For auditory reproduction, participants clicked the mouse (at which point the mouse image disappeared) to initiate a tone and clicked again to terminate it when they felt that tone had been played for the same length as the stimulus duration. The experiment lasted for about 25 min .

Figure 2. Results of Experiment 2. Each dash represents a participant's averaged reproduction for each stimulus duration in the long (red) or short (blue) reproduction range; the squares represent the averaged reproductions at the group level.

## Results and discussion

About 6\% (216 reproductions) of the data were excluded as outliers (the high exclusion rate was due to the fact that participants sometimes accidentally pressed rather than held down the spacebar due to the influence of the auditory reproduction method). For the overlapping durations, an ANOVA using reproduction context and stimulus duration as within-participant variables reveals a significant main effect of reproduction context $\left(F_{(1,19)}=27.73, p<.001, \eta^{2}=.59\right)$, with longer reproductions of the overlapping stimulus durations in the long compared to the short reproduction context. Reproductions also increased as a function of stimulus duration $\left(F_{(1,19)}=131.5, p<.001, \eta^{2}=.87\right)$. There was no significant interaction between reproduction context and stimulus duration $\left(F_{(1,19)}=0.13, p=.724, \eta^{2}=.01\right)$.

The results thus replicated, with a within-participant design, the finding in Experiment 1 that reproduction experience calibrates duration reproductions. That is, a duration was reproduced as longer if it was done in the context of long reproductions compared to short reproductions. They also suggest that people construct taskspecific priors (i.e. past motor vs. auditory reproduction experience in the current experiment) in their time estimation, an issue that awaits further empirical verification.

In Experiment 3, we further explore whether manipulating the perception context alone leads to a range bias. If reproduction experience, but not perception experience, calibrates reproduction, we should not see a range bias in this experiment.

## Experiment 3

## Methods

Participants. 20 volunteers ( 14 females, $20.0 \pm 1.2$ in age) took part in Experiment 3.

Design. We manipulated perception context (short vs. long) within-participants in a blocked design. As in Experiment 1, Experiment 3 used an alternative-task paradigm (reproduction or comparison). The two perception contexts were created using three ranges of durations: the short perception context consisted of 6 short durations ( $600-$ 1600 in steps of 200 ms ) serving as comparison durations and 6 mid durations ( $1200-2200$ in steps of 200 ms ) serving as reproduction durations; the long perception context consisted of the 6 mid durations serving as reproduction durations and 6 long durations ( $1800-2800$ in steps of 200 ms ) serving as comparison durations. Thus, the two perception contexts had the same range of durations to be reproduced (i.e. both had the mid durations for reproduction) but differed in the range of durations to be perceived (long and mid durations for the long perception context but short and mid durations for the short perception context). If the perception context manipulation leads to a range bias, we should expect the mid durations to be reproduced as longer in the long than in the short perception context. Alternatively, if the range bias is driven by reproduction experience only, we should expect the mid durations to be reproduced as equally long between the two perception contexts.

Materials. As in Experiment 1, a shorter ( 0.1 log shorter) and longer ( 0.1 log longer) comparison duration were created for each of the comparison durations. Three blocks of materials were created for both the short and the long perception context. In each block, each stimulus duration was presented twice for reproduction and twice for comparison (once with a longer comparison duration and once with a shorter comparison duration), amounting to 24 trials in each block. Two experimental versions were created: the three blocks of the short perception context preceded those of the long perception context in one version and the order was reversed in the other. A short practice block of 4 trials preceded the first block. In order to prevent possible spillover of the perception context in the first three blocks to the last
three blocks, a compulsory 2-min break was inserted after the first three blocks; additionally, a practice block of 12 trials preceded the $4^{\text {th }}$ block.

Procedure. The experimental setting and the trial structure were identical to those in Experiment 1; that is, after the presentation of a stimulus duration, depending on the ensuing cue, participants either reproduced the stimulus duration or compared it with an upcoming duration. During the 2-min break, participants were allowed to do whatever they liked as long as they remained seated in the test cubicle. The experiment took about 25 min .

Figure 3. Results of Experiment 3. Each dash represents a participant's averaged reproduction for each stimulus duration in the long (red) or short (blue) perception context; the squares represent the averaged reproductions at the group level.

## Results and discussion

The trimming criterion led to the exclusion of 5\% (80 data points) of all the reproduced durations. An ANOVA with perception context as a within-participant factor and reproduction durations $(1200-2200)$ as a within-participant continuous variable revealed no significant main effect of perception context $\left(F_{(1,19)}=0.82, p=.377, \eta^{2}=.04\right)$, suggesting that the reproductions of stimulus durations were similar between the two perception contexts. Reproduction increased as a function of the stimulus duration $\left(F_{(1,19)}=\right.$ 255.3, $p<.001, \eta^{2}=.93$ ). There was no significant interaction $\left(F_{(1,19)}=1.18, p=290, \eta^{2}=.06\right)$.

The failure for the perception context manipulation to induce a range bias suggests that participants did not use their perception experience to infer stimulus duration for their reproductions. In Experiment 4, we changed all the comparison trials in Experiment 3 into reproduction trials so that the long and short perception context had respectively a long and short reproduction range (i.e. we additionally introduced the reproduction context manipulation). If people use reproduction experience to calibrate their time estimation, we should restore the range bias that was missing in Experiment 3.

## Experiment 4

## Methods

Participants. Another 20 volunteers ( 14 females, $19.9 \pm 1.1$ in age) took part in the experiment.

Design, materials and procedure. These were the same as those in Experiment 3 except that the comparison trials in Experiment 3 were changed into reproduction trials. Thus, the short perception context had 6 short durations ( $600-1600$ in steps of 200 ms ) and 6 mid durations ( $1200-2200$ in steps of 200 ms ), all to be reproduced; the long perception context had 6 mid durations ( $1200-2200$ in steps of 200 ms ) and 6 long durations ( $1800-2800$ in steps of 200 ms ), all to be reproduced.

Figure 4. Results of Experiment 4. Each dash represents a participant's averaged reproduction for each stimulus duration in the long (red) or short (blue) perception/reproduction context; the squares represent the averaged reproductions at the group level.

## Results and discussion

We excluded 3\% (106 data points) of all the reproduced durations as outliers. We compared the reproductions of the 6 overlapping stimulus durations ( $1200-2200$ in steps of 200 ms ) between the two perception (and indeed reproduction) contexts. In contrast to the finding in Experiment 3, the ANOVA showed a significant main effect of perception/reproduction context $\left(F_{(1,19)}=10.00, p=.005, \eta^{2}\right.$ $=.34$ ), with longer reproductions of the stimulus durations when they were part of the long than the short perception/reproduction context. Reproductions increased as a function of the stimulus duration $\left(F_{(1,19)}=255.6, p<.001\right.$, $\eta^{2}=.93$ ). The two variables did not interact significantly $\left(F_{(1,19)}=0.44, p=.514, \eta^{2}=.02\right)$, suggesting a central tendency in the reproduced durations in both contexts.

The most striking observation is the return of the range bias for the overlapping stimulus durations when different reproduction ranges were introduced, in contrast to Experiment 3, where the reproduction range was the same between the two perception contexts. Such a finding clearly
suggests that the reproduction experience, rather than the perception experience, drives the range bias.

## Prior updating

A crucial prediction of Bayesian inference in time perception is that the prior is constantly updated. If the prior in time reproduction is based on previously reproduced rather than perceived durations, as our experiments have shown, we should predict the most recently reproduced (but not perceived) duration to have an influence on the prior, and hence on the posterior, such that a longer reproduced (but not perceived) duration in the preceding trial leads to a longer reproduced duration in the current trial.

The comparison trials in Experiments 1 and 3 allowed us to examine the possible influence of the preceding perceived (i.e. stimulus) duration on the prior belief (and the reproduced duration in the current trial). We used linear mixed effects modelling for these analyses, where we included as predictors the stimulus duration of the current trial and the stimulus duration in the preceding trial. For Experiment 1, though reproductions increased as a function of the current trial's stimulus duration ( $\beta=556.28, S E=35.56, t_{(31.0)}=15.65, p<$ .001 ), they were insensitive to the magnitude of the stimulus (i.e. perceived) duration in the preceding comparison trial ( $\beta$ $\left.=-1.75, S E=17.64, t_{(28.1)}=-0.10, p=.922\right)$. The same pattern was also observed in Experiment 3 ( $\beta=241.36, S E=16.73$, $t_{(19.4)}=14.43, p<.001$, for current stimulus duration; $\beta=-$ 36.90, $S E=26.35, t_{(19.1)}=-1.40, p=.177$, for preceding stimulus duration).

We next analyzed reproductions taking into account the preceding reproduced duration (i.e. when the preceding trial was a reproduction trial) in all the 4 experiments. Reproductions always increased as a function of the stimulus duration of the current trial $\left(\beta=570.52, S E=23.86, t_{(31.1)}=\right.$ 23.91, $p<.001 ; \beta=643,41, S E=45.47, t_{(19.0)}=14.15, p<$ $.001 ; \beta=225.05, S E=20.50, t_{(17.6)}=10.98, p<.001 ;: \beta=$ 413.54, $S E=22.89, t_{(19.0)}=18.07, p<.001$; for Experiments $1-4$ respectively) and also of the preceding trial $(\beta=191.46$, $S E=16.99, t(38.2)=11.27, p<.001 ; \beta=89.34, S E=16.64$, $t_{(18.4)}=5.37, p<.001 ; \beta=151.48, S E=19.95, t_{(20.6)}=7.59, p$ $<.001 ; \beta=125.94, S E=15.96, t_{(17.7)}=7.89, p<.001$; for Experiments 1-4 respectively). These findings consistently suggest that the prior was updated by a recent reproduction output such that a recent longer reproduction increased the prior mean, which in turn increased the posterior mean, resulting in a longer reproduction in the current trial.

## General discussion

In four experiments, we showed that people use their past (in particular the most recent) reproduction experience to calibrate their duration reproduction. These results are inconsistent with previous Bayesian inference accounts of timing (and magnitude estimation in general), whereby people use previously perceived durations to calibrate their noisy memory of stimulus duration, which in turn is used to guide reproduction (Jazayeri \& Shadlen, 2010; Di Luca \& Rhodes, 2016; Cicchini et al., 2015; Petzschner et al., 2015).

Such a memory-optimizing account is explicitly spelled out in Petzschner et al. (2015) as a Bayesian inference account of magnitude estimation in general. In this account, people perceive a magnitude (e.g., a duration) and keep a noisy memory of it. Later they use their prior belief to infer an optimal estimate based on this noisy memory, and this estimate represents the inferred stimulus duration that is used to guide subsequent response (e.g., time reproduction).

Instead, the current findings support a task-oriented Bayesian inference account, where people directly use the noisy memory of the stimulus duration and their past reproduction experience to infer a reproduction estimate. Note that, unlike previous accounts, such an estimate is not an updated version of the stimulus duration but should instead be viewed as a planned reproduced duration.

If it is the case that Bayesian inference is task-oriented (i.e. the inference serves the task at hand), then we should expect the source of the prior information to vary across different magnitude tasks. For instance, it is possible that, whereas time reproduction recruits prior reproduction experience, time comparison may instead recruits prior perception experience as the task would involve making inferences about perceived durations. It is also possible, as Experiment 2 suggested, that different reproduction tasks may resort to task-specific priors. These remain to be tested in future studies.

#### Abstract

Previous research has shown that the sequence in which concepts are studied changes how well they are learned. In a series of experiments featuring naturalistic concepts (psychology concepts) and naïve learners, we extend previous research by showing that the sequence of study changes the representation the learner creates of the study materials. Interleaved study leads to the creation of relatively interrelated concepts that are represented by contrast to each other and based on discriminating properties. Blocked study, instead, leads to the creation of relatively isolated concepts that are represented in terms of their central and characteristic properties. The relative benefits of these representations depend on whether the test of conceptual knowledge requires contrastive or characteristic information. These results argue for the integrated investigation of the benefits of different sequences of study as depending on the characteristics of the study and testing situation as a whole.

Keywords: study sequence; interleaving; interrelated concepts;

## Introduction

The sequence of study while learning concepts changes what is learned and how well it is learned. Therefore, it is perhaps not surprising that understanding how students should organize their study to promote learning has emerged as a major area of active interest in educational and cognitive science research. Previous research has focused on how different sequences might improve learning (Birnbaum et al., 2013), and how the benefits of different sequences might interact with different study conditions (Carvalho \& Goldstone, 2015), materials (Carvalho \& Goldstone, 2014), individual characteristics (Sana et al., 2016), or selfregulation (Carvalho et al., 2016).

When hard-to-discriminate concepts are studied in an interleaved fashion, by alternating the study of the different concepts, learning is improved compared to when different concepts are studied in separate blocks (Kornell \& Bjork, 2008). However, the benefit of interleaved study is not universal. For example, it has been shown that when studying concepts that have high within-category diversity in their properties (for example, the category mammal which includes bats, cows, and whales), studying each concept in separate blocks can result in better learning (Carvalho \& Goldstone, 2014). This apparent inconsistency lead to the proposal that different sequences of study emphasize different properties of the studied materials and thus might be more appropriate for different types of concept learning tasks
(Carvalho \& Goldstone, 2014). The Sequential Attention Theory (Carvalho \& Goldstone, 2015), proposes a mechanism through which attention and encoding during blocked study are progressively directed towards the similarities among successive items belonging to the same category whereas attention and encoding during interleaved study are progressively directed towards the differences between successive items belonging to different categories. Because of this influence on cognitive processing, Carvalho and Goldstone (2015) propose that the sequence of study can accelerate or delay learning, depending on whether the constraints created by the sequence of study match those of the encoding situation (e.g., interleaved study in situations critically hinging on the encoding of differences between concepts, such as the study of highly similar concepts), or mismatch it (e.g., blocked study in the same situations).

In this work, we aim to extend these results to demonstrate that different encoding experiences will result in different representations that will be more or less appropriate depending on the requirements of the testing situation. Our proposal is as follows: because different information is encoded with different sequences of study, different sequences of study potentiate different representations of what was studied. More specifically, encoding the differences between concepts through interleaved study will tend to lead to the creation of interrelated concepts whose representations are contrasted away from each other by emphasizing or exaggerating their distinctive characteristic relative to each other (Corneille et al., 2006; Goldstone, 1996). Conversely, blocking will tend to lead to encodings of the similarities within each concept that will, in turn, create relatively isolated, stand-alone, representations (Goldstone, 1996).

These different representations, once created, are suited for different uses. Although an interrelated representation of two concepts will be helpful in a new context in which discriminating the previously learned concepts is important, isolated representations of the same concepts may not be as useful. Conversely, an isolated representation of a concept will include more information about all the properties of that concept, whether or not they serve to distinguish it from the other learned concepts, making it ideal for situations in which these details are relevant, such as when the concept must be differentiated from other new concepts possessing new distinctive features.

Students often create flashcards as a study and self-testing tool (Hartwig \& Dunlosky, 2012). These flashcards might
include a definition or an example of a concept on one side of the card and the correct response on the other. When studying using examples, students might choose to study all the cards from one concept in a block or to interleave cards from different concepts. One important question, then, is if different sequences of examples will influence students' performance for different types of tests - a question that, to the best of our knowledge, has not been addressed before. This is not only an important question at the theoretical level - to know the representational differences created by different sequences - but also at the practical level because changing the sequence of study materials is an easy and cheap intervention that might have substantial influences on learning outcomes (Dunlosky et al., 2013). In fact, previous researchers have emphatically advocated presenting information interleaved whenever possible, warning students about the perils of blocked study (e.g., Bjork, Dunlosky, \& Kornell, 2013), and it has been suggested as an important factor of which all new instructors should be aware (Deans for Impact, 2015).

For this purpose, we developed two experiments in which learners studied concepts of psychology (e.g., "Hindsight bias"; Rawson et al., 2015) in one of the sequences and were then tested in different situations, similar to common study practices by students. Importantly, some of the tests required discrimination between different concepts (e.g., multiplechoice test), whereas others required an independent representation of each concept (e.g., writing a definition). We consider writing a definition to require an independent representation because these definitions can be expressed without referring to other learned concepts. For example, a participant could write a definition for "availability heuristic" without having learned or remembered any of the other presented concepts (Goldstone, 1996). We predict that for tests that emphasize isolated, independent knowledge of the properties of each concept, such as writing a definition, participants will perform better following blocked study. Conversely, for tests that require discriminating different concepts, i.e., those that involve choosing between several options, participants will perform better with interleaved study.

## Experiment 1

## Method

Table 1: Participant demographic characteristics for Experiments 1 and 2.

| Experiments 1 and 2. |  |  |
| :---: | :---: | :---: |
| Pair | Exp. 1 | Exp. 2 |
| Mean Age (SD) | $33(10)$ | $36(11)$ |
| Gender (\% Females) | $45.5 \%$ | $68 \%$ |
| Education (\% Bachelor's or | $50 \%$ | $64 \%$ |
| higher) | $0.04(0.21)$ | $0.21(1.13)$ |

Participants. A group of twenty-eight people were recruited through Amazon's Mechanical Turk (https://www.mturk.com/). Data from 6 participants were excluded from analyses because of possible compliance
issues (see below for details). The demographic characteristics of participants in the overall sample are presented in Table 1.
Stimuli. We used a stimulus set of introductory concepts and examples created by Rawson et al. (2015). The stimuli included 10 concepts taught in Introductory Psychology and 10 example situations for each concept, collected from textbooks of Introductory Psychology. The concepts were divided into two groups by relatedness. Each group contained unrelated concepts only, whereas across groups pairs of related concepts existed (see Table 2). Relatedness of the concepts was judged by the authors by comparing the definitions of the concepts and confirmed by analyzing the pattern of errors in multiple-choice questions without feedback in a pilot study. Previous research looking at sequence of study using these materials used this concept grouping as well (Rawson et al., 2015).

Table 2: Groups of concepts used in Experiment 1 and Experiment 2. Each row includes a pair of related concepts.

Columns contain only unrelated concepts.

| Pair | Group A | Group B |
| :---: | :---: | :---: |
| 1 | Availability Heuristic | Representativeness <br> heuristic |
| 2 | Door-in-the-face | Foot-in-the-door |
| technique | technique |  |
| 3 | Hindsight bias | thinfing |
| 4 | Fundamental | Deindividuation |
| 5 | Mertribution exporrore effect | Social facilitation |

Design and Procedure. This Experiment had two conditions manipulated within-subject: Study Sequence (Blocked vs. Interleaved) and Type of Test (Multiple-Choice Test vs. Definition Match Test vs. Write Definitions Test).

The experiment had three phases: pretest, study and test. Participants completed one pretest, two study phases and two tests phases in the following order: Pretest - Study 1 - Test 1 - Study 2 - Test 2. The first and second study phases were the same in every aspect except for the sequence of study and the concepts studied. One study phase was interleaved and the other blocked (order counterbalanced across participants). A different group of to-be-learned concepts was used in each study phase. In the interleaved condition learners studied an example of each concept before studying the same concept again (e.g., ABCABC...). Conversely, in the blocked condition learners studied all examples of each concept before starting a new concept (e.g., AABBCC...). Moreover, the test phase only tested the concepts learned in the immediately preceding study phase. Between each study and test phase participants completed a distractor task by watching a 4-minute video on an unrelated topic and answering a question about that video.

During the pretest phase participants were told that they would be presented with several psychology concepts that they were asked to rate regarding their familiarity/knowledge. Participants were told that not
knowing the concepts was not an issue for the study, would not impact their eligibility or payment, and that they should be honest in their responses. On each trial, the name of a concept was presented and participants had to rate on a scale from 1 ("Not familiar at all") to 7 ("Very familiar") how familiar they were with that concept. Following each rating, participants were asked to provide an example of that concept, or enter "I don't know" if they did not know any. Participants completed the pretest for the ten to-be-studied concepts across both study phases.

Following the completion of the pretest, participants completed the study phase. During the study phase, participants studied examples of situations depicting each of five concepts, one at a time and were asked to choose the name of the concept they thought the example instantiated. Participants were given feedback after each response. During study, participants studied five examples of each of the five concepts.

During the test phase, participants completed three types of tests: Multiple-Choice, Writing Definitions and Match Definitions, always in that order. The Multiple-Choice test used the same procedure as the study phase with new examples and without feedback. In the Writing Definitions, test participants were shown the name of each of the concepts studied one at a time and asked to write the best definition possible for that concept, based on what they had learned in the previous study phase. In the Match Definitions test participants were presented with the textbook definition of each concept, one a time, and asked to identify what concept that definition belonged to by pressing the corresponding button on the screen. The order of trials within each of the tests was randomized across participants. None of the test phase tasks had any time limit.

## Results and Discussion

Because the study was conducted online without experimenter supervision, we first inspected the data in order to identify potential compliance issues. For each participant, we calculated the median response time during both study phases. The sample's median response time to complete the study phase was 10.5 seconds per problem (max: 22.9 sec./problem; min: $0.73 \mathrm{sec} . /$ problem). We calculated the 10th and the 90 th percentiles for the distribution of median response times, $3.3 \mathrm{sec} . / \mathrm{problem}$ and $16 \mathrm{sec} . / \mathrm{problem}$ respectively, and used these values as a measure of noncompliance in the task. Responding too fast (faster than the 10th percentile) is likely due to participants who are not reading the problems and just advancing through the experiment quickly; similarly, longer response times (above that of the 90 th percentile) are likely due to potentially distracted participants. Six participants were identified based on this analysis and their data were excluded from further analyses.

All the analyses below are ANCOVA analyses including average pretest score and counterbalancing condition as covariates.

Pretest. To analyze the data from the pretest we calculated 25th, 50 th and 75 th percentiles of the ratings (see Table 3). As can be seen, most participants showed little or no knowledge of the to-be-studied concepts (mean of approximately 2 in a 1-7 scale). The provided examples further confirmed this interpretation.

| Table 3: Pretest results for Experiments 1 and 2 (1-7 scale). |  |  |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: |
|  | 25 <br>  <br> Percentile | Percentile | 75 <br> Percentile | $M$ | SEM |
| Exp <br> 1 | 1.00 | 1.55 | 2.03 | 1.71 | 0.16 |
| Exp | 1.34 | 1.79 | 2.39 | 1.97 | 0.16 |
| 2 |  |  |  |  |  |

Study Phase. Mean performance during the blocked study phase was $72 \%$ (SEM $=5 \%$ ), whereas during interleaved study it was $67 \%$ (SEM $=5 \%$ ). This difference was not statistically significant, $F(1,20)=1.95, p=.169, \eta^{2}{ }_{G}=.012$. Test Phase. Two trained coders, blind to condition assignment, rated as correct or incorrect each of the written definitions. These two coders agreed $87 \%$ of the time and inter-coder reliability was high, Cohen's Kappa $=.725, p<$ .0001. Disagreements were resolved by a third coder, also blind to condition assignment of the responses.
Performance for the test phase is depicted in Figure 1. As can be seen in the figure, the type of tests varied in their level of difficulty, with participants performing better in the Definitions Match test and worse in the Write Definitions test, $F(2,42)=17.62, p=<.0001, \eta^{2}{ }_{G}=0.151$. Although there was no overall main effect of study sequence $F(2,42)$ $=1.36, p=.256, \eta^{2}{ }_{G}=.006$, there was a significant interaction between type of test and study sequence, $F(2,42)=5.26, p$ $=.022, \eta_{G}^{2}=.022$.

Figure 1: Results for the Test Phase of Experiment 1. Dotted lines represent chance level. Error bars represent standard errors of the mean.

To further investigate this interaction, we compared the effect of type of study sequence on each of the tests by calculating the difference in performance following blocked and interleaved study for each type of test (interleaved blocked). The difference in performance between the two conditions varied across type of test, $F(2,42)=5.10, p=$ $.011, \eta^{2}{ }_{G}=.110$. Planned contrasts using FDR correction indicate that the effect of study sequence was significantly
different when comparing the Write Definitions test ( $M=$ $.15, S E M=.06)$ with the Multiple-Choice test $(M=.009$, SEM $=.03$ ), $\mathrm{p}=.033$, and the Match Definitions test $(M=$ $.02, S E M=.05$ ), $p=.040$, but not when comparing the Multiple Choice and the Match Definitions tests, $p=.844$.

These results are consistent with our proposal that blocked study encourages learners to develop independent, standalone representations rather than highlighting diagnostic features (i.e., those that discriminate between the concepts). Interleaved study emphasizes features that discriminate between concepts, which would be more helpful for a subsequent categorization task than a task that requires generation of stand-alone definition of the concept.

## Experiment 2

Our main proposal in this paper is that blocked study creates relatively independent representations of each concept studied which emphasizes the concept's characteristic features. These independent representations include more details from each concept than what is fostered by the relatively interrelated representations created during interleaved study. In the context of studying examples of different concepts, we proposed that blocked study allows learners to more successfully write definitions of the concepts because a definition requires the type of knowledge that blocked study promotes; it is generally possible to write good definitions for the learned psychology concepts without mentioning other psychology concepts learned at the same time. Consistent with this hypothesis, Experiment 1 showed that following blocked rather than interleaved study, learners were more successful at writing definitions of concepts, but the groups did not differ on classifying examples.

However, when two concepts are highly related (e.g., foot-in-the-door and door-in-the-face technique) their definitions can be aptly construed in relation to each other. If they are studied together, one central feature to include in the definition is the feature that discriminates them. Thus, the fact that in the previous experiments learners studied in the same session concepts that were dissimilar from each other and varied in many properties (see Table 2) might have contributed to the pattern of results seen. Would studying similar concepts together change the pattern of results observed?

Studying related concepts together changes the learning task in at least three critical ways. First, studying similar concepts in the same session might result in the necessity to discriminate between similar situations in order to find the subtle differences between the two types of concepts. It has been shown before that the interrelated representations promoted by interleaved study are likely to improve learning in these situations of learning highly similar concepts (Carvalho \& Goldstone, 2014). Second, the features that discriminate these related concepts are also characteristic features of the concept, unlike what is the case when the concepts are dissimilar (see Table 2). This means that interleaved study could promote representations appropriate for a writing definitions test through identification of
differences between concepts, whereas these differences would not be likely to be highlighted in the previous experiment.

In sum, when similar items are studied in the same session, there are several reasons to believe that performance would benefit from interleaved study, even when the test requires learners to write definitions. However, when similar items are studied in separate sessions, as in Experiment 1, blocked study would promote best performance in a test requiring isolated representations, such as writing definitions.

To test this, we used a procedure similar to how students often organize their study. In most natural situations students are likely to randomly assign the topics to be studied to a study session or to follow the sequence of their textbook or instructor. Therefore, in this experiment we randomly assigned concepts to being studied either interleaved or blocked, instead of using different pre-defined groups of concepts that guarantee low between-category overlap as in the previous experiment. This results in a situation where similar concepts might be studied together or separately. We compare performance on multiple-choice and writing definitions tests following blocked or interleaved study in each one of these situations.

## Method

Participants. A group of 36 people completed the experiment following recruitment through Amazon's Mechanical Turk (https://www.mturk.com/). Data from 3 participants were excluded due to self-reported previous participation in another study with the same materials. Data from an additional 8 participants were excluded from analyses because of possible compliance issues (see below for details). The final sample included 25 participants. Table 1 includes the demographic characteristics of participants in the overall sample.
Stimuli and Procedure. In this experiment, we used the same set of materials as in Experiment 1 and Experiment 2, but concepts were randomly assigned to be studied interleaved or blocked. Thus, in this experiment we did not force related concepts to be studied in separate phases.

The procedure was similar to the procedure used in Experiment 1 except for the following differences. Participants studied only eight concepts, four interleaved and four blocked. During study, participants saw four situations depicting each one of the concepts. After study, participants played a game of Tetris for 30 seconds.

The test phase included only a multiple-choice test and a writing definitions test, always presented in that order. During the multiple-choice test participants saw a total of four novel examples of the concepts studied, presented one at a time, and were asked to indicate which concept it illustrated.

## Results and Discussion

We identified potentially non-compliant participants using the participants' response times during study. The sample's median response time to complete the study phase was 8.4
seconds per problem (max: $22.8 \mathrm{sec} . /$ problem; min: 0.47 sec./problem). The $10^{\text {th }}$ and $90^{\text {th }}$ percentiles for the distribution of median response times were $2.6 \mathrm{sec} . / \mathrm{problem}$ and $16 \mathrm{sec} . /$ problem respectively. Eight participants were identified as outliers based on their falling outside of this range and their data were excluded from further analyses.

In all the analyses presented below, mean pretest score and counterbalancing condition were included as covariates.
Pretest. As in the previous experiments, participants showed little to no pre-training knowledge of the to-be-studied concepts (see Table 3).
Study Phase. Mean performance during the blocked study phase was $79 \%$ ( $S E M=2.5 \%$ ), while during interleaved study it was $73 \%(S E M=4 \%)$. However, this difference was not statistically significant, $F(1,25)=2.65, p=.116, \eta^{2}{ }_{G}=$ 0.04.

Figure 2: Results for the Test Phase of Experiment 2. Dotted lines represent chance level. Error bars represent standard errors of the mean.

Test Phase. Two trained coders, blind to condition assignment, rated as correct or incorrect each of the Written Definitions provided. The two coders agreed $84 \%$ of the time and inter-coder reliability was high, Cohen's Kappa $=.611$, p $<.0001$. Disagreements were resolved by a third coder, also blind to the condition assignment of the responses.

To analyze the results from the two tests used in this experiment we classified each concept based on whether it had been studied blocked or interleaved and whether its related concept (see Table 2) had been studied in the same sequence or in different sequences. When both related concepts were studied in the same phase and in the same sequence (e.g., "foot-in-the-door technique", "door-in-theface technique" studied blocked), they were both classified as "Blocked" and "Same Sequence." However, when only one of the related concepts was studied, or the two related concepts were studied in different phases/sequences, both were marked "Different Sequences."

This classification of the concepts resulted in empty cells for participants who did not have both concepts studied in the Same Sequence and concepts studied in Different Sequences for both interleaved and blocked study. Because traditional repeated-measures ANOVA does not allow for the existence of empty cells and we wanted to maximize the inclusion of all data collected, here we used mixed model analyses and report Wald $F$ tests and respective $p$-values using KenwardRoger's approximation (Kenward \& Roger, 1997). The results are depicted in Figure 2.

As we saw in the previous experiments, overall learners performed better on the Multiple-Choice test than when writing definitions, Wald $F(1,33.842)=91.68, p<.0001$. Similarly, the sequence of study had no overall effect on performance, Wald $F(1,33.948)<1$. No interaction was found between these two variables, Wald $F(1,92.007)<1$.

However, the relatedness between concepts presented in the same sequence influenced performance. Overall, when participants studied the two related concepts in the same sequence their performance was lower ( $M=46.52 \%, S E M=$ $1.50 \%$ ) than when related concepts were not in the same sequence ( $M=62.41 \%, S E M=1.04 \%$ ), Wald $F(1,24.284)$ $=15.60, p=.0006$. Item relatedness also interacted with sequence of study and type of test, Wald $F(1,98.522)=6.83$, $p=.010$.

To further analyze this interaction, we explored the test results for each type of test separately. For the MultipleChoice test, only the effect of relatedness reached statistical significance, Wald $F(1,24.264)=9.43, p=.005$. However, for the Writing Definitions test, in addition to a significant effect of item relatedness, Wald $F(1,25.649)=9.81, p=$ .004 , we also found a significant interaction between item relatedness and sequence of study, Wald $F(1,29.282)=6.71$, $p=.015$ (see right panel of Figure 5). As predicted by the results of Carvalho and Goldstone (2014), the relative relatedness between items modulates the relative benefit of each sequence for the Writing Definitions test. Moreover, consistent with the results of Experiment 1, we see that when similar items are not studied in the same sequence, performance in the Write Definitions test benefits from blocked study, although this effect was only marginally significant, $t(35)=1.90, p=.066, d=0.317$.

## General Discussion

Overall, the results presented here show that the different sequences of study affect performance differently for different types of test. Studying examples of different concepts in a blocked sequence improves performance in a test requiring learners to provide a definition of the concept studied, whereas for other tests there is no difference in performance between the two sequences of study.

Consistently with previous research, we have argued that this pattern of results is related to the acquisition of different knowledge with each sequence. Whereas blocked study results in the creation of a relatively isolated representations (i.e., a stand-alone, independent representation of each concept), interleaved study results in interrelated representations (i.e., focusing on how a concept differs from other(s) studied at the same time; Corneille et al., 2006; Goldstone, 1996). Going one step further, these different representations are likely to be the result of differences in the underlying attentional and encoding processes (Carvalho \& Goldstone 2015). The information attended to and encoded during study will dictate what type of representation is brought to a new situation and therefore what is available at test.

Moreover, we also saw that the effect of study sequence is modulated by whether discrimination based on subtle differences is necessary or not during study or test, such as is the case with the related concepts presented together in Experiment 2. We argued that this is the result of the pressures of the study and testing situation: when studying related concepts, interleaved study (and the interrelated representations it promotes) helps learners determine what discriminates between closely related concepts. This interpretation is consistent with the results of Carvalho and Goldstone (2014) showing that when learners studied similar categories, interleaved study improved learning, whereas when studying dissimilar categories, blocked study improved learning. Although the sample sizes used in the studies reported here might seem small, it is important to note that all critical comparisons were within-subject manipulations which increases the analytic power and that the effect sizes reported here are large and in line with previous similar research.

In sum, the two main contributions of the present work are as follow; first, it goes beyond existing demonstrations that blocking is better/worse than interleaving by showing how sequence affects what is learned by creating different representations given the same content. Second, it provides evidence for the context-dependent nature of learning and how the benefits of each sequence depend on the learning situation. This evidence adds to previous demonstrations that the best sequence of study depends on the type of material being studied (Carvalho \& Goldstone, 2014; Patel et al., 2016), the type of study task (Carvalho \& Goldstone, 2015; Rawson et al., 2015), and whether students actively decide how to organize their study (Carvalho et al., 2016). These results also show the importance of developing theories of why one intervention is better than another. We have proposed a theory based on the similarities of the materials being learned and the nature of the task. When concepts are similar to each other, learners prioritize learning discriminating features. Writing definitions generally benefits from stand-alone representations unless the concepts being defined are similar to each other and benefit by being contrasted. The study of how an intervention interacts with the learning situation, we would argue, has the potential to not only provide a fuller understanding of how learning takes place, but also provide richer, more precise, recommendations for practice (Jonassen, 1982).

## Acknowledgments

We are grateful to Katherine Rawson for sharing the stimuli set with us. Dustin Finch, Kaley Liang, Ashton Moody, Alifya Saify, and Shivani Vasudeva assisted with response coding. # Is there an explicit learning bias? Students beliefs, behaviors and learning outcomes 

Paulo F. Carvalho (pcarvalh@andrew.cmu.edu)<br>Elizabeth A. McLaughlin (mimim@cs.cmu.edu)<br>Kenneth R. Koedinger (koedinger@cmu.edu)<br>Human-Computer Interaction Institute, Carnegie Mellon University, 5000 Forbes Ave<br>Pittsburgh, PA 15213 USA

#### Abstract

Learning by doing refers to learning practices that involve completing activities as opposed to explicit learning (e.g., reading). Although the benefits of learning by doing have been described before, it is still relatively uncommon in instructional practice. We investigated how much students employ learning by doing in online courses, and whether it is associated with improved learning outcomes. Spending more time completing activities had a larger impact on learning outcomes than spending more time reading, even in the case of mostly declarative content, such as in a Psychology course. Moreover, learning by doing is more efficient: grade improvements of 1 standard-deviation require $10-20 \%$ less time in learning by doing than reading. Finally, we contrast this evidence with students' a priori intuitions on best study strategies for their online course. Students overestimate the value of explicit learning through reading, and underestimate the value of active learning.

Keywords: learning by doing; retrieval practice; self-regulated learning; doer effect

## Introduction

A lot of instruction is focused on explicit learning (for example, through textbook reading, classroom lectures, and online videos). The underlying assumptions often are (a) that most knowledge we expect students to acquire in our courses is declarative in nature and, (b) perhaps, that even procedural knowledge can initially be acquired this way. Consistent with these beliefs, much emphasis has been devoted to the creation of video-based Massive Open Online Courses (MOOCs) and text-based online courses.

The emphasis on explicit learning is in stark contrast to established phenomena in cognitive psychology, advocating for the use of testing (Roediger \& Karpicke, 2006) and active learning (Wieman, 2014) as better learning tools. The testing effect describes the positive effects of engaging in selftesting, instead of additional passive study (for a review see Roediger \& Karpicke, 2006). This effect has been repeatedly shown in laboratory settings with diverse materials, including word pairs and text passages (e.g., Karpicke \& Blunt, 2011; Karpicke \& Roediger, 2008). The success of the testing effect in the laboratory led to some in-classroom studies looking at its extensibility as a tool to promote students' learning, also with positive outcomes (e.g., McDaniel et al., 2007).

Why might active practice not be used in the classroom? One possibility is that the effect is limited to controlled laboratory contexts in which other aspects of real-world instruction do not vary. There is currently a lack of evidence
from large-scale classroom studies demonstrating the benefits of testing over reading outside the lab. Another possibility is that the advantage of learning by doing is specific to some types of materials (e.g., procedural knowledge), thereby limiting its use by instructors and students. Indeed, there is some evidence showing that, under some circumstances, additional passive reading practice, compared to doing activities, might result in better learning (Sweller \& Cooper, 1985). In the KLI framework, Koedinger and colleagues (2012) postulate that the learning goals and the nature of the materials being studied are the determining forces behind whether reading or doing are better for improving learning.

In sum, conceivably, learning by doing is not used because it is not effective in real-world contexts or across a wide range of knowledge types. Moreover, there is an underlying assumption that when the focus of learning is declarative knowledge, the emphasis should be on reading activities that would foster the formation of connections between concepts and the creation of robust declarative knowledge (Anderson \& Schunn, 2000). Nonetheless, learning by doing is important because most of human expertise involves tacit knowledge of the cues and conditions for deciding when, where, and what knowledge to bring to bear in complex situations (Zhu et al., 1996). In this view, there might be no verbal shortcut to acquiring expertise; it might be best acquired by repeated practice.

In our research, we explore whether learning by doing is a better way of learning across different types of knowledge (i.e., declarative and procedural), and whether it is more efficient. We compare learning outcomes of students enrolled in two online courses as a function of frequency and time spent completing practice activities (doing) vs. reading.

## Students' study behavior and their beliefs about the best study strategy

Even if a class is designed to encourage students to learn by doing, including extensive self-testing and guided practice activities but minimal text, it is an open question whether students a) realize its potential, b) use it, and c) whether selfdirected learning by doing in the classroom is as effective as its guided counterparts in the laboratory. These questions are theoretically and practically important because previous research on other cognitive approaches to improve learning have repeatedly shown a difference in outcomes between when students are in control of their study and when they are not (Carvalho et al., 2016; Ciccone \& Brelsford, 1976), as
well as a lack of awareness by the students on how to best organize their study (Karpicke et al., 2009).

Koedinger et al. $(2015,2016)$ illustrated the power of learning by in the context of online courses used in real classrooms. The Open Learning Initiative (OLI) at Carnegie Mellon University (CMU) is a learning environment that includes several courses each focusing on rich and interactive learn-by-doing activities, aligned with student-centered learning outcomes, and designed around science-based learner models. By analyzing student self-regulated study behavior in online classes taught at different universities using OLI materials, Koedinger et al. $(2015,2016)$ identified a "doer effect" - completing more practice activities is a stronger predictor of student performance than completing more reading activities.

## The present work

The present work builds on early evidence of the "doer effect" and extends it. One explanation for why completing more doing activities has a larger impact on learning than completing more reading activities is that completing doing activities may be more time intensive. If students devote more time to studying, regardless of how they do it, they are more likely to learn more. In other words, more learning results from the time devoted to an activity (e.g., reading or doing), not from the activity itself. Conversely, if learning by doing is more beneficial because it engages students in an active learning process (Wieman, 2014), it should be associated with better learning outcomes even if students spend comparatively less time engaging in that activity. To investigate this question, we compare the time spent reading and doing, and its relative impact on learning outcomes. Is it the case that reading for longer periods results in better learning outcomes than doing for shorter periods?

Additionally, to probe the generalizability of learning by doing even for declarative knowledge, we investigate students' behavior in two courses. An introductory psychology course focusing mostly on declarative knowledge and a computation course focusing on both declarative and procedural (learning how to code) knowledge.

Finally, we investigate students' beliefs about the usefulness of using learning by doing in their study. At the start of each course, as part of an optional unit, students completed a question on what they thought was the best strategy to study for the course. Are students' a priori beliefs on how to study biased towards explicit learning (i.e., reading)?

## The "doer effect" in a Psychology MOOC

## Method

Sample. Our analyses include data from 783 students enrolled in an online "Introduction to Psychology as a Science" MOOC offered by the Georgia Institute of Technology through Coursera. We included in the analyses students registered in OLI for whom pretest, quizzes and the
final exam data were available. For a description of the entire sample see Koedinger et al. (2015).
Description of the course. The course "Introduction to Psychology as a Science" was designed as a 12 -week introductory survey course, and is often taught during the first year of college. For each week of class, the course targeted a major topic area (e.g. Memory, Sense and Perception, Abnormal Behavior). Elements of CMU's Open Learning Initiative (OLI) "Introduction to Psychology" course were incorporated into Georgia Tech's "Introduction to Psychology as a Science" MOOC. OLI materials including text and interactive activities were available to students, in addition to the lectures, quizzes and other Coursera-based activities of the larger course. Each sub-topic was supported by a pre-recorded video lecture ( $10-15$ minutes, with downloadable slides) and included matched modules and learning outcomes in the OLI learning environment. A highstakes quiz assessed students against these outcomes at the end of each week.

The OLI modules included a variety of expository content (text, examples, images, and video clips) and a large number of interactive activities. Broadly, these activities serve two purposes. "Learn By Doing" activities, intended to support student outcome achievement, provide feedback and robust hints to support students. Figure 1 shows an example of a "Learn by Doing" activity from the Personality module covered in week 9 of the course. Another type of activity, "Did I Get This" activities, provided a self-comprehension check for students. These activities were created in conjunction with the OLI text materials and complement it by providing testing ("Did I Get This") or active learning ("Learn by Doing") activities that cover the concepts described in the text.

Figure 1: Screenshot of an OLI "Learn By Doing" activity from the module on Personality.
Research questions, measures, and analysis plan. We explore three main research questions: Q1: Does completing more practice ("doing") activities, compared to completing more reading activities, predict better learning outcomes?; Q2: Does spending more time on practice ("doing") activities, compared to time spent on reading activities, predict better learning outcomes?; Q3: What are students' beliefs regarding "best study strategies" for an online course?

To approach these questions, we created the following analyses plan. First we calculated our dependent measures:
number of reading and doing activities and total time spent in each. We started by identifying for each student the number of doing and reading activities. A doing activity was identified as responding to at least one practice activity in the OLI. A reading activity was identified as opening a text webpage in the OLI. Because opening a text webpage does not necessarily mean a student was reading, we adjusted the total number of activities by removing extremely short reading activities (below the $10^{\text {th }}$ percentile of reading time for all reading activities for that student). Our reasoning is that when students took extremely short amounts of time in a page, they might not have in fact read the associated text.

Table 1: Study strategies students could choose from. The metacognitive activity in the Psychology MOOC course included only the first 4 strategies. The Computing OLI course included all strategies in this table.

| Strategy | Description |
| :--- | :--- |
| Game the <br> System | Do activities without reading text. Select different <br> answer choices until correct. |
| Do-Read | Do first activity and if cannot answer, read relevant <br> text. |
| Read-Do | Read text and complete do activities as they come <br> up |
| Read | Read text, skip doing activities. |
| Do | Complete some activities, then go back to text and <br> look for a similar example to read. |

Because doing activities were contained inside webpages, often surrounded by text, time spent doing and reading for each activity/page was inferred from recorded data as follows. Timestamps were recorded for when a student opened a OLI page, when a student made a choice in each step of an activity (e.g., selected an option in a multiplechoice question), checked their responses in activities, asked for hints in the activities, and closed the page. From these logs, we could infer doing time as the time difference between the initial step and the final step of an activity. All other time spent (from opening to closing) in the page was considered reading time. However, this process does not include the time spent reading the doing activity text before starting the activity. To correct for this, the time spent completing each doing activity also includes a proportion of the time right before completing the first step (the other portion being classified as time spent reading). For reading time, we calculated the difference between the time when a webpage was initially accessed and the time an activity was started, as well as the time between an activity was finished and the another one started or the webpage was closed plus the portion of the time immediately before the first step of each activity. However, initial analyses of the time spent in each page revealed a number of large outliers (several standard deviations above the student mean for the student). These times might be indicative that a student left the webpage opened while completing other activities (potentially not related to the course). To correct for this, in addition to removing very short reading times (for
consistency with the number of reading activities analysis above), we also replaced very long reading times (above the $90^{\text {th }}$ percentile for that student) with the average reading time for that student. This way, we hope to reduce the influence of situations during which the student had the page opened but was not actively reading the text presented.

Our dependent measures included the summed quiz score across the 11 quizzes and the final exam score, all multiplechoice questions. Each quiz was worth 10 points. The final exam had 35 questions (each worth 1 point). To account for differences in student prior knowledge, we entered pretest score as a predictor in the models. The pretest, completed at the start of the course, was composed of multiple-choice questions from content covered in most of the units of the course and was graded from 0-20 points.

We converted the raw scores for the independent measures of student behavior as well as the dependent measures into standardize $z$-scores for ease of comparison across measures. We analyzed the effect of each independent measure on each dependent measure separately using a logistic regression model (in $R$ code):

$$
\begin{aligned}
& \text { zQuiz[zExam] }=\operatorname{lm}(z \text { Pretest }+ \text { zNumDoAct } \\
& [\text { zTotalDoTime }]+\text { zNumReadAct[zTotalReadTime }]+ \\
& \text { zNumDoAct[zTotalDoTime] }{ }^{*} \text { zNumReadAct[zTotalReadTi } \\
& \text { me }], \text { data }=\text { oli_do_read })
\end{aligned}
$$

Finally, to identify students' beliefs regarding best studying strategies (Q3), we took the students' responses in an activity during the "Learning Strategies" module included in the beginning of the OLI course. In this optional module (not included in the other analyses), students were introduced to several key research findings in learning sciences, and "best strategies" to achieve best learning. In one of the activities included in this unit students were asked to choose which of four study strategies they thought would yield best results in the course (see Table 1). To describe students $a$ priori study strategy judgments, we calculated the proportion of students who chose each of these alternatives before starting their study in the course. Each student could choose one or more of the options, out of the four offered: "Game the system", "Do-Read", "Read-Do", and "Read" (see Table 1).

## Results and Discussion

Table 2: Descriptive statistics for the main measures of students' study behavior and independent measures in the Psych MOOC

|  | $M(S D)$ | Median | $25^{\text {th }}$ <br> Prctl. | $75^{\text {th }}$ <br> Prctl. |
| :---: | :---: | :---: | :---: | :---: |
| Read Time <br> (mins) <br> Doing Time <br> (mins) | 9408 <br> $(5377)$ | $833(748)$ | 478 | 244 |
| \#Read Activities | $287(210)$ | 245 | 156 | 384 |
| \#Doing | $435(265)$ | 541 | 152 | 683 |
| Activities | $11(3.5)$ | 11 | 9 | 12265 |
| Pretest | $89(18.3)$ | 94 | 83 | 101 |
| Quizzes | $27(5.8)$ | 28 | 24 | 31 |
| Final Exam |  |  |  |  |

Descriptive measures of student behavior. As it can be seen in Table 2, students spent on average more time reading than doing ( 9000 min vs. 800 min , respectively); conversely students completed more doing than reading activities (435 vs. 287 , respectively). This overall descriptive data is consistent with the nature of the OLI course, which included a large number of short doing activities and text passages.
Q1: More "doing" activities predicts better learning outcomes. Results of the logistic regression predicting Quiz and Exam performance using number of doing and reading activities are presented in Table 3.

The regression analysis showed that higher quiz and exam scores are predicted by completing a larger number of doing activities $(\beta=0.40, p<.0001$ and $(\beta=0.24, p<.0001$, respectively), and by completing more reading activities ( $\beta=$ $0.11, p=.001$ and $\beta=0.11, p=.03$, respectively).

Importantly, the relative benefit of completing more doing activities was 2.4 to 3.6 times larger than completing more reading activities.

Overall, these results support those found by Koedinger et al. (2015, 2016), showing that completing more doing activities predicts better learning outcomes to a greater degree than completing more reading, even when we correct for the existence of very short (potentially off-task) reading events.

Finally, contrary to some intuitive predictions of the complementary nature of the two types of learning activities, their positive effect on learning outcomes are not additive. Completing more doing activities is more beneficial when students completed less reading activities (and vice-versa; $\beta$ $=-0.15, p<.0001$ and $\beta=-0.04, p=.40$, respectively).

Table 3: Results of logistic regression for both courses. Coefficients are standard deviations from the mean (z-scores).

|  |  | Quiz |  |  |  |  | Exam |  |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| Course | DV | $\begin{gathered} \mathrm{Adj} \\ R^{2} \end{gathered}$ | Doing Coef. | Reading Coef. | Interact Coef. | Effect <br> Ratio | $\begin{gathered} \mathrm{Adj} \\ R^{2} \end{gathered}$ | Doing Coef. | Reading Coef. | Interact Coef. | Effect <br> Ratio |

| MOOC | Total <br> Time | . 19 | $\begin{gathered} 0.39 \\ (0.04) \end{gathered}$ | $\begin{gathered} 0.11 \\ (0.04) \end{gathered}$ | $\begin{gathered} -0.19 \\ (0.03) \end{gathered}$ | 3.5 | . 11 | $\begin{gathered} 0.19 \\ (0.05) \end{gathered}$ | $\begin{gathered} 0.13 \\ (0.04) \end{gathered}$ | $\begin{gathered} -0.09 \\ (0.03) \end{gathered}$ | 1.5 |
| Computing | Number Activities | . 42 | $\begin{gathered} 0.56 \\ (0.02) \end{gathered}$ | $\begin{gathered} 0.23 \\ (0.02) \end{gathered}$ | $\begin{gathered} -0.16 \\ (0.06) \end{gathered}$ | 2.43 | . 08 | $\begin{gathered} 0.28 \\ (0.02) \end{gathered}$ | $\begin{gathered} 0.05 \\ (0.02) \end{gathered}$ | $\begin{gathered} -0.05 \\ (0.02) \end{gathered}$ | 5.6 |
| OLI | Total Time | . 10 | $\begin{gathered} 0.19 \\ (0.03) \end{gathered}$ | $\begin{gathered} 0.27 \\ (0.03) \end{gathered}$ | $\begin{gathered} -0.03 \\ (0.003) \end{gathered}$ | 0.70 | . 02 | $\begin{gathered} 0.15 \\ (0.04) \\ \hline \end{gathered}$ | $\begin{gathered} 0.08 \\ (0.03) \end{gathered}$ | $\begin{gathered} -0.02 \\ (0.003) \end{gathered}$ | 1.9 |

Q2: More time in doing activities predicts better learning outcomes. The results of the logistic regression predicting Quiz and Exam performance using total time doing and reading are also presented in Table 3. The regression analyses showed that higher quiz and exam scores were predicted by spending more time doing ( $\beta=0.39, p<.0001$ and $\beta=0.19$, $p<.0001$, respectively), as well as reading ( $\beta=0.11, p=.006$ and $\beta=0.13, p=.001$, respectively).

Importantly, because reading requires, on average, more time than doing (see mean and standard deviations in Table 3 ), for each 1 standard-deviation ( 18.3 points, $17 \%$ total score) improvement in the total quiz score, students had to complete only a total of 18.45 hours of doing work during the 12 weeks of the course (or 1.5 hours/week), but 166.22 hours of reading work during the same period (or 13.8 hours/week). Similar improvements in final exam score require 16.16 hours of doing work but 168.77 hours of reading work over the entire course. Finally, similarly to what we saw when analyzing number of activities completed, spending more
time completing doing activities is more beneficial when students spend less time reading (and vice-versa; $\beta=-0.19, p$ $<.0001$ and $\beta=-0.09, p=.005$, respectively). This result further indicates that the benefits of the two types of activity is not additive.

Q3: Students overestimate the benefits of reading. Only a subset of students $(N=389)$ from the original sample described above also completed the "Learning Strategies" module (the module was optional). Table 4 shows the percentage of students who chose each possible study strategy as well as the percentage of students who chose exclusively each option. As it can be seen from the table, the large majority of students ( $93 \%$ ) chose "reading and completing the activities as they appear" ("Read-Do") as the best strategy. In fact, Read-Do was the most popular as the exclusive choice. Did students who chose a strategy focused on learning by doing spend more time doing than reading? To evaluate this question, we looked at the relative time spent doing vs. reading depending on the strategy the student chose.

Table 4: Percentage of students who selected each strategy as best for learning in the course.

| Course | N | Game the system |  | Do-Read |  | Read-Do |  | Read |  | Do |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  |  | Only <br> selection | Selected | Only <br> selection | Selected | Only <br> selection | Selected | Only <br> selection | Selected | Only <br> Selection |  |
| Psychology <br> MOOC | 389 | $8 \%$ | $8 \%$ | $32 \%$ | $5 \%$ | $93 \%$ | $61 \%$ | $6 \%$ | $0.05 \%$ | N/A | N/A |
| Computing <br> OLI | 950 | $3 \%$ | $0 \%$ | $36 \%$ | $4 \%$ | $94 \%$ | $40 \%$ | $4 \%$ | $0 \%$ | $36 \%$ | $0.05 \%$ |

For each student, we calculated the difference between total time doing and total time reading (doing-reading). More positive values in this measure indicate more time doing relative to time spent reading. We compared students who chose only the strategy "Do-Read", those who chose that strategy and another strategy, and those who chose any other strategy. Students who chose only the "Do-Read" strategy ( $M$ $=-7202, S D=6139$ ), or that strategy in addition to another ( $M=-7694, S D=4414$ ), spent relatively more time completing doing activities than those who did not choose that option $(M=-9746, S D=4983 ; t(386)=2.238, p=.026$ and $t(386)=3.63, p<.0001$, respectively).

## The "doer effect" in an online Computing Course

One of the goals of this research was to investigate whether engaging in learning by doing is an effective learning strategy for different types of knowledge. To extend the nature of the types of knowledge covered, we ran the same analyses with data from students' study behavior in an online version of a computing course. The content of this course is substantially different from the more expositive nature of an introductory psychology course. The course design followed the same overall principles and was similar to the Psychology course in terms of number of activities available to the students (see Koedinger et al., 2016 for details).
Sample. Our analyses include data from 2261 students enrolled in the online computing course "Information Systems" at University of Maryland University College (UMUC) using the OLI platform. We included in the analyses below students registered in OLI for whom quiz scores and a final grade were available. No pretest was available in this course.
Research questions and analyses plan. The same research questions and analyses plan as for the Psychology MOOC were used. The dependent measures used were the percentage correct across all quizzes and the final grade in number (1-5). Regression models do not include a pretest score.

## Results and Discussion

Descriptive measures of student behavior. Similar to what we found in the Psychology MOOC course, students spent on average more time reading than doing; conversely students completed more doing than reading activities (see Table 5).
Q1: More "doing" activities predicts better learning outcomes. Better quiz and exam scores are predicted by completing more doing activities ( $\beta=0.56, p<.0001$ and $\beta$ $=0.27, p<.0001$, respectively), as well as more reading activities $(\beta=0.22, p<.0001$ and $\beta=0.05, p=.02$, respectively; see Table 3). Moreover, we found similar ratios of benefit of doing over reading (2.43-5.6) as in the Psych MOOC, as well as a counter-intuitive interaction whereby the effect of doing activities is greater for lower amounts of reading, but only when predicting quiz scores (and viceversa; $\beta=-0.16, \mathrm{p}<.0001$ and $\beta=-0.05, p=.02$, respectively).

Table 5: Descriptive statistics for the main measures of students' study behavior and independent measures in the Computing course

| \#Read Activities | $30(31)$ | 24 | 26 | 1749 |
| \#Doing <br> Activities | $70(55)$ | 64 | 14 | 136 |
| Percent Correct <br> Quizzes | $7.98(2.8)$ | 8.5 | 5.82 | 10.44 |
| Final Grade | 3.89 <br> $(1.25)$ | 4 | 3 | 5 |

Q2: More time in doing activities predicts better learning outcomes. Better quiz and exam scores are predicted by spending more time completing doing activities ( $\beta=0.19, p$ $<.0001$ and $\beta=0.14, p<.0001$, respectively), as well as more time reading $(\beta=0.27, p<.0001$ and $\beta=0.08, p=.01$, respectively; see Table 3). There is also an interaction, whereby the positive effect of more time spent in doing activities is larger when students spend less time reading (and vice-versa; $\beta=-0.03, p<.0001$ and $\beta=-0.02, p<.0001$, respectively). Although for the quiz scores we see a larger impact of more reading time compared to more doing time (as evidence by a ratio smaller than 1 ), for both quiz and exam scores it is clear that spending more time completing doing activities is more beneficial and efficient because it takes on average less time to complete more doing activities and this has an impact on performance. For example, for a 1 standard deviation ( $2.8 \%$ ) improvement in quiz scores, students would have to spend 70.9 hours over the duration of the course completing doing activities, but a whopping 326.13 hours reading - a gain of more than $20 \%$.
Q3: Students overestimate the benefits of reading. Among the subset of students who completed the question on what they believed was the best learning strategy $(N=950)$, the large majority of students indicated that they should read all the text and complete all activities as they show up ( $94 \%$, see Table 4). Only a small number of students indicated that they should focus mostly on the doing activities (36\%). Moreover, the students' a priori strategy preference did not predict their relative time spent doing, $F(2,938)<1, p=.558$, demonstrating that even students who completed more doing activities are probably unware of its benefits.

## General Discussion

The results of this research indicate that self-regulated learning by doing is associated with larger learning gains than learning by reading. More importantly, besides being a desirable learning strategy, it might also be more efficient. Across two different online courses focusing on different types of content, we found that students who completed more doing activities showed larger learning gains in shorter time (between 10 and $20 \%$ less time to achieve similar improvements). This result is important for two reasons: (1)
it emboldens efforts to include more active, doing activities in lessons, as an alternative to reading activities, and (2) it shows the generalizability of learning by doing to different kinds of materials, even materials often thought of as involving declarative, as opposed to procedural, knowledge.

Learning by doing as described here involved effortful (Roediger \& Karpicke, 2006), active engagement and knowledge manipulation by the student (Wieman, 2014), with timely feedback (Roediger \& Karpicke, 2006). All these properties have been associated with better learning outcomes compared to passive learning situations such as reading. Any of these factors might have contributed to the benefits of spending more time completing doing activities. Interestingly, the benefits of learning by doing were larger when students spent less time reading, suggesting that the two types of activity might be non-additive. An interesting hypothesis for future research is whether learning by doing could replace some or all of the learning that takes place from reading. Can effective learning of declarative knowledge be done exclusively by doing with feedback?

Importantly, we found that students do not realize the potential of learning by doing. Students seem to overestimate the value of explicit, verbal, learning and underestimate the value of active learning, as seen by their overwhelming support for strategies that emphasize reading and weak support for strategies that emphasize doing. Similar dichotomies between best learning outcomes and students $a$ priori judgements of best study practices have been described before (see Roediger \& Karpicke, 2006), and underscore the important role of familiarizing students with empirically tested best-practices.

Finally, the naturalistic character of the data and the approach used here have great potential. Natural datasets (such as the two used in this investigation) are increasingly available and allow for a wider investigation of the generalizability, effectiveness and adequacy of learning methods, theories, and approaches developed in the laboratory. This approach can play a key role for the future of learning science because of the novel insights that can only be gained from studying how learning takes place in natural contexts by their natural agents (Jones, 2016). However, admittedly, the research presented here does not allow us to establish causal links or discriminate between alternative theories of why learning by doing is a more efficient learning strategy. It is possible that the differences in learning by completing reading and doing activities presented here are due to a third variable; though previous research suggests that might not be the case (Koedinger et al., 2016). Nonetheless, the research presented here can stimulate future controlled studies that establish causal links, and investigate which characteristics of learning by doing in classroom contexts contribute to its benefits.

#### Abstract

We present a schema-based model of a classic neuropsychological task, the Wisconsin Card Sorting Task (WCST), where competition between motor and cognitive schemas is resolved using a variation of a neuroanatomically detailed model of the basal ganglia (Gurney et al., 2001). We show that the model achieves a good fit with existing data at the group level, and correctly identifies two distinct cognitive mechanisms held to underlie two distinct types of error. However, at the individual level, the correlations amongst other error types produced by the model differ from those observed in the human data. To address this, we cluster participant performance into distinct groups and show, by fitting each group separately, how the model can account for the empirically observed correlations between error types. Methodologically, this demonstrates the importance of modelling participant performance at the sub-group or individual level, rather than modelling group performance. We also discuss implications of the model for the WCST performance of elderly participants and Parkinson's patients.

Keywords: schema theory; contention scheduling; basal ganglia; Wisconsin Card Sorting Task; modelling individual performance

## Introduction

Schema theory is a framework based on the idea that behaviour in many areas depends on abstractions over instances, i.e., schemas. In these abstract terms, schema theory is very general. It has been applied in domains ranging, for example, from event memory (Bartlett, 1932) to motor control (Schmidt, 1976). Norman and Shallice (1980) applied the theory in the domain of routine sequential action. Their theory proposes that action schemas work in a cooperative or sequential fashion, but also compete with each other for activation. While schema theory is helpful in representing functional interactions in the action-perception cycle, it is not committed to a specific neural implementation. However, at the neural level the basal ganglia have been proposed as a good candidate for resolving competition between schemas in order to carry out action selection (Redgrave et al., 2001). In part this is because of their recurrent connections with the cortex.

In this paper we present a model of the Wisconsin Card Sorting Task (WCST) where competition between motor and cognitive schemas is resolved using a variation of a neuroanatomically detailed model of the basal ganglia. We
use a genetic algorithm to search the model's parameter space and obtain a good fit for the data. Further analysis of correlations between error types, however, suggests the need to model individual participant data. Yet for reasons of computational efficiency this is impractical. We therefore cluster participant performance into a small number of distinct groups (5) and run separate genetic algorithms to fit the groups individually. The results capture both group performance and correlations between error types across individuals.

## The Task and the Model

In the WCST, participants are required to sort a series of cards into four categories based on binary (i.e., correct / incorrect) feedback. Each card shows one, two, three or four shapes, printed in one of four colours, and there are four shapes (triangle, star, cross, circle). It is therefore possible to sort cards according to colour, number or shape. To succeed, participants must match each successive card with one of four target cards (One Red Triangle, Two Green Stars, Three Yellow Crosses, Four Blue Circles), and use the subsequent feedback to discover the appropriate rule, but once they have discovered the rule (as indicated by a succession of 10 correct sorts), the experiment changes the rule without notice. The task yields a number of dependent measures, including the number of rules obtained (with a deck of 64 cards), the number of cards correctly sorted, the number of perseverative errors (where negative feedback is ignored) and the number of set-loss errors (where the participant fails to stick with a successful rule).

The model comprises three cognitive schemas and four motor schemas (see Fig. 1). ${ }^{1}$ Cognitive schemas represent the selection rules (Sort by Colour, Sort by Number, Sort by Shape) while the four motor schemas represent the acts of putting the stimulus card below each of the four target cards. Each schema has an activation level that varies over time as a function of input from various sources. Cognitive schemas are fed by an external channel that changes by a fixed amount according to external positive/negative feedback. Motor schemas are fed by cognitive schemas, and this signal is rule-dependent. If, for instance, the stimulus card displays

[^43]

Figure 1: Schematic of the model, not showing competition between schemas. Cognitive schemas (top row) send signals to the motor schemas (bottom row)

Figure 2: Schematic of the competition between schemas. The basal ganglia units compute the amount of inhibition that each schema receives given the activation of the others.
three red circles, the colour schema will excite the fourth motor schema (Four Blue Circles), the shape schema will excite the third motor schema (Three Yellow Crosses), and the colour schema will excite the first motor schema (One Red Triangle). Motor schemas are also fed by environmental cues depending on the stimulus card feature. Thus, when cognitive schemas are not strong enough to influence motor schemas, action selection may be driven by stimulus features only.

This simple model is complemented by a mechanism that implements and resolves competition between schemas within each hierarchical level: cognitive and motor schemas feed into two parallel computational mechanisms that each return a signal in the form of inhibition to the individual channels at each level (see Fig. 2 for an illustration at the cognitive level). In the brain, this competition between schemas is thought to be carried out by the basal ganglia

Figure 3: Schematic of the basal ganglia. Legend: Cortex-Thalamic complex (CTX-THAL), Striatum (STR), Subthalamic nucleus (STN), Globus Pallidus Internal/External Segment (GPi and GPe)
(Gurney et al., 2001). Corticobasal loops are mostly segregated (Alexander et al., 1986) and this is reflected in the model through the independence of information processed in the basal ganglia units at the two levels (cognitive and motor).

The model also implements a rudimental learning mechanism. This consists in a fixed change in signal to the cognitive schemas following a reward. Its purpose is to analyse how baseline levels of signal influence schema selection and ultimately, performance on the WCST. Manipulation of the thresholds of saturation functions in cortical units and associated basal ganglia units represent dopamine signalling in the cortex and in the basal ganglia, respectively. Therefore, the mechanism underlying cognitive control is a feedback-driven signal to the cognitive schemas.

## Computation in Individual Units

The model consists of 7 cortical units, 3 of which control cognitive operations and 4 of which control motor operations (see Fig. 1). These units correspond to schemas. Cognitive and motor units send their signal to their respective striatal units (see Fig. 3). Subthalamic units connect all units at the same hierarchical level (cognitive or motor), ensuring that the basal ganglia units act as a competitive suppressor of schemas as a function of the other schemas' outputs.

Individual units are connected as shown in Fig. 3. Their computations are shown below. In all cases, $u_{i}$ represents the entry signal to the unit, $a_{i}$ is the result of integration along the time domain, and $o_{i}$ represents the output of the individual units. The function $\sigma$ computes the sigmoid function of the input, ensuring output values are bounded between 0 and 1. Sigmoid functions have a fixed slope and threshold. Varying the threshold of cortical or striatal units alters the way competition between units is carried out, and can be considered a function of tonic dopamine present in the circuit. (In a separate simulation it has been shown that the level of external dopamine from the substantia nigra pars compacta ( SNpc ) unit can be simulated by varying the threshold of the saturation curve in the striatum $\left(\beta_{c t x}\right)$, without making use of an additional unit.)

## Cortical Units:

$$
\begin{gathered}
\mathbf{u}_{\mathrm{i}} \Leftarrow \sum_{\mathrm{j}} \mathbf{w}_{\mathrm{i}, \mathrm{j}} \cdot \mathbf{u}_{\mathrm{i}}+\mathbf{o}_{\mathrm{ext,i},}+\mathbf{o}_{\text {thal, }, \mathrm{i}} \\
\mathbf{a}_{\mathrm{i}}(\mathbf{t}) \Leftarrow \boldsymbol{\delta} \cdot \mathbf{a}_{\mathbf{i}}(\mathbf{t}-\mathbf{1})+(\mathbf{1}-\boldsymbol{\delta}) \cdot \mathbf{u}_{\mathbf{i}}(\mathbf{t}-\mathbf{1}) \\
\mathbf{o}_{\mathbf{i}} \Leftarrow \boldsymbol{\sigma}\left(\mathbf{a}_{\mathrm{i}}\right)
\end{gathered}
$$

Striatum (D1 and D2):

$$
\begin{gathered}
\mathbf{u}_{\mathbf{i}} \Longleftarrow \mathbf{o}_{\mathrm{ctx}, \mathbf{i}} \\
\mathbf{a}_{\mathbf{i}}(\mathbf{t}) \Leftarrow \boldsymbol{\delta} \cdot \mathbf{a}_{\mathbf{i}}(\mathbf{t}-\mathbf{1})+(\mathbf{1}-\boldsymbol{\delta}) \cdot \mathbf{u}_{\mathbf{i}}(\mathbf{t}-\mathbf{1}) \\
\mathbf{o}_{\mathbf{i}} \Leftarrow \boldsymbol{\sigma}\left(\mathbf{a}_{\text {strD1/D2,i}}\right)
\end{gathered}
$$

## Subthalamic Nucleus:

$$
\begin{aligned}

& \mathbf{a}_{\text {stn }, \mathbf{i}}(\mathbf{t}) \Leftarrow \boldsymbol{\delta} \cdot \mathbf{a}_{\text {stn, } \mathrm{i}}(\mathbf{t}-\mathbf{1})+(\mathbf{1}-\boldsymbol{\delta}) \cdot \mathbf{u}_{\text {stn, } \mathrm{i}}(\mathbf{t}-\mathbf{1}) \\
& \mathbf{o}_{\mathrm{stn}, \mathrm{i}} \Longleftarrow \sigma\left(\mathrm{a}_{\mathrm{stn}, \mathrm{i}}\right)
\end{aligned}
$$

Globus Pallidus (External Segment):

$$
\begin{gathered}
\mathbf{u}_{\text {gpe }, \mathbf{i}} \Leftarrow \mathbf{w}_{\text {stn_gpe }} \cdot \sum_{\mathbf{i}} \mathbf{o}_{\text {stn,i}}+\mathbf{w}_{\text {strD2_gpe }} \cdot \mathbf{o}_{\text {strD2,i }} \\
\mathbf{a}_{\mathbf{g p e}, \mathbf{i}}(\mathbf{t}) \Leftarrow \boldsymbol{\delta} \cdot \mathbf{a}_{\mathbf{g p e}, \mathbf{i}}(\mathbf{t}-\mathbf{1})+(\mathbf{1}-\boldsymbol{\delta}) \cdot \mathbf{u}_{\text {gpe }, \mathbf{i}}(\mathbf{t}-\mathbf{1}) \\
\mathbf{o}_{\mathbf{g p e}, \mathbf{i}} \Leftarrow \boldsymbol{\sigma}\left(\mathbf{a}_{\text {gpe }, \mathbf{i}}\right)
\end{gathered}
$$

Globus Pallidus (Internal Segment):

$$
\begin{aligned}
& \mathbf{u}_{\text {gpi,i }}(\mathbf{t}) \Longleftarrow \mathbf{w}_{\text {stn_gpi }} \cdot \sum_{\mathrm{i}} \mathbf{o}_{\text {stn,i }}+\mathbf{w}_{\text {gpe_gpi }} \cdot o_{\text {gpe }, \mathbf{i}}(\mathbf{t}-1) \\
& +\mathbf{w}_{\text {strD1_gpi }} \cdot \mathbf{o}_{\text {strD1,i }}(\mathbf{t}-1) \\
& \mathbf{a}_{\mathrm{gpi}, \mathrm{i}}(\mathbf{t}) \Leftarrow \boldsymbol{\delta} \cdot \mathbf{a}_{\mathrm{gpi}, \mathrm{i}}(\mathbf{t}-\mathbf{1})+(\mathbf{1}-\boldsymbol{\delta}) \cdot \mathbf{u}_{\mathrm{gpi}, \mathrm{i}}(\mathbf{t}-\mathbf{1}) \\
& \mathbf{o}_{\mathrm{gp} \mathbf{i}, \mathbf{i}} \Longleftarrow \sigma\left(\mathbf{a}_{\mathrm{gp}, \mathrm{i}, \mathrm{i}}\right)
\end{aligned}
$$

## Thalamus:

$$
\begin{gathered}
\mathbf{u}_{\mathbf{i}} \Leftarrow \mathbf{o}_{\mathrm{gpi}, \mathbf{i}} \\
\mathbf{a}_{\mathbf{i}}(\mathbf{t}) \Leftarrow \boldsymbol{\delta} \cdot \mathbf{a}_{\mathbf{i}}(\mathbf{t}-\mathbf{1})+(\mathbf{1}-\boldsymbol{\delta}) \cdot \mathbf{u}_{\mathbf{i}}(\mathbf{t}-\mathbf{1}) \\
\mathbf{o}_{\mathbf{i}} \Leftarrow-\boldsymbol{\sigma}\left(\mathbf{a}_{\mathbf{i}}\right)
\end{gathered}
$$

## Feedback

Feedback takes place after each trial. If the selected response is correct, the external signals $o_{\text {ext }, i}$ to the cognitive units ${ }^{2}$ that correspond to the matched features are increased by a fixed amount $b_{l}$. If the selected response is incorrect, inputs to those units that correspond to the matched features are decreased by a fixed amount $b_{l}$.

## Simulation of Wisconsin Card Sorting Test

## Simulation of an Individual Task

To simulate the WCST, a virtual deck of 64 cards is produced, shuffled and presented to the model. All the units perform the computation outlined in the previous section. The first motor unit to reach a fixed activation value (measured as the area under the time-curve, rather than simply as a threshold) is selected. After the selection and feedback, a new card is presented. The resulting plot for activation of the cognitive units is shown in Fig. 4.

As can be seen in Fig. 4, when the first card is presented the system must work out that 'colour' is the first correct

[^44]

Figure 4: Activation of cognitive schemas during a complete run (involving sorting all 64 cards). Solid lines represent the actual activation while dashed lines represent the external input due to positive/negative feedback. Processing cycles are represented on the horizontal axis.
sorting criterion. Feedback alone is not sufficient, as the selected card may match more than one feature. Basal ganglia units intervene by supressing the inappropriate cognitive schemas, enabling the correct schema to be permanently selected. When the sorting criterion changes (after 10 correct responses) the system tends to perseverate for a short period of time, before selecting the correct criterion again. Feedback-dependent external activation and resolution of competition both play a role in activating the correct cognitive schemas. Whereas the activation of cognitive schemas is regulated by feedback, the activation of motor schemas is regulated by cognitive schemas and environmental cues.

## Parameters

The model has a number of parameters. One important parameter is the threshold of the saturation curve of the striatum, represented by the threshold of the sigma function applied to the striatal output $\left(\beta_{\mathrm{str}}\right)$. Extreme values of this parameter (substantially greater than or less than 0.5 ) disrupt the competition between schemas. When the threshold is too high schemas are driven by their input values and they undergo increasingly homogenous inhibition from the basal ganglia. This phenomenon is analogous to the Parkinson's disease dopamine depletion in the SNpc (Cooper \& Shallice, 2000).

## Dependent Measures

Performance was scored according to a range of measures as indicated in Heaton (1981). Completed Categories (CC) and Total Errors (TE) measure the overall performance. A Set

Figure 5: Comparison between Simulation and Data from neurologically healthy young participants. $Z$ values indicate the z score of the difference between human and simulated data for each dependent measure.

Loss Error (SL) is counted whenever an incorrect response is selected after 5 or more correct responses, where at least one is unambiguous (i.e., the card matches only one feature). A Perseverative response (PR) is counted whenever a response would have been correct under the previous rule. (A subject can score a perseverative response even before completing the first category: if three consecutive responses are made selecting the same sorting rule, that rule will be the criterion that the subject can perseverate to.) Those perseverative responses that are also incorrect responses are counted as Perseverative Errors (PE). Non-perseverative errors (NPE) are calculated as the Total Errors (TE) minus Perseverative Errors (PE).

## Results

Results for two sets of 48 participants ( 48 healthy young adults and 48 simulated participants) are depicted in Fig. 5. The figure compares the aggregate results from the simulation (Sim) with the aggregate data from the human participants (Data).

A genetic algorithm attempted to find the best parameters that produce low $t$ statistics and low $z$ statistics between data and simulation. Given the presence of a multitude of parameters that influence each other in a non-linear fashion, a perfect fit is unattainable. However, the model appears to do a good job in reproducing group mean and standard errors, as shown by the figure.

## Correlational Analysis

Analysing aggregate data is not sufficient to assess model performance, since a model should also aim to dissociate between psychological constructs (Cassimatis et al., 2008). Therefore, correlational analysis between the most informative variables (TE, PE, SL) was also performed, using bootstrapping and sampling the mean value to obtain 1000 points. Multiple runs of the sampling algorithm produce very similar results. Fig. 6 and Fig. 7 show the

Figure 6: Correlations - Neuropsychological Data

Figure 7: Correlations - Simulation
correlation matrices for these variables in both the human data and the simulation.

The correlation matrices show that the simulation correctly identifies that the mechanism that produces set loss error can be dissociated from the process that causes other types or errors. However, the simulation fails to reproduce the high correlation ( $r=.91, p<.01$ ) between Total Errors and Perseverative Errors. In addition, it displays a weak but significant negative correlation ( $r=-$ .31, $p<.01$ ) that is not present in the empirical data.

## Discussion

The model yields an adequate fit for young participants on the WCST. Computation in the model appears to be stable, in that minimal parameter variations do not disrupt functioning. The model also correctly reflects the independence between Set Loss Errors (SL) and Total Errors (TE) found in the human data, suggesting a dissociation in the cognitive processes that produce those errors.

However, the model is subject to several limitations. The lack of positive correlation between PE and TE in the simulation is both puzzling and concerning. One possibility,
however, is that this apparent failing reflects the implicit assumption that performance of the human participants can be modelled by a single set of parameter values (i.e., by a group of 48 virtual participants with identical cognitive characteristics). We explore this possibility in the following section.

## Grouping Data

## Introduction

In the light of the failure of the model to reproduce the empirically observed correlations between TE and PE, we analyse how data from young participants can be clustered into a small number of groups based on the three critical dependent variables reflecting errors (TE, PE, SL).

These three types of errors have been specifically chosen because they are most representative of performance failures. Data clustering was calculated using a k-means algorithm with $\mathrm{k}=5$ (purely for reasons of computational efficiency). Two points were excluded because they were outliers. The algorithm was initialised based on the observation of the spatial 3D distribution of points. The most distinctive features are the accumulation of points around the origin, the sparseness of points as total and perseverative errors increase, and an isolated cluster of points with SL equal to 1 .

Fig. 8 shows how the clustering of the groups and Table 1 shows mean and standard deviation of the dependent variables in the individual groups.

## Simulation

After clustering the groups, as outlined in Table 1, we run five genetic algorithms separately to determine best-fitting parameter values for each group. In each case, seven model parameters were initially randomised to values within their reasonable ranges, and model errors recorded. A t-value between the simulation's and the original experimental data was computed and its mean used as the inverse of the GA's fitness value. Table 1 shows performance errors of the simulation with the highest fitness and Fig. 9 shows a 3D representation of the individual values.

Table 1: Data Groups

| G | N | TE | PE | SL |
| :---: | :---: | :---: | :---: | :---: |
| $1 \bullet$ | 18 | $8.89(S D=2.03)$ | $6.22(S D=2.03)$ | $0(S D=0)$ |
| $2 \bullet$ | 13 | $14.85(S D=1.77)$ | $8.77(S D=1.92)$ | $0(S D=0)$ |
| $3 \bullet$ | 5 | $28.00(S D=1.73)$ | $18.40(S D=2.30)$ | $0(S D=0)$ |
| $4 \bullet$ | 7 | $14.71(S D=2.63)$ | $9.57(S D=0.53)$ | $1(S D=0)$ |
| $5 \bullet$ | 3 | $22.33(S D=2.08)$ | $11.67(S D=1.15)$ | $0(S D=0)$ |

Table 2: Simulation of the five clusters

| G | N | TE | PE | SL |
| :---: | :---: | :---: | :---: | ---: |
| $1 \bullet$ | 18 | $8.83(S D=1.38)$ | $5.89(S D=1.08)$ | $0.11(S D=0.32)$ |
| $2 \bullet$ | 13 | $14.31(S D=1.55)$ | $9.23(S D=1.17)$ | $0.08(S D=0.28)$ |
| $3 \bullet$ | 3 | $22.00(S D=5.00)$ | $7.33(S D=0.58)$ | $0.67(S D=1.15)$ |
| $4 \bullet$ | 6 | $15.00(S D=2.53)$ | $10.83(S D=1.72)$ | $0.5(S D=0.55)$ |
| $5 \bullet$ | 2 | $18.50(S D=2.08)$ | $9.50(S D=0.71)$ | $0.00(S D=0.00)$ |

## Discussion

Results from the simulation are shown in Table 2. In total, 4 outliers have been excluded from the analysis (2, 1 and 1 from categories 3, 4 and 5, respectively). These outliers may conceivably have been produced by the model's unstable response to increasingly higher parameter values. Clustering the participant data into a small number of more homogenous groups greatly increases the correlation between TE and PE ( $r$ increases from .04 to .50 , compared with the observed value of .92 ) and decreases the correlation between SL and TE/PE, improving the fit of the model in both respects. Fig. 10 displays the new correlation plots worked out combining all of the five simulations together.

## General Discussion

The model we presented combines a variation of the Cooper and Shallice (2000) model of action selection and a variation of the Gurney et al. (2001) model of the basal ganglia. One of the strengths of this combined model is the possibility to generalise it to other cognitive control tasks (e.g. Stroop task, Probabilistic Reversal Learning, Eriksen Flanker Task, etc.) and to accommodate the presence of

Figure 9: Simulated data with five clusters

Figure 10: Correlation between performance errors aggregating the values from five different set of parameters
units representing other brain areas where different computation is performed (e.g., amygdala, cerebellum), enabling the simulation of cognitive tasks in broader contexts (e.g. Emotional Stroop Task, WCST in cerebellar patients). In principle, this enhances the contention scheduling theory with neuroanatomical detail, allowing a more precise localisation of processes in a particular task, and integration with functional neuroimaging data. In addition, this implementation allows for the inclusion of two distinct learning mechanisms in the cortex and the basal ganglia: the current model can potentially be updated to a learning-based model by developing these mechanisms.

With respect to cortical learning, in the model as it stands, the supervisory system that controls how subjects respond to positive and negative feedback is fixed and consequently performance tends to be too robust to basal unit dysfunctions. This might be addressed by incorporating dynamic learning that allows supervisory control to vary according to the schemas' activations, resulting in low or high baseline levels of dopamine in the striatum having a greater impact on cognitive performance.

The present paper makes the case for modelling subgroup data (or, whenever possible, individual data), instead of aggregate results, and presents evidence of how data clustering improves the model overall fit. Clustering is especially advisable for models of higher-order cognition, where subjects tend to have variable attention and may use qualitatively different cognitive strategies.

A final conclusion emerges from two joint observations: First, fitting clusters with increasingly extreme error values becomes increasingly more problematic. Second, another set of simulations (not reproduced here) shows that damaging the cortical and subcortical units threshold does not seem to produce the level of decline in performance found in Parkinson's disease patients without dementia (Paolo et al., 1996). Since healthy older controls have a different performance profile than the younger controls against which the current model was assessed, the loss of dopaminergic
cells in SNpc does not alone explain the inferior performance in the elderly and PD patients ${ }^{3}$.

These two joint findings suggest that the cognitive mechanisms producing perseverative and set loss errors might be independent only for a small number of errors. As that number increases, these two mechanisms might be correlated and possibly causally related. New experimental data to confirm this hypothesis is warranted.

# Distributional learning and lexical category acquisition: What makes words easy to categorize? 

Giovanni Cassani, Robert Grimm, Steven Gillis, and Walter Daelemans<br>Computational Linguistics and Psycholinguistics (CLiPS) Research Center<br>Department of Linguistics, University of Antwerp, 13 Prinsstraat<br>B-2000 Antwerpen, Belgium<br>\{name.surname\}@uantwerpen.be

#### Abstract

In this study, results of computational simulations on English child-directed speech are presented to uncover what distributional properties of words make it easier to group them into lexical categories. This analysis provides evidence that words are easier to categorize when (i) they are hard to predict given the contexts they occur in; (ii) they occur in few different contexts; and (iii) their contextual distributions have a low entropy, meaning that they tend to occur more often in one of the contexts they occur in. This profile fits that of content words, especially nouns and verbs, which is consistent with developmental evidence showing that children learning English start by forming a noun and a verb category. These results further characterize the role of distributional information in lexical category acquisition and confirm that it is a robust, reliable, and developmentally plausible source to learn lexical categories.

Keywords: Distributional bootstrapping; Lexical category acquisition; Statistical learning; Computational psycholinguistics; Language acquisition

## Introduction

Distributional bootstrapping (Maratsos \& Chalkley, 1980) is an influential account of how children start breaking into language, and specifically of how they start grouping words into lexical categories such as nouns and verbs. More specifically, it claims that children use patterns of co-occurrences across linguistic units, such as words and morphemes, to group words that share similar contexts. Several computational simulations have shown that distributional information is a rich, useful, and usable source of knowledge about lexical categories (Mintz, 2003; Redington, Chater, \& Finch, 1998; St. Clair, Monaghan, \& Christiansen, 2010). Moreover, a number of behavioral experiments have confirmed that children use this information to group words together (Mintz, Wang, \& Li, 2014; Reeder, Newport, \& Aslin, 2013).

Research on distributional bootstrapping has mostly focused on investigating which contexts constitute the best cues for the acquisition of lexical categories. Several proposals that have been put forward share the approach of grouping together those words that share similar contexts of occurrence, but differ in the starting assumptions and the types of contexts they evaluate. For example, Mintz (2003) suggested that frequent frames, i.e. trigrams consisting of two words flanking an empty slot $\left(a X_{\_} b\right)$, are a psychologically plausible and highly effective type of context for acquiring lexical categories. St. Clair et al. (2010), on the contrary, provided evidence that better categorization can be achieved by using bigrams $\left(a \_X+X \_b\right)$ that can be readily combined to obtain trigram level information.

This paper aims to explore distributional bootstrapping further and uses computational simulations to answer the following research question: what distributional properties of words make it easier to categorize them on the basis of the contexts they co-occur with? The relation between distributional properties of words and the extent to which these can be easily categorized in terms of lexical categories has been largely neglected in previous research, but characterizing it is important for two main reasons. Firstly, it generates predictions about the effect that several distributional properties of words have on lexical category acquisition in English speaking children: testing them can shed further light on the plausibility of distributional learning as an underlying mechanism for lexical category acquisition. Importantly, it is not enough that a model behaves like humans: a statistical analysis of what drives the model's behavior is necessary to assess whether it is driven by the same factors that affect human behavior. Secondly, it can help to constrain the development of psychologically motivated models of lexical category acquisition, by showing what information children are sensitive to when solving the task of grouping words into lexical categories.

In this work, computational simulations are used to carry out a categorization experiment whose outcome is used as the dependent variable in a regression analysis aimed to uncover the effect of several distributional properties of words on categorization accuracy. Results shed light and generate predictions on the mechanisms underlying distributional learning of lexical categories, and ultimately provide information to guide and constrain the development of psychologically motivated models of bootstrapping in language acquisition.

## Methods

## Corpora and pre-processing

In order to perform the computational simulations, transcribed interactions involving children and caretakers available in the CHILDES database (MacWhinney, 2000) were used. More specifically, the Manchester corpus (Theakston, Lieven, \& Pine, 2001) from the British English part, and the Suppes corpus (Suppes, 1974) from the American English part were selected, since they have both been widely used in previous research on distributional bootstrapping of lexical categories. The Suppes corpus consists of transcripts of one child, Nina, recorded from $1 ; 11$ to $3 ; 3$, while the Manchester corpus contains data of 12 children, recorded for varying periods within the age range $1 ; 8$ to $3 ; 0$. Both come with an au-
tomatic categorization in terms of Part-of-Speech (PoS) tags, which can be accessed on the MOR tier of the CHILDES annotation scheme. The child-directed speech from the corpora was pre-processed to deal with some aspects of the transcriptions. Two dummy symbols, \#start and \#end, were inserted at the beginning and end of each utterance. This manipulation is motivated by evidence that sentence boundaries provide useful distributional information (Freudenthal, Pine, \& Gobet, 2008). It also allows us to exploit every utterance from the corpus, including single word utterances: words occurring in isolation are considered to be occurring in the bigrams \#start_X and $X_{\_} \# e n d$, and in the trigram \#start_X_\#end.

Corpora from individual children were processed separately using a sliding window approach: starting from the first lexical element of the utterance, each word was considered as target, and all bigrams and trigrams occurring next to it were collected. These types of contexts were chosen given that they have been widely explored in previous research (Mintz, 2003; Monaghan \& Christiansen, 2008; St. Clair et al., 2010). As an example, consider the following utterance from the Manchester corpus: \#start are~v you~n going~v to $\sim f u n c t$ put $\sim v$ that $\sim a d v$ one $\sim n$ inside $\sim a d v$ ? \#end. The first target word, are, occurs in two bigrams, \#start_X and X_you~n, and two trigrams, \#start_X_you~n and $X_{-} y o u \sim n_{-}$going $\sim v$. For words in the middle of the utterance, three trigrams are available. The tags after the tilde indicate the lexical category to which each word belongs according to the automatic categorization. The original categories were collapsed to a coarser set, consisting of five categories: nouns ( $n$ ), including pronouns; verbs ( $v$ ), including auxiliaries, copulas, and nonfinite forms ${ }^{1}$; adjectives (adj), adverbs (adv), and function words (funct). The idea is to zoom in on the open classes, conflating the closed class words in a single category given that function words are categorized later in development. No lemmatization is performed, and all information about lexical categories is preserved ${ }^{2}$, although it is only used to evaluate whether categorization has been successful.

In order to minimize both the number of assumptions and that of possible decisions in the design of the experiment, all bigrams and trigrams are considered: some will turn out to be more informative to the categorization task than others, but the analysis of this aspect of the problem falls outside of the scope of this study. Larger $n$-grams are not considered due to the limited size of the corpora: they would be too infrequent to affect categorization.

## Experimental setting

A categorization experiment was carried out, in which words were clustered together based on the similarity of the contexts in which they occurred in corpora of English child-directed speech (Redington et al., 1998). Words that tend to occur

[^46]in the same contexts are considered to be more similar and clustered together: target words are categorized correctly if they are assigned the correct lexical category by the computational simulation. The experiment was performed using Memory-Based Learning (MBL, (Daelemans \& van den Bosch, 2005)), a class of machine learning algorithms which implements an exemplar-based strategy and categorizes new items using retrieval of or similarity to items stored in memory, with no explicit abstraction.

The categorization experiment consists of two main phases, which are referred to as training and testing in the paper. During training, co-occurrence counts between target words and contexts are collected on a portion of the input data and stored in memory. Each word is represented as a vector of counts, with each count indicating the co-occurrence frequency of the corresponding word and context. During testing, a new portion of the input is considered and the same procedure is applied. At the end of this second stage, the learner has created two matrices of co-occurrence counts. Each word from the test matrix is categorized by comparing its vector of co-occurrences with all the vectors from the training matrix, looking for the most similar one; the two are then clustered together. During learning, the model has no access to the correct lexical categories of the words and only groups them together based on their co-occurrence patterns, in an unsupervised way. At the end of the process, the category of two words that were clustered together is inspected: if they share the same lexical category, the word from the test set has been categorized correctly. In this framework, the only factor driving clustering is similarity, which is a well-documented cognitive mechanism in categorization (Sloutsky, 2003).

In order to divide each individual corpus into a training and a test set, utterances of child-directed speech were ordered chronologically and split in two parts: (i) the first $70 \%$ of the utterances were allocated for training; and (ii) the last $30 \%$ of the utterances were used as test set. To evaluate how different distributional properties interact with time, operationalized as a larger exposure to the input language, an incremental training approach was implemented. In detail, training started on the first $40 \%$ of all the utterances, then proceeded on the first $45 \%$, always increasing by 5 percentage points, up to the full training set ( $70 \%$ of the total utterances). The test set was kept constant to make sure that any change in performance came from the knowledge inferred from the training set and not by differences in the test set.

The TiMBL package (Daelemans, Zavrel, van der Sloot, \& van den Bosch, 2009) was used to carry out the simulation, using the default IB1 algorithm (Aha, Kibler, \& Albert, 1991) and cosine as a distance metric, because of its robustness to different frequencies in the co-occurrence vectors, and setting the number of nearest neighbors to 1 . Moreover, no feature weighting based on co-occurrence statistics from the training corpus was applied during the categorization experiment: this allows us to perform the categorization experiment without weighting contexts according to their informativity, avoiding
the effect of supervision on classification, which would be psychologically questionable and bias the results.

Importantly, no claim is put forward that children actually keep track of all available bigrams and trigrams, or that they implement an analogue of the IB1 algorithm with the chosen parameter setting. The interest of the current analysis is purely in the information that supports learning and in the analysis of the effects that distributional properties of words have on categorization, as operationalized using MBL.

## Statistical analysis

Four pieces of distributional information were computed for each word on the test set (last $30 \%$ of utterances of each corpus) and used as predictors in a regression model:

Token frequency: the log-transformed frequency count of each token. The transformation is motivated by evidence from Keuleers, Diependaele, and Brysbaert (2010) that lexical frequency effects are better captured by logtransformed frequency counts. A positive effect of frequency is expected (Ambridge, Kidd, Rowland, \& Theakston, 2015), since more frequent items are typically learned better than less frequent ones.

Contextual diversity: the log-transformed count of how many different contexts a word occurs in. A negative effect for contextual diversity is predicted: if a word occurs in many different contexts, its co-occurrence vector is noisy and it is harder to reliably group it with other words. This is the case, e.g., of function words, like conjunctions and determiners: they occur in all sort of contexts, making it hard to group them with similar words.

Average conditional probability: the average conditional probability of a word given all the contexts it occurs with. Consider a toy example where the context the $X$ occurs 100 times, 15 of which with the word cat: $p($ cat $\mid$ the_ $X)$, is thus 0.15 . Assume also that the word cat occurs 40 times in the context $a_{-} X$, which in turn occurs 200 times: $p\left(c a t \mid a_{-} X\right)$ is 0.2 . In order to obtain the average conditional probability for the word cat, $p(c a t \mid t h e \quad X)$ and $p\left(c a t \mid a_{-} X\right)$ are averaged, yielding 0.175 . This independent variable is predicted to have a negative effect on categorization: high conditional probability means that the contexts in which a target word occurs do not occur with other words, making it hard to find shared contexts of occurrence between the target and other words.

Entropy: the entropy of the co-occurrence vector of a word (Shannon, 1948), normalized by the number of contexts it occurs with, so that entropy lies between 0 and 1 . The entropy of a word is low when it occurs in the same context the majority of the times, while the more even the distribution of co-occurrences for a word, the higher its entropy. Entropy relates to diversity and its effect should go in the same direction: the more a word occurs equally frequently in the contexts it co-occurs in, the noisier its co-occurrence
vector and the harder it is to correctly group it with similar words. Importantly, normalized entropy provides a related but different piece of information than contextual diversity: the normalization ensures that the number of different contexts a word occurs in does not affect entropy.

A further independent variable was considered for both words and contexts, i.e. time, operationalized as the amount of training input on which the computational simulations were trained: time goes from 0 (i.e. $40 \%$ of all utterances in the corpus used as training set) to 6 ( $70 \%$ of all utterances in the corpus used as training set). Time should have a positive effect, since exposing the model to more input language should provide more reliable and robust information about co-occurrence patterns.

The analysis was restricted on words that appeared in all 13 individual corpora ( 12 from the Manchester corpus and 1 from the Suppes corpus), to reduce the effect of idiosyncrasies and focus on general patterns. All words with a token frequency of 1 were also excluded from the analysis, because when this is the case, contextual diversity and entropy are fully determined. If a word occurred only once, then it also occurred in only one context (diversity of 1 ), and its entropy is 0 , because the full probability mass is on the only context the word occurred in.

In order to analyze how easy it is to categorize a word, logistic mixed-effects models (Baayen, Davidson, \& Bates, 2008) were fitted using the "lme4" package in R (D. Bates, Maechler, Bolker, \& Walker, 2015). Random intercepts for corpus ( 13 levels) and word ( 456 levels, i.e. the single words that survived the filtering steps just detailed) were included. The categorization outcome of each word was used as a binary dependent variable, with each correctly categorized word coded as 1 . Covariates were included in a step-wise fashion, according to the improvement in fit measured by the Akaike Information Criterion (AIC, (Akaike, 1973)).

## Results

The best converging logistic mixed-effects model included main effects for average conditional probability, entropy, time, and contextual diversity. Adding a main effect for token frequency resulted in the model not converging. Two-way interactions between time and conditional probability, entropy, and lexical diversity were tested; however, when these were entered, the model did not converge. Table 1 provides the $\beta$ s estimated for this model, expressed on the log-odds scale, while Figure 1 represents the effects graphically, with accuracy expressed as proportion. The final model resulted in a marginal $R^{2}$ of 0.055 and in a conditional $R^{2}$ of 0.913 , suggesting that while the effect of predictors is significant, they do not explain much variance in the data. This is further addressed in the discussion.

As predicted, the average conditional probability of a word given the contexts in which it occurs has a strong negative effect on the estimated accuracy ( $\beta=-12.17, t=-11.56, p<$ 0.001 ), and the same is true for the entropy of the distribu-

Table 1: Mixed-effects model fitted to analyze what distributional properties make words easier to categorize. Estimates (Est.) and standard errors (Std. Err.) are provided on the logodds scale. (Cond. Prob.: average conditional probability of words given contexts; Cont. Div.: contextual diversity.

| Ind. Vars. | Est. | Std. Err. | $z$ | $p$ val. |
| :--- | ---: | ---: | ---: | ---: |
| (Intercept) | 14.185 | 1.298 | 10.928 | $<.001$ |
| Cond. Prob. | -12.170 | 1.053 | -11.560 | $<.001$ |
| Entropy | -11.027 | 1.215 | -9.077 | $<.001$ |
| Time | 0.078 | 0.011 | 6.838 | $<.001$ |
| Cont. Div. | -0.893 | 0.255 | -3.509 | $<.001$ |

tion of co-occurrence counts of a word over all the contexts it occurs in ( $\beta=-11.027, t=-9.077, p<0.001$ ). Time has a significantly positive effect $(\beta=0.078, t=6.838, p<0.001)$, showing that the clustering algorithm is actually exploiting the larger amount of input language to better group similar words together. Finally, contextual diversity has a significant negative effect ( $\beta=-0.893, t=-3.509, p<0.001$ ), suggesting that words are easier to categorize when they occur in fewer contexts, matching the initial hypothesis. As it was reported, adding frequency resulted in convergence issues: this is most likely due to the filtering step. It is possible that surviving words had similar frequency counts, making it impossible for the model to find sufficient variation to estimate the effect of token frequency on categorization accuracy, once contextual diversity already entered the model (since it improved the fit more than token frequency).

## Discussion

The results that have been presented point to a relation between distributional properties of words and the degree to which it is easy to categorize them into lexical category. The easiest words appear to (i) be on average hard to predict given the contexts in which they occur; (ii) have a very skewed distribution of co-occurrence counts with the contexts they occur in, meaning that they tend to occur most often in one or few contexts; and (iii) tend to generally occur in few contexts.

First, being able to predict a word given the contexts it occurs in is detrimental to categorization. This entails that effective categorization depends on some uncertainty in the co-occurrence patterns of words and contexts. Since categorization works on similarity (Sloutsky, 2003), two words can only be grouped together if they occur in the same context, i.e. they have something in common. The negative effect of conditional probability of words given contexts also points to a feature that contexts should have in order to be useful and usable, namely that they need to occur with more than one word. As a matter of fact, the conditional probability of words given contexts is computed by dividing the co-occurrence count of the word and the context by the frequency count of the context itself. For the average conditional probability of word given context to be low, each context must occur with other words

Figure 1: Main effects, with confidence bands, of average conditional probability, entropy, time, and contextual diversity on how easy it is to categorize a word in terms of lexical categories. The order, from top to bottom, reflects the improvement in fit brought by each predictor. The $y$-axis represents probabilities estimated from the log-odds reported in Table 1. Each axis is automatically scaled to provide a clear depiction of the effect. The plots were obtained using the effects package in R (Fox, 2003).
a substantial amount of times. This hypothesis fits evidence provided by Matthews and Bannard (2010) that children find it easier to group words together when these occur in contexts that, in turn, occur with several different words.

The negative coefficients of entropy and contextual diversity complement the negative effect of average conditional probability: the latter indicates that words are easier to categorize when they tend to occur in contexts only a fraction of the times the contexts themselves occur. $\beta$ s for normalized entropy and contextual diversity, on the contrary, tell that words are easier to categorize when they tend to occur most often in one or few contexts. The ideal situation is thus that of a word that always and only occurs in a single context, which however occurs with many other words, which also only occur in that context (to reduce noise). The effects of entropy and contextual diversity indicate that uncertainty in word-context co-occurrence patterns is necessary at the context level but detrimental at the word level: words need to occur in few contexts for effective categorization. This is likely due to the fact that when contextual diversity and entropy are high, the co-occurrence pattern of a word can be very noisy.

The distributional properties that make a word easier to categorize are rather distinctive of content words, especially nouns: knowing a context, e.g. a determiner, it is hard to predict exactly which noun will appear next to it, because many different nouns (and some adjectives) are possible, which translates into a low conditional probability of words given contexts. Moreover, it is likely that a noun occurs with one of the few determiners or possessive pronouns of the English language, thus scoring low on contextual diversity, and that most of the times it occurs with just a couple of specific determiners or possessive pronouns, scoring low on entropy. In order to get a grasp of which lexical categories easier words belonged to, those words that were categorized correctly for at least $80 \%$ of the 13 individual corpora at the last stage of training were selected. This analysis highlighted 127 such words: 2 function words, 101 nouns, and 24 verbs. This shows that the distributional properties of words that make them easier to categorize strongly correlate with lexical categories, and that the same features are a possible candidate to explain why certain lexical categories are formed earlier than others ${ }^{3}$. Furthermore, the majority of the 51 words that are never categorized correctly predominantly consists of function words (26) and adverbs (18), the categories that are learned later in development (E. Bates, Dale, \& Thal, 1995). The observation that nouns are categorized best also relates to the observation that children form a productive noun category earlier than any other category (Tomasello, 2000). The reported evidence lends support to the hypothesis that the so-called noun bias can be traced back to the distributional properties of words belonging to different lexical categories (Cassani, Grimm, Daelemans, \& Gillis, submitted), showing

[^47]that regardless of the fact that the set of target words contained an equal number of nouns and verbs, noun categorization is more effective.

The reported evidence also parallels and complements results about word learning, which suggest children find it easier to learn words (particularly nouns) when they occur in a variety of different contexts (Hills, Maouene, Riordan, \& Smith, 2010). While a comprehensive experiment is still lacking that explicitly contrasts the effect of contextual diversity on word learning and categorization, it emerges that this factor impacts both phenomena, although in opposite directions. While a higher contextual diversity is beneficial for word learning, it is detrimental to word categorization, as appears from the statistical analysis reported here. Further research about the interplay between different frequency effects (Ambridge et al., 2015) is needed to clarify to what extent distributional learning drives and explains language acquisition in its many different aspects and sub-tasks.

Lastly, this study investigated a fully distributional explanation of the developmental pattern of lexical category acquisition. However, the low $R^{2}$ shows that the distributional properties we investigated leave a substantial portion of variance unexplained, calling for further research on which properties affected the machine learner and whether these also influence children during lexical category acquisition. Moreover, current research has highlighted the importance of other sources of information during lexical category acquisition and word learning (Roy, Frank, DeCamp, Miller, \& Roy, 2015), including morphology, phonetics, semantics and prosody (Monaghan \& Christiansen, 2008). The influence of these sources of information should be further analyzed to complement research on distributional bootstrapping.

Summarizing, this study provided evidence about the effect of different distributional properties of words on the acquisition of lexical categories from distributional information. Conditional probability, entropy, and contextual diversity have a negative effect on categorization accuracy. Words with these features tend to be content words, mostly nouns, which also appear to be the words children start grouping earlier and most effectively. Future studies should assess the cross-linguistic validity of these findings, to understand whether the same distributional properties have similar effects in typologically different languages. Moreover, a similar approach - performing statistical analysis on the outcome of computational simulations - could be used to investigate what distributional properties make contexts more useful. Finally, other computational models should be tested, to compare their outcome to developmental data and shed light on which architectures are closer to what children actually do.

## Conclusion

The evidence presented in this study shows that specific distributional properties of words determine how easy it is to cluster them together based on the similarity of their cooccurrence patterns. In detail, words are easier to categorize
(i) when they are hard to predict given the contexts they occur in, (ii) when they generally occur in few contexts, and (iii) when they tend to occur more often in one context, having low entropy. This study extends previous research on distributional bootstrapping by providing evidence that distributional properties also affect which words are categorized more easily and which lexical categories are formed earlier.

# Knowledge transfer in a probabilistic Language Of Thought 

Samuel J. Cheyette, Steven T. Piantadosi<br>\{scheyett, spiantad\} @ ur.rochester.edu<br>Department of Brain and Cognitive Sciences<br>University of Rochester, Rochester NY, 14627 USA

#### Abstract

In many domains, people are able to transfer abstract knowledge about objects, events, or contexts that are superficially dissimilar, enabling striking new insights and inferences. We provide evidence that this ability is naturally explained as the addition of new primitive elements to a compositional mental representation, such as that in the probabilistic Language Of Thought (LOT). We conducted a transfer-learning experiment in which participants learned about two sequences, one after the other. We show that participants' ability to learn the second sequence is affected the first sequence they saw. We test two probabilistic models to evaluate alternative theories of how algorithmic knowledge is transferred from the first to second sequence: one model rationally updates the prior probability of the primitive operations in the LOT based on what was used in the first sequence; the other stores previously likely hypotheses as new primitives. Both models perform better than baselines in explaining behavior, with the human subjects appearing to transfer entire hypotheses when they can, and otherwise updating the prior on primitives.

Keywords: Knowledge transfer; Concepts; Language Of Thought; One-shot learning

## Introduction

One of the most remarkable capabilities of human cognition is the ability to rapidly create algorithms that are applicable to a new situation. For instance, an adult can quickly pick up a new card game, absorbing the rules and intuiting the strategy. Yet even the simplest card game is complex: it requires knowledge of basics like moves and turns; and it requires complex reasoning abilities, such as general-purpose strategic maneuvers in games. It seems more generally that humans' capacity to infer a lot from sparse data must be undergirded by a flexible array of useful concepts about many domains developed over a lifetime. For example, knowing about strategy in Texas Hold 'Em makes it possible to quickly pick up many other types of poker without reverting to a novice level, because requisite concepts across types of poker share similarities - betting, bluffing, winning hands. Yet this still leaves open the question: what are the representations and computations that make such effective transfer of abstract knowledge in this and myriad other domains possible?

Part of humans' adeptness in learning about new domains quickly may lie in their ability to map old conceptual structures to new ones, allowing them to infer abstract knowledge. This relational reasoning ability has often been characterized as "analogical" in nature (Markman, 1997), and many theories of analogical inference have been proposed on this basis (e.g. Gick \& Holyoak, 1980; Gentner, 1983; Holyoak \& Thagard, 1989; Hummel \& Holyoak, 1997). Gentner’s 1983 theory of "structure-mapping", formalized later as the "Structure Mapping Engine" (SME) (Falkenhainer et al., 1989), is an influential framework for describing analogical inference. On this account, situations or facts are given descriptions in
predicate logic, the components of which are either objects, relations, or attributes. The goal of a learner when presented with two situations is to make a mapping between these components by finding structural correspondences, and then inferring facts about one situation from the mapping to the other.

A commonality among SME and other theories of analogical transfer is their assumption of static knowledge representations. But structure only captures a limited subset of human knowledge. Other kinds of knowledge, such as learned processes or algorithms are untouched by these theories. In the poker example above, the algorithm of shuffling or bluffing may be transferred whole cloth to a new kind of poker. These abilities may be borrowed and incorporated into the algorithms that reason strategically. This kind of reuse would be much more like a programming language library-a location from which pieces of algorithms can be copied and reusedthan just a recognition of a correspondence of pieces. Indeed, in the same way that SME allows for powerful new inferences based on structure, transfer of algorithmic pieces could be part of the answer to how children eventually acquire algorithmically sophisticated representations: learners who can transfer algorithmic pieces need not construct entirely new representations each time they encounter a new domain.

Here, we experimentally and computationally test transfer of algorithmic components of representations by modeling concept learning as program induction over compositional functions, a system often called a "Language Of Thought" (Fodor, 1975). Under the LOT, a learner's job is to induce simple generative programs from primitive functions that match their observations of the world. In essence, this model treats learning as programming: there are a small set of "built in" operations that must be composed correctly in order to express richer algorithmic knowledge. This family of models has successfully been applied to explain human behavior in many rule-learning domains (Piantadosi \& Jacobs, 2016), including kinship and taxonomies (Kemp et al., 2008; Katz et al., 2008; Mollica \& Piantadosi, 2015), number (Piantadosi et al., 2012), causality, (Goodman et al., 2011), and words (Siskind, 1996; Piantadosi et al., 2008), among others.

Unlike structure mapping theories, LOT models are able to account for concept learning without requiring a significant amount of pre-developed knowledge. On the other hand, LOT models do not provide an account of humans' ability to transfer abstract knowledge between already-learned concepts. In general, it is an open question how LOT models can adapt their inductive biases and primitive representations through experience.

One possibility is that primitives are weighted in their prior according to their past utility as in the "Rational Rules" model
(Goodman et al., 2008). On this account, the prior is computed integrating out the production probabilities, allowing for a reduction in the penalty for repeated use of the same production rule. Among other things, this model has been used to explain selective attention effects, the finding that people tend to focus on as few features as possible to explain an observation.

Another possible way of explaining knowledge transfer in a LOT model is that upon learning a useful program, people store that program as a primitive for later re-use. This approach seems potentially more powerful than only updating priors over primitives themselves, as it could provide a basis for building increasingly complex, hierarchical conceptual structure. Indeed, Dechter et al. (2013) demonstrated how program recombination and re-use can facilitate and improve learning in the domains of both arithmetic and Boolean logic, using program induction over combinatory logic expressions. Others have explored models of sub-program re-use in Probabilistic Context Free Grammars, such as adaptor grammars (Johnson et al., 2006) and fragment grammars (O'Donnell et al., 2011). However, it has yet to be determined empirically if any of these models can explain human transfer of knowledge.

We ran a sequence-learning experiment to test human knowledge transfer, training people on one sequence and then testing them on a transfer sequence. We manipulated the congruity of the sequence pairs, corresponding to the abstract similarity of the training and transfer sequences. The results from our experiment suggest that having seen a congruous sequence in the past has a significant beneficial effect on accuracy. We modeled participants' learning curves in a probability-matching model and three probabilistic LOT models: a Rational Rules-type model that updates the prior of production rules in previously useful concepts; a model that adds previously useful concepts in full to its set of production rules; and a baseline model LOT model that does not update between training and transfer sequences. We compared the fit of each model to human data from our experiment. We found that the LOT model that re-uses high probability hypotheses from training provides the best fit to the data in the congruous condition, and the Rational Rules model provides the best fit in the incongruous condition. These findings suggest that learners transfer entire concepts when they can, and otherwise prefer previously used primitives.

## Experiment

We used a one-shot transfer learning paradigm in which participants were shown pairs of sequences which could either have come from similar LOT programs or not. To determine effects of knowledge transfer, we tested whether participants' overall accuracy on the the second sequence varied as a function of the first.

Participants 360 participants were recruited from Amazon Mechanical Turk, whose ages varied from 20 to 67 . They were paid 50 cents to complete the experiment, which took roughly $3-5$ minutes.

## Make a guess about the next color.

Figure 1: Example of display participants saw in the experiment.

## Method

Design The task involved a repeated binary choice, in which participants had to pick between two colored symbols (orange and blue) 15 times in learning both the training and transfer sequence. There were a total of 12 stimuli of which 6 were designated training sequences and 6 were designated transfer sequences. The manipulation was a fullfactorial between-subjects design with respect to the stimuli, so every possible combination of these sequences was tested, with only two shown to any given subject. An example of the display shown to participants is given in Figure 1. Note that every participant in both conditions saw the exact same training sequences - the differences in stimuli between conditions were only in the transfer sequence (the second of the two).
Stimuli The particular stimuli we chose were partly designed to allow for differing levels of compression in encoding in the LOT model. Some pairs of stimuli involve very simple repetitions, e.g. $\left(\left(A^{2} B\right)^{N}\right)$ and $\left(\left(A^{3} B\right)^{N}\right)^{1}$, which in our model are expressible in short hypotheses. Other patterns are not as efficiently compressible in our model, such as the repetition of $\left((A B)^{2} B\right)$. But, more importantly, they were designed such that the congruous pairs had abstract similarity, such that learning the first might help with learning the second. For instance, a congruous counterpart of the sequence $\left(A^{2} B^{3}\right)^{N}$ is the sequence $\left(A^{2} B^{4}\right)^{N}$, since a simple change to the description of one would result in the other. Every sequence in the first set had a congruous counterpart in the second set. The full set of stimuli is shown in Table 1, with congruous pairs adjacent.
Procedure Participants each saw two sequences, one after the other. Starting with no information about each sequence and ending with the entire sequence displayed on the screen, participants chose the symbol they thought was most likely given the previous values of the sequence they could see. After each guess, feedback appeared on the screen as to whether or not they were correct, and the correct symbol was placed at the end of the sequence on the screen. After participants completed the first sequence, it was erased from the screen, and they then completed the same task for the second sequence, starting from the beginning.

[^48]

Figure 2: This plot shows participants' accuracy in the transfer sequence over all 15 trials in the congruous (blue) and incongruous (red) conditions. The dots on top and bottom represent participants responding correctly or incorrectly at that trial, respectively. The decreasing transparency of squares of dots on top shows increasing numbers of correct responses, and the fact that the blue squares on top are less transparent than the red squares on top represents better learning in the congruous than incongruous condition. The two curves are the best-fit logistic regression predictions for the congruous and incongruous conditions.

| Training | Transfer |
| :--- | :--- |
| $\left(A^{2} B^{3}\right)^{N}$ | $\left(A^{2} B^{4}\right)^{N}$ |
| $B^{5}(A B)^{N}$ | $A^{4}(B A)^{N}$ |
| $\left(A^{2} B\right)^{N}$ | $\left(A^{3} B\right)^{N}$ |
| $\left(A B A B^{2}\right)^{N}$ | $\left(B A B A^{2}\right)^{N}$ |
| $B^{6} A^{N}$ | $A^{4} B^{N}$ |
| $B A^{2} B A^{3} B A^{4} \ldots B A^{i-1} B A^{i}$ | $A B A B^{2} A B^{3} \ldots A B^{i-1} A B^{i}$ |

Table 1: The full set of stimuli in our experiment is comprised of the first 15 symbols of each of these sequences. The congruous pairs are adjacent, and any non-adjacent pair is considered incongruous. The notation $X^{N}$ used here can be understood as N repetitions of sequence X . The bottom-most congruous pair is not as easily expressible in this way, but can be understood as incrementally increasing runs of one symbol interspersed by the other.

Participants were instructed to make their best guess about the next value of each sequence, even if they were unsure. They were told nothing about whether the two sequences were related, only that they both involved strings of colored symbols.

## Results

Our primary concern in analysis is to determine both the effect of sequence step and the effect of congruity on learning the transfer sequence. To determine both in a single analysis, we ran a logistic regression with both factors as fixed effects as well as random subject and sequence intercepts.

The results of this analysis revealed both a main effect of sequence step $(\beta=0.12, z=15.8, p<0.001)$ and congruity ( $\beta=0.70, z=4.69, p<0.001)$. The interaction between congruity and sequence step was not significant $(z=-0.12)$.

The fits from this analysis are shown in Figure 2, with the curves representing the best-fit regression lines for the congruous (blue) and incongruous (red) conditions.

Collapsing over all sequences and sequence steps in the transfer sequence, and just considering the average correct response given condition, those in congruous condition responded correctly more often $(M=0.75)$ than those in the incongruous condition ( $M=0.61$ ). The lack of interaction between congruity and sequence step implies that there is a lingering but constant beneficial learning effect in the congruous condition compared to the incongruous condition, but that the speed of learning in the two conditions is roughly the same.

## Model

The general modeling framework we used is a probabilistic Language Of Thought. In this approach there are a set of primitive, typed, and compositional operations, analogous to the statements that define programming languages (e.g. for Python 'if', 'elif', 'while', 'True', etc... would be considered primitive operations). The set of operations defines the "grammar", and the allowed rules for composing them are the rules for a Probabilistic Context Free Grammar (PCFG). The list of all possible compositions of production rules defines the entire hypothesis space. Since the number of possible hypotheses produced in our grammar is infinite, we use Metropolis-Hastings, a Markov Chain Monte Carlo (MCMC) sampling method, to provide a finite approximation to the entire space.

Each hypothesis H can be assigned a probability for any observed data D , which is computed via Bayesian inference: $P(H \mid D) \propto P(D \mid H) P(H)$. The likelihood, $P(D \mid H)$ is determined by how well the output of the hypothesis matches the
data. The prior probability $P(H)$ is computed according to the prior rule for PCFGs, which is the product of the prior probability of each primitive production rule $R$ composing $H: P(H)=\prod_{R \in H} P(R)$. The highest posterior probability hypothesis is therefore the most concise one that fits the data.

In the likelihood, we assume that hypotheses' output may be slightly noisy, giving each digit in the output sequence a 0.01 chance of being flipped. This likelihood formulation weights generated sequences higher in the likelihood in proportion to their similarity with the observed data. In addition to the intuitive plausibility of a similarity-weighting likelihood metric, this likelihood helps MCMC learn correct hypotheses by providing a graded (non-modal) posterior space. We performed no model fitting, and all parameters were used "out-of-the-box".

We ran a Metropolis-Hastings sampler for 100,000 steps and stored the top 100 hypotheses with the highest posterior found on each incremental prefix of the sequence.

## Hypotheses

In our model, hypotheses output binary sequences, corresponding to the binary colored symbols in the experiment. The production rules - which are the same across models are themselves operations on sequences and integers that return sequences. The production rules we chose were simply chosen to roughly be the minimal set necessary to concisely represent the sequences humans saw:

- $A^{\infty}$. Returns the symbol $A$ repeating unboundedly.
- $B^{\infty}$. Returns the symbol $B$ repeating unboundedly.
- Alternate $\left(I N T_{1}, I N T_{2}\right)$. Returns the sequence of alternations of $I N T_{1}$ and $I N T_{2}$. E.g. Alternate $(2,3) \Rightarrow\left(A^{2} B^{3}\right)^{\infty}$.
- Increment $\left(I N T_{1}\right)$. Returns the sequence of alternating repetitions of increasing length, starting from length $I N T_{1}$. E.g. Increment $(2) \Rightarrow A^{2} B^{3} A^{4} B^{5} \ldots A^{N-1} B^{N} \ldots$
- Append $\left(S E Q_{1}, S E Q_{2}\right)$. Returns $S E Q_{2}$ on $S E Q_{1}$. E.g. Append $\left(A^{2}, B^{2}\right) \Rightarrow A^{2} B^{2}$.
- Weave $\left(S E Q_{1}, S E Q_{2}\right)$. Returns $S E Q_{2}$ weaved between $S E Q_{1}$. E.g. Weave $\left(A^{2}, B^{2}\right) \Rightarrow(A B)^{2}$.
- Take $\left(S E Q_{1}, I N T_{1}\right)$. Returns the first $I N T_{1}$ items from $S E Q_{1}$. E.g. Take $\left((A B)^{5}, 2\right) \Rightarrow A B$.
- Invert $\left(S E Q_{1}\right)$. Returns the inversion of $S E Q_{1}$. E.g. $\operatorname{Invert}\left(B^{3} A\right) \Rightarrow A^{3} B$.

In these rules, $I N T$ could expand to the integers $1 \ldots 10$.

## Models of Learning

We implemented three different LOT models to test various possibilities about human concept learning from experience: a baseline model which does not update; a model that updates the prior of primitives; and a model that adds previous highposterior programs to its set of primitives. Each model was run on all 36 conditions in the experiment. Additionally, we
implemented a unigram model of the sequence to compare against the LOT models. The LOT models all started with the same production rules, which we assumed to have a uniform prior probability. All models were implemented using a freely available software package called LOTlib (Piantadosi, 2014).

Non-Updating Model In the baseline model, the primitives and their priors were fixed between the first and second sequence, and did not change.
Rational Rules Model We implemented a version of the Rational Rules model (Goodman et al., 2008), which updates the priors over primitives according to their posteriorweighted production rule count. This corresponds to a Dirichlet-Multinomial model, in which counts of each production rule in the Maximum A Posteriori (MAP) hypothesis from the training sequence are summed and subsequently used in computing the primitives' priors when learning the transfer sequence. Since a higher count corresponds to a decreased penalty for use in a tree, this is essentially a way of increasing the prior for primitive production rules useful in learning the training sequence. We assumed a uniform prior over production probabilities in the training sequence.
Re-Use Model Upon learning a concept, people may store and re-use this concept as a primitive. The way we captured this idea in our model was by placing the MAP hypothesis from the end of the training sequence as a primitive for generating hypotheses in the transfer sequence. The hypothesis space over primitives was re-normalized such that the primitives retained a uniform prior probability after this primitive was added.
Unigram Model We implemented a unigram model that responds proportionally to the probabilities of previous symbols. More specifically, we modeled this as a beta-binomial over the counts of the digits with a uniform prior. The counts were updated starting on the first sequence and continued through the second sequence. This is a baseline comparison, as it implements (smoothed) probability matching without taking into account any contingency.

## Results

Figure 3 shows the model's performance (with human data for comparison) at each step, collapsed over all sequences. The top panels display performance in the congruous condition and the bottom four show performance in the incongruous condition. It's worth noting again that these are predictions made with no model parameter tuning, but the rankorder speed of learning between models is unlikely to be affected by this. The first interesting thing to note is how well, and how quickly, each of the models learns in the congruous and incongruous conditions. The Re-Use model shows the greatest disparity between conditions, guessing accurately on average $66 \%$ of the time in congruous case and $54 \%$ of the time in the incongruous case, a difference of $12 \%$. This is substantially higher than the difference in the Rational Rules model (4\%), the unigram model (1\%), and the no-updating

Figure 3: Overall model correctness overtime in the congruous (top) and incongruous (bottom) conditions, collapsed overall all sequences. The human data is shown in red in each plot, as comparison. The dashed line is the just the constant of $\mathrm{y}=0.5$, for comparison.

| Condition | Analysis | No Update | Rat. Rules | Re-Use | Unigram |
| :--- | :--- | :--- | :--- | :--- | :--- |
| Congruous | Mean Squared Error $(x 10)$ | 0.57 | 0.37 | $\mathbf{0 . 1 7}$ | 0.65 |
| Congruous | $R^{2}$ | 0.60 | 0.70 | $\mathbf{0 . 7 2}$ | 0.13 |
| Congruous | Log Likelihood | -853 | -796 | $\mathbf{- 7 3 6}$ | -870 |
| Incongruous | Mean Squared Error $(x 10)$ | 0.16 | $\mathbf{0 . 1 2}$ | 0.13 | 0.23 |
| Incongruous | $R^{2}$ | 0.67 | $\mathbf{0 . 7 5}$ | 0.75 | 0.56 |
| Incongruous | Log Likelihood | -4322 | $\mathbf{- 4 2 6 8}$ | -4280 | -4412 |

Table 2: Overall performance measured in Mean Squared Error, $R^{2}$, and Log Likelihood, for each of the models in both the congruous and incongruous condition. The best fit for each metric is bolded. Note that the log likelihoods can be compared like AIC values since there are no free parameters.
model ( $0 \%$ ). This difference in the re-use model is most similar to humans, who responded correctly $75 \%$ of the time in the congruous congruous and $61 \%$ of the time in the incongruous condition, a change of $14 \%$.

To more precisely compare the model and human fits for each sequence, we report the Mean Squared Error (MSE), $R^{2}$, and Log Likelihood to aggregate human responses, for each sequence and condition in Table 2. In both conditions, all the LOT models were significantly better fits than the unigram model. In the congruous condition, the Re-Use model was clearly a better fit than any other LOT model or the unigram model. The reason it out-performs all the other models in this case is primarily that none of the others learn the sequences fast enough. In the incongruous condition, the LOT models in this case perform more similarly than in the congruous condition, but the Rational Rules model provides a slightly better fit of the three according to each metric.

## Discussion

The fact that the Re-Use model has the highest accuracy in the congruous condition (and closest to human-level) suggests that it is a better model of how humans' inferences benefit from helpful experience. The Re-Use model also displays the greatest disparity in accuracy between the two conditions,
though still not quite as large in the gap in human performance between conditions ( $12 \%$ versus humans' $14 \%$ ). Interestingly, the models display much more similar learning curves in the incongruous case. This means that the disparity in performance in the two conditions may be entirely due to the relative benefit of congruous experience - insofar as it changes primitives or their priors beneficially - but not as much to hindrance from incongruous experience. If true, this would predict that humans would perform about as well on the transfer sequence with no training sequence at all as with an incongruous training sequence.

To understand the Re-Use model's performance, it is informative to look at the actual representations that allow it to learn more quickly than the other models in the congruous condition. For each sequence, the MAP hypothesis from the first sequence is used in the MAP representation of the second sequence by the final step. Indeed, it is often orders of magnitude higher in the posterior than any other hypothesis. For instance, consider the case where the model sees:

$$
\left((A B)^{2} B\right)^{3}
$$

as training followed by:

$$
\left((B A)^{2} A\right)^{3}
$$

as transfer. The MAP hypothesis for the training sequence is displayed in orange in Figure 4.

This hypothesis gets added as a primitive, which we can call $M A P_{1}$. The shortest program on the transfer sequence that fits the data by the final step (and before), is simply invert $\left(M A P_{1}\right)$, which is the entirety of the tree in Figure 4. This, of course, generates the inverse sequence generated by $M A P_{1}$, which is a simple and low-cost transformation when treating $M A P_{1}$ as a primitive. The tree representing the MAP hypothesis for the transfer sequence in the Re-Use model is much higher in the prior than the MAP representation both the Rational Rules model and the No-Update model construct, since it only uses two primitives, compared to their use of eight.

Figure 4: The Re-Use model's MAP hypothesis for generating repetitions of $\left((B A)^{2} A\right)$ in the congruous condition. The part in orange is the MAP hypothesis from learning the training sequence $\left((A B)^{2}\right) B$, and the blue is a transformation on it, treating it as a primitive production rule.

It is also interesting that the Rational Rules model provides the best fit in the incongruous condition, closely followed by the Re-Use model. This suggests that even when people can't transfer a whole concept, they still prefer using primitives of past hypotheses. One possibility to explore in the future is combining the Rational Rules and Re-Use models. Another potentially powerful model could account for partial sub-tree re-use. This would reflect the possibility that people not only store useful programs in their entirety, but store useful subprograms. This added flexibility in recombination has been modeled using adaptor grammars (Johnson et al., 2006) and fragment grammars (O’Donnell et al., 2011). But inference in these models is substantially more complicated than models considered in this paper, and the extent of human flexibility in this regard remains an open question.

## Conclusion

Our experiment showed that people benefit in learning a sequence given prior experience with an abstractly congruous sequence. By considering congruity as a function of similarity in LOT program-space, we can understand human knowledge transfer as changes in the representations and biases of LOT models. We showed that a LOT model that treats previously learned programs as primitive rules is the best fit to human data in the congruous condition. On the other hand, we found that the LOT model that rationally updates the prior
on existing production rules is the best fit in the incongruous condition. This provides evidence that people spontaneously transfer knowledge of both whole programs and their subcomponents when learning.

#### Abstract

Word learning research has shown that learners constrain the hypothesis space for word meanings by using multiple sources of information, such as cross-situational regularities of word-context co-occurrences or syntactic cues, like the number of arguments. These studies typically focus on word meaning development where these cues can be helpful but not necessary. As such, it sheds little light on the acquisition of anaphors, which requires tracking syntactic dependencies across situations. To test whether or how learners track this information, we conducted a novel anaphor learning experiment with English and Japanese speakers, manipulating cross-situational regularities in anaphors and their syntactic dependencies. Results show both English and Japanese speakers closely track the frequency of interpretive possibilities for novel anaphors. However, they demonstrate difficulties learning long-distance reflexives, which are compatible with either local or non-local antecedents. This suggests that successful anaphor learning requires more than cross-situational regularities of interpretive possibilities.

Keywords: anaphors; binding; language acquisition; statistical learning; word learning

## Introduction

Sentences (1) and (2) illustrate that the interpretation of local reflexives like himself and pronouns like him rely on structural relationships to their antecedents (the noun phrase that the reflexive or pronoun refers to, e.g. himself $=$ John in (1), but him = Bill in (2)).
(1) Bill said that John kicked himself.
(2) Bill said that John kicked him.

This complementarity suggests that these anaphors respect different locality constraints; informally, English reflexives can only be bound by antecedents in the same clause, whereas pronouns must not be bound by antecedents in the same clause (Chomsky, 1981).

Other languages have different types of anaphors. For example, Japanese has a long-distance (LD) reflexive zibun, and replacing himself with this LD reflexive in the Japanese
translation of (1) results in an ambiguous sentence, as zibun can refer to either Bill or John. This suggests that in Japanese and other related languages, the local domain for zibun is expanded to the whole sentence, thereby allowing both the local and non-local antecedents.

This cross-linguistic variation suggests that the interpretive possibilities for anaphors are not universally determined, and must be learned from language experience. Learning the interpretive possibilities of anaphors requires learners to infer the intended meaning of the utterance based on the utterance context. For example, the nature of the events described by (1) and (2) is different: one is reflexive, while the other is transitive. Thus acquiring anaphors requires the learner to simultaneously track the syntactic relations between the anaphor and its antecedent, as determined by the context of the utterance. Critically, learning that the LD reflexive can take either a local or nonlocal antecedent requires tracking such information across multiple situations in which the LD reflexive is used with either one.

Previous word learning research has investigated how learners use such cross-situational regularities or syntactic structures to learn word meanings. For example, 2.5 yearolds acquired the meaning of a novel verb (e.g. pim) dependent solely on the frequency with which the verb was presented with a particular video of a particular action (Scott \& Fisher, 2012; for similar work on nouns see Smith \& Yu, 2008). While there is an on-going debate over whether learners gradually update word meaning hypotheses across situations, or whether learners instead iteratively test and revise successive hypotheses across situations (see Medina, Snedeker, Trueswell, \& Gleitman, 2011), both lines of work critically point to the fact that information across trials contributes to the word learning process.

Much work has also explored how learners use syntactic frames to constrain the meaning of novel words (syntactic bootstrapping; see Gleitman, 1990). For example, Yuan and Fisher (2009) showed that when infants heard a series of
transitive sentences with two arguments (e.g. Jimmy blicked the cat) in the absence of contextual information, they reliably interpreted the novel verb as referring to a causative event that requires two participants. On the other hand, presenting a series of intransitive sentences led infants to interpret the novel verb as referring to a single participant event. Such work shows that learners can use information from syntactic structures to narrow their hypotheses about word meanings.

In sum, the work reviewed above shows that learners make use of both distributional and linguistic cues. However, few studies have investigated the mechanism of anaphora acquisition, which requires tracking the crosssituational regularities of syntactic relations themselves. Research on anaphora acquisition mechanisms not only fills this empirical gap, but also provides a novel window into the constraints on cross-situational, statistical learning mechanisms.

The present study uses a novel anaphor learning experiment to investigate if and how participants use crosssituational co-occurrences of word form, contextual information, and syntactic structure. During the learning phase, participants are presented with sentence-picture pairs that contextually constrain the intended meaning of the target English sentence like (1) or (2) with a novel anaphor. We used three novel anaphors, following the interpretive possibilities of local reflexive (botu), pronoun (sumu), as well LD reflexive (togu). We included these three anaphor types for three reasons. First, this combination of anaphors is attested in Japanese and other languages, and therefore provides an ecologically valid anaphor system. Second, for English speakers, the Japanese LD reflexive is a new category of anaphor, so this allows us to simulate an actual learning process. Third, the local reflexive and pronoun are expected to be readily learnable for English speakers since both exist in English, and are also presented with a single interpretive possibility across trials. Thus, these anaphors can be used to validate this novel experimental procedure.

In order to probe the effectiveness of distributional information, we manipulated the frequency of two interpretive possibilities for the LD reflexive (i.e., local antecedent, akin to the meaning of (1), or non-local antecedent, akin to the meaning of (2)) by creating three between-subjects learning conditions: a Balanced condition where there were $50 \%$ local and $50 \%$ non-local antecedents; an LD-majority condition where $80 \%$ of the time the antecedent was non-local, and only local $20 \%$ of the time; and a Local-majority condition, where $80 \%$ of the time the antecedent was local, and only non-local $20 \%$ of the time.

If anaphor acquisition relies on accruing information and testing hypotheses across situations, then we would expect that a learner in the Balanced condition would be best able to learn the Japanese-style LD reflexive; encountering both interpretive possibilities should maximize learners' chances to realize the optionality of local and non-local antecedents.

However, there are two additional biases that may affect how learners use distributional information. For example, it
has been proposed that in the absence of clear disambiguating information, learners are often biased to adopt syntactic structures that are easier to process in subsequent comprehension (e.g. Fedzeschkina, Newport, \& Jaeger, 2016; Hawkins, 1999). With respect to processing LD reflexives, it has been found that at least in processing of Chinese LD reflexives, readers are biased to access local antecedents due to constraints on the working memory mechanism (e.g., Dillon et al., 2014). If this bias extends to anaphor acquisition, learners may struggle to learn the availability of the non-local antecedent with the LD reflexive, whereas even a relatively small percentage of input supporting the local antecedent may be sufficient to learn the availability of the local antecedent. Under this account, learners may in fact represent our LD-majority condition as if it were a 'Balanced' condition, because this local binding bias would enhance the availability of the local antecedent while dampening that of the non-local antecedent. If this is the case, then learners in the LDmajority condition - instead of the Balanced - should be best able to realize the optionality of local and non-local antecedents with the LD reflexive.

Another potential source of bias, which may be particularly relevant to the present study, is the influence of anaphors in the participants' native languages. The second language (L2) acquisition literature has found evidence for strong first language influence on the L2 acquisition of anaphors. For example, Yuan (1998) showed that Japanese speakers learning the Chinese LD reflexive were more likely to accept non-local antecedents than English speakers learning Chinese. Conversely, Japanese speakers learning English struggled to rule out non-local antecedents for English reflexives in a similar task (Hirakawa, 1990). Together, these results suggest that learners tend to 'transfer' and expect the same anaphors in their L2. Given that our study explores how adult learners acquire a novel anaphor, anaphors in the native language may constrain what can be learned within a single experimental session.

To investigate the native language influence on anaphor acquisition, we conducted this experiment with English native speakers and Japanese native speakers. If prior knowledge affects novel anaphor acquisition, then we would expect a contrast between the English and Japanese group: English speakers should struggle to learn the optionality in the LD reflexive, whereas Japanese speakers should be able to correctly learn the novel LD reflexive based on their knowledge of zibun in their native language.

## Experiment

## Participants

Fifty-seven native English-speaking members of the Johns Hopkins University community participated in the experiment. They were compensated with course credit or $\$ 10$ cash. According to self-reports, none of the participants knew languages with LD reflexives. Participants were randomly assigned to one of the three learning manipulation
conditions. All participants completed a learning phase and then a test phase in the same session.

In addition, 57 native Japanese-speaking students from Tsuda College participated in the Japanese version of the same experiment. They were compensated $¥ 1000$. Performance in an English cloze task (adapted from Kobayashi, 2002) revealed intermediate syntactic and semantic knowledge in English (maximum possible score: $25 ; \mathrm{M}=15.529, \mathrm{SE}=4.130$ ), suggesting the relative dominance of Japanese over English.

## Materials

Learning Phase Trials The 78 sentences for the Learning Phase were English sentences with clausal embedding (e.g. John $\{$ said/remembered $\}$ that Susan combed $\{b o t u / t o g u / s u m u\}$ ), where botu, togu and sumu were the novel words used as the local reflexive, LD reflexive, and pronoun respectively. These anaphors were not marked for gender. Three main clause verbs (comb, wash, fan) were used once with both said and remembered. Using these six sentence frames, three male and three female character names were permuted to create 24 sentences containing the local reflexive and 24 containing the pronoun. For the local reflexive sentences, one sentence for each main clause verb was replaced with a mono-clausal sentence with the same verb. Taking these local reflexive sentences (including the mono-clausal sentences) and adding 6 additional embedded clause sentences following the same procedure described above created the 30 sentences containing the LD reflexive.

In order to make the intended interpretation of each sentence clear, throughout the experiment pictures were paired with each sentence to form a trial. Local reflexive sentences were depicted with pictures showing the syntactically local noun phrase as the antecedent of the anaphor; pronoun sentences were depicted with pictures showing the syntactically non-local noun phrase as the antecedent of the anaphor (as in Figure 1). Critically, LD reflexive sentences were depicted with either type of picture; referred to as the local antecedent in the former case, and the non-local antecedent in the latter.

Figure 1: An example picture-sentence pair with togu (the novel LD reflexive), which illustrates the non-local antecedent (Adam washing David). The local antecedent version of this trial type would picture Adam washing himself inside the speech bubble.

Learning Conditions The picture-sentence pairs were used to create three different distributions of LD reflexive interpretations. For the Balanced condition, 15 LD reflexive sentences were paired with local antecedent pictures (including the necessarily local mono-clausal sentences, which appeared with a single character performing an action to themselves, with no speech bubble); the remaining 15 sentences appeared with non-local antecedent pictures. For the LD-majority condition, 24 sentences appeared with nonlocal antecedent pictures, while the remaining six sentences (including the three mono-clausal sentences) appeared with local antecedent pictures. For the Local-majority condition, 24 sentences (including the three mono-clausal sentences) appeared with local antecedent pictures, while the remaining 6 appeared with non-local antecedent pictures. This resulted in an $80 \% / 20 \%$ distribution in the two unequally distributed conditions.

Picture Verification Test To create the sentences for the picture verification test, one set of six embedded clause sentence frames for each anaphor was reused with three new main clause verbs (splash, paint, measure). To create the trials, half the sentences were paired with their appropriate picture as described above to make match trials, and the other half was paired with the inappropriate picture (e.g. a non-local picture with a local reflexive sentence) to make mismatch trials, making sure that a roughly equal number of each anaphor, embedding and main clause verbs were in both sets of trial types. ${ }^{1}$

Materials for the Japanese experiment For the Japanese version of this experiment, the Japanese sentence materials were constructed in a very similar way as in the English experiment. However, because Japanese verbs are more selective in their argument structure, we were forced to change the events depicted in order to maintain natural sounding sentences, opting for a construction where the anaphor is marked with the dative particle -ni. The events depicted in the Japanese learning materials were: sticking tape to someone (__ni gamutepu-wo haru), wrapping a ribbon around someone (__ni ribbon-wo makitsukeru), and loading a $\log$ onto someone (__ni maruta-wo noseru). In the test they were: spilling water onto someone (__ni mizuwo kakeru), putting paint on someone (_ni enogu-wo nuru), and pinning an award on someone (__ni bajji-wo tsukeru). All stimuli were presented in Japanese using hiragana and kanji, with novel anaphors spelled in katakana.

## Procedure

The procedure was identical for the two language groups, but the Japanese version was carried out in Japanese by trained native Japanese-speaking research assistants.

[^49]Learning Phase This experiment was implemented in PsychoPy (Pierce, 2007). During the Learning Phase the participant was presented with one picture-sentence trial at a time. They were instructed to read the sentence aloud, and take as long as they needed to figure out the meaning of the novel word. They used the space bar to progress to the next trial, working at their own pace.

Participants were instructed to infer the meaning of novel words they would encounter in the experiment. The instructions explicitly stated that the novel words may or may not correspond to existing words in their native language. After the instructions, there were three blocks of learning trials, consisting of 26 trials each, with eight sentences each for the local reflexive and pronoun, and 10 LD reflexive sentences (including 1 mono-clausal local and one LD reflexive sentence).

In order to motivate participants during the learning phase, these learning blocks were interspersed with two quiz blocks containing 12 picture verification test trials, four for each anaphor. At the start of the first quiz block participants were given brief instructions telling them to respond 'match' if the sentence appropriately described the picture based on what they thought the novel words meant. There were two practice trials. No feedback was provided.

The order of these learning blocks, and of the quiz blocks was counter-balanced across participants to control for any list order effects. The trial presentation order was randomized within each block using PsychoPy's trial randomization function. Participants typically completed this phase in 20-30 minutes.

Test Phase Participants were given the picture verification test as described above for the quiz trials. Again, they were told to indicate if the sentence described the picture by pressing either ' $f$ ' for match or ' $j$ ' for mismatch. The trials were presented randomly, with a break halfway through. Participants typically completed the test phase in 20-30 minutes.

## Results

For statistical analyses of the data, the picture verification responses from each language group were entered into a mixed logit model (Jaeger, 2008) with the acceptance response (i.e. the picture and the sentence description match) as the dependent variable. We used learning condition, picture antecedent and anaphor type, and the twoand three-way interactions as predictors, and participant and item as random effects.

English Figure 2 shows the results for the English-speaking participants. On average, participants in all three learning conditions were more likely to accept the local reflexive with a local antecedent ( $\beta=1.568, \mathrm{z}=13.239, \mathrm{p}<.000$ ) and less likely to accept the pronoun with a local antecedent ( $\beta=$ $-1.531, \mathrm{z}=-12.833, \mathrm{p}<.000$ ). This was an expected pattern given that local reflexives and pronouns exist in English, and the input provided consistent information. This

Figure 2: Mean acceptance rates, split by each anaphor given a particular antecedent, across the three learning conditions, from English speaking participants.
reassured us that the task was achievable given consistent input. We turn now to the optionality in the LD reflexive.

With respect to the acquisition of the LD reflexive, we had initially expected participants in the Balanced condition to show the best ability to accept the LD reflexive in both local and non-local antecedent trials. However, this expectation was not confirmed, as the acceptance rate for the LD reflexive was not high in either local or non-local antecedent trials (Figure 2). In order to explore the impact of distributional regularities, we conducted planned pairwise analyses and compared response rates for the LD reflexive across the three learning conditions. Participants in the Local-majority condition and LD-majority condition showed a reliable preference to accept the LD reflexive with the antecedent that was frequently presented in the input (Local-majority condition: $\beta=1.211, \mathrm{z}=6.336, \mathrm{p}<.001$; LD-majority condition: $\beta=-1.024, \mathrm{z}=-5.201, \mathrm{p}<.001$ ). Finally, when response rates for the LD reflexive were compared across the three conditions, participants only showed a strong preference for an antecedent in the Local condition ( $\beta=1.211, \mathrm{z}=6.336, \mathrm{p}<.001$ ) and the LD condition ( $\beta=-1.024, \mathrm{z}=-5.201, \mathrm{p}<.001$ ), not the Balanced condition. Furthermore, in a model considering only acceptance rates of the LD reflexive in the Balanced condition, there was no significant preference for either antecedent ( $\beta=0.614, \mathrm{z}=1.547, \mathrm{p}=.122$ ), suggesting that participants in the Balanced condition truly were responding at chance on a given LD reflexive trial. This pattern of responses suggests that participants' behavioral response patterns reproduced the distributional regularities they observed in their input.

Moreover, participants in the LD-majority condition were less likely to accept the local antecedent with the LD reflexive compared to those in the Local-majority condition ( $\beta=-0.823, \mathrm{z}=-6.119, \mathrm{p}<.000$ ), or those in the Balanced condition ( $\beta=-0.347, z=-2.593, p=.010$ ). Similarly, participants in the Local-majority condition were more likely to accept the LD reflexive with local antecedents compared to those in the Balanced condition $(\beta=0.340, \mathrm{z}=$
2.775, $\mathrm{p}=.006$ ), and the LD-majority condition ( $\beta=0.823$, $\mathrm{z}=6.119, \mathrm{p}<.000$ ). These patterns suggest that participants in the unequally distributed learning conditions also reproduced the rate at which the local or non-local antecedents appeared in their input.

Japanese Figure 3 shows the results for the Japanesespeaking participants. Overall, Japanese speakers' response patterns were very similar to those of English speakers. Participants across the three learning conditions accepted the local reflexive more often with local antecedents $(\beta=$ $1.196, \mathrm{z}=10.524, \mathrm{p}<.001$ ) and rejected the pronoun with local antecedents $(\beta=-1.275, \mathrm{z}=-10.519, \mathrm{p}<.001)$. Japanese speakers were also sensitive to the distributions in their learning condition. When participants in the Balanced condition were compared to those in the Local-majority condition, there was no significant difference in their acceptance rates for the two antecedents with the LD reflexive $(\beta=0.208, z=1.378, p=.168)^{2}$. But like English speakers, participants in the LD condition compared to the Balanced were less likely to accept the LD reflexive with a local antecedent ( $\beta=-0.637, \mathrm{z}=-4.757, \mathrm{p}<.000$ ).

Pairwise analyses of the LD reflexive data at each group level again reveal the similarity between English and Japanese speakers. Participants only showed a strong preference for a local antecedent in the Local-majority condition ( $\beta=0.787, \mathrm{z}=4.065, \mathrm{p}<.001$ ) and non-local antecedent in the LD-majority condition ( $\beta=-1.062, \mathrm{z}=$ $-5.228, \mathrm{p}<.001$ ), but no clear preference was observed in the Balanced condition. Furthermore, in comparison to participants in the Local-majority condition, those in the LD-majority condition were less likely to accept the LD reflexive with local antecedents ( $\beta=-0.679, \mathrm{z}=-5.228, \mathrm{p}<$ .000). Finally, when response rates for the LD reflexive were compared across the three conditions, participants only

Figure 3: Mean acceptance rates, split by each anaphor given a particular antecedent, across the three learning conditions, from Japanese speaking participants.

[^50]showed a strong preference for an antecedent in the Local condition ( $\beta=0.787, z=4.065, p<.001$ ) and the LD condition ( $\beta=-1.062, \mathrm{z}=-5.228, \mathrm{p}<.001$ ), not the Balanced condition. In the model considering only acceptance rates of the LD reflexive in the Balanced condition, there was again no significant preference for either antecedent ( $\beta=-0.493, \mathrm{z}=-1.215, \mathrm{p}=.224$ ).

Overall, participants across both language groups show strikingly similar response patterns. They were only willing to accept each anaphor following the distribution of antecedent co-occurrences provided in their input, even when the optionality presented there resembled their native language (i.e. Japanese speakers). Results also suggest that the chance responding in the Balanced condition across both language groups was not the result of different individuals preferring different antecedents, rather as a group these participants are simply reproducing the statistical regularities in their input.

## Discussion

The present study used a novel anaphor learning paradigm to investigate cross-situational learning of novel anaphors. Overall, we found that participants in our study appear to track the distribution of syntactic structures across situations to constrain their anaphor acquisition. The fact that learners reproduced the distribution of local vs. non-local interpretations for the LD reflexive indicates that the input distribution was guiding the process of anaphor acquisition. This kind of probability-matching behavior, which has been reported in other statistical learning paradigms (e.g. Hudson Kam \& Newport, 2005), further illustrates humans' ability to reproduce and learn regularities in their input from simple frequency tracking (c.f. Estes, 1976). Furthermore, the fact that there was little difference between the two language groups - specifically the fact that Japanese speakers, like English speakers, treated the LD reflexive as a local reflexive or pronoun based on their learning condition rather than following the interpretive possibilities of their native zibun - suggests that biases to copy and reproduce regularities in the input distribution played a more important role than other potential biases (e.g. processing biases or L1 influence).

One of the main research questions in this study concerned how participants handle the optionality in the interpretive possibilities of the LD reflexive, and how manipulating the distribution of those two options would affect acquisition. The results demonstrate that learners struggle to acquire the optionality of the LD reflexive, regardless of their native language. Participants in the unequally distributed learning conditions appeared to treat the antecedent that only appeared $20 \%$ of the time as noise, ignoring it during learning, and accepting roughly that same rate of 'noise' during test (for all three anaphors). In other words, participants in the LD-majority and Local-majority conditions simply treated the LD reflexive as another form of either the pronoun or local reflexive, respectively.

Participants in the Balanced condition appear to be roughly at chance in accepting or rejecting the provided antecedent.

These results and conclusion raise an important question for future research: if distributional regularities are not useful in acquiring anaphors that allow for more than one interpretation, how do speakers of languages like Japanese acquire the interpretative optionality of their LD reflexives?

One possible explanation is that learners must first be confident about one possible antecedent before allowing optionality. For example, learners in the two unequally distributed learning conditions may have settled on one interpretation, without having received enough evidence to allow optionality. Learners in the Balanced condition, however, were not confident about either antecedent. To test this, an on-going follow-up experiment is exploring the effect of presentation order and the frequency of particular antecedents, e.g. presenting a majority of either local or non-local antecedents before introducing the kind of optionality we presented in the Balanced condition.

Alternatively, this difficulty could be explained by a uniqueness principle, i.e., bias against many-to-one meaning-form mappings. Learners must learn that both multiple semantic and syntactic mappings are acceptable for LD reflexives, so future work should investigate this bias at both levels. For example, highlighting the distinctiveness of the LD reflexive's interpretive optionality may increase learners' acceptance of optionality. To this end, sentences with relative clauses may help learners disambiguate between anaphor types: in "The woman standing next to Susan splashed her/herself," zibun is only interchangeable with herself, not her because Susan does not c-command the anaphor. The current data can only address the acquisition of the locality constraint, and not the c-command requirement on the structural relation between antecedent and anaphor, but learning both in tandem may be critical for successful acquisition of an LD reflexive.

Sentences where the reflexive is in the subject position of an embedded clause could also provide evidence that the LD reflexive differs from the local reflexive in its syntactically constrained interpretive possibilities (e.g. "John said that zibun-wa awesome."). While such a sentence is not possible with a local reflexive, it is grammatical for zibun precisely because the LD reflexive can take an antecedent outside the local clause (in contrast to the local reflexive's more restricted locality constraint). Providing these sentences in the learning input may provide further evidence to learners about the distinctiveness of the LD reflexive, and increase their confidence that optionality is integral to the LD reflexive type anaphor itself and not noise in the input.

In short, findings from the present study provide an important step towards understanding the constraints on cross-situational learning of anaphoric expressions. We suggest that successful acquisition of an LD reflexive may require that learners incrementally acquire interpretive possibilities in sequence, or that they are presented with an additional syntactic cue that unambiguously indicates the availability of the non-local antecedent interpretation.

# Expected Utility in Romantic Relationships: Satisfaction as a Cue for Romantic Partnership Dissolution 

Samantha E. Cohen (cohense@indiana.edu)<br>Psychological and Brain Sciences and Cognitive Science Program, 1101 W. $10^{\text {th }}$ Street Bloomington, IN 47405 USA<br>Peter M. Todd (pmtodd@indiana.edu)<br>Psychological and Brain Sciences and Cognitive Science Program, 1101 W. $10^{\text {th }}$ Street Bloomington, IN 47405 USA

#### Abstract

The choice to enter and leave a romantic relationship can be framed as a decision-making problem based on expected utility of the partnership over time, akin to a forager deciding whether to stay in a particular patch based on the amount of resources it provides. We examined the temporal trajectory of three traits that may correspond to resources in romantic relationships-trust, love, and satisfaction-to determine whether they behave like depleting or replenishing patches from a foraging perspective. All three rise over time in intact relationships-suggesting replenishment-but plateau or fall in dissolved relationships-suggesting depletion. Survival analysis demonstrated that higher ratings of all three quality variables decreased the risk of romantic dissolution. The results suggest that these cues are lower in dissolved relationships, indicating individuals could potentially use them as cues for leaving an unsatisfactory relationship patch via aspiration-level cognitive mechanisms.

Keywords: foraging theory; romantic relationships; survival analysis; relationship dissolution; mate choice

All good things must come to an end, including romantic relationships. In some cases, it is not until death that we part, but many relationships end before that point through someone's active choice. Relationship dissolution is a highintensity and long-lasting stressor (Simpson, 1987; Sprecher, 1994), indicating that avoiding it is important to people. Yet most people seem to enter relationships that eventually end and are often caught off-guard when it occurs, indicating that it can be difficult to predict. Individuals cannot usually determine the expected outcome of a relationship prior to entering the relationship itself, meaning they may continuously evaluate their relationship and decide whether one's relationship is likely to (or should) end. Previous work in this choice domain has tackled the brighter side of romance, such as how individuals choose a relationship partner (e.g. Beckage, Todd, Penke, \& Asendorpf, 2009), but less work has examined how individuals decide to move on. What cues do individuals consider when choosing to end a relationship, and how are they incorporated into choices?

How long to stay with something typically depends on what one is getting out of it. Individuals clearly expect to get something out of romantic relationships, given that many expend significant time, money, and energy searching
for and maintaining them. The best-studied aspects of relationship quality (or utility) include relationship satisfaction, intensity of love, and level of trust. Metaanalyses have found that measures of relationship quality more strongly influenced relationship dissolution than either individual traits (e.g. neuroticism) or external factors (e.g. social network overlap; Le et al., 2010). Daters may thus consider the amount of utility, quality, or other valued attribute produced in a relationship when choosing whether to exit it and attempt to find a better relationship. This utilitarian view departs from the traditional cultural emphasis on the holistic nature and complexities of romance. However, for a significant portion of human history, relationships were designed to be mutually beneficial to a couple and their extended families, and relationships with little expected gain were avoided.

It is not novel to suggest individuals attempt to get the best relationship possible (whatever that might be), but few have connected the study of romantic relationships to theoretical models of choice. Problems involving searching for and maximizing resources are well studied within the foraging literature in biology. Optimal foraging theory (OFT; Stephens \& Krebs, 1986) considers how foragers maximize their total gain (e.g. calories) in an environment. Foragers traverse a landscape filled with patches of some resource (e.g. berry bushes), choosing to enter and obtain (e.g. consume) those resources before leaving to find new or better patches. The relationship-foraging model (Cohen \& Todd, 2017) treats the search for successive relationships as a foraging problem. Entering a relationship could be thought of as entering a "patch" that provides some mix of satisfaction, love and other benefits. Relationship foragers search through a social landscape of potential romantic partners, choosing to pass by some, entering into a relationship with others (and reaping the benefits), and possibly eventually departing in search of another. Depending on just what sort of patch a relationship is like, OFT can make predictions about how long people should stay in the relationship patches they find.

One commonly-studied type of patch is characterized by resources that are depleted over time as the forager consumes them. Berry bushes are a common example of this type of patch, with the ripe berries being continually consumed until the forager decides to leave. For these
bushes, the rate of return (e.g. calories consumed per unit time) is expected to increase rapidly early on as a forager enters a patch, with a diminishing rate of return as resources are consumed. The Marginal Value Theorem (Charnov, 1976) in OFT states that individuals should leave such depleting patches when the rate of return within the current patch is less than the rate of return that is expected from the environment at large, given optimal search behavior and expected search costs.

But not all patches only deplete over time-some may deplete and replenish (such as a berry bush with new berries ripening across weeks), and some may produce a roughly constant output for extended periods. Immobile barnacles settled on a tide-pool rock capturing food floating past are partaking of such long-lasting patches. These and other animals are known as sit-and-wait foragers (Beachly, Stephens, \& Toyer, 1995), as once they have found a patch location of this non-depleting type they can stay there exploiting it for a long time. In such situations, "simply staying put can make good economic sense" (p. 265), but leaving is also predicted when patch quality declines or other circumstances change, such that the forager could get a better rate of return by looking (and exploiting) elsewhere.

How do relationships compare to these types of patches? Some aspects seem typically to start high and deplete over time, such as the novelty of a new partner. But others do not appear to be capped-there is probably no preset amount of satisfaction, love, or trust that one can get in a relationship, unlike the fixed number of ripe berries currently in a bush. This suggests that various measures of relationship quality may not only fall but also can replenish over time, and can even stay level or grow indefinitely.

It is important for specifying the relationship-foraging model to determine whether any aspect of relationship quality follows the assumptions of OFT regarding particular types of patchy resource, whether depleting, or replenishing, or constant. A depleting patch should show high (or rapidly growing) initial rate of return, then falling over time. A replenishing patch would have a rate of return that falls and rises, possibly repeatedly. Finally, a constant patch would have a rate of return that rises (possibly very quickly) to a roughly steady state.

In this work, we assess ratings of three types of quality in a romantic relationship: satisfaction, love, and trust. We examine how these factors change over time, to determine which may be useful in predicting relationship dissolution given different patch definitions in the relationship-foraging model. The data come from self-reports from intact and dissolved romantic relationships.

Previous research has demonstrated that aspects of quality, especially satisfaction, tend to increase dramatically at the start of a relationship (Rusbult, 1983) followed by relative stability or decreasing levels over time (Levenson \& Gottman, 1985; Rusbult, 1983; Sprecher, 1999). In one of the rare longitudinal works, satisfaction and commitment to the relationship increased over time (Rusbult, 1983). Sprecher (1999) measured several aspects of quality at
yearly intervals in couples and found the opposite result: Satisfaction was significantly lower for both genders and love was significantly lower for men at the first yearly interval, but otherwise, ratings were remarkably stable. Only the longest-lasting couples (those lasting the full 4 year study period) reported an increase in quality, with a slight increase in commitment and satisfaction for women in the final year. Thus, we expect that longer-lasting relationships will report greater satisfaction, and possibly other quality variables such as trust, although this pattern will not hold for love beyond the earliest time points.

These trajectories diverge depending on the eventual relationship outcome. Among relationships remaining intact (at least, during the duration of a particular study), satisfaction and commitment stabilize or slowly increase over time (Rusbult, 1983; Sprecher, 1999). Individuals exiting a dissolved relationship report decreased satisfaction but only slight decreases in love, suggesting relationships tend to end due to changes in satisfaction rather than love (Sprecher, 1994; Sprecher 1999). These diverging paths lead to large disparities in commitment and satisfaction between couples remaining intact and those ending (Rusbult, 1983; Simpson, 1987). Hence, we expect that reports on satisfaction and trust, but not love, to be higher for intact than dissolved couples.

In the next section we analyze the time-course of selfreported ratings of different types of relationship quality, to assess their similarity to rates of return for depleting, replenishing, and constant patches. We then use survival analysis to test whether these self-reported aspects of quality influence the likelihood of exiting a relationship (i.e., leaving a relationship patch).

## Method

A survey was used to assess relationship length versus quality of intact and dissolved romantic relationships in undergraduates. All procedures were approved by the Indiana University Institutional Review Board.

## Participants

A sample of 700 undergraduates was collected from the Indiana University psychology subject pool. To qualify, participants needed to have at least one romantic experience, including but not limited to casually going on dates, being in a committed relationship, or getting married. Forty-five participants who indicated they had never been in any sort of romantic relationship or did not indicate whether they were in a relationship currently were not included in the analyses. Of the remaining 655 participants, $62.0 \%$ were currently in a romantic relationship. All 655 participants indicated the type of relationships they were giving us ratings for (whether their current relationship or their most recent dissolved relationship); $50.8 \%$ were describing committed relationships (but not engaged or married), 44.4\% were casual relationships and early relationships without a clear classification, $2.4 \%$ were engaged or married, and the remaining $2.3 \%$ fell outside these
categories. Of participants primarily identifying with a single racial group ( $n=616$ ), $72.1 \%$ identified as white, $14.90 \%$ as Asian, $8.1 \%$ as black, and $4.9 \%$ as Hispanic or Latino. Subjects were primarily heterosexual (91.3\%) females (58.6\%) between the ages of 18-21 (90.2\%). Participants were compensated with course credit.

## Measures

Participants completed a survey for approximately 30 minutes online through Qualtrics. Participants currently in a romantic relationship (intact couples) were asked to describe various qualities of their current relationship. Individuals not currently in a relationship were asked to imagine their most recent romantic relationship prior to its dissolution (dissolved couples). Duration of the relationship was measured from its current state (for intact couples) or its final duration (for dissolved couples) in months ( $n=395$ ) and month- and year-based categorical bins ( $n=655$ ) (see Figure 1).

Participants reported three measures of relationship quality on Likert scales:

- Love: "How in love with your partner are you?"
- Trust: "How much do you trust your partner?"
- Satisfaction: "In general, how satisfied are you with your current relationship with your partner?"

Love was measured only for participants indicating they were in love with their partner (meaning a rating is not available for all participants) and ranged from 1 (not very) to 9 (intensely) ( $n=391, M=7.55, S D=1.50$ ). Trust ranged from 1 (not at all) to 9 (completely) ( $n=655$, $M=6.79, S D=2.05$ ). Relationship satisfaction ranged from 1 (extremely dissatisfied) to 7 (extremely satisfied) ( $n=655, M=5.33, S D=1.75$ ). The upper endpoint for the satisfaction scale was different from the other two scales because satisfaction is typically measured on a bipolar 7point scale (e.g. Simpson, 1987), so scores are compared only via correlations.

## Results

To determine whether love, trust, or satisfaction follow appropriate rate of return curves to be considered depleting, replenishing, or constant resources as found in foraging theory, we plotted their mean trajectories over categorical duration groups (see Figures 2, 3, and 4, respectively). Note that each of these trajectories are constructed across subjects, as we only have zero or one data point on each scale from each subject. Love (Pearson's $\mathrm{R}, r=0.20, n=222$, $p=.003$ ) and trust ( $r=0.11, n=395, p=.02$ ) both weakly but significantly positively correlated with relationship duration, but satisfaction did not ( $r=0.03, n=395, p>.05$ ). This suggests that love and trust are generally higher at longer relationship durations, while satisfaction is relatively stable. The variables were highly intercorrelated, with significant, moderate relationships between love and trust ( $r=0.51$,
$n=391, p<.001)$, love and satisfaction ( $r=0.29, n=391$, $p<.001$ ), and trust and satisfaction ( $r=0.48, n=655, p<.001$ ).

While love showed a dramatic increase over the first few months, in line with our prediction, each variable overall tended to continually increase slightly as duration grew, rather than forming a curve of diminishing returns with a plateau (although the curve of trust beyond one year might be described as a plateau).

Figure 1: Distribution of relationship lengths for both dissolved and intact relationships.

Comparing dissolved and intact couples' ratings of each variable, intact couples generally had equal or greater quality across relationship durations with lower variability. Looking at all time points together, there was also greater quality for intact over dissolved relationships as a whole (Independent Samples T-Test, love: $\mathrm{t}(391)=5.11$, trust: $\mathrm{t}(655)=10.02$, satisfaction: $\mathrm{t}(655)=9.58$, all $p<.001$.

The rapid initial rise in love overall is driven largely by ratings of dissolved relationships, which start at much lower levels before plateauing. Intact relationships vary in love by little more than a point across durations. This is somewhat surprising-were the data longitudinal, we could conclude that individuals experiencing strong feelings of love early in a relationship are more likely to stay together. However, for the present work, we can only say that individuals looking back on dissolved, low-duration relationships report them as low in love, while those who are still in them report more intense feelings of love. Trust shows a slight increase overall for both intact and dissolved couples (the few data points for 3-5 year dissolved couples makes that mean value unreliable). Satisfaction is relatively stable both overall and for intact couples, but varies widely, rising and falling, for dissolved couples.

## Survival Analysis

While the quality-over-time plots are indicative of general trends, they do not accurately reflect the outcome of all relationships. Many of the currently intact relationships in our sample will end after the completion of the study. That is, the eventual outcome for these relationships is unknown (or censored), and we should not assume that they will never end.

Figure 2: Mean intensity of love for individuals currently in an intact relationship, reporting a previous dissolved relationship, and overall. Error bars are $\pm 1$ SE.

Figure 3: Mean intensity of trust for individuals currently in an intact relationship, reporting a previous dissolved relationship, and overall. Error bars are $\pm 1 \mathrm{SE}$.

Figure 4: Mean intensity of satisfaction for individuals currently in an intact relationship, reporting a previous dissolved relationship, and overall. Error bars are $\pm 1$ SE.

To more fully assess how each quality variable interacts with relationship duration while accounting for these possible eventual dissolutions, a survival analysis of relationship duration was run using the lifelines package in Python 3.5 (Davidson-Pilon, 2016). This analysis measures the connection of specified variables with the likelihood of relationship dissolution over time by estimating the number of relationships currently intact that will eventually dissolve at any particular duration. If a variable has no impact on relationship dissolution (and hence inversely duration), then it is not likely to be a resource that matters in terms of relationship foraging. However, if a resource increases or decreases the risk of dissolution (hence, a shorter or longer duration, respectively), it is something to be actively avoided or sought out, respectively, from the perspective of relationship foraging.

A Cox Proportional Hazard model of relationship duration (in months, available for $n=395$ ) was fit individually to satisfaction, trust, and love to determine how they affect the risk of dissolution. Dissolved relationships were coded as observed events, and non-numeric durations (e.g. "more than 24 months") were excluded.

Table 1 shows the coefficients for each factor, which indicate the change each factor causes to the baseline hazard rate of dissolution based on length of the relationship alone. A positive coefficient indicates a heightened risk of dissolution relative to the baseline; a negative coefficient indicates a reduced risk of dissolution.

All three variables were significantly predictive of reduced risk of dissolution ( $p<.001$ ), such that individuals reporting greater love, trust, or satisfaction would have longer relationships on average (with love having the

Table 1: Results of the Cox Proportional Hazards model, where the $\log$ of the coefficient indicates the proportional dissolution risk compared to the baseline hazard rate.

| Variable | Events/Observations | Cox Coefficient $(\beta)$ | $\mathrm{e}^{\beta}$ | $p$ | $95 \%$ CI |
| :--- | :--- | :--- | :--- | :--- | :--- |
| Love | $73 / 221$ | -0.432 | 0.649 | $<.001$ | -0.649 to -0.216 |
| Trust | $184 / 395$ | -0.391 | 0.677 | $<.001$ | -0.512 to -0.270 |
| Satisfaction | $184 / 395$ | -0.285 | 0.752 | $<.001$ | -0.409 to -0.161 |

greatest impact and satisfaction the least). This is in line with our predictions and corroborates the patterns in Figures 2-4 while also considering possible eventual dissolutions beyond the durations in our data.

## Discussion

Examining changes in relationship quality over time revealed that longer relationships had reliably elevated levels of love and trust (but not satisfaction), contrary to our predictions. Our findings of satisfaction stability across relationship lengths mirror those of Sprecher (1999), while our continual rise in trust and love is in line with Rusbult (1983)'s pattern of satisfaction increase.

As we expected, intact relationships showed significantly higher and more consistent rates of return in trust and satisfaction than dissolved relationships, in line with findings by Rusbult (1983). However, contrary to expectations, love was also higher in intact couples than dissolved couples. Sprecher (1994) previously found that love, but not satisfaction, generally remains high for dissolved couples, suggesting dissolution may be based on satisfaction alone. Results from our survival analysis showing that greater love was associated with lower likelihood of dissolution also countered Sprecher's finding. All three variables were thus higher in intact than dissolved relationships, and were predictive of dissolution. This suggests that these dyadic relationship factors may be used as criteria for choosing when to exit a relationship, or may co-vary with other factors predictive of dissolution.

The goal of this work was to examine whether particular aspects of relationship quality follow the time courses expected for depleting, or replenishing, or constant resource patches, to enable characterization of a relationship-foraging model (Cohen \& Todd, 2017). The three qualities of love, trust, and satisfaction show rising levels over time on average for all relationships (intact and dissolved), suggesting that they are replenishing resources. It is important from a foraging perspective though to consider dissolved relationships separately, where a decision to leave the relationship-patch was made by at least one party; there love seems to plateau, suggesting a constant resource, while trust and satisfaction may actually decrease somewhat at the longest duration, suggesting depletion. Here more data is needed to better specify the form of these functions and what kind of patches they may conform to.

How might individuals use different aspects of quality to choose when to leave a relationship patch? If relationships
are like depleting patches, then OFT predicts that people will usually decide to leave and break up the relationship when its quality declines below the level they could expect to get elsewhere, without necessarily having any other relationship to move to. If relationships are like nondepleting sit-and-wait patches, then people would not be expected to leave while quality remains constant (or grows), but if they encounter another potential relationship of possibly higher value this could prompt a shift to that new patch, depending on switching costs. These strategies could make use of key cognitive comparison abilities.

First, while individuals would benefit from being able to accurately track their current relationship quality over time, previous work suggests that they may not be good at it (Sprecher, 1999). Regardless of the actual change in relationship quality, humans have a tendency to say that things have changed for the better. Individuals reporting annual current ratings of love and satisfaction for four years show very little significant differences between temporal samples, but report increases when asked how their feelings have changed over time (Sprecher, 1999). This suggests that individuals are not especially accurate at recalling past rates of return from a relationship, at least explicitly. However, given the relatively stability of quality after the first few months, individuals could conceivably hold a single average of quality and accurately characterize the overall quality of the relationship. Searchers are generally sensitive though to the rates of return from other possible relationships (interdependence theory; Thibaut \& Kelley, 1959). That is, one's satisfaction with a relationship's quality can depend on comparison to the quality one could expect from currently available alternative mates (Rusbult, 1983; Simpson, 1987; Thibaut \& Kelley, 1959). Thus we might expect relationship-leaving strategies to depend on comparison to other current possibilities or to averages of past experienced quality levels.

Second, by comparing the current relationship quality to a single previous average level or to the expected level of another currently possible relationship, individuals can use a simple aspiration value heuristic to assess the value of staying in their current relationship. Previous work in romantic partner choice shows individuals use aspirationlevel heuristics when choosing to enter a new relationship based on the attractiveness of potential mates at speeddating events (e.g. Beckage et al., 2009), so conceivably, this mechanism may apply to choosing to exit a relationship as well. The decision threshold could be based on the gap in
quality between successful and unsuccessful relationships over time. In our data, the size of this gap generally increased over time, which would predict continual dissolutions over time. Individuals may also consider the length of time spent below an aspiration value, given that a large gap between initial and long-term quality (for love, at least) is expected in all relationships in the early stages.

Relationships may be a different type of patch from just depleting or non-depleting: one where the quality level (return rate) increases the more the forager puts effort into it (up to a point). Moreover, the forager does not usually know how high the return rate will grow until they get there. (nor know how low the return may fall if it ever does start to decline). How should an individual decide whether to stay in such a situation? This may depend on how rapidly the rate of return is increasing or decreasing at particular stages of the relationship as a consequence of particular amounts of effort. New models will be needed to explore this, going beyond some of the strong simplifying assumptions made in existing models of non-depleting patch foraging. For instance, rather than having patches switch from being good to being bad instantaneously and searchers switch from not knowing anything about the return rate to knowing it precisely (Beachly et al., 1995), more realistic models for relationship foraging should include gradual change in rates of return and gradual learning of those rates.

A limitation of this work is that each relationship quality variable was measured at only one point, so intra-individual change in quality cannot be examined. Instead, we calculated the expected curves of returns over time using population averages. These patterns of change in quality do though mirror those from related longitudinal work. While not ideal, this replication provides some reassurance that using single observations per individual gives a relatively realistic representation, at least of the overall shapes of these curves, though future iterations of this model should use longitudinal data. Relatedly, there could have been systematic differences in ratings between those participants who were currently in relationships and so were asked to give current ratings, and participants who were not currently in relationships and so were asked to recall ratings from their earlier, now-dissolved relationship. For participants asked to recall their ratings of quality prior to their previously relationship's breakup, it is inevitable that this type of recall could skew ratings of quality, likely negatively. In addition, ratings could differ depending on who initiated dissolution. If the person did the breaking up, then they may rate their relationship quality as decreasing before the breakup; but if the person was on the receiving end, they may not rate quality as declining so much. Getting data from both parties in multiple relationships would help address this issue. We only asked for ratings of love from those participants who indicated they were in love, which may have skewed results positively (although they still showed a significant difference between intact and dissolved relationships). Finally, this work used a college sample, and the results may not generalize to the overall
population, especially given that most college students are not yet old enough to have had many long-term relationships.

Using a new framework, relationship-foraging modelling, and a technique that is relatively uncommon in cognitive science research, survival analysis, we found that some aspects of relationship quality may be considered depleting or replenishing resources from a foraging perspective, depending on how the relationship proceeds. Further research will explore whether thinking about relationships in terms of resource-filled patches that people can exploit and deplete or work to replenish themselves over time can help us understand how and when couples decide to stay or leave to forage for greener pastures.

#### Abstract

Sensitivity to the causal structure underlying phenomena is critical to expert understanding. Fostering such understanding in learners is therefore a key goal in education. We hypothesized that observing analogical gestures-which represent relational information in visuospatial formatwould lead learners to notice and reason about underlying causal patterns, such as positive and negative feedback. Participants watched brief video lectures about the human body and the plant kingdom, which were delivered along with gestures representing either: 1) visuospatial details (iconic gesture condition); or 2) relational structure (analogical gesture condition). In a subsequent classification task, relative to participants who saw iconic gestures, participants who saw analogical gestures were more likely to sort the phenomena described in the videos-as well as novel phenomena-by their causal structure (e.g., positive feedback). The results suggest that analogical gestures can be harnessed to foster causal understanding.

Keywords: analogy; relational reasoning; gesture; learning; complex systems

## Introduction

A deep understanding of any complex phenomenon-from the ebb and flow of the tides, to the rise and fall of blood pressure-requires an understanding of the causal structure that gives rise to it (Lagnado, Waldmann, Hagmayer, \& Sloman, 2007; Mackie, 1980; Sloman, 2005). Yet this is no trivial task. The causal relations that govern phenomena throughout the physical and social world are often embedded in a wealth of concrete, causally irrelevant particulars (e.g., Rottman, Gentner, \& Goldwater, 2012). Thus a key question for cognitive scientists and educators alike is: How do people come to understand causal structure, and how can we foster this understanding?

We focus here on an important arena of causal understanding: namely, causal systems-abstract patterns of causation, such as positive and negative feedback, that occur in a wide range of phenomena (Fernbach \& Sloman, 2009; Rottman, Gentner, \& Goldwater, 2012; see also Day, Motz, \& Goldstone, 2015). Feedback systems can be found in the human body, in household appliances, in economic markets, and in plant physiology, to name just a few domains. For
example, in a simple two-factor positive feedback system, an increase in one causal factor causes an increase in a second factor, which in turn causes an increase in the first factor; in a negative feedback system, an increase in one causal factor causes an increase in a second factor, which then causes a decrease in the first factor. The challenge such systems present for a learner are considerable: To notice, for instance, the abstract causal likeness between human perspiration and a flush toilet-i.e., that both involve negative feedback-one has to look past a host of visuospatial and sensory differences between the two. One way that expertise in noticing such causal patterns comes about is through repeated opportunities to compare examples across domains, as happens over an extended science education (Rottman et al., 2012). Indeed, such a process can be induced in the laboratory by having learners analogically compare disparate examples of causal systems (Goldwater \& Gentner, 2015), much as comparison can promote relational learning more generally (Christie \& Gentner, 2010; Doumas \& Hummel, 2013; Gentner, Loewenstein, Thomspson, \& Forbus, 2009; Gick \& Holyoak, 1983; Jung \& Hummel, 2011; Kotovsky \& Gentner, 1996; Kurtz, Boukrina, \& Gentner, 2013).

Here we explore a less-studied route through which it may be possible to foster causal understanding: analogical gestures. In previous work, we found that, people produce gestures in abundance when explaining feedback systems (Cooperrider, Gentner, \& Goldin-Meadow, 2016). These gestures were analogical in that they used space, not to represent concrete spatial details, but to represent relational structure: they used locations to distinguish causal factors, motion to show increases and decreases to those factors and causal relationships between them, and complex movements to summarize the overall relational structure of the systems. Strikingly, these gestures occurred in abundance even though participants were explaining systems that were not inherently spatial and were, by design, devoid of the kinds of concrete details that usually prompt gestures. These laboratory findings provide insights into how people express spatial analogies in gesture, and also raise an important further question: Might using such analogical gestures during instruction foster understanding of causal patterns?

Figure 1: A selection of gestures from one of the video explanations, describing the phenomenon of anxiety attacks. In the version seen by participants in the iconic condition, all the gestures represented concrete aspects of the phenomenon (panels $\mathrm{a}, \mathrm{b}$, and d); in the version seen in the analogical condition, the gestures represented the two causal factors (e) and the pattern of increase and decrease to those factors ( f and h ). For all phenomena, the contrasting versions of the explanations used the same number of gestures, included beat gestures in the same places ( c and g ), and used an identical audio track.

Gesture is ubiquitous in everyday conversation as well as in the classroom (Goldin-Meadow, 2003). Despite being more implicit than speech (McNeill, 1992), gesture is an important medium for communicating ideas (Hostetter, 2011), including abstract ideas about relational structure (Jamalian \& Tversky, 2012). Moreover, gesture has been found to boost learning in a range of content domains (Ping \& Goldin-Meadow, 2008; Singer \& Goldin-Meadow, 2005; Valenzeno, Alibali, \& Klatzky, 2003). While prior studies have focused on gesture's consequences for young learners, gestures conveying abstract concepts have also been attested in lectures to older students, in disciplines ranging from literary studies to mathematics (Corts, 2006; Mittelberg, 2008; Núñez, 2008).

Importantly, the gestures used in everyday communication and the classroom come in different varieties, and may not all be equally effective in conveying ideas about causal structure. A first type is iconic gestures. These are produced in the course of explaining concrete, visuospatially rich content, and are used to represent size and shape, location, motion, and spatial relationships (Alibali, 2005; Alibali \& Hostetter, 2008; McNeill, 1992). A second type of gesture is more abstract, using location, motion, and spatial relationships to represent ideas and relationships that are not inherently spatial. Such gestures include those described in our prior work on explanations of feedback systems (Cooperrider, et al., 2016), and also a range of other content domains (Cienki \& Muller, 2008; Cooperrider \& Goldin-Meadow, 2017; Goldin-Meadow, 2003). It is this latter type-analogical gestures-that we
predict would lead observers to notice and reason about causal structure. Iconic gestures, by contrast, may have no effect on causal understanding, or may even hinder it by highlighting concrete particulars.
In the present study, we test the idea that analogical gestures can be used to foster understanding of causal systems - patterns which are often buried beneath concrete particulars. To this end, we created two sets of short video lectures: one in which an actor accompanies his explanations of phenomena in the human body and plant kingdom with iconic gestures that depict concrete visuospatial details (iconic gesture condition); another in which the actor accompanies his explanations with analogical gestures depicting relational structure (analogical gesture condition). We hypothesized that participants in the analogical gesture condition would be more likely to notice the underlying causal structure of the phenomena described in the lectures and, moreover, that these participants would be more likely to discern causal structure when encountering novel phenomena.

## Methods

## Participants

60 undergraduate students from Northwestern University participated in exchange for course credit. 15 participants were eliminated for failing a video comprehension check (described below), and two were eliminated for admitting during debriefing that they listened to the audio but did not watch the screen. In all, 43 participants ( 21 iconic condition,

22 analogical condition; 24 men; $M$ age $=18.7$ years) were included in the analyses.

## Materials and procedure

Video Stimuli Drawing on materials from prior studies (Rottman et al., 2012; Smith \& Gentner, 2014), we developed short descriptions of four phenomena: anxiety attacks (a positive feedback system within the domain of the human body); blood pressure regulation (negative feedback, human body); bracken fern growth (positive feedback, plant kingdom); and prayer plant cycles (negative feedback, plant kingdom). The descriptions balanced concrete details (e.g., for the anxiety attacks description: the "heart feeling like it is pounding") with clues to causal structure ("this will lead to even more intense symptoms"). We filmed an actor delivering each of these ( $\sim 45 \mathrm{sec}$ ) explanations in two versions: one with iconic gestures depicting concrete aspects of the phenomenon described, and one with analogical gestures representing the causal factors involved in the phenomenon and the behavior of those factors (Fig. 1). The iconic gestures were based on the actor's intuitions about what would be most natural; the analogical gestures were inspired by the gestures produced spontaneously by participants when describing highly abstract versions of feedback systems (Cooperrider et al., 2016). For each phenomenon, the two versions had the same number of target-i.e., iconic or analogical-gestures (5-7 per explanation), as well as the same number of beat gestures (2-3), which were included to make the explanation more naturalistic. Finally, to control for differences in prosody, the audio track of the actor speaking was identical in the two versions. This was achieved by: 1) recording a primary audio track, 2) filming the actor talk and gesture in sync with the primary track while it played, 3 ) aligning the video with the primary track and removing the secondary audio.

Classification Task We developed a phenomenon classification task inspired by the Ambiguous Sorting Task (AST) used in prior studies (Rottman et al., 2012; Goldwater \& Gentner, 2015). Participants were first presented with written descriptions of three new phenomena: blood clots (positive feedback, human body); spotted knapweed growth (negative feedback, plant kingdom); and internet routers (common cause, technology). These three phenomena served as the "seed" categories into which further descriptions would have to be classified. The central feature of the task, as with the AST variants used previously, is that nature of the categories is up to the participant to decide: the seed phenomena represent three different domains as well as three different causal structures, thus affording both kinds of classification.

After reviewing the seed phenomena, the participant classified eight further written descriptions, one at a time. Four of these were descriptions of novel phenomena; the other four were written versions of the videos watched earlier. Note that only six of the phenomena were "critical" in that classifying by domain and by causal structure were
mutually exclusive: all four novel phenomena and two of the familiar ones (blood pressure, bracken fern). The other two familiar phenomena (anxiety, prayer plants) shared the same combination of domain and causal structure as the seed phenomena (e.g., anxiety attacks and blood clotting are both in the domain of the human body and both positive feedback systems).

Other Assessments Participants completed two further assessments of causal system understanding: a battery of inference questions and a diagram task. Both concerned only the four phenomena familiar from the videos. For the inference battery, participants answered eight questions (two per phenomenon) querying general behaviors of-and predictions about - the systems described. For the diagram task, participants were shown contrasting diagrams of positive and negative feedback, with a detailed explanation of the symbols used (e.g., plus and minus signs). Participants were then asked to match each of the videos seen previously to the correct diagram.

Procedure All video stimuli and assessments were implemented in Qualtrics and displayed on a desktop computer. The experiment started with a brief video introduction by the lecturer, which was the same for both conditions. Participants then watched the four videos in a fixed order, in the versions corresponding to their condition assignment, i.e., for a participant in the iconic condition, the iconic gesture versions of all four explanations. After watching each video, participants answered two multiplechoice questions about their basic content (e.g., which symptoms of anxiety were mentioned). These questions were intended as an attention check, and participants who got one or more wrong were excluded.

After the final video, participants proceeded to the classification task. The seed phenomena were presented as fixed blocks of text on the screen; the to-be-classified phenomena were presented, one at a time, on moveable digital "cards." Participants were instructed to: "Decide which of the descriptions [i.e., the seed phenomena] the card [i.e., the to-be-classified phenomenon] is most similar to, and drag it to that pile." The eight phenomena were presented in a fixed order, with the four novel ones first, followed by the four familiar ones. We had participants sort the novel phenomena first to encourage them to think deeply about the task, rather than sort by first impulse. After the classification task, participants completed the inference question battery and the diagram task, both in a fixed order, and were debriefed. In all, the task took around 20 minutes.

## Results

## Classification Task

Our primary measure was the mean proportion of phenomena that participants classified by domain (human body, plant kingdom, or technology), by causal structure (positive feedback, negative feedback, or common cause),

Figure 2: The mean proportion of critical phenomena classified by domain, by causal structure, or by other criteria in the two gesture conditions. Error bars represent standard error of the mean.
or by other criteria. We first considered only the six critical items-that is, those for which classification by domain or by causal structure were mutually exclusive. Participants in the iconic gesture condition classified a higher proportion of the critical phenomena by domain than did participants in the analogical gesture condition (iconic: $M=.37, S D=.20$; analogical: $M=.19, S D=.16 ; t=-3.2, d f=41, p=.003$, Cohen's $d=-0.98$ ). Conversely, participants in the analogical gesture condition classified a higher proportion of the critical phenomena by causal structure than did participants in the iconic gesture condition (analogical: $M=$ $.64, S D=.18$; iconic: $M=.47, S D=.20 ; t=3.02, d f=41, p$ $=.004$, Cohen's $d=0.92$ ) (Fig. 2). Participants in the two conditions sorted by some other criterion to the same extent (iconic: $M=.17, S D=.15$; analogical: $M=.17, S D=.15 ; t$ $<.001, d f=41, p=1$ ). Importantly, the same pattern of significance holds when looking only at the four novel phenomena (by domain: $p=.01$; by causal structure: $p=$ .01 ; by other: $p=.88$ ). Indeed, for all eight phenomena, a higher proportion of participants in the analogical gesture condition sorted by causal structure than did participants in the iconic gesture condition.

To get a better sense of individual participants' classification behavior, we also zoomed in on the two critical phenomena that were featured in the videos: blood pressure regulation and bracken fern growth. Note, again, that to classify these by causal structure, participants had to resist the temptation to group the blood pressure description with the human body seed (blood clots) and the bracken fern description with the plant kingdom seed (spotted knapweed). Yet not a single participant in the analogical gesture condition classified both these phenomena by domain, compared to six participants in the iconic gesture condition who did (two-tailed Fisher's exact, $p=.009$ )

## Other assessments

Inference Question Battery Participants in both conditions answered the majority of inference questions correctly and at close to ceiling, with no difference between the conditions (iconic: $M=.90, S D=.12$; analogical: $M=.86$, $S D=.13, t=-1.09, d f=41, p=.28)$.

Diagram Task Participants in both conditions answered the majority of diagram questions correctly and at close to ceiling, but with those in the analogical gesture condition performing marginally better (iconic: $M=.80, S D=.19$; analogical: $M=.89, S D=.13, t=1.82, d f=41, p=.08$ ).

## Discussion

The present study investigated the hypothesis that seeing certain types of gestures would lead observers to notice and understand causal structure. Specifically, we expected that analogical gestures, which represent relational structure spatially, would foster understanding of causal structure better than would iconic gestures, which represent concrete visuospatial details. This hypothesis was borne out. Participants in the analogical gesture condition noticed the causal structure of the phenomena described in videos, and were also more likely to notice causal structure in entirely new phenomena. Given the design of our classification task, this was no easy feat. To classify by causal structure, participants had to look past compelling differences of content to find deeper similarities, or look past compelling content similarities to discern deeper differences. Our prior work showed that people spontaneously produce analogical gestures when explaining causal systems; the current study builds on these findings to show that such analogical gestures have important consequences for learning.

Our leading interpretation of the present findings, again, is that observing analogical gestures led participants to notice and reason about causal structure. A second-and not mutually exclusive-possibility is that the concrete gestures in the iconic condition hindered participants from the discerning the underlying relational structure by lavishing them with vivid details. Follow-up studies with a "no gesture" control condition would clarify whether our two gesture conditions are indeed pulling observers in opposite directions or, if not, which gesture type is driving the observed pattern of results. This question is of clear theoretical interest, but we also note that, in teaching contexts, gesture is ubiquitous, perhaps even inevitable. Thus, from a practical perspective, the important question is not whether teachers should gesture about the phenomena they are explaining, but how. Our results suggest that iconic gestures, as natural as they are, may not always be the best choice. It may be that the best instructors already intuit this, using gestures that highlight relational structure when possible.

By what specific mechanism(s) did analogical gestures have their beneficial effects? We hypothesize that these gestures helped convey the causal content of each phenomenon by capturing it in schematic spatial form.

Indeed, space is a familiar and intuitive format in which to represent and reason about relational structure (e.g., Gattis, 2004; Tversky, 2011). But we think there may have also been another important reason for the efficacy of analogical gestures: namely, that they invited comparison and uniform representation across the scenarios. Participants in the analogical gesture condition viewed four videos, all featuring qualitatively similar gestures. For example, all four parsed the phenomena into causal factors by establishing locations in space, and all showed the increases and decreases to those factors as vertical movements. The gestures in the iconic gesture condition also had some commonalities across videos (e.g., the gestures in both human body videos indexed body parts), but they were hardly as schematic and alignable. Prior work has shown that using the same words in superficially different contexts prompts observers to compare those contexts (Clement, Mawby, \& Giles, 1994; Gentner, 2003), and using similar gestures across different examples may have similar effects. The idea that such a mechanism drives the current results is consistent with earlier findings that prompting people to compare examples of feedback systems fosters causal understanding (Goldwater \& Gentner, 2015). Thus, while we refer to the abstract gestures in the present study as "analogical" because they rely on a structured mapping between spatial structure and relational structure (Cooperrider et al., 2016), they are also "analogical" in another sense: they invite observers to form analogies across the different contexts in which they are used. Future studies might assess these mechanisms by comparing a condition in which the analogical gestures are qualitatively similar and thus alignable across lessons-as in the present study-with a condition in which the analogical gestures are more heterogeneous and thus less alignable.

What makes the present findings perhaps surprising is that co-speech gestures are largely implicit (Goldin-Meadow, 2003; McNeill, 1992). People seem to produce gestures spontaneously and unreflectively, and do not always notice the ones that others produce. Indeed, when we queried participants at the end of the present experiment about what they thought of the lecturer's gestures, several participants demurred, saying that they "didn't notice them." And yet, despite this "under the radar" quality, these gestures have clear consequences for learning (for a recent review, see Novack \& Goldin-Meadow, 2015). Another question for further research is whether the implicit nature of gesture is key to its benefits. Would the techniques that speakers use to make gesture more salient-e.g., looking at their own gestures (Cooperrider, 2017)—make gesture even more powerful in instruction? And would more explicit forms of visuospatial communication, such as diagrams (Novick, 2003; Tversky, 2011) or sketches (Forbus, Usher, Lovett, \& Wetzel, 2011), also be effective in fostering causal understanding?

## Conclusion

Sensitivity to causal structure is a hallmark of expert understanding. Discovering how to foster such sensitivity is an important goal for cognitive scientists and educators across the natural and social sciences. Our results suggest that a ubiquitous dimension of communication-gesturemight be harnessed to this end. Analogical gestures like those in the present study have been elicited in the lab (Cooperrider et al., 2016), but their importance in instruction has not been investigated. The present findings offer first steps toward figuring out whether those gestures have consequences for learners and, if so, why.

## Acknowledgments

Funding for this study was provided by the NSF Spatial Intelligence and Learning Center (SBE 0541957, Gentner and Goldin-Meadow are co-PIs), the Office of Naval Research (ONR (N00014-16-1- 2613 to Gentner), and NICHD (R01-HD47450 to Goldin-Meadow).

#### Abstract

Spatial construction-creating or copying spatial arrangements-is a hallmark of human spatial cognition. Spatial construction appears early in development, predicts later spatial and mathematical skills, and is used throughout life. Despite its importance, we know little about the cognitive processes underlying skilled construction. Construction tasks are highly complex but analyses have tended to focus on broad-stroke measures of end-goal accuracy. In this paper we introduce a novel behavioral coding formalism to characterize an individual's entire construction process, examine many individuals' processes in aggregate, and summarize patterns that emerge. The results show high consistency at certain points occurring throughout the construction, but also indicate flexibility in the interim paths that lead to and diverge from these points. Our approach offers a new method that can more precisely describe the behavioral patterns observed during construction in order to reveal the underlying cognitive processes engaged, and capture individual differences in building expertise.

Keywords: spatial skills; spatial cognition; block copying; computational model

## Introduction

Spatial construction-the activity of creating novel spatial arrangements or copying existing ones-is a hallmark of human spatial cognition. These activities naturally occur during childhood and adolescence and are related to later achievements in science, technology, engineering, and mathematics (STEM) fields (Hsi, Linn, \& Bell, 1997; Kell, Lubinski, Benbow, \& Steiger, 2013; Verdine, Golinkoff, Hirsh-Pasek, Newcombe, et al., 2014). Moreover, spatial play during early schooling-including spatial building tasks-contributes to school readiness (Verdine, Golinkoff, Hirsh-Pasek, \& Newcombe, 2014; Wai, Lubinski, \&

Benbow, 2009), developmental of logico-mathematical abilities (Casey et al., 2008; Cheng \& Mix, 2012; Nath \& Szücs, 2014), and math performance in middle and high school (Stannard, Wolfgang, Jones, \& Phelps, 2001; Wolfgang, Stannard, \& Jones, 2003).

Despite the importance of spatial construction skills, little is known about the cognitive processes underlying their origins and development. Part of the reason for this is that spatial construction skills are highly complex, yet the cognitive characterization of these skills and their measurement has been quite limited. For example, although evaluation of block construction tasks has long been recognized as an important assessment of spatial skills (Bailey, 1933), most methods of assessment only evaluate the end product (accuracy), and fail to measure the construction process. Studies have generally reported broad stroke outcome measures such as time to complete a structure (Akshoomoff \& Stiles, 1996; Frick, Hansen, \& Newcombe, 2013), binary measures of block placement as correct or incorrect (Brosnan, 1998; Hoffman, Landau, \& Pagani, 2003; Stiles \& Stern, 2001), or summary ratings for the complexity, planning, or organization of free-play block designs (Caldera et al., 1999; Casey \& Bobb, 2003; StilesDavis, 1988; Stiles \& Stern, 2001). Even studies that aim to characterize development of construction processes or strategies have used analytic categories that are limited in their generality for understanding construction. For example, some have suggested that children start with simple iterative methods (i.e. stacking blocks on top of one another), then move to sequential combinations of methods (i.e. first creating a line of blocks next to one another, then creating a stack), and finally come to flexibly shift between multiple methods (Stiles-Davis, 1988; Stiles \& Stern, 2001; Stiles, Stern, Trauner, \& Nass, 1996). These
characterizations tell us little about the step-by-step processes that the user takes when carrying out a complex construction, nor how the ever-expanding set of outcomes grows over time.

More recent studies have attempted to provide a more precise characterization of the process occurring during construction. Verdine and colleagues characterized children's placement errors, including whether a block was placed in the correct layer, in correct orientation relative to other blocks, and with the correct attachment studs connected (Verdine, Golinkoff, Hirsh-Pasek, Newcombe, et al., 2014; Verdine, Golinkoff, Hirsh-Pasek, \& Newcombe, 2016). Researchers in computer science have generated step-by-step instructions for assembling block models based on physical constraints such as avoiding 'floating blocks' not supported from below (Zhang, Igarashi, Kanamori, \& Mitani, 2016). Both studies begin to characterize the temporal and incremental nature of block construction.

Each of the approaches discussed above provides a description of the accuracy of a block construction at points intermediate to building or at the end; but none provides a characterization of an individual's complete construction process. Yet, variability and/or consistency across individuals' construction processes may reveal much about the underlying cognitive and perceptual abilities and biases that influence the builder's construction choices.

The incremental process of adding blocks to a structure can unfold in many ways, with different strategies leading to the same successful solution. Some of this variation may be unimportant-merely small tweaks in the options one can use to complete a construction. Other aspects of variation are likely to reflect important cognitive processes. For example, limitations of attention and memory make it likely that certain strategies or processes will be preferred as they may reflect more efficient use of available cognitive resources (Ballard, Hayhoe, Pook, \& Rao, 1997). Certain strategies may also reflect the builder's understanding of the physical principles engaged during building. For example, the effect of gravity could bias the builder to construct from the bottom layer upwards (Zhang et al., 2016). Finally, construction strategies may be related to perceptual or semantic groupings of the blocks within the structure. The sub-parts which the builder chooses to construct, and the order in which they are created may be driven by the builder's perceptual parsing of the model being copied. More generally, there may be systematic commonalities in the construction paths that builders use, and these may vary depending on the builder's level of skill.

Understanding the principles underlying construction requires methods that can characterize the builder's full construction process. Ideally, the best analysis would completely describe the entire construction process, capturing any imaginable construction outcome as well as each step of building along the way. This kind of characterization would be as relevant for a simple stack of blocks as it would be for an elaborate castle or an abstract collection of connected pieces.

To our knowledge, such methods have never been reported. Therefore, in this paper, we report a new method for characterizing the precise nature of processes involved when people carry out a relatively simple construction task: using blocks to copy a target model. To do this, we ask adults to carry out a simple building task, using a set of Duplos ${ }^{\mathrm{TM}}$. We describe our new method for coding block construction behavior that uses a novel computer interface. Our method characterizes each partial assembly created during the building process as a step taken along a path from the start to the end of construction. We then evaluate common states and predominant path types traversed by adults as they move through the construction process. Finally, we make inferences about the underlying cognitive mechanisms engaged during block construction.

## Method

## Participants

Twenty-seven healthy adults 18-53 years old ( $M=21 ; 4, S D$ $=6 ; 6$ ) participated in the study. A university ethical review board approved the study's procedures, and all participants provided informed consent.

## Materials

Participants were asked to copy six different block models of varying size, each consisting of 4,6 , or 8 blocks. Each participant copied each of the six models in randomized order, but always began with the two smallest models (models 1 and 2). Figure 1 shows each of the six models.

We used Duplo ${ }^{\text {TM }}$ blocks for the construction copy task. These blocks were chosen for several reasons. First, the attachment mechanism allowed the blocks to be connected to each other in fixed ways. The attachment studs permitted precise specification of the relationships between blocks above and beside one another. In addition, the limited set of colors (red, yellow, green, blue) of each shape ( $2 \times 2$ square, $4 \times 2$ rectangle) were ideal for the precise measurement system we developed.

Figure 1: The block models used in this study. Models 1 and 2 contain four blocks, models 3 and 4 contain six blocks, and models 5 and 6 contain 8 blocks.

We mounted a PrimeSense Carmine RGBD camera in an overhead configuration to record participants' behaviors as
they carried out the construction task, at a rate of 30 frames per second. All videos were coded using our annotation interface. The coder viewed the video recording frame-byframe on a desk-top computer.

## Procedures

Participants were seated at a table marked with an outline of a rectangular area ( $14.75 \times 24.00 \mathrm{in}$.) in which they completed their block construction copy. During data collection, the experimenter observed participants in real time on a video display monitor. A vertical black barrier was placed on the table behind the construction area to obscure the video display monitors from the participant and to avoid distraction. Figure 2 shows the testing equipment setup used for the study.

In the procedure, the experimenter first placed the model at a $45^{\circ}$ angle in the rear left corner of the marked construction area on the table. Each model was presented in a standardized orientation so that the greatest number of model surfaces were visible to the participant. Then, the experimenter placed the corresponding loose blocks on the table in the center of the construction area by emptying them from a small bag. This ensured random starting positions for each of the blocks used to construct the copy. Participants were instructed to take their time and to copy the model, building as efficiently and accurately as possible.

Figure 2: Overhead camera and blocks set up for the block copying task. The model was placed at the rear left of the table, and blocks for the copy construction were placed at the center.

## Analytic Rationale

To account for the broad range of construction behaviors and resulting complex patterns in the copy, we developed a new behavioral coding system, executed in a custom designed computer interface. The video frames for each trial from each participant were coded as a series of actions, each of which culminated in a state. Each action captured the start and end time of a change made to the copy as it was being constructed. Actions could be comprised of a single relationship, such as placing two blocks adjacent on the
table. Other actions included a complex set of simultaneous relationships such as adding a single block in a location that was both above and beside other blocks. Actions could be constructive, such as adding a block or connecting multiple parts, or deconstructive, such as removing a block or separating a structure into two parts.

Each relationship was defined specifically by the set of attachment studs involved. For example, if two rectangle blocks were placed horizontally adjacent to each other along the principal (long) axis, then four studs on each block would be involved in the adjacency. Alternatively, if they were attached along the secondary (short) axis, only two studs on each block would be implicated. Block studs were identified according to the column and row on each block, so the coded data specified the exact relationship between sets of two blocks.

Each action modified the environment to result in a new block state, defined as a set of block attachments present in the copy. Since the construction process occurred over time, each action included a time stamp that allowed block states to be ordered. Here, we refer to the ordered sequence of states over time as a construction path, where actions represent transitions connecting one state to the next. To illustrate, Figure 3a shows six observed states (illustrated as images of block configurations) and 11 observed actions (directed arrows). Any set of arrows that lead from the first null state to the final correct copy state could comprise a construction path.

## Data analysis

One researcher coded all videos. The initial state of the model was always a null state in which no blocks were connected. Each other state along the path to the final copy was attained via a constructive or deconstructive action taken at the preceding state. Since each participant could take any number of actions, construction path length was not balanced across individuals. We also used the coded data to count the number of unique state transitions for all participants in aggregate. Results of the analysis are described below. Principles of the results are true across all six models, but we illustrate using two models as examples.

## Results

Overwhelmingly, the most common actions were correct single-block placements over time. Participants tended to take efficient paths that traversed an average of just over $\mathrm{n}-1$ states for a model that contains n blocks. This held true for all six of the models, including the four-block models 1 and $2(M=3.3, S D=0.9$ and $M=3.1, S D=0.6$, respectively), the six-block-models 3 and 4 ( $M=5.0, S D=0.7$, and $M=$ $5.5, S D=1.8$, respectively), and the eight-block-models 5 and $6(M=7.4, S D=0.9$, and $M=7.9, S D=1.7$, respectively). Strikingly, the observed correct states represented only a small proportion of total possible correct states. For example, for the six-block model 3 (shown in

Figure 3b), 79 possible correct states exist ${ }^{1}$. In aggregate, our sample executed a total of 136 actions, but only created 16 different correct states ( $27 \%$ of all possible correct states). An additional three erroneous states were observed in model 3; these will be discussed later.

Figure 3: Observed paths for models 2 (a) and 3 (b). Paths begin at the top, where the null state represents no blocks connected. Images represent block states; arrows connecting images represent actions. Numbers adjacent to arrows represent the number of times that action was executed.

Of the 16 observed states for model 3 (Fig 3b), some were created by a majority of participants, while others were rare. We found the same pattern in the observed paths, that is, the actions moving from state to state. Though all observed paths led to a correct copy construction, some were highly likely, while others were highly unlikely. For example, the first image in the fourth row in Figure 3b was created by a great majority of participants ( $96.3 \%$ ). The most common

[^51]path to achieve this state led from the fifth image in the third row of Figure 3b, such that 17 of the 26 ( $65.4 \%$ ) people who created the same penultimate state achieved it by placing the green square on the second layer.

The most commonly traversed states created points of convergence. Convergence points represented a single subassembly that results from several different preceding actions. We observe that convergence points tend to be highly likely states, which most or all participants created along the way to a complete construction. As shown in Figure 3b, most participants (66\%) passed through the state in which three blocks are joined with horizontal adjacency to create the base of the copy (second image, second row). The observed frequencies of convergence points are remarkable when one considers that only a fraction of all possible efficient paths go through these states.

We also observed points of divergence. Divergence points represented cases where participants, when presented with identical partial assembly states, chose to proceed with several different actions. For example, about $70 \%$ of those who created the base of model 3 b proceeded to place the green then the blue square in the second layer. The other $30 \%$ instead placed the same two blocks in the opposite order, first placing the blue and then the green square in the second layer. This is illustrated in Figure 3b, in the third and fifth images of the third row.

Our results demonstrated some commonalities across the six different models. The most frequently constructed partial assembly states for all six of the models represented a complete layer. Across all six models, $83.6 \%$ of participants began their copy construction by creating the base layer. For the models with six or eight blocks, $77.4 \%$ and $86.5 \%$ of participants created the complete second layer as a partial assembly, respectively. Across all six models, each complete layer state is visited more frequently than would be expected by chance, even with the most conservative comparison against only other observed states with the same number of blocks (all $p$ 's $<.001$ ).

Many participants' construction paths (75.5\%) traversed all complete layer states, although this is by no means necessary in order to achieve a correct copy. Specifically for the most complex model, model 6 , those participants who traversed each complete layer partial assembly state in their individual construction path also tended to have the shorter path lengths $(t(24)=-2.57, p=.017)$. In other words, when faced with a complex block copying task, building layer by layer appears to be both highly likely and highly efficient. These observations provide insight into the importance of layers, which may be driven by the builder's understanding of physical properties such as gravity and/or perceptual biases that suggest a natural parse in terms of layers.

Although most block placements were correct (i.e. replicated part of the model in the copy), there were some errors-that is, states that did not represent a correct part of the model. These errors contributed to deviations from the main construction paths. If erroneous states are included in our calculation, the number of possible block states in given
a starting set of 4 , 6 , or 8 blocks is vast, but finite. For example, a mathematician recently estimated that there are nearly a billion possible ways to connect six uniform rectangular Lego ${ }^{\text {TM }}$ blocks contiguously (Abrahamsen \& Eilers, 2011). The model and our instructions to participants constrained their behavior such that even though errors occurred, only an extremely small proportion of all possible states were observed.

The errors observed in this sample also provided insight into the cognitive limitations of our adult participants. Two categories of errors were observed. First, spatial errors occurred when a participant utilized the correct block, but placed it in incorrect orientation relative to the rest of the copy. For example, in model 2, one participant placed the yellow square block with incorrect relationship relative to the red and green rectangles underneath, shown in the first image of the first row in Figure 3a. Second, block identity errors occurred when a participant created the correct form in their copy, but used the wrong color block relative to the model. For example, for model 3, one participant used the yellow rectangle to create the base of their copy instead of the green rectangle (first image, first row of Figure 3b).

Overall, our results provided rich detail about the step-bystep process undertaken by our adult participants in the block copying task. We observed only a small portion of all possible correct states, and a yet smaller portion of all possible states including erroneous ones. The distribution of the sample across different construction paths was not uniform, but rather demonstrated commonalities across the six models. Specifically, convergence points were observed corresponding to completed copy layers, and divergence was observed in the order of block placement within a single layer. Most common construction paths involved the sequential construction of horizontal layers, beginning with the base and building upward.

## Discussion

Our study presented a precise, quantitative method for understanding how people carry out a simple block construction task. Using a novel behavioral coding method together with computational modelling, we precisely described the block construction process as a temporal sequence of states. This approach shed light on the cognitive processes that support spatial construction tasks.

A description of state transitions illustrated commonalities among the construction paths that participants used for each of the six models. Convergence points tended to correspond to the completion of a horizontal layer in the model, while divergence points tended to correspond to various orders of placing blocks within a layer. We hypothesize that convergence points can be interpreted as boundaries between perceptual or semantic chunks-that is, they represent sub-goals that builders had in mind as they approached and carried out the task. Although we did not provide any pre-determined conceptual units or clear perceptually-based chunks (such as sub-parts built from same-colored blocks), participants nonetheless created these
chunks in systematic ways. The location of convergence points, for example, at the completion of a horizontal layer, may indicate that participants grouped or chunked the models principally into horizontal layers or "floors".

It is likely that the underlying structure of sub-goals will vary substantially, depending on a variety of factors. For example, a model that is organized to highlight salient perceptual units, such as multiple vertically adjacent blocks of the same color, could induce a construction path that would take most builders through a convergence point organized as a vertical chunk, and not the horizontal layers observed in the present study. In this case, we anticipate that adults would attend to the imposed perceptual units and change their construction strategy to build using sub-goals defined by these color-units. Similarly, incorporating conceptual structure into the models could radically alter people's construction paths-heads and eyes on structures that look like animals, or wheels on structures that look like vehicles could serve as the chunks or sub-goals to be built. The role of conceptual knowledge in the reproduction of complex figures has a long history in the domain of chess, where experts are known to reproduce board configurations using sub-structures that reflect high-level concepts such as attack and defend (Chase \& Simon, 1973).

In our simple construction task, errors were relatively rare. Errors were characterized as either spatial relationship or block identity errors. We hypothesize that spatial errors indicate problems with spatial working memory, in translating information observed in the model into the working copy. Block identity errors, on the other hand, may involve object working memory, or a prioritization of spatial configuration over color information. These error types are likely linked to the relative simplicity of the models we used; analysis of error patterns for more complex models may well reveal more variation.

We see our method as a powerful way to examine the nature of sub-goals and errors, applicable to a variety of visual-spatial construction tasks involving conceptual or perceptual chunks. The extent to which observed construction paths and construction errors change over variations in the target model would provide insight into how building principles change across target types. In addition, our method permits evaluation of variation in construction paths across different participant populations including construction experts compared to novices, and developmental populations of children at different ages.

We believe that our analytic method has great potential for revealing the fine-grained nature of many tasks that require step-by-step actions, which in turn require rich cognitive capabilities, including representation of the goal as well as strategies for moving from a start state to an end state. Such general task requirements are ubiquitous throughout life-from the toddler who learns to operate an iPad to the adult who learns to cook a gourmet meal. Our insight is that understanding complex skills requires a finegrained and precise approach, exemplified by the method we have introduced. Block construction serves as a first
demonstration of the utility of our approach, but it is by no means the end.

# Mathematical invariants in people's probabilistic reasoning 

Fintan J. Costello (fintan.costello@ucd.ie)<br>School of Computer Science, University College Dublin, Dublin 4, Ireland<br>Paul Watts (watts@thphys.nuim.ie)<br>Department of Mathematical Physics, National University of Ireland Maynooth, Maynooth, Ireland

#### Abstract

Recent research has identified three invariants or identities that appear to hold in people's probabilistic decision making: the addition law identity, the Bayes rule identity, and the QQ identity (Costello and Watts, 2014, Fisher and Wolfe, 2014, Costello and Watts, 2016b, Wang and Busemeyer, 2013, Wang et al., 2014). Each of these identities represent specific agreement with the requirements of normative probability theory; strikingly, these identities seem to hold in people's probability judgments despite the presence of strong and systematic biases against the requirements of normative probability theory in those very same judgments. We assess the degree to which two formal models of probabilistic reasoning (the 'probability theory plus noise' model and the 'quantum probability' model) can explain these identities and biases in probabilistic reasoning.

## Introduction

A fundamental goal of science is to find invariants: constant relationships that hold between different variables. While such invariants occur frequently in the 'hard' sciences, they are rare in behavioural science. Recent work, however, has identified three invariants that appear to hold in people's probabilistic reasoning: the addition law, Bayes rule and ' QQ ' ('Quantum Question') identities (Costello and Watts, 2014, Fisher and Wolfe, 2014, Costello and Watts, 2016b, Wang and Busemeyer, 2013, Wang et al., 2014). Each identity describes a constant relationship that holds between different probabilistic judgments, and each represents specific agreement with the requirements of probability theory. Strikingly, these identities hold in people's probability judgments despite the presence of strong biases, or systematic deviations from probability theory, in those very same judgments. We assess two formal models of probabilistic reasoning (the probability theory plus noise model, Costello and Watts, 2016, and the quantum probability model, Wang et al. 2014) in terms of their ability to explain these invariant identities and biases.

## Identities in probabilistic reasoning

We use the following notation. We take $P(A)$ to represent the normatively correct probability of event $A$. We take $P_{*}(A)$ to represent a subjective estimate of $P(A)$. The QQ identity involves the relationship between probability estimates when questions are presented in specific orders. We take $P_{B A}(A)$ to represent the subjective estimated probability of $A$ when questions are presented in the order $B A$ (when people are asked to estimate $P(A)$ immediately after being asked to estimate $P(B)$ ) and take $P_{A B}(A)$ to represent the estimate when
questions are in the reverse order. Since a subsequent estimate for $P(B)$ cannot affect the results obtained from a prior estimate for $P(A), P_{*}(A)=P_{A B}(A)$ and $P_{*}(B)=P_{B A}(B)$.

## The QQ identity

Consider a situation where people are asked questions in two alternative orders $A B$ or $B A$. This situation is commonly seen in polls; for example, in a Gallup poll conducted in September 1997, half of participants were asked the question "Do you think Al Gore is honest and trustworthy?" followed immediately by the question "Do you think Bill Clinton is honest and trustworthy?", while the other half of participants were asked the same questions in the reverse order (Moore, 2002). People's answers in such situations are often strongly influenced by the order of question presentation $\left(P_{A B}(A) \neq P_{B A}(A)\right)$. In the Clinton-Gore questions, for example, $76 \%$ of participants answered 'yes' to the Gore question when it was asked first $\left(P_{A B}(A)=0.76\right)$, while $66 \%$ answered yes when it was asked second $\left(P_{B A}(A)=0.66\right)$ : the prior presentation of the Clinton question produced a bias, reducing the likelihood of a 'yes' answer to the Gore question. Simultaneously, however, results (both from experimental studies and from polls) show that the following identity tends to hold reliably in sequential question answering:
$P_{A B}(A \wedge B)+P_{A B}(\neg A \wedge \neg B)-P_{B A}(A \wedge B)-P_{B A}(\neg A \wedge \neg B)=0$
(where $A \wedge B$ represents a 'yes' answer to both $A$ and $B$ and $\neg A \wedge \neg B$ represents a 'no' answer to both questions). This expression has a value of -0.003 in answers to the ClintonGore questions, for example. This identity holds for questions across a wide range of different topics in 72 different national representative surveys in the US, and in laboratory studies of the effects of order in question answering, even though these surveys show significant bias due to question order (Wang et al., 2014). This is just as predicted by the quantum probability model, and is seen as providing 'the strongest form of support' for that model (Wang et al., 2014).

## The Addition Law and Bayes Rule identities

A number of identities must hold in standard probability theory. One such identity is the addition law, which requires that

$$
\begin{equation*}
P(A)+P(B)-P(A \wedge B)-P(A \vee B)=0 \tag{1}
\end{equation*}
$$

must hold for all events $A$ and $B$. Two other 'expansion' identities require that

$$
\begin{align*}
& P(A \wedge B)+P(A \wedge \neg B)-P(A)=0  \tag{2}\\
& P(A \wedge B)+P(\neg A \wedge B)-P(B)=0 \tag{3}
\end{align*}
$$

must hold for all events $A$ and $B$. Consider experiments where we ask people to estimate various probabilities $P(A), P(B)$, $P(A \wedge B), P(A \vee B), P(A \wedge \neg B), P(B \wedge \neg A)$ (not in any fixed ordering), and combine those estimates as in the various identities. Results show that, when we combine people's probability estimates for a given pair of events $A, B$ as in the addition law identity, the average value obtained is equal to probability theory's required value of 0 . When we combine the same estimates for the same events $A, B$ as in the two expansion identities, the average value is not equal to 0 ; instead, the average value is positive (typically around 0.25 ) and is similar for both of these expansion identities. In other words, people's probability estimates reliably agree with probability theory for the addition law identity, but deviate from probability theory for the two expansion identities.

The addition law identity applies to direct or marginal probabilities. Similar results hold for identities that involve conditional probabilities. One such identity is the additive form of Bayes rule, which requires that

$$
\begin{equation*}
P(B \mid A) P(A)-P(A \mid B) P(B)=0 \tag{4}
\end{equation*}
$$

must hold for all events $A$ and $B$. Two parallel 'Bayes expansion' identities require that

$$
\begin{align*}
& P(A \wedge B)-P(A \mid B) P(B)=0  \tag{5}\\
& P(A \wedge B)-P(B \mid A) P(A)=0 \tag{6}
\end{align*}
$$

must hold for all events $A$ and $B$. Experimental results for these identities follow those seen above: for the Bayes Identity the average value in people's estimates is equal to 0 , while for the two Bayes expansion identities, the average value is positive (typically around 0.12 , half the value seen for expansion identities in Equations 2 and 3) and is similar for both of these expansion identities (see Table 1). Results for these identities don't just hold when averaging across events: they also hold separately for each individual pair of events $A$ and $B$, and they hold for estimates about familiar everyday events, medical diagnoses, future political or economic outcomes, or personality-description scenarios (Costello and Watts, 2014, Fisher and Wolfe, 2014, Costello and Watts, 2016b).

These patterns of agreement with the addition law and Bayes rule identity and simultaneous violation of the expansion identities (with approximately the same positive value for Equations 2 and 3 and approximately half that value for Equations 5 and 6), are predicted by the probability theory plus noise model. Confirmation of these predictions has been taken as evidence that the probability theory plus noise
model 'may provide a fully general account of the mechanisms by which people estimate probabilities' (Costello and Watts, 2016b).

The quantum probability model, then, accounts for the QQ identity and for biases due to order effects, while the noise model accounts for the addition law and Bayes rule identities and for biases in the expansion identities. Can either model explain all three sets of results? In the next section we show that the quantum model is in principle unable to explain the addition law and Bayes rule results. We then show that the noise model gives a natural account for all these results.

## The quantum probability model

The quantum probability model (Wang and Busemeyer, 2013, Wang et al., 2014) assumes that people's probabilistic reasoning follows the mathematical rules used to calculate event probability in quantum theory. A fundamental aspect of quantum theory is that the probability of two quantum events can depend on the order in which those events are measured. This order dependence allows the quantum probability model to address various order effects seen in people's sequential inference and judgment.

Probability has a geometric interpretation in quantum theory, based on the projection of vectors. We avoid this geometric interpretation here and instead focus on explaining how quantum probability agrees with, and deviates from, standard probability theory. In quantum probability, an observable defines the set of all possible distinct outcomes for a given measurement: the set of possible answers to the question represented by that measurement. The primary theoretical distinction between quantum and standard probability lies in the idea of 'compatible' or 'incompatible' observables. Two observables are compatible if both observables can be measured simultaneously. If two observables are compatible, quantum probability theory reduces exactly to standard probability theory in all cases. This means that if two observables are compatible then all the probability theory identities described above have a value of 0 , and there are no order effects in judgment.

Incompatible observables, by contrast, cannot be measured simultaneously, and measurement outcomes depend on the order of measurement. If all probabilities are measured with the same ordering then again quantum probability theory reduces exactly to standard probability theory (if all probabilities are of the form $P_{A B}()$, for example, then all relationships between those probabilities match the requirements of standard probability theory and all probability theory identities hold). If probabilities are measured with different orderings, however, then quantum probability deviates from standard probability, producing biases in judgment and order effects in sequential question answering such as $P_{A B}(A) \neq P_{B A}(A)$ and $P_{A B}(A \wedge B) \neq P_{B A}(A \wedge B)$.

## Addition law and Bayes rule identities

The addition law and Bayes rule identities apply in cases where questions are not presented in some specific order $A B$

Table 1: Predicted values of the noise model and the quantum model for a series of probability theory identities. Standard probability theory requires these identities to have a value of 0 . Observed average values for these identities are from Costello and Watts (2016b), Experiment 1. Similar average values hold for each individual pair $A, B$ in that experiment and in a range of other experiments.

| identity |  | noise model | quantum model |  |  | observed |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  |  | compatible | incompatible: order $A B$ | incompatible: order $B A$ |  |
| (1) | $P(A)+P(B)-P(A \wedge B)-P(A \vee B)$ |  | 0 | 0 | $\delta_{A}$ | $\delta_{B}$ | 0.01 |
| (2) | $P(A \wedge B)+P(A \wedge \neg B)-P(A)$ | $d$ | 0 | $-\delta_{A}$ | 0 | 0.26 |
| (3) | $P(A \wedge B)+P(\neg A \wedge B)-P(B)$ | $d$ | 0 | 0 | $-\delta_{B}$ | 0.23 |
| (4) | $P(B \mid A) P(A)-P(A \mid B) P(B)$ | 0 | 0 | $\Delta_{A B}$ | $\Delta_{A B}$ | 0.006 |
| (5) | $P(A \wedge B)-P(A \mid B) P(B)$ | $d / 2$ | 0 | $\Delta_{A B}$ | 0 | 0.12 |
| (6) | $P(A \wedge B)-P(B \mid A) P(A)$ | $d / 2$ | 0 | 0 | $-\Delta_{A B}$ | 0.12 |

or $B A$, but instead are order independent. In this situation there are no order effects for simple probabilities (the probability of $A$ is $P_{*}(A)=P_{A B}(A)$ and that of $B$ is $P_{*}(B)=P_{B A}(B)$ ). Order effects for incompatible observables still apply when people are asked to estimate conjunctive or disjunctive probabilities such as $P(A \wedge B), P(A \wedge \neg B)$ or $P(A \vee B)$. For such conjunctions or disjunctions the quantum probability model assumes a particular characteristic ordering for observables that depends on the causal link between those observables. Complex probabilities such as $P(A \wedge B)$ are estimated using this characteristic ordering. This means that the relationship between a simple probability $P_{*}(A)$ and the conjunctive probabilities $P(A \wedge B)$ and $P(A \wedge \neg B)$ will depend on this characteristic ordering. In particular, when the characteristic ordering of observables for conjunctions is $A B$ we have

$$
\begin{equation*}
P_{*}(A)=P_{A B}(A)=P_{A B}(A \wedge B)+P_{A B}(A \wedge \neg B) \tag{7}
\end{equation*}
$$

as in standard probability theory (since the ordering of observables is the same for all three probabilities in this expression, quantum probability reduces to standard probability in this case). When the characteristic order of observables for conjunctions is $B A$, however, we have

$$
\begin{equation*}
P_{*}(A)=P_{A B}(A)=P_{B A}(A \wedge B)+P_{B A}(A \wedge \neg B)+\delta_{A} \tag{8}
\end{equation*}
$$

where $\delta_{A}$ is a 'quantum interference' term for observable $A$. This quantum interference term represents deviation from the requirements of probability theory in the estimate $P_{*}(A)$, and arises from the difference between probabilities measured in the orders $A B$ and $B A$. Note that quantum interference is not an error term here: it is a constant that specifies the relationship between $P_{*}(A)$ and $P_{B A}(A \wedge B)+P_{B A}(A \wedge \neg B)$ for a given participant and a given pair of events $A B$. Parallel results arise for the probability of $B$, where with the characteric ordering $B A$ we have

$$
\begin{equation*}
P_{*}(B)=P_{B A}(B)=P_{B A}(A \wedge B)+P_{B A}(\neg A \wedge B) \tag{9}
\end{equation*}
$$

as in probability theory, while with the ordering $A B$ we have

$$
\begin{equation*}
P_{*}(B)=P_{B A}(B)=P_{A B}(A \wedge B)+P_{A B}(\neg A \wedge B)+\delta_{B} \tag{10}
\end{equation*}
$$

where $\delta_{B}$ is the interference term for the estimate $P_{*}(B)$.

From these expressions for $P_{*}(A)$ and $P_{*}(B)$ we derive the quantum probability model's predictions for values of the addition law and the two expansion identities (Equations 1, 2 and 3 ) in three separate situations: where observables are compatible, where the ordering of observables is $A B$, and where the ordering is $B A$. The first three lines of Table 1 shows these predictions. From Table 1 we see that, if observables are compatible, all three identities have a predicted value of 0 (contrary to experimental results). If observables are measured in the order $A B$ or $B A$, however, one expansion identity has a predicted value of 0 and the addition law and the other expansion identity have values that deviate from 0 by exactly the same magnitude but with opposite signs (contrary to experimental results). The quantum probability model's predictions are inconsistent with the experimental results in all three situations.

In quantum probability theory a conditional probability $P(A \mid B)$ is necessarily measured in the order $B A$ (with the given event occurring first and the conditional event occurring after). This means that the relationships

$$
\begin{align*}
& P_{B A}(A \wedge B)=P(A \mid B) P_{B A}(B)=P(A \mid B) P_{*}(B)  \tag{11}\\
& P_{A B}(A \wedge B)=P(B \mid A) P_{A B}(A)=P(B \mid A) P_{*}(A) \tag{12}
\end{align*}
$$

necessarily hold in quantum probability (since the probabilities in these expressions are all measured in the same order, and so follow the requirements of probability theory). We define

$$
\Delta_{A B}=P_{A B}(A \wedge B)-P_{B A}(A \wedge B)
$$

to represent the effect of order on conjunctive probability judgments $P_{A B}(A \wedge B)$ and $P_{B A}(A \wedge B)$. Then substituting from Equations 11 and 12 into the Bayes rule and 'Bayes expansion' identities (Equations 4, 5 and 6), we derive predictions in three separate situations, as before (see Table 1). Here we see that, if observables are compatible, all three identities have a predicted value of 0 (contrary to experimental results). If observables are measured in the order $A B$, one expansion identity has a predicted value of 0 and the Bayes rule and the other expansion identity have the same values, deviating from zero by $\Delta_{A B}$ (contrary to experimental results). If observables are measured in the order $B A$, one expansion identity has a
predicted value of 0 and the Bayes rule and the other expansion identity have values that deviate from zero by exactly the same magnitude of $\Delta_{B}$ but with opposite signs (again, contrary to experimental results). The quantum probability model's predictions are inconsistent with the experimental results in all three situations.

## The QQ identity

Consider our definition of $\Delta_{A B}$ to represent order effects for the conjunctive probability judgments $P_{A B}(A \wedge B)$ and $P_{B A}(A \wedge B)$. A necessary mathematical consequence of quantum probability is that exactly the same order effects apply to conjunctive probabilities $P_{B A}(\neg A \wedge \neg B)$ and $P_{A B}(\neg A \wedge \neg B)$, and so we have

$$
P_{A B}(A \wedge B)-P_{B A}(A \wedge B)=\Delta_{A B}=P_{B A}(\neg A \wedge \neg B)-P_{A B}(\neg A \wedge \neg B)
$$

and therefore the QQ identity holds for events $A$ and $B$ in the quantum probability model. Wang et al. (2014) estimate the size of the order effect in each of their 72 different polls or experimental studies via the related measure

$$
Z=\max \left\{\begin{array}{c}
\left|P_{B A}(A \wedge B)-P_{A B}(A \wedge B)\right|+ \\
\left|P_{B A}(\neg A \wedge \neg B)-P_{A B}(\neg A \wedge \neg B)\right| \\
\left|P_{B A}(A \wedge \neg B)-P_{A B}(A \wedge \neg B)\right|+ \\
\left|P_{B A}(\neg A \wedge B)-P_{A B}(\neg A \wedge B)\right|
\end{array}\right.
$$

(so that the overall order effect is equal to the summed absolute values of the order effects for $A \wedge B$ and $\neg A \wedge \neg B$, or for $A \wedge \neg B$ and $\neg A \wedge B$, whichever is greater). The greater the value of this measure, the larger the order effect. They find statistically significant order effects in most of these polls or studies, but reliable agreement with the QQ identity. The fact that this QQ identity appears to hold simultaneously with such order effects has been taken as clear evidence that 'human judgments follow quantum rules' (Wang et al., 2014).

## The probability theory plus noise model

The probability theory plus noise model assumes that people estimate probabilities via a mechanism that is fundamentally rational (following standard frequentist probability theory), but is perturbed in various ways by the systematic effects or biases caused by purely random noise or error. This approach follows a line of research leading back at least to Thurstone (1927) and continued by various more recent researchers (see, e.g. Dougherty et al., 1999, Erev et al., 1994, Hilbert, 2012). This model explains a wide range of results on bias in people's direct and conditional probability judgments across a range of event types, and identifies various probabilistic expressions in which this bias is 'cancelled out' and for which people's probability judgments agree with the requirements of standard probability theory (see Costello and Watts, 2014, Costello and Mathison, 2014, Costello and Watts, 2016a,b,c).

In standard probability theory the probability of some event $A$ is estimated by drawing a random sample of events, counting the number of those events that are instances of $A$, and
dividing by the sample size. The expected value of these estimates is $P(A)$, the probability of $A$; individual estimates will vary with an approximately normal distribution around this expected value. The probability theory plus noise model assumes that people estimate the probability of some event $A$ in exactly the same way: by randomly sampling items from their memory, counting the number that are instances of $A$, and dividing by the sample size. Since memory is subject to various forms of random error, the model assumes that items have some probability $d<0.5$ of being counted incorrectly. Given this error, a randomly sampled item can be counted as $A$ in two mutually exclusive ways: either the item truly is an instance of $A$ and is counted correctly (this occurs with probability $P(A)(1-d)$, since $P(A)$ items are truly instances of $A$, and items have a $(1-d)$ chance of being read correctly), or else the item truly is not an instance of $A$ and is counted incorrectly as $A$ (this occurs with probability $(1-P(A)) d$, since $(1-P(A))$ items are truly not instances of $A$, and items have a $d$ chance of being read incorrectly). The expected value for a noisy estimate for the probability of $A$ is thus

$$
\begin{equation*}
P_{*}(A)=P(A)(1-d)+(1-P(A)) d=(1-2 d) P(A)+d \tag{13}
\end{equation*}
$$

and we expect individual estimates $p_{*}(A)$ to vary independently around this expected value. This equation represents a pattern of regressive bias moving probability estimates $P_{*}(A)$ away from the true, objectively correct probability $P(A)$. Reasoning just as above, the model similarly predicts an expected value for the conditional probability $P(A \mid B)$ of
$P_{*}(A \mid B)=\frac{(1-2 d)^{2} P(A \wedge B)+d(1-2 d)[P(A)+P(B)]+d^{2}}{(1-2 d) P(B)+d}$
These expressions account for various observed patterns of bias in people's direct and conditional probability judgment (see Costello and Watts, 2014, 2016b).

## Addition law and Bayes rule identities

This model makes predictions about the values of various probability theory identities. If we substitute Equation 13 into the addition law identity, for example, we get an expected value of

$$
P_{*}(A)+P_{*}(B)-P_{*}(A \wedge B)-P_{*}(A \vee B)=0
$$

and so this model predicts that this expression should have a value of 0 , and just as seen in experimental results (Costello and Watts, 2014, 2016b, Fisher and Wolfe, 2014). Similarly, if we substitute Equation 13 and Equation 14 into the Bayes rule identity, we get an expected value of

$$
P_{*}(B \mid A) P_{*}(A)-P_{*}(A \mid B) P_{*}(B)=0
$$

and again the model predicts a value of 0 , just as just as seen in experimental results.

Agreement with probability theory for the addition law and the Bayes rule identity arises, in this model, despite significant regressive bias due to random noise in individual probability estimates making up these expressions. This is because
in these identities the various biases due to random noise in those individual probability estimates all cancel out. For other probability theory identities, however, this model predicts no cancellation of regressive effects. For example, substituting the expression from Equation 13 into the two 'expansion' identities (Equation 2 and 3), we get

$$
\begin{aligned}
& P_{*}(A \wedge B)+P_{*}(A \wedge \neg B)-P_{*}(A)=d \\
& P_{*}(A \wedge B)+P_{*}(\neg A \wedge B)-P_{*}(B)=d
\end{aligned}
$$

and the model predicts the same positive value for both identities, again just as observed in experimental results (Costello and Watts, 2016b, Fisher and Wolfe, 2014).

For the two 'Bayes expansion' identities (Equation 5 and 6) we get

$$
\begin{aligned}
& P_{*}(A \wedge B)-P_{*}(A \mid B) P_{*}(B) \\
& =d(1-d)-d(1-2 d)[P(A)+P(B)-2 P(A \wedge B)] \\
& P_{*}(A \wedge B)-P_{*}(B \mid A) P_{*}(A) \\
& =d(1-d)-d(1-2 d)[P(A)+P(B)-2 P(A \wedge B)]
\end{aligned}
$$

Since probability theory requires that $0 \leq P(A)+P(B)-$ $2 P(A \wedge B) \leq 1$ for all $A$ and $B$, and since $d<0.5$ by assumption, we see that
$d^{2} \leq d(1-d)-d(1-2 d)[P(A)+P(B)-2 P(A \wedge B)] \leq d(1-d)$
and values for both these identities will be distributed between $d^{2}$ and $d(1-d)$ in a way that depends on $P(A)+$ $P(B)-2 P(A \wedge B)$. The average value for $P(A)+P(B)-$ $2 P(A \wedge B)$ (across uniformly distributed probabilities that are constrained to be consistent with probability theory) is 0.5 , and so the average value for this expression is equal to $d / 2$, the centerpoint of this range. The model thus predicts the same average positive value for these identities; a value half that for the first two expansion identities. Again, this is just as seen in experimental results (Costello and Watts, 2016b).

## The QQ identity and order effects

The probability theory plus noise model, as presented above, assumes that when $P(B)$ and $P(A)$ are estimated sequentially, the value given for $P(A)$ is not influenced by the prior value given for $P(B)$. This is because the model assumes that people estimate some probability $P(A)$ by drawing a sample of items at random from memory, and counting the proportion that are $A$. To allow sequential effects in the noise model, we can relax this assumption, and say that the chance of a given item being sampled from memory is influenced by the degree to which that item is already active or 'primed'. Since the estimation of probability $P(B)$ involves drawing a sample of items and counting the proportion that are $B$, those items that were counted as $B$ are more active (are primed), and so are more likely to be included in the 'random' sample of items drawn when estimating $P(A)$, causing an order effect.

Suppose that the chance of an already primed item being sampled is $s$. Also suppose that $P(B)$ has just been estimated
in a previous sample: $P_{*}(B)$ then represents the proportion of items in that previous sample that were read as $B$. A sample is now drawn to estimate $P(A)$. Each item drawn to make up that new sample has a probability $s P_{*}(B)$ of coming from the primed set of items that were already read as $B$, and a probability $1-s P_{*}(B)$ of being drawn randomly from the set of all items in memory. For the $s P_{*}(B)$ items in our sample that were previously read as $B$, the probability of one of those items being read as $A$ is $P_{*}(A \mid B)$; this is the conditional probability of an item being read as $A$, given that it was read as $B$. For the remaining items that were just sampled randomly from memory, the probability of one of those items being read as $A$ is simply $P_{*}(A)$. Given that we have just given an estimate for the probability $P(B)$, then, the expected value for an immediately following estimate for $P(A)$ will be

$$
P_{B A}(A)=s P_{*}(B) P_{*}(A \mid B)+\left(1-s P_{*}(B)\right) P_{*}(A)
$$

and, substituting from Equations 13 and 14 and simplifying we get

$$
\begin{equation*}
P_{B A}(A)=P_{*}(A)+s(1-2 d)^{2}[P(A \wedge B)-P(A) P(B)] \tag{15}
\end{equation*}
$$

From Equation 15 we see that $P_{B A}(A) \neq P_{*}(A)$ and so $P_{B A}(A) \neq P_{A B}(A)$ will hold in this model in general, with the probability of a 'yes' answer to question $A$ when that question comes first being different from the probability of a 'yes' answer when question $A$ immediately follows question $B$. This model thus produces order effects in question answering, just as seen in experimental data.

Despite these order effects, the QQ identity also holds in this model. To see this, consider that, since $P_{*}(B)$ is the probability of answering 'yes' to a question $B$ and $P_{B A}(A)$ is the probability of answering 'yes' to a question $A$ that immediately follows a question $B$, the probability of answering 'yes' to both questions when presented in the order $B A$ is

$$
\begin{aligned}
& P_{B A}(A \wedge B)=P_{*}(B) P_{B A}(A) \\
& =P_{*}(B) P_{*}(A)+P_{*}(B) s(1-2 d)^{2}[P(A \wedge B)-P(B) P(A)]
\end{aligned}
$$

and the probability of answering 'yes' to both questions in the order $A B$ is

$$
\begin{aligned}
& P_{A B}(S \wedge B)=P_{*}(A) P_{A B}(B) \\
& =P_{*}(A) P_{*}(B)+P_{*}(A) s(1-2 d)^{2}[P(A \wedge B)-P(B) P(A)]
\end{aligned}
$$

and so

$$
\begin{align*}
& P_{B A}(A \wedge B)-P_{A B}(A \wedge B) \\
& =s(1-2 d)^{2}[P(A \wedge B)-P(B) P(A)]\left[P_{*}(B)-P_{*}(A)\right] \tag{16}
\end{align*}
$$

Using the same line of reasoning for the probability of answering 'no' to both questions, we get
$P_{A B}(\neg B \wedge \neg A)-P_{B A}(\neg B \wedge \neg A)$
$=s(1-2 d)^{2}[P(\neg B \wedge \neg A)-P(\neg B) P(\neg A)]\left[P_{*}(\neg A)-P_{*}(\neg B)\right]$
Substituting from Equation 13 and rearranging we have

## References

$$
\begin{aligned}
P_{*}(\neg A)-P_{*}(\neg B) & =(1-2 d)[1-P(A)]+d-(1-2 d)[1-P(B)]-d \\
& =P_{*}(B)-P_{*}(A)
\end{aligned}
$$

and from standard probability theory we have

$$
P(\neg A \wedge \neg B)-P(\neg A) P(\neg B)=P(A \wedge B)-P(B) P(A)
$$

and so

$$
\begin{align*}
& P_{A B}(\neg A \wedge \neg B)-P_{B A}(\neg A \wedge \neg B) \\
& =s(1-2 d)^{2}[P(B \wedge A)-P(B) P(A)]\left[P_{*}(B)-P_{*}(A)\right] \tag{17}
\end{align*}
$$

giving
$P_{A B}(A \wedge B)+P_{A B}(\neg A \wedge \neg B)-P_{B A}(A \wedge B)-P_{B A}(\neg A \wedge \neg B)=0$
and this model satisfies the QQ identity.

## Conclusions

Much research on people's probabilistic reasoning over the last 50 years has focused on the various significant biases seen in probability estimation and judgment. Invariants such as the addition law, the Bayes rule identity, and the QQ identity, which hold simultaneously with these biases, reveal an important fact: they show us that these biases are systematically and quantatitively related and can be explained mathematically. We can see this in the case of the QQ identity, where there are reliable order effects (biases) in responses which nonetheless cancel out when responses are combined in the identity. We also see this in the addition law and Bayes rule identities, where there are reliable biases in probability estimates which again, cancel out when those estimates are combined in those identities.

In this paper we've shown that, unlike the quantum probability model, the probability theory plus noise model is able explain the satisfaction of three invariants in people's probabilistic judgment (the addition law, Bayes rule and QQ identities) alongside the occurence of various forms of systematic bias in those same judgments. These results support the theoretical proposal in that account, which is that human probabilistic judgment is based on a rational process (one that follows frequentist probability theory) that is subject to random noise. It is important to stress that we are not suggesting that people's probability estimates are themselves rational. This is clearly not the case: there is very extensive evidence demonstrating that people's probability estimates are systematically biased away from the requirements of probability theory. We argue that these biases are a consequence of the influence of random noise on the probability estimates generated by an underlying rational process. While this noise is random, it has systematic, directional effects (our noisy model's expected averages for probability estimates are systematically biased away from the 'true' probability values, in a way that seems to match the biases seen in people's estimates) which are cancelled out in these three identities. This model gives a new and useful perspective on the various systematic biases seen in people's probabilistic reasoning.

# Experts are better than novices when imagining wines, but not odors in general 

Ilja Croijmans<br>Centre for Language Studies, Radboud University, Nijmegen, NL<br>Laura Speed<br>Centre for Language Studies, Radboud University, Nijmegen, NL<br>Artin Arshamian<br>Centre for Language Studies, Radboud University, Nijmegen, NL; Division of Psychology, Department of Clinical Neuroscience, Karolinska Institutet, Stockholm, SW<br>Asifa Majid<br>Radboud University, The Netherlands; Donders Institute for Brain, Cognition, and Behaviour, Radboud University, Nijmegen, NL; Max Planck Institute for Psycholinguistics, Nijmegen, NL

#### Abstract

Olfactory imagery is disputed to exist in novices, but is reported to be easier for smell experts. It plays an important role in wine expertise. Previous research shows experts' superior cognitive abilities do not transfer beyond their domain of expertise. This leads to two questions: do wine experts have more vivid imagery for the multisensory experience of wine? And how general is wine experts' olfactory imagery? Wine experts and novices completed a questionnaire measuring the vividness of imagery for the color, smell, and flavor of wine. In addition, all participants completed a questionnaire on general smell imagery. Wine experts were better than novices at imagining wines in all modalities, but not better at imagining smells in general. Novices reported the strongest imagery for the appearance of wine, but experts showed no difference between the senses. So mental imagery becomes more vivid with expertise; but only for imagery directly expertise related.

#### Abstract

The inference of or-introduction, $p$, therefore $p$ or $q$, is fundamental in classical logic and probability theory. Yet traditional research in the psychology of reasoning found that people did not endorse this inference as highly as other onepremise valid inferences. A radical response to this finding is to claim that or-introduction is in fact invalid. This response is found in the recent revision of mental model theory (MMT). We argue that this revision of the theory leads to a number of logical problems and counterintuitive consequences for valid inferences, and present an experiment extending recent studies showing that people readily accept or-introduction under probabilistic instructions. We argue for a pragmatic explanation of why the inference is sometimes considered odd. The inference is not odd when people reason from their degrees of belief.

Keywords: or-introduction; reasoning; mental models; probabilistic approach

## The New Paradigm and earlier MMT

There has been a paradigm shift in the psychology of reasoning (Oaksford \& Chater, 2013; Over, 2009), from binary approaches focussed on drawing conclusions from arbitrary assumptions, to Bayesian and probabilistic accounts focussed on people's degrees of belief and belief revision and updating in reasoning.

## The probabilistic approach

A central position in the probabilistic approach is that most reasoning in both everyday life and science takes place under uncertainty. This uncertainty cannot be captured in classical binary logic, but it can be in probability theory (Adams, 1998; Coletti \& Scozzafava, 2002).

A basic hypothesis in this new approach is that people's degree of belief in a conditional statement, $\mathrm{P}($ if $p$ then $q)$, does not correspond to the probability of the material conditional of classical logic (which is equivalent to not-p or $q$ ), but instead to the conditional probability, $\mathrm{P}(q \mid p)$. The proposal is that people arrive at this conditional probability by performing a Ramsey test, a mental simulation in which they hypothetically add $p$ to their beliefs, make any changes necessary to preserve consistency, and judge the probability of $q$ on this basis (Evans \& Over, 2004; Ramsey, 1929/1990; Stalnaker, 1968). The identity $\mathrm{P}($ if $p$ then $q)=$ $\mathrm{P}(q \mid p)$ is generally called The Equation (Edgington, 1995) and has received strong empirical support (Evans, Handley,

Neilens, \& Over, 2007; Evans, Handley, \& Over, 2003; Oberauer, Geiger, Fischer, \& Weidenfeld, 2007; Oberauer \& Wilhelm, 2003; Fugard, Pfeifer, Mayerhofer, \& Kleiter, 2011; Barrouillet \& Geauffroy, 2015).

## Probabilities in earlier MMT

Earlier versions of mental model theory (MMT) proposed that people reason by creating a mental representation of the logical possibilities in which the premises of an inference are true (e. g. $p \& q$ is true in one possibility: that in which both $p$ and $q$ are true; whereas $p$ or $q$ is true in three possibilities: when $p$ is true and $q$ false, when $p$ is false and $q$ true, and when $p$ and $q$ are both true). Each of these possibilities is called a model. People then eliminate any models of the premises that contradict one another (e. g. if Premise 1 of an inference is $p$ or $q$ and Premise 2 is not- $p$, then people eliminate the two models of Premise 1 in which $p$ is true). Finally, people formulate an informative conclusion based on any models remaining after eliminating inconsistencies. It was further held that people make errors in reasoning because they tend to represent only what is true in a model, and to leave implicit what is false, and because they tend to leave implicit and then forget entire models.

MMT was originally formulated within the binary approach to reasoning. Hence it focussed on the truth or falsity of a statement, given the truth of some other statements, and proposed the core meaning of conditionals to correspond to the material conditional (Johnson-Laird \& Byrne, 1991, 2002).

However, MMT was early on extended to reasoning with extensional probabilities, representing these as proportions of models or numerical "tags" on models (Girotto \& Johnson-Laird, 2004, 2010; Johnson-Laird, Legrenzi, Girotto, Legrenzi, \& Caverni, 1999; c. f. Geiger \& Oberauer, 2010) in a way consistent with the rules of probability theory.

MMT has also been recently extended to subjective probabilities (Khemlani, Lotstein, \& Johnson-Laird, 2014). However, a problem with this account is the lack of clarity in its computational level specification. For example, it proposes that people intuitively grasp that the "logical relation" $p$ or not-p has a probability of 1 , but also that people intuitively compute $\mathrm{P}(p$ or $q)$ by taking the average of $p$ and $q$ (cf. Juslin, Nilsson, \& Winman, 2009) - even though the logical connective is the same in both cases. The account also provides no means for computing correct
conditional probabilities, and can therefore not account for their occurrence. This contrasts with the earlier proposal in MMT of the subset principle for computing extensional conditional probabilities (Johnson-Laird et al., 1999), which could account for both errors and normative responses.

## New MMT

Johnson-Laird and colleagues recently proposed a radical revision of MMT that claims to integrate logic further with probability (Johnson-Laird, Khemlani, \& Goodwin, 2015). The revision changes the meanings of conditionals, conjunctions and disjunctions. These statement types are still represented using the same models as before, but whereas in previous versions of MMT a statement was true when at least one of its models was true, in the new version of the theory a statement is true when all of its models are possible (Johnson-Laird et al., 2015).

A positive consequence of this revision, in our view, is that the paradoxes of the material conditional are now considered invalid. For example, the inference $q$, therefore if $p$ then $q$ is considered invalid because the model for $q$ does not establish that all three models of the material conditional are possible. But the revision creates a number of logical problems and counterintuitive consequences for other inferences (Baratgin, Douven, Evans, Oaksford, Over, \& Politzer, 2015; Over \& Cruz, in press).

## Logical problems with new MMT

## "Possible", "true", and "valid"

Johnson-Laird et al. (2015) argue that a statement is true when all of its models are possible. But it is not clear what is meant by "possible". It cannot be logical possibility, because logically the four combinations of the truth and falsity of $p$ and of $q$ ( $p \& q, p \&$ not- $q$, not- $p \& q$, not- $p \&$ not- $q$ ) are always possible unless they contain a contradiction (Baratgin et al., 2015). Moreover, with logical possibility the new version of MMT would imply that the tautology $p$ or not $-p$ is false because the $p \&$ not- $p$ model is not possible (Baratgin et al., 2015).

Yet a narrower notion of possibility does not seem to work either. This can be seen if we apply the idea that a statement is true whenever all of its models are possible to statements that have a single model. The theory then implies that a statement $p$ is true when it is possible. But it can be possible, and readily conceivable, for us to sleep a little longer tomorrow, and yet be false if we wake up early instead. Truth does not follow from mere possibility, no matter how it is defined (Over \& Cruz, in press).

A further problem arises when the notion of truth in new MMT is used to assess the validity of an inference. JohnsonLaird et al. (2015) continue to define an inference as logically valid when its conclusion is true in every case in which its premises are true. If a statement is true when all of its models are possible, then by implication an inference is valid when the truth of the premises establishes that all models of the conclusion are possible. This formulation of
the concept of validity is of course difficult to understand without a clear definition of "possible". But one way of operationalising it could be as follows. An inference is valid in new MMT when the models of the premises contain all the models of the conclusion. This operationalisation renders the paradoxes invalid. But it leads to counterintuitive conclusions for other inferences. For example, it implies that the inference $p$ or $q$, therefore $p$ is valid, even though it is counterintuitive and invalid in classical and probabilistic logics. At the same time, the account implies that the inference not- $p$, therefore not-( $p$ \& $q$ ) is invalid, but this is an intuitive inference to make, and it is valid in classical and probabilistic logics.

## Or-introduction

In what follows we focus on the inference of orintroduction, $p$, therefore $p$ or $q$. This inference is valid in classical logic and in the probabilistic approach because it is incoherent to judge that $\mathrm{P}(p)>\mathrm{P}(p$ or $q)$. It was also valid in previous versions of MMT.

Past studies using binary instructions (asking participants to assume the premises to be true, and then to judge whether the conclusion also had to be true) found that people accept the inference less frequently than other valid inferences (Braine, Reiser, \& Rumain, 1984; Orenes \& Johnson-Laird, 2012; Rips, 1983). But the probabilistic approach and previous versions of MMT agreed that the lower acceptance rate can be explained through pragmatic factors: $p$ is a stronger, more informative statement than $p$ or $q$, and so it is pragmatically infelicitous to assert $p$ or $q$ when one has enough information to assert $p$ (Grice, 1989). Orenes \& Johnson-Laird (2012) specified this position further, suggesting that the pragmatic infelicity of the inference comes from the fact that the conclusion $p$ or $q$ includes a model in which the premise $p$ is false. We agree with Grice (1989) that it is potentially misleading to assert $p$ or $q$ in a conversation, suggesting that $p$ is possibly false, after inferring $p$ or $q$ from $p$ (Gilio \& Over, 2012).

However, in the new version of MMT or-introduction is considered invalid for the same reason as the paradoxes: the model for $p$ does not establish that the three models for the disjunction are possible. This revision does not take into account the more recent finding that under probabilistic instructions (asking participants for their degree of belief in the premise, and for their degree of belief in the conclusion given their degree of belief in the premise) or-introduction is accepted to a high degree, indistinguishable from that of other, uncontroversially valid inferences (Cruz, Baratgin, Oaksford, \& Over, 2015; Politzer \& Baratgin, 2016). According to the probabilistic approach, people accept the inference under probabilistic instructions because pragmatic constraints related to what is asserted in a conversation tend to be eliminated or reduced when people are asked directly for their subjective beliefs. Conversational principles about not misleading our hearers (Grice, 1989) do not apply when we are making inferences from our own beliefs as premises to further beliefs in a subjective mental process.

The assumed invalidity of or-introduction also disables central logical and probabilistic principles. For example, if or-introduction is invalid, then so is a version of the inference in which the disjunction is "packed": p, therefore superset of $p$. For example, there is tea, therefore there is tea or coffee can be paraphrased as there is tea, therefore there is a hot beverage. Or-introduction thus enables us to establish basic set-subset relations. If people are unable to establish such relations, then the MMT account of reasoning with categorical syllogisms breaks down. Or-introduction is also used in the proofs of many fundamental theorems of probability theory, such as the theorem of total probability, $P(p)=P((p \& q)+P(p \&$ not $-q))$, which is itself derived from the fundamental logical principle that $p$ is equivalent to $(p \& q)$ or $(p \& n o t-q)$. MMT cannot integrate logic and probability theory while implying that such principles are invalid.

In what follows we analyse in more detail the relation between or-introduction and two further inferences: andelimination, $p \& q$, therefore $p$, and or-MP: if $p$ or $q$ then $r$, $p$, therefore $r$.

## And-elimination = or-introduction

And-elimination appears to be valid in the new version of MMT, because the model of the premise contains all the models of the conclusion. But the validity of andelimination implies the validity of or-introduction, and vice versa, as follows:

$$
\begin{array}{ll}
p \& q \text {, therefore } p & \\
\text { not- } p \text {, therefore not- }(p \& q) & \text { (by reductio ad absurdum) } \\
\text { not- } p \text {, therefore not- } p \text { or not- } q & \text { (by de Morgan) } \\
p, \text { therefore } p \text { or } q & \text { (by substitution of terms) }
\end{array}
$$

Mental model theory could argue that it does not accept this proof because one or more of the rules used in the derivation are itself invalid in the theory. But the invalidity of such elementary logical rules would have counterintuitive consequences for a wide range of further inferences.

## Or-MP: or-introduction through the back door

The inference if $p$ or $q$ then $r, p$, therefore $r$ can be called orMP because it is the short form of a two-step inference, in which one first uses or-introduction to infer $p$ or $q$ from $p$, then then uses $p$ or $q$ together with if $p$ or $q$ then $r$ to infer $r$ through the inference of modus ponens (MP).

Under binary instructions or-MP is endorsed to a degree at least as high as MP (Rips, 1983). The inference also appears to be valid in new MMT because the models of the premises contain all the models of the conclusion. But as outlined above, or-MP includes or-introduction as a component.

Followers of MMT might reply that, in the new version of the theory, or-MP is valid directly without the intermediate step of or-introduction. But the validity of or-MP also implies the validity of or-introduction in a direct way. If we substitute $p$ or $q$ for $r$, the resulting inference is if $p$ or $q$
then $p$ or $q, p$, therefore $p$ or $q$. The first premise is a tautology, which always holds and does not have to be assumed, and the rest is explicit or-introduction (c. f. Over \& Cruz, in press).

We conducted an experiment to test people's intuitions about the validity of or-introduction, and its relation to andelimination and or-MP, using probabilistic instructions.

## Method

## Participants

A total of 121 participants from English speaking countries completed the experiment through the online platform Prolific Academic. After removing cases that failed a test question or included trial reaction times of 3 sec or less, 112 participants remained for analysis. They had a mean age of 29 years (range: 18-73), and a varied formal-educational background. All indicated having at least good English language skills. Participants' percentage rating of task difficulty was on average $48 \%$.

## Design and materials

Participants were shown the 6 inferences of Table 1 (two further inferences investigating other questions are not discussed here due to space constraints). Inferences 1 to 5 were presented three times, with three different premise probabilities $(100 \%, 80 \%$, and $60 \%)$. Inference 6 was only presented with a premise probability of $100 \%$ because one of its premises is a tautology. Premise probability was varied with the aim of generalising the results to different premise probabilities, and was not associated with particular predictions. For each trial, participants' task was to judge how likely the conclusion of the inference can be, given the likelihood of the premise.

Table 1. The inferences investigated.

| Name | Form |
| :---: | :---: |
| 1 or-introduction | $p \therefore p$ or $q$ |
| 2 and-elimination | $p \& q \therefore p$ |
| 3 Paradox 1 | $q \therefore$ if $p$ then $q$ |
| 4 Paradox 2 | not-p $\therefore$ if $p$ then $q$ |
| 5 or-MP (a) | if $p$ or $q$ then $r, p \therefore r$ |
| 6 or-MP (b) | if $p$ or $q$ then $p$ or $q, p$ $\therefore p \text { or } q$ |

$$
\text { Note. " } \therefore \text { " = "therefore". }
$$

The experiment involved three comparisons. The first was between inference 1 (or-introduction) and inference 2 (andelimination). The probabilistic approach predicts people will give similar ratings to these two inferences because the validity of one implies the validity of the other, and asking directly for people's degree of belief in the conclusion is expected to reduce pragmatic factors that may have led to lower acceptance rates of or-introduction using binary instructions (Orenes \& Johnson-Laird, 2012; Rips, 1983). In contrast, new MMT would predict inference 2 to be
accepted to a high degree but inference 1 to be rejected, because inference 2 is valid but inference 1 is invalid in the new version of the theory.

The second comparison was between inference 1 (orintroduction) and inferences 3 and 4 (the paradoxes of the material conditional. The probabilistic approach predicts people will accept inference 1 to a higher degree than inferences 3 and 4 because the first is valid but the latter two invalid. In contrast, new MMT would predict that people will reject all three inferences to a similar degree, because they are considered invalid for the same reason in the theory.

The third comparison was between inference 1 (orintroduction) and inferences 5 and 6 (or-MP). The probabilistic approach predicts people will endorse inferences 1,5 and 6 to a similar degree, because they are all valid. New MMT would predict inference 5 to be accepted as valid (by assuming it to be computed in a direct way without the intermediate step of or-introduction), but inferences 1 and 6 to be rejected because or-introduction is invalid on their account.

On each trial participants saw an inference embedded in a pseudo-naturalistic context story. The context stories changed on every trial, and were randomly allocated to the inferences for each participant. The order of occurrence of the inferences was also varied randomly for each participant. With 8 inferences (two not reported here) and 3 probabilities (and inference 6 only being paired with a probability of $100 \%$ ), there were 22 trials overall, plus two control trials to check whether participants were paying attention.

## Procedure

After going through the instructions and three practice trials involving different inferences to those in Table 1, participants worked through the 24 trials of the experiment. They then provided demographical information and indicated whether they had taken part seriously. The final page provided debriefing information. The experiment took on average 13.2 minutes to complete.

## Results and discussion

To compare the above predictions of the probabilistic approach and the revised version of MMT, two linear mixed model analyses were performed. The procedure for model construction followed the recommendation of Barr, Levy, Scheepers, \& Tily (2013) of implementing the maximum possible random effects structure justified by the design. The models included a random intercept for participants, but random effects for material could not be included because the random allocation of materials to inferences had as a consequence that there were not enough repetitions of the same type of material within each cell of the design. Predictor variables were centred around their grand mean to avoid problems of multicollinearity when including interaction terms. Comparisons of the main $F$-test results with likelihood-ratio tests led to the same pattern of
significant and non-significant effects. Effect sizes were calculated using the formulas suggested by Snijders and Bosker (2012), requiring the use of ML as opposed to reML as estimation method. The results are displayed in Figure 1.

## Analysis 1: Inferences 1 to 5

We first fitted an overall model with inference (1 to 5) and probability $(100 \%, 80 \%, 60 \%)$ as independent variables ${ }^{1}$. Judgments of conclusion probability increased with increasing premise probability, $F(2,1568)=118.76, p$ $<.001, \eta_{\mathrm{p}}^{2}=.074$. Mean probability judgments differed between inferences, $F(4,1568)=269.09, p<.001, \eta_{\mathrm{p}}{ }^{2}=$ .334. The size of the effect of premise probability also differed between inferences, $F(8,1568)=13.06, p<.001$, $\eta_{\mathrm{p}}^{2}=.055$.

Figure 1. Judgments of conclusion probability for inferences 1 to 5 as a function of premise probability. Error bars show 95\% CIs.
${ }^{1}$ Following the notation of Snijders \& Bosker (2012), the equation for measurement $i$ of participant $j$ was given by:
$y_{i j}=\gamma_{00}+\gamma_{10} x_{1 i j}+\gamma_{20} x_{2 i j}+\gamma_{30} x_{1 i j} x_{2 i j}+u_{0 j}+\epsilon_{i j}$ This random coefficients model had 17 parameters: 1 for the fixed effect of the intercept, 4 for the fixed effect of inference, 2 for the fixed effect of premise probability, 8 for the fixed interaction between inference and premise probability, 1 for the variance of the intercept, and 1 for the residual variance. The fact that the predictors were centred is not represented in the equation due to space constraints. The equations for the other linear mixed models computed in the analyses followed the same principles, but are not reported due to limitations of space.

Figure 1 suggests that the interaction between inference and premise probability can be traced back to the lack of an effect of premise probability for inference 4 . Follow-up analyses showed that there was indeed no effect of premise probability for inference $4, F(2,224)=1.06, p=.35, \eta_{\mathrm{p}}^{2}=$ .005. However, the size of the effect of premise probability still varied between inferences $1,2,3$ and $5, F(2,1232)=$ $189.60, p<.001, \eta_{\mathrm{p}}^{2}=.017$.

Follow-up analyses to the effect of inference showed that there was no significant difference in probability judgments for inference $1(M=75.14, S E=1.34)$ and inference $2(M=$ $78.02, S E=.82)\left(F(1,560)=3.23, p=.073, \eta_{\mathrm{p}}{ }^{2}=.005\right)$. This is in accordance with the predictions of the probabilistic approach, because or-introduction and andelimination can be derived from one another as valid inferences. The result is at odds with new MMT, which predicts the second to be valid but the first invalid.

Judgments for inference 1 were higher than those for inference $3(M=59.66, S E=1.77)(F(1,560)=70.028, p<$ $\left..001, \eta_{\mathrm{p}}^{2}=.085\right)$ and than those for inference $4(M=37.58$, $S E=1.70)\left(F(1,560)=424.164, p<.001, \eta_{\mathrm{p}}^{2}=.371\right)$. This is again in accordance with the probabilistic approach, for which or-introduction is valid, but the paradoxes of the material conditional are not. It goes counter to new MMT, in which the three inferences are invalid for the same reason.

Judgments for inference $5(M=83.85, S E=1.03)$ were slightly higher than those for inference $1(F(1,560)=33.47$, $\left.p<.001, \eta_{\mathrm{p}}{ }^{2}=.044\right)$ and than those for inference 2 ( $F(1$, $672)=14.990, p<.001, \eta_{\mathrm{p}}^{2}=.022$ ). Taken by itself this finding is in accordance with both the probabilistic approach and new MMT, because both predict the inference to be valid. Small differences in the acceptance of valid inferences are not a problem for either theory, as long as the difference between responses to valid and responses to invalid inferences is larger, as Figure 1 clearly corroborates. The slightly higher acceptance of or-MP than of orintroduction and and-elimination is in accordance with the fact that or-MP includes MP as a component, and MP tends to be endorsed at ceiling. Responses to inference 5 become more consequential to the questions investigated here when compared to those of inference 6.

## Analysis 2: Inferences 1, 5, and 6

We next fitted a model with inference $(1,5,6)$ as the independent variable, using responses for a premise probability of $100 \%$. Judgments for inference 1 ( $M=85.60$, $S E=1.98$ ) were again slightly lower than those for inference $5(M=92.63, S E=1.98)(F(1,112)=8.34, p=$ $\left..005, \eta_{\mathrm{p}}^{2}=.027\right)$ and than those for inference $6(M=91.32$, $S E=2.03)\left(F(1,112)=4.69, p=.032, \eta_{\mathrm{p}}^{2}=.019\right)$. Judgments for inference 5 did not differ from those for inference $6(F(1,112)=.31, p=.58)$. Thus version (a) of or-MP (if $p$ or $q$ then $r$, $p$, therefore $r$ ) and version (b) of the inference (if $p$ or $q$ then $p$ or $q$, $p$, therefore $p$ or $q$ ) were endorsed to the same degree, even though version (b) explicitly contains or-introduction as a component. This is
in accordance with the probabilistic approach, under which the two inferences are equivalent, but at odds with new MMT, which would predict version (b) of the inference to be rejected because or-introduction is invalid in its account.

An interesting, not anticipated finding concerns the pattern of results for the paradoxes (inferences 3 and 4). For inference 4 there was no effect of premise probability, and judgments of conclusion probability were consistently low. Judgments for inference 3 were also clearly lower than those for inferences 1,2 , and 5 , but they did covary positively with premise probability.

A first account of this difference could be as follows. In the case of inference 4 , not- $p$, therefore if $p$ then $q$, premise and conclusion contain no elements in common, and so the fact that the premise is uninformative about the conclusion is clearly apparent. Without any information about the conclusion, people assign a low probability to it, expressing that it does not follow from the premise. In the case of inference $3, q$, therefore if $p$ then $q$, the premise is also uninformative about the conclusion, and so any response is coherent. But in the absence of further information, it is reasonable to infer that a given probability of $q$ will remain invariant under the assumption of $p$. It therefore makes sense for responses to covary positively with premise probability.

## General discussion

We investigated the inference of or-introduction and its relation to and-elimination and or-MP. Earlier research using binary instructions had found or-introduction to be accepted less frequently than and-elimination (Rips, 1983). The recent revision of MMT argues that or-introduction is in fact invalid. But the assumptions of this revision have inconsistencies and counterintuitive consequences for other inferences. We extended recent findings (Cruz et al., 2015; Polizer \& Baratgin, 2016) using probabilistic instructions and found that or-introduction is accepted to a high degree, indistinguishable from that of and-elimination. People's responses to or-MP were slightly higher than those for orintroduction and and-elimination, even though or-MP contains or-introduction as a component. These findings are in accordance with the predictions of a Bayesian approach to the study of reasoning, but not with those of new MMT.

With the exception of the paradoxes, the findings could also have been accounted for in earlier versions of MMT concerned with extensional probabilities (Girotto \& Johnson-Laird, 2004, 2010; Johnson-Laird et al., 1999; c. f. Orenes \& Johnson-Laird, 2012). These earlier formulations converged with the probabilistic approach in holding that or-introduction is valid, but is sometimes odd for pragmatic reasons. The results of this experiment provide further evidence for the pragmatic explanation. The findings also suggest that people tend to reason using or-introduction in a more logical and less biased way under probabilistic than under binary instructions. People's inferences from their own degrees of belief to further degrees of belief do not seem to be governed by the conventions of conversation for
speakers and hearers in open discussions, but rather by the Bayesian principles of belief revision and updating, as proposed in the new paradigm in the psychology of reasoning.

#### Abstract

The delay discounting perspective, which assumes an alternative-wise processing of attribute information, has long dominated research on intertemporal choice. Recent studies, however, have suggested that intertemporal choice is based on attribute-wise comparison. This line of research culminated in the tradeoff model (Scholten \& Read, 2010; Scholten, Read, \& Sanborn, 2014), which can accommodate most established behavioral regularities in intertemporal choice. One drawback of the tradeoff model, however, is that it is static, providing no account of the dynamic process leading to a choice. Here we develop a dynamic tradeoff model that can qualitatively account for empirical findings in intertemporal choice regarding not only choices but also response times. The dynamic model also outperforms the original, static tradeoff model when quantitatively fitting choices from representative data sets, and even outperforms the best-performing dynamic model derived from Decision Field Theory in Dai and Busemeyer (2014) when fitting both choices and response times.

Keywords: intertemporal choice; tradeoff model; dynamic models, random utility, discrimination threshold

## Introduction

Many human decisions, mundane or momentous, involve choices between outcomes that materialize at different times in the future, ranging from dieting and exercising plans to education and saving decisions. Research on such intertemporal choices has a long history and has revealed various behavioral regularities. For example, it was found that large rewards suffer less proportional discounting than small ones do (the magnitude effect; e.g., Green, Myerson, \& McFadden, 1997), and that people's preference between options that have different delays can reverse as time passes (e.g., Green, Fristoe, \& Myerson, 1994). Various descriptive models have been developed to account for these empirical phenomena. Among them, the tradeoff model (Scholten \& Read, 2010; Scholten, Read, \& Sanborn, 2014) currently appears to be one of the most promising models since it provides a unified framework for qualitatively explaining a majority of the empirical findings. Most crucially, it can account for the nonadditivity in delay discounting (e.g.,

Scholten \& Read, 2010; Scholten, Read, \& Sanborn, 2014), which eludes any model built on the notion of delay discounting.

One drawback of the tradeoff model, however, is its static nature. As a result, it lacks an account of the dynamic process leading to the explicit intertemporal choices. Nevertheless, any decision is a result of some process that unfolds in time. The characteristics of the process affect the final decision as well as process-related variables such as response time. Therefore, a static model provides only an incomplete description of intertemporal choice, and an account of the underlying dynamics is required for a more comprehensive understanding thereof.

In this paper, we propose a modified tradeoff model of intertemporal choice that has a dynamic structure and can thus account for both choice and response time data. We show that this dynamic tradeoff model can qualitatively accommodate key findings in the literature regarding both choice patterns and relationship between choices and response times. In two model-comparison analyses, we further show that the dynamic model can even outperform promising competing models when fitting empirical data quantitatively.

## The Tradeoff Model

To account for intertemporal choice, research has for a long time been mainly conceptualized using the notion of delay discounting, according to which the delay of a reward decreases its present subjective value. One major concern of this approach has been to find the most appropriate form of the discount function, which describes how subjective value decreases with increased delay length. A critical assumption in this endeavor is that each option has a discounted utility or present value independent of other competing options. Importantly, this predicts that intertemporal choice should be transitive: if, among three options $\mathrm{X}, \mathrm{Y}$, and Z , one chooses $X$ over $Y$ and $Y$ over $Z$, then he or she should also choose $X$ over $Z$.

A series of studies by Read, Scholten, and colleagues, however, demonstrated that the transitivity of intertemporal choices is sometimes violated for a triple of options $\mathrm{S}, \mathrm{M}$,
and L with increasing money amounts and delay lengths (e.g., Scholten et al., 2014). For example, when facing Option S of receiving \$30 in one week, Option M of receiving $\$ 35$ in two weeks, and Option $L$ of receiving $\$ 40$ in three weeks, some people might choose Option S over Option M, choose Option M over Option L, but choose Option L over Option S. In each pair, one option has a smaller but sooner reward (smaller-but-sooner, or SS, option), and the other has a larger but later reward (larger-but-later, or LL, option). The cyclical choice pattern suggests that such people prefer the SS options for adjacent pairs of options (e.g., Option S vs. Option M), but the LL option for the distant pair (Option S vs. Option L). By contrast, others may instead choose the LL options for adjacent pairs but the SS option for the distant pair. The former cyclical pattern can be accounted for by assuming that the amount of discounting associated with a given difference in delay (i.e., the interval between one and three weeks) is smaller when it is treated as a whole than when it is divided into subintervals (e.g., two subintervals of one week), whereas the latter implies the opposite. Together, these patterns suggest nonadditivity in delay discounting.

To accommodate violation of transitivity in intertemporal choice, several alternatives to discounting models were developed, culminating in the tradeoff model. The key difference between the tradeoff model and previous delay discounting models lies in how attributes are assumed to be processed. In contrast to the notion of alternative-wise delay discounting, the tradeoff model assumes that people process attribute information in intertemporal choice by comparing options within each attribute, and that advantages on one attribute (e.g., reward amount) are traded off against the disadvantages on the other attribute (e.g., waiting time). Such an attribute-based approach has been shown to better capture the empirical data quantitatively than the traditional alternative-based approach reflected in the delay discounting paradigm (Dai \& Busemeyer, 2014).

According to the tradeoff model, when choosing between an SS option with a money amount of $\mathrm{x}_{\mathrm{S}}$ and a delay length of $\mathrm{t}_{\mathrm{S}}$, and an LL option with a money amount of $\mathrm{x}_{\mathrm{L}}$ and a delay length of $t_{\mathrm{L}}$, a decision maker (DM) compares the effective compensation with the effective interval. Let $\mathrm{v}(\mathrm{x})$ denote a value function and $\mathrm{w}(\mathrm{t})$ denote a time weighting function. The effective compensation is defined as the difference in the value of the two money amounts, that is, $\mathrm{v}\left(\mathrm{x}_{\mathrm{L}}\right)-\mathrm{v}\left(\mathrm{x}_{\mathrm{S}}\right)$, and the effective interval is defined as the difference in the weighted delay lengths, that is, $w\left(t_{L}\right)$ $\mathrm{w}\left(\mathrm{t}_{\mathrm{s}}\right)$. In addition, the effective interval is assumed to be weighed against the effective compensation by a tradeoff function $\mathrm{Q}\left(\mathrm{w}\left(\mathrm{t}_{\mathrm{L}}\right)-\mathrm{w}\left(\mathrm{t}_{\mathrm{S}}\right)\right)$ to make the decision. The SS option should be preferred when $\mathrm{Q}\left(\mathrm{w}\left(\mathrm{t}_{\mathrm{L}}\right)-\mathrm{w}\left(\mathrm{t}_{\mathrm{s}}\right)\right)$ is larger than $\mathrm{v}\left(\mathrm{x}_{\mathrm{L}}\right)-\mathrm{v}\left(\mathrm{x}_{\mathrm{S}}\right)$, and the LL option should be preferred when $\mathrm{Q}\left(\mathrm{w}\left(\mathrm{t}_{\mathrm{L}}\right)-\mathrm{w}\left(\mathrm{t}_{\mathrm{S}}\right)\right)$ is smaller than $\mathrm{v}\left(\mathrm{x}_{\mathrm{L}}\right)-\mathrm{v}\left(\mathrm{x}_{\mathrm{S}}\right)$.

In the latest version of the tradeoff model (Scholten et al., 2014), the subjective value of a money amount $x$ is given by

$$
\begin{equation*}
v(x)=\frac{1}{\gamma} \log (1+\gamma x) \tag{1}
\end{equation*}
$$

where $\gamma$ represents diminishing absolute sensitivity to differences in money amount, the time weight of a delay length $t$ is given by

$$
\begin{equation*}
w(t)=\frac{1}{\tau} \log (1+\tau t) \tag{2}
\end{equation*}
$$

where $\tau$ represents diminishing absolute sensitivity to differences in delay length, and

$$
\begin{equation*}
Q\left(w\left(t_{L}\right)-w\left(t_{S}\right)\right)=\frac{\kappa}{\alpha} \log \left(1+\alpha\left(\frac{w\left(t_{L}\right)-w\left(t_{S}\right)}{\vartheta}\right)^{\vartheta}\right) \tag{3}
\end{equation*}
$$

in which $\kappa>0$ represents delay sensitivity, $\vartheta>1$ represents superadditivity, and $\alpha>0$ represents subadditivity. To accommodate probabilistic choice patterns (Dai \& Busemeyer, 2014), it is further assumed that the choice probability of the LL option over the SS option is given by a ratio rule, that is,

$$
\begin{equation*}
\operatorname{Pr}(\mathrm{LL} \mid\{\mathrm{SS}, \mathrm{LL}\})=\left(\frac{v\left(x_{L}\right)-v\left(x_{S}\right)}{Q\left(w\left(t_{L}\right)-w\left(t_{S}\right)\right)}\right)^{1 / \epsilon}, \tag{4}
\end{equation*}
$$

where $\varepsilon>0$ represents response noise. With these assumptions, the models can accommodate a large number of behavioral regularities in intertemporal choice, such the aforementioned magnitude effect, preference reversal, and nonadditivity in delay discounting.

## A Dynamic Version of the Tradeoff Model

One important aspect of intertemporal choice that the tradeoff model cannot explain is the recent finding regarding a relationship between choices and response times in intertemporal choice (Dai \& Busemeyer, 2014). Specifically, it was found that pairs of options that give rise to extreme choice proportions tend to be associated with faster response times than pairs with more moderate choice proportions. We refer to this relationship as the fast-andextreme effect. Because the tradeoff model is silent on the temporal dynamics underlying intertemporal choice, it lacks an account of this finding. Here we present a modification of the model to equip it with a dynamic structure while keeping its key assumption of attribute-based processing.

As the original tradeoff model, we assume that a DM performs intertemporal tradeoffs by comparing the effective intervals with the effective compensations. However, unlike the latest implementation of the model (Scholten et al., 2014), in the modified version we assume a more straightforward comparison that goes without the mediation of the tradeoff function. Specifically, we assume that $v\left(x_{L}\right)$ $\mathrm{v}\left(\mathrm{x}_{\mathrm{S}}\right)$ is directly compared to $\mathrm{w}\left(\mathrm{t}_{\mathrm{L}}\right)-\mathrm{w}\left(\mathrm{t}_{\mathrm{S}}\right)$. To accommodate the probabilistic nature of intertemporal choice, we make two further assumptions. First, both the effective compensation and the effective interval are assumed to be random, denoted as $\mathrm{V}\left(\mathrm{x}_{\mathrm{L}}\right)-\mathrm{V}\left(\mathrm{x}_{\mathrm{S}}\right)$ and $\mathrm{W}\left(\mathrm{t}_{\mathrm{L}}\right)-\mathrm{W}\left(\mathrm{t}_{\mathrm{S}}\right)$, respectively, to reflect the uncertainty in these subjective evaluations. Second, it is assumed that a decision is made when the absolute difference between the two (random) quantities is larger than a positive value; otherwise the DM acquires another sample of the effective compensation and interval without accumulating preferences from previous samples. This process continues until a decision can be made. Note that the first assumption echoes the notion of random utility in economics (e.g., McFadden, 1973), while
the second assumption is built on the concept of discrimination threshold in psychophysics (Fechner, 1860).

To derive quantitative predictions, we assume that the effective compensation and effective interval follow independent normal distributions, with respective variance proportional to the mean of the distribution. As a result, the difference between effective compensation and effective interval is also normally distributed with

$$
\begin{equation*}
\mu=\left[v\left(x_{L}\right)-v\left(x_{S}\right)\right]-\left[w\left(t_{L}\right)-w\left(t_{S}\right)\right], \tag{5}
\end{equation*}
$$

and

$$
\begin{equation*}
\sigma=\sqrt{c\left\{\left[v\left(x_{L}\right)-v\left(x_{S}\right)\right]+\left[w\left(t_{L}\right)-w\left(t_{S}\right)\right]\right\}} \tag{6}
\end{equation*}
$$

in which $c$ is a proportional constant to be estimated from the data. ${ }^{1}$ Given the assumption of non-accumulative sampling until a sufficiently large difference is obtained, the choice probability of the LL option is given by

$$
\begin{equation*}
\operatorname{Pr}(L L \mid\{S S, L L\})=\frac{\Phi\left(\frac{\mu-\delta}{\sigma}\right)}{\Phi\left(\frac{\mu-\delta}{\sigma}\right)+\Phi\left(\frac{\mu-\delta}{\sigma}\right)}, \tag{7}
\end{equation*}
$$

in which $\Phi$ represents the cumulative distribution function of a standard normal distribution, and $\delta$ denotes the smallest positive difference (i.e., the positive discrimination threshold) required to make a decision.

Because the modified model goes without the tradeoff function and the related ratio choice rule (which are critical for the original model to accommodate the nonadditivity in delay discounting), an alternative mechanism is required in order to retain this capability. To this end, we further assume that the discrimination thresholds for choosing the SS and LL options (i.e., $\delta_{\mathrm{S}}$ and $\delta_{\mathrm{L}}$ ) are different, echoing the general idea of decision bias in the literature of choice models (e.g., Busemeyer \& Townsend, 1993). ${ }^{2}$ In this case,

$$
\begin{equation*}
\operatorname{Pr}(L L \mid\{S S, L L\})=\frac{\Phi\left(\frac{\mu-\delta_{L}}{\sigma}\right)}{\Phi\left(\frac{\mu-\delta_{S}}{\sigma}\right)+\Phi\left(\frac{\mu-\delta_{L}}{\sigma}\right)} . \tag{8}
\end{equation*}
$$

To derive predictions on response time distributions for the modified tradeoff model, we assume that the time it takes to assess a sample follows a Gamma distribution with a scale parameter of $\theta$ and a shape parameter of 2 . Because empirical distributions of response time tend to be singlepeaked (rather than monotonously decreasing), we fix the shape parameter at 2 instead of 1 . The total response time is assumed to be the sum of time(s) required for all samples drawn until a decision is made, plus a nondecision time. With these assumptions, we analytically derive joint probability density functions for both choices and response times (see Dai, Pleskac, \& Pachur, 2016). Such analytical solutions are usually not available for other dynamic choice models. This ends our description of the modified tradeoff model (hereafter the dynamic tradeoff model). See Figure 1 for the dynamic structure of the model.

[^52]
## Explanatory Power of the Dynamic Tradeoff Model

Because the dynamic tradeoff model inherits the assumption of attribute-based processing, it can accommodate several key findings in intertemporal choice, including the magnitude effect, the common ratio effect, and the common difference effect. According to the magnitude effect, larger amounts appear to be discounted at a lower rate than smaller ones. For example, if a DM is indifferent between receiving $\$ 100$ now and receiving $\$ 200$ in a year, suggesting an annual discount rate of $50 \%$, then the same person would tend to prefer receiving $\$ 2000$ in a year to receiving $\$ 1000$ now, suggesting an annual discount rate lower than $50 \%$. From an attribute-based perspective, this change in discount rate can be easily explained by noticing that the effective compensation between $\$ 1000$ and $\$ 2000$ is much larger than that between $\$ 100$ and $\$ 200$, whereas the effective intervals for the two choice scenarios are just the same.

Figure 1: The dynamic structure of the modified tradeoff model of intertemporal choice.

The common ratio effect (i.e., the delay duration effect in Dai and Busemeyer [2014]) implies that increasing the delays of both options proportionally would shift people's preference toward the SS option. In this case, the change in attribute values produces a larger effective interval while keeping the same effective compensation, with the observed effect as a natural result. Finally, the common difference effect suggests that postponing both options by the same length would increase people's preference to the LL option. This effect is accounted for by the attribute-based approach together with the nonlinearity of the time weighting function (i.e., $w(t)$ ). The particular form of the function (i.e., Equation 2) entails that increasing both delays by the same length would lead to a smaller effective interval and thus shift preference towards the LL option.

With the assumption of distinct discrimination thresholds for choosing the SS and LL options, it can be shown that the dynamic tradeoff model can produce nonadditivity in delay discounting demonstrated as a violation of transitivity.

Specifically, when the probabilistic nature of choice is considered, a violation of transitivity is usually formalized as a violation of weak stochastic transitivity (WST; Davidson \& Marschak, 1959). WST requires that for a triple of options $\mathrm{X}, \mathrm{Y}$, and Z , if $\mathrm{P}_{\mathrm{XY}} \geq 0.5, \mathrm{P}_{\mathrm{YZ}} \geq 0.5$, then $\mathrm{P}_{\mathrm{XZ}}$ should also be no smaller than 0.5 , in which $\mathrm{P}_{\mathrm{AB}}$ represents the probability of choose option A over option B in a binary choice. In other words, a violation of WST occurs when $\mathrm{P}_{\mathrm{XZ}}$ $<0.5$ given the two preconditions. This is consistent with the dynamic tradeoff model. For example, for the aforementioned triple of options with increasing money amounts and delay lengths, the dynamic tradeoff model would predict $\mathrm{P}_{\mathrm{SM}}=0.53, \mathrm{P}_{\mathrm{ML}}=0.58$, but $\mathrm{P}_{\mathrm{SL}}=0.35$ when $\gamma$ $=0.05, \tau=0.01, \mathrm{c}=1, \delta_{\mathrm{S}}=0.01$, and $\delta_{\mathrm{L}}=2$, violating WST.

Besides showing intransitive intertemporal choices produced by sub- or superadditivity in delay discounting, Scholten et al. (2014) also suggested a more intricate pattern of intransitive intertemporal choice called relative nonadditivity. Specifically, intransitive intertemporal choices tend to show subadditivity when differences between delay lengths are large relative to the differences between money amounts, and show superadditivity when the differences between delay lengths are large relative to those between money amounts. To account for this pattern, Scholten et al. defined additivity in delay discounting in terms of a product rule of choice odds and showed that this definition naturally led to the pattern of relative nonadditivity. According to this definition, subadditivity occurs when

$$
\begin{equation*}
\Omega_{L S}>\Omega_{M S} \times \Omega_{L M} \tag{9}
\end{equation*}
$$

in which $\Omega_{\mathrm{XY}}$ denotes the choice odds of option X over option Y , that is, $\mathrm{P}_{\mathrm{XY}} / \mathrm{P}_{\mathrm{YX}}$, and superadditivity occurs when

$$
\begin{equation*}
\Omega_{L S}<\Omega_{M S} \times \Omega_{L M} \tag{10}
\end{equation*}
$$

According to Scholten et al., the ratio choice rule of the static tradeoff model is the key component for explaining relative nonadditivity.

The dynamic tradeoff model, which goes without the ratio choice rule, can account for the same phenomenon. According to the dynamic model, $\Omega_{\mathrm{MS}}$ and $\Omega_{\mathrm{LM}}$ tend to be smaller than 1 when differences between delay lengths are large relative to the differences between money amounts, so is $\Omega_{\mathrm{LS}}$. Given the choice rule of the dynamic model (i.e., Equation 7 for equal discrimination thresholds for choosing the SS and LL options, or Equation 8 for distinct discrimination threshold), it can be shown that the same conditions tend to render $\Omega_{L S}>\Omega_{M S} \times \Omega_{L M}$. For example, for a triple of options $\mathrm{X}, \mathrm{Y}$, and Z with increasing reward amounts of 10,11 , and 12 dollars, and increasing delay lengths of 5,10 , and 15 days, $\Omega_{\mathrm{MS}}=0.074, \Omega_{\mathrm{LM}}=0.105$, but $\Omega_{\mathrm{LS}}=0.026>0.008=\Omega_{\mathrm{MS}} \times \Omega_{\mathrm{LM}}$ when $\gamma=\tau=0.05$, c $=1$, and $\delta_{\mathrm{S}}=\delta_{\mathrm{L}}=0.05$. To the contrary, with the same set of model parameters but another triple of options $X^{\prime}, Y^{\prime}$, and Z' with increasing reward amounts of 10,20 , and 30 dollars, and the same increasing delay lengths of 5,10 , and 15 days, $\Omega_{\mathrm{MS}}=3.15, \Omega_{\mathrm{LM}}=2.30$, but $\Omega_{\mathrm{LS}}=4.14<7.26=\Omega_{\mathrm{MS}} \times \Omega_{\mathrm{LM}}$. In the first triple, the differences between delay lengths are
large relative to those between reward amounts, whereas in the second triple, the latter are large relative to the former.

Besides accounting for major empirical regularities in choice, the dynamic tradeoff model can also accommodate the fast-and-extreme effect, one robust relationship between choices and responses in intertemporal choice (Dai \& Busemeyer, 2014). According to the model, the more strongly the expected difference between effective compensation and effective interval differs from zero, the higher the probability of obtaining a difference large enough in each sample and the further away ratio of $\Phi\left(\frac{\mu-\delta}{\sigma}\right)$ to $\Phi\left(\frac{-\mu-\delta}{\sigma}\right)$ is from 1. The former leads to faster response times because fewer samples are required to trigger a decision, whereas the latter leads to more extreme choice proportions.

In summary, the dynamic tradeoff model can qualitatively accommodate all the major findings in intertemporal choice that are captured by the static tradeoff model; in addition, it can also qualitatively accommodate the fast-and-extreme effect, a prominent relationship between choices and response times that eludes the static tradeoff model. In the next section, we show further that the dynamic model can also quantitatively fit empirical data better than promising competing models.

## Quantitative Model Comparisons

We conducted two model-comparison analyses to show the power of the dynamic tradeoff model in quantitatively fitting empirical data. First, we compared it with the latest, full version of the static tradeoff model (Scholten et al., 2014) in terms of their performance in fitting choice data only. Second, we compared the dynamic tradeoff model with the best-performing model in Dai and Busemeyer (2014)—which is built on Decision Field Theory (DFT; Busemeyer \& Townsend, 1993)—with regard to their performance in fitting choice and response time data simultaneously. The DFT model assumes a sequential sampling approach and an attention shift mechanism for making intertemporal choices. Specifically, it suggests that a DM attends to either the money or the delay attribute at a time and evaluates the relevant difference between options to update his or her preference. This preference updating process continues over time as the DM switches attention between the two attributes until the preference level of one option reaches a preference threshold to trigger a decision. See Dai and Busemeyer for more details of the DFT model.

## Method

We used data from three representative empirical studies to assess the performance of the models in accounting for individual-level data. The first data set came from Study 1 in Dai (2014), in which half or all the choice questions for each individual had an immediate SS option. The second data set came from Dai (2016), which focused on the nonadditivity in delay discounting and involved only delayed SS and LL options. The third data set came from

Study 3 in Dai and Busemeyer (2014), which examined the magnitude effect, the common ratio effect, and the common difference effect, and again involved only delayed SS and LL options. All three data sets contained participants who showed the fast-and-extreme effect. A total of 138 participants contributed data to the analysis: 61 from the first data set, 40 from the second, and 37 from the third. In all three studies, the choice questions for each participant were adjusted to suit the time preference level of the individual, and each question was presented multiple times. In this way, moderate choice proportions could be induced at an individual level to better distinguish probabilistic models from one another.

The models were fitted to individual data from each data set using the predicted functions of choice probability or joint probability density functions of choices and response times. We used the SIMPLEX algorithm implemented in the fminsearch function of Matlab to find the maximumlikelihood parameter estimates of each model, which was then used to calculate the Bayesian Information Criterion (BIC; Schwarz, 1978). The BIC is a common measure for relative model performance and expresses a model's ability to capture the data, taking into account its complexity (based on the number of free parameters). A lower BIC indicates a better balance between goodness of fit and model complexity and thus a more desirable model.

To evaluate the absolute performance of the dynamic tradeoff model, we compared its predictions with the observed data in terms of the fast-and-extreme effect. Specifically, we categorized all repeatedly presented questions into five equal-interval groups regarding observed choice proportions of the LL options and then calculated the mean observed and predicted response times for each question. The observed and predicted response times within each bin were then averaged to obtain overall measures of the observed and predicted results regarding response time. The fast-and-extreme effect suggests that mean response times associated with moderate choice proportions should be longer than those with extreme choice proportions.

## Results

Table 1 presents the results of comparing the static and dynamic tradeoff models in terms of the numbers of participants whose data were better described by either model when fitting only choice data, whereas Table 2 shows the results of comparing the dynamic tradeoff model with the best-performing DFT model in Dai and Busemeyer (2014) when fitting both choice and response time data. In each comparison, the dynamic tradeoff model outperformed the other model both separately for each data set and aggregated across all data sets. ${ }^{3}$ Furthermore, Figure 2 shows that the dynamic tradeoff model reproduces the observed fast-and-extreme effect, supporting the validity of the model as a descriptive account. The difference in mean response time between questions with extreme choice

[^53]proportions (i.e., $p<0.2$ or $p>0.8$ ) and those with moderate choice proportions (i.e., $0.2 \leq p \leq 0.8$ ) was statistically significant for both observed $(t=-9.83, p<.001)$ and predicted data $(t=-5.08, p<.001)$.

Table 1: Number of Participants Whose Choice Data Were Better Described by the Static or Dynamic Tradeoff Model.

| Data Set | Static model | Dynamic model |
| :---: | :---: | :---: |
| 1 | 10 | 51 |
| 2 | 1 | 39 |
| 3 | 18 | 19 |
| Across | 29 | 109 |

Table 2: Number of Participants Whose Choice and Response Time Data Were Better Described by the BestPerforming DFT Model in Dai and Busemeyer (2014) or the Dynamic Tradeoff Model.

| Data Set | DFT model | Dynamic tradeoff model |
| :---: | :---: | :---: |
| 1 | 18 | 43 |
| 2 | 14 | 26 |
| 3 | 15 | 22 |
| Across | 47 | 91 |

Figure 2. Average mean response times for questions with different observed choice proportions of the LL options.

Error bars show 95\% confidence intervals.

## Discussion

The static tradeoff model (Scholten et al., 2014) represents one of the most successful cognitive models to describe intertemporal choice. However, up to now there have been no attempts to examine how this modeling approach could be extended to also account for the dynamics of the underlying decision process. Here we developed a dynamic modification of the tradeoff model, which can accommodate not only key choice regularities but also the response time data and prominent regularities therein (e.g., the fast-andextreme effect). We also showed that this modified model quantitatively outperforms the original static tradeoff model when fitting choice data and the best-performing DFT model in Dai and Busemeyer (2014) when fitting both
choice and response time data. The model's ability to capture the data both qualitatively and quantitatively underlines the value of developing dynamic accounts of intertemporal choice for a better understanding of this central topic in both psychology and economics.

## A General Framework for Developing Dynamic Models of Choice

When developing the dynamic tradeoff model, we invoked and combined two time-honored concepts: the notion of random utility in economics and the concept of discrimination thresholds in psychology. Combining these concepts seems to offer a promising, but so far neglected, approach to developing dynamic choice models, and we argue that it could be applied to transform existing static models of choice also in other domains. For example, it could be applied to extend static models of risky choice into dynamic ones as long as the corresponding models can reasonably offer a measurement of the relative attractiveness of each option and the variability thereof. With dynamic models, both choice and response time data from empirical studies can be utilized to compare competing models for a more powerful model selection. Dai, Pleskac, and Pachur (2016) conduct a more comprehensive development and analysis of such a random-utility-with-discriminationthreshold (RUDT) framework, and compare it to other dynamic approaches to modeling intertemporal choice.

## Future Directions

In addition to the fast-and-extreme effect discovered in Dai and Busemeyer (2014), recent studies (Dai, 2014) have suggested another striking but less common relationship between choices and response times in intertemporal choice. Specifically, it was found that, within each choice question, the option chosen more frequently also tended to be chosen more quickly than the other option. Unfortunately, this fast-and-frequent effect poses a severe challenge to both the best-performing DFT model in Dai and Busemeyer and the dynamic tradeoff model developed here. Both models predict that the conditional response time distribution given choosing one option should be identical to that given choosing the other option. As a consequence, the option chosen more frequently is predicted to have the same mean response time as the other option, contradicting the fast-andfrequent effect. It is possible, however, to modify the dynamic tradeoff model to accommodate this effect (Dai et al., 2016). Specifically, by assuming that the discrimination thresholds are not fixed across successive samples but converging, it is possible to account for the pattern. To put DFT models of intertemporal choice on equal footing, attempts should be made to improve them as well. Future research should explore alternative forms of the tradeoff model under the RUDT structure and compare them with appropriate competing models to examine the performance of the dynamic tradeoff model.

## Conclusion

Most existing models of intertemporal choice, including the original tradeoff model, are static and thus lack a proper account of the dynamic processes leading to a choice. In this paper, we showed how the static tradeoff model can be modified into a dynamic one with a general structure built on the concepts of random utility and discrimination threshold. The advantages of the dynamic tradeoff model are demonstrated by its capability to qualitatively accommodate empirical findings and its better performance in quantitative model comparisons. Future studies should further explore the capacity of this approach for explaining more phenomena in intertemporal choice and beyond.

# What is Learning? A Definition for Cognitive Science 

Jim Davies (jim@jimdavies.org)<br>2202B Dunton Tower, Institute of Cognitive Science, Carleton University<br>1125 Colonel By Dr., Ottawa, Ontario, K1S 5B6, Canada

#### Abstract

Many intuitive notions of "learning" do not support the diverse kinds of learning across different situations and learners. In this paper I offer a functional definition of learning from a cognitive science perspective, which attempts to account for the presence of learning in different physical substrates. The definition is that a particular event should be considered a good example of "learning" to the degree to which the following characteristics describe it: 1) a system undergoes change to its informational state or processing 2) the change is for the purpose of more effective future action, 3 ) the change is in response what the system experiences, and 4) the system executes the change, rather than some outside force. Episodes are better examples of learning according to how many of these characteristics they have. I discuss benefits and limitations of this characterization.

Keywords: learning; philosophy; conceptual analysis; cognitive science; functionalism; substrate neutrality

## Introduction

According to Daniel Reisberg (Wilson \& Keil, 2001), learning "can be understood as a change in an organism's capacities or behavior brought about by experience." The Oxford Companion to Philosophy defines it as "the acquisition of a form of knowledge or ability through the use of experience." These examples are reasonable and intuitive first passes, but are not defended.

Perhaps the simplest definition of learning would be "the creation of memory," but this merely pushes the definitional difficulty to the term "memory." Nevertheless, this discussion will assume that all memory-creating processes are examples of learning (as a sufficient condition), though I will not use the term in the definition.

In this article, I will present and defend a definition of "learning" for cognitive science. My goals are that this definition will cover all accounts of learning that we observe in natural and artificial systems, and reject cases of change that should not be considered learning.

My approach assumes a version of functionalism as applied to mental concepts: that many entities in our world should be defined not
by their physical properties, but by how they interact in an information processing system.

The definition is that a particular event should be considered a good example of "learning" according to the degree to which the following characteristics describe it: 1) a system undergoes change to its informational state or processing, 2) the change is for the purpose of more effective future action, 2) the change is in response what the system experiences, and 3) the system executes the change, rather than some outside force. This is a "family resemblance" characterization, rather than one of necessary and sufficient conditions, though in this paper I will discuss the characteristics as though they were necessary for purposes of clarifying the benefits and drawbacks of including each one.

## What Can Learn?

Learning is prototypically thought of as something animals do. But some plants have a limited form of memory, and the encoding of this memory can be considered a form of learning. The venus flytrap, for example, has hairs around its trap to detect the presence of food. These hairs have haptic sensors. But the trap will not close immediately upon triggering these sensors, which is good, because closing and opening the trap is expensive in terms of energy and, for opening it again, time. So the plant will only close when another sensor detects touch within 20 seconds of the first touch elsewhere-effectively detecting a bug walking across the plant. This prevents the trap from closing when hit with raindrops, twigs, or other non-food entities (Chamovitz, 2012). This is a very simple, very short-term memory. But even in humans we do not require that encodings be long-term to be considered memory, such as the phonological loop (Baddeley, 1992). Because we classify some explicitly short-term stores as memory in humans suggests that it is
sensible to refer to flytraps as systems that can, because they can create memories, learn.
Perhaps even more surprising are examples of learning recently discovered in single-celled organisms (Boisseau, Vogel, \& Dussutour, 2016). Even slime molds can habituate to stimuli.

Our immune systems effectively remember past experiences to better deal with future infections. Immune system learning behaves a bit like classifier systems in artificial intelligence (Farmer, Packard, \& Perelson, 1986), and can even overlearn, as seen in autoimmune disorders.

Beyond the vast variety of organisms that can learn, we also have an entire field of machine learning to consider: pieces of software created by human beings that learn. Neither immune systems, plants, AIs nor slime mold cells have nervous systems, but they are capable of limited kinds of learning, suggesting that there should not be a biological, let alone a neuronal, condition.

## Human Learning at Different Levels of Analysis

When we examine human learning, we can see it happening at many levels of analysis. I will use a running example of learning to avoid eating food that makes one ill.

Neuroscientists now know a lot about how association and feedback can change neurons and how they communicate. This can happen, for example, through synaptic changes: neurons encode association through long-term potentiation and depression (associative learning; Cooke \& Bliss, 2006), and can engage in supervised learning (Ishikawa, Matsumoto, Sakaguchi, Matsuki, \& Ikegaya, 2014). An immediate nausea response could trigger an instance of supervised learning, "punishing" neurons that were involved with consuming the food, and their relationships to sensing that that food was present.

Synapatic changes in taste receptors allow us to habituate to bitter foods and drinks-children sometimes vomit when they first taste the foods that many adults enjoy. We evolved to dislike bitter foods, generally speaking, because they are more often lacking in nutrition (Sandell \& Breslin, 2006). Eating bitter foods that don't sicken us gradually habituates the sensors in our tongue to the particular taste.

In addition to synaptic changes, the brain learns through creation, movement, destruction, and the changing of the shape of neurons.
Moving up to the information processing level, every major cognitive architecture has a theory of learning. The most popular control system used in cognitive architectures is the production system (e.g., ACT-R, Soar, EPIC, and OpenCog all use them). When something bad happens, recentlyfired productions are "punished," making the system less likely to get itself in the same situation again. In connectionist architectures, learning changes connection weights in neural networks using learning algorithms such as backpropagation (Chauvin \& Rumelhart, 1995).

At the behavioral level, we can describe a person's reluctance to eat a food that previously made them sick with the theory of conditioning.
I have shown how the same event of an individual agent learning not to eat a particular food can be effectively described as learning at different levels, but we might describe other examples of learning in distributed cognitive systems (Hutchins, 1995). A theater company might better learn how to market its performances, or a game development team might better learn how to use feedback from user testing to make better products.
The idea of distributed cognitive systems (and the related notion of extended minds) is controversial (Davies \& Michaelian, 2016), but those who accept their existence would probably consider them capable of learning.

## "Systems" Learn

To conclude this section, it is a mistake to define learning so that only humans and other animals are included. We can see learning in single-celled organisms, artificial intelligences, immune systems, and plants. Nor can we define learning as something only "agents" do. Distributed cognitive systems learn, but these are, perhaps, not best described as "agents" or "organisms."
As such, I suggest the term "system," meaning a complex of elements that engage in information processing in pursuit of goals or preferences, be they explicit (as in a person's desire to be not hungry) or implicit.

## Information Processing

In the proposed definition, the changes to the system need to be changes to the representation or processing of information. For purposes of this definition, information is defined as anything that has a representational use in a system-be it symbolic or subsymbolic. That is, the information stands for something else, be it a physical referent in the world, a utility to the system, an internal category, or anything else.
To make this clearer, I will describe systems that are not information processors. A memoryfoam mattress changes in response to your lying down on it. It does so for purposes of your comfort-so it even has a function. It was designed to adapt to the environment, just as machine learning programs were designed to adapt to theirs. The mattress even has the word "memory" in its label.

According to my definition, the mattress is a poor example, because the change is not informational. The change in topography of the mattress does not mean anything to anybody in its normal use (if you came home and found that nobody was on your mattress but there was a deformity, you might use that deformation to conclude someone had been on it recently. In this case, the mattress deformation becomes a representation (to you), and is arguably a part of some distributed processing information system including you and the mattress.)
Similarly, a knife is not learning when you sharpen it, and your muscles are not learning when they get stronger because of a workout.

But all of these cases are merely physical changes, and in learning, these physical changes are important only because they encode changes to information storage and processing. Changes in knife sharpness and muscle tone are functional changes, but not of information processing systems. Instances of biological plasticity that do not involve information processing (like the growth of a callus) are not considered learning.

## The Purpose of More Effective Action

The intuitive notion of learning is that when the system learns something, it is somehow improved. It either knows something it didn't before, or is
able to do something it couldn't before, or can do it better.
This characteristic poses some immediate problems, because not everything people learn is good for them. If people tell you something that isn't true, and you believe them, then you have learned something false. And even though some false beliefs might help us, we can assume that, in general, false beliefs lead to poorer behavior (mental or physical) in the future.

Some learned behaviors are bad for us. In the case of post-traumatic stress disorder (PTSD), we learn behaviors that are problematic in nontraumatic situations (such as diving beneath the table whenever a helicopter flies by, or having nightmares that plague one for years; see Levin, 2000). I'll refer to learning false things, and the learning of maladaptive behaviors as "bad learning."
For the definition to be able to include bad learning, it is insufficient to say that learning must always leads to better behavior. However, we can avoid the problem by saying that it learns with the purpose of better future behavior.
I will explain with an analogy to digestion. We might describe the purpose of digestion as altering large, insoluble food molecules into smaller molecules that can be used as nutrition. The fact that we can digest poisons and non-nutritional food does not mean that the function of digestion isn't to nourish the organism. A system can be used poorly without removing its function. For the same reason, just because we can engage in bad learning does not mean that the function of learning isn't to promote better future behavior, nor that those bad things aren't learned.

Similarly, we remember lots of true but trivial facts that we might not productively use (or, indeed, even retrieve) ever again. In these cases, too, these declarative memories are not being used for better future action. But they are encoded because they might be useful someday. The mind remembers things without the certainty of what, exactly, will and won't be useful in the future. Will it be important to remember that Jill was wearing a red sweater? Probably not, but if we need to describe her to someone else, that fact might turn out to be useful.

We can see how memory is biased in terms of what it expects will be useful, however. For example, people tend to better remember things likely to be relevant to future events. The existence of a push pin will be better recalled if it is on the floor, where it might be stepped on, than if it is safely in a box (Zwaan, Van den Broek, Truitt \& Sundermeier, 1996). Words related to survival are better remembered than other words (Nairne, 2010).

When an organism gets hit in the head, and suffers some deficit as a result, we would not want to consider this learning. Although brain damage affects the information processing of a system, the purpose of being hit in the head (if there even is one) is not to promote better future behavior, so the definition excludes this.
Another challenging example is the deliberate, direct physical change to a brain. When a doctor performs neurosurgery, or prescribes psychoactive medication, the purpose is better future behavior. If, in the future, we are able to "download" skills directly into our heads, as is done in Matrix films, should this be considered learning? In this account it is a bad example of learning, because the system is not changing itself. However, if, somehow, somebody managed to brain surgery on oneself, then my account would have to accept that as learning, strange as it sounds.

We sometimes deliberately alleviate mental tiredness by taking a rest, drinking coffee, or eating something. These activities have the purpose (among others, perhaps) of better future behavior. And some of these examples are the agent changing itself. Although rest and consuming coffee and food might be best described at a biological level, rather than at an information processing level, it is likely that there is an information processing level of description of how these activities promote better behavior. My definition includes these activities as decent examples of learning. The only characteristic missing is "experience," because the psychological experience of doing brain surgery on oneself or drinking coffee is not what causes the change (beyond placebo effects).

This raises the question of what counts as "experience." A body can experience hair loss at a
barber, arguably, but what we want to capture here should not include experiences irrelevant to a cognitive system. I suggest that we ignore consciousness and say that an experience is limited to what the sensory apparatus of the system can detect. For an immune cell, it has receptors for detecting pathogens. A committee has analogues to sensory apparatus in the sense organs of the people that make it up.

Should the system be required to change itself for it to be considered learning, or are outside forces acting on a system acceptable? I will deal with issues regarding this question next.

## Cultural and Evolutionary Learning

Some might want to describe learning at the sociological level. For example, in Fiji there is a cultural taboo: pregnant and lactating women may not eat certain kinds of fish. It turns out that avoiding consumption of these fish reduces a woman's chances of being getting fish poisoning by $30 \%$ during pregnancy and $60 \%$ during breastfeeding (Henrich \& Henrich, 2010).

It is common for cultural taboos to have practical value that the people in the culture are not aware of. Often these are framed in terms of religion (for an example, see Harris, 1978). These taboos are refined over the course of generations. No single individual need engage in learning for this to happen, though individuals encode the information state of the cultural system. If we look at culture as an evolving entity, and, in particular, the ideas in the culture as undergoing evolutionary selection, we can see how ideas that facilitate reproduction will have a better chance of enduring over the years than others (Richerson \& Boyd, 2008).

What we observe, then, is that the society itself is doing the learning. The society, in this respect, is a cognitive system that is distributed over time, and we can observe the information changes it makes to act better in the future.

One might also look at a species as a system that learns through Darwinian evolution. Sweller and Sweller (2006) suggest that this happens, analogically mapping long-term memory with a genome; learning from other humans with biological reproduction; problem solving with
random mutation, and so on. Although I have not found an analogous argument for culture, it seems that one could easily be made.

But is evolutionary change "for the purpose of better future behavior?" We often can take a design stance to evolutionary processes to help us understand them, but biologists take great pains to make it clear that evolution is not goal-directed. Darwinian evolution is not purposeful (unless it is artificial selection, or is designed by a programmer in a simulation).

Specific behavioral phenotypes can be described as having purposes. As Daniel Dennett describes it, cuckoo chicks push other birds out of the nest. As scientists, we can ask why, and get a description at the level of neurons, but it is also profitable to look at the function of this behavior: to maximize resource acquisition from the cuckolded parent bird (1987). The function is a "free floating rationale." But application of this to the evolutionary process itself is more problematic. The products of evolution might be purposeful, even if evolution itself is not.

My point here is not take a strong stance on whether or not the changes to cultures and species that we see over time should count as learning, but to discuss how different definitions of learning would or would not include them. The definition I'm suggesting in this paper would render these poorer examples, because the changes are not for the purpose of better future behavior in genetic nor in cultural evolution, the changes are (arguably) not occurring through experience (can a culture or species experience something?) and finally because the system is not changing itself (this is clear for the genome, and possibly true for a culture). We still might metaphorically describe them as learning, and doing so might help us understand or teach these concepts.

## Limitations of the Analysis

"Learning" happens to be a word in English, the lingua franca of science. However, we need to be careful not to assume that the existence of a word means that it necessarily refers to a natural kind. Other languages might break up the world in different ways, and ultimately whether learning
exists in a way that happens to be captured by the English word for it is an empirical question.
This paper is in the tradition of a classical-styled conceptual analysis, looking for and suggesting conditions for what would count as an instance of "learning," and this is, admittedly, old-fashioned.

Is there a better way to do it? An earthquake can be described and explained using theories and equations from geology, but it turns out that these same theories apply to quakes that happen elsewhere as well-moons, starts, other planets, etc. Thus it makes sense to suggest that the idea of a "quake" extends beyond those that happen on Earth (United States Geological Survey, 2012).

This makes sense because we have a theory that is broadly, and successfully, applied. Admittedly, this is not happening with learning. Perhaps future descriptions of learning will be more theorybased. That is, we come up with a theory of learning (or a particular kind of learning), and then see to which phenomena in the world the theory can be productively applied. These future investigations might mean that "learning," as we conceive of it in English, isn't a sensible scientific category at all (Churchland, 1989, suggests that no sensible scientific categories should be based on folk psychology).

However, there is no general theory of learning yet, and if we think of cognitive science as the study of cognition independent of the substrate that supports it, it is helpful to have some idea of what we mean by learning. This paper is intended to be a start to the discussion, and more of a stepping-stone for future refinement rather than the final answer.

## Conclusion

We've known for a long time that the search for necessary and sufficient conditions for concepts is often a fruitless task, so the definition should be seen as a list of family-resemblance features. My suggested definition is that an event is a better fit for the category "learning" depending on the degree to which the characteristics in the following list describe it:

1. The change happens to an information processing system
2. The change happens with the purpose of better future action
3. The change happens in response to the system's experience
4. The change is executed by the system itself, rather than some outside influence

This definition covers the intuitive and prototypical instances of learning, but renders as poor examples some processes that we might want to productively talk about as learning, such as evolutionary processes over species and cultures.

With hope, future research will ground the definition of learning in a theory of learning process, in contrast to my attempt to define it from a conceptual analysis.

# Re-representation in comparison and similarity 

Samuel Day (days@susqu.edu)<br>Jennifer Asmuth (asmuth@susqu.edu)<br>Department of Psychology, Susquehanna University<br>514 University Ave., Selinsgrove, PA 17870 USA

#### Abstract

Re-representation is a crucial component of structure mapping theory, allowing individuals to notice structural commonalities between situations that do not initially have identical relational representations. Despite its theoretical importance, however, this concept has been the subject of very little empirical work. In two experiments, we find that a case's participation in one comparison systematically changes its perceived similarity to new cases, in a pattern consistent with re-representation. Additional work rules out alternative explanations based on relational priming.

Keywords: analogy; re-representation; similarity

## Introduction

Consider how similar you find the following events:

- Nicole finally got out of the bad relationship that had prevented her from pursuing her own interests.
- As the zoo keeper was busy cleaning its habitat, the Burmese python was able to escape its open cage.

If you are like the participants in our research, you were probably willing to call these events fairly similar, at least after a little bit of consideration. In a very literal sense, these cases differ in significant ways-in their settings, their characters, their implications, even in the species of their protagonists. At a more abstract level, however, they share important structural features. Specifically, both situations describe characters who are able to escape from a confining environment.

The dominant model for understanding structured comparisons such as these is Gentner's $(1983,1989)$ structure mapping theory (SMT). According to this model, individual cases involve hierarchically-structured mental representations of labeled relations, each of which may take other relations or entities as arguments. For example, the common relational structure in the sentences above might be conveyed through a proposition such as: ESCAPED_FROM(ESCAPER, CONFINING_ENVIRONMENT). In this formulation, ESCAPED_FROM is a relation: it describes a relationship between multiple entities, and is therefore represented as a predicate that takes multiple distinct arguments. These arguments represent the assignment of entities to the relation's roles.

Comparison, according to SMT, involves a process of mapping in order to establish a structural alignment between the representations. The goal of this process is to define correspondences between the representations while following certain important rules and constraints. For example, although two corresponding objects may be quite dissimilar (e.g., Nicole and the python), relations in two representations will only be
mapped to one another if they are semantically identical. Another constraint, the principle of one-to-one correspondence, states that each element in one representation may be mapped to no more than one element in the other. Additionally, if relations in two representations correspond to one another, those relations' arguments must also correspond (the principle of parallel connectivity).

In the example cases above, the ESCAPED_FROM relations in the two representations would be placed in correspondence, which is allowed because they are identical. In order to maintain parallel connectivity, the arguments of those relations would then be mapped in a role-consistent way, despite their surface differences: Nicole would correspond with the python (they are both "escapers"), and her bad relationship would correspond with the snake's cage (as the confining environments).

Structure mapping theory has been a very successful model for understanding a wide range of cognitive phenomena, including similarity, analogy, classification and knowledge transfer (see Markman \& Gentner, 2001). However, in the basic form described above, it would quickly run into significant problems in the real world. For example, as noted, SMT asserts that relations may only be mapped to one another if they are semantically identical. However, it is not difficult to find cases that are perceived as analogically similar despite having nonidentical relations. For example, people can easily recognize the structural similarity between Bill drove to the store and Bill jogged to the store, even though their relations do not perfectly match (Gentner \& Kurtz, 2006). Or consider the sentences John is taller than George and Martha is shorter than Mary. Despite the conspicuous appropriate mapping (John and Mary are both taller), strict enforcement of the identity requirement would lead to a failed match, since TALLER_THAN and SHORTER_THAN are clearly not the same.

Fortunately, researchers have proposed a way around this problem. Specifically, it is theorized that representations may undergo a process of re-representation, in which structural and conceptual changes occur in order to enable potential relational matches (see Falkenhainer, Forbus \& Gentner, 1989; Holyoak, Novick \& Melz, 1994; Kotovsky \& Gentner, 1996; Kurtz, 2005). A variety of methods for re-representation have been proposed. For example, a cognitive system may store information about the similarity of different relations (e.g., knowing that drive is relatively similar to jog; Holyoak \& Thagard, 1989), or may initiate a search for common superordinate relations (e.g., both drive and jog are examples of move; Falkenhainer, et al., 1989). Another approach is to decompose a relation into its component structure (e.g., Gentner, 1983; Gentner \& Kurtz, 2006). For example, buying a book and taking a book do not initially
contain a match, but their relations can be decomposed into representations such as:

- BUY(book) $\rightarrow$ CAUSE(PAY_FOR(book), OBTAIN(book))
- TAKE(book) $\rightarrow$ CAUSE(PICK_UP(book), OBTAIN(book))
which would reveal an identically-matching predicate: OBTAIN.
Despite the importance of re-representation to the overall theory of structure mapping, however, it has been the subject of very little empirical work. The primary experimental research directly addressing the issue comes from Gentner and Kurtz (2006). Participants in their studies were willing to call two sentences analogous when the verbs were nearly synonymous (Fred reclined on the couch and Carl lay on the couch) or semantically "near" to one another (Fred reclined on the couch and Carl sat on the couch), but not when they were semantically "distant" in meaning (Fred reclined on the couch and Carl sneezed on the couch). Interestingly, response times were significantly longer when judging the "near" verbs than the synonyms. This finding is interpreted as evidence for rerepresentation, which would have required additional processing in order to determine a match. The authors also reported a tendency for participants to use new language (terms not present in either sentence) in their later justifications for their similarity ratings, consistent with a change in how those cases were represented. They acknowledged, however, that this might have reflected processes occurring during the justification task itself rather than the initial comparison.

In our studies, we use similarity ratings to assess potential rerepresentation. Similarity is a fundamental psychological process thought to play a role in everything from stimulus generalization in classical conditioning (Pavlov, 1927; Shepard, 1987) to categorization (e.g., Smith \& Medin, 1981), retrieval (e.g., Hintzman, 1984), inference (e.g., Osherson, et al., 1990) and problem solving (e.g., Ross, 1987). Similarity ratings have also been used successfully in prior research as a measurement of representational change (e.g., Boroditsky, 2007; Goldstone, Lippa \& Shiffrin, 2001). In the present experiments, we examine whether participation in one comparison can alter a case's mental representation in a way that changes its perceived similarity to new cases.

For example, consider the similarity between these cases:

- While testing a network security system, the computer scientist inadvertently released a destructive virus onto the internet.
- As the zoo keeper was busy cleaning its habitat, the Burmese python was able to escape its open cage.

Participants in our studies were able to recognize important structural commonalities between the described events, and responded with fairly high similarity ratings. In this case, the two situations are similar because they both describe someone inadvertently releasing something dangerous. According to SMT, this perceived similarity would require them to establish a common relational representation for the overlap between the cases, such as re-representing both in terms like: RELEASE(AGENT, RELEASED_ENTITY). But consider
what would happen if a participant then compared one of those cases to a new situation, as in:

- As the zoo keeper was busy cleaning its habitat, the Burmese python was able to escape its open cage.
- Nicole finally got out of the bad relationship that had prevented her from pursuing her own interests.

Now the relational structure of the first sentence, established during the prior comparison, would be incompatible with that of the second, because the RELEASE relation is not identical with the ESCAPE relation. (Of course, this depends on some assumptions about participants' mental representations, but ones that are borne out by our data-see General Discussion.) At this point, it is possible that the participant might devote the additional processing effort required to change the representational structure yet again, in search of potential shared relations. However, in most real-world experiences-as in most experimental settings-we believe that individuals will tend to exert a more modest level of processing, in this case typically relying on the representation that has already been created. If so, they would determine that the two cases in the second comparison are simply not very similar to one another.

In these two experiments, we examine whether similarity ratings are reliably higher when one of the compared cases has recently participated in another comparison that involves the same shared relational structure, relative to recent comparisons involving a different structure. For control purposes, the relevant test comparisons were always the same across participants-only the preceding comparison varied between conditions. In Experiment 1, we establish this basic effect, while Experiment 2 both replicates this finding and rules out alternative explanations based on relational priming.

## Experiment 1

Participants Thirty participants were recruited through Amazon's Mechanical Turk in return for $\$ 1.00$ payment.

Materials and Design The study was computer-based, and was administered online. After reading the instructions, each participant read 18 sentence pairs, presented on-screen one at a time. Participants were asked to rate the similarity of each pair by clicking on a horizontal 15 -point scale. Above the scale was a prompt, "How similar are these situations?", and the scale's endpoints were labeled Very dissimilar and Very similar. The entire task took approximately five minutes to complete.

We developed six Standard sentences, each of which could reasonably be construed according to two different relational structures, which we will refer to as Structure $A$ and Structure B (see Figure 1 for a visual depiction of the overall design). For example, the sentence about the python and the zoo keeper described in the Introduction could be represented as an example of "being able to escape from a confining environment," or as an example of "inadvertently releasing something dangerous." Each of these Standards was involved in two consecutive comparisons.

Figure 1: Design of Base-Test comparison pairs in Experiment 1.

We will refer to the first of these comparisons for each Standard as the Base comparison. The other sentence in the Base comparison varied between participants: approximately half of the participants compared the Standard to an unambiguous example of Structure A, while the remainder compared the Standard to an example of Structure B. The subsequent trial was the Test comparison. The sentences in this comparison were the same for all participants: the Standard was compared to a new example of Structure A. Ratings from the six Test comparisons (one for each Standard) provided the relevant measurement in our experiment. While the sentences in the Test comparisons were identical for all participants, they were classified as either Same trials or Different trials, according to whether the preceding Base comparison involved the same relational structure (Structure A) or a different structure (Structure B). Our primary question within this experiment is whether similarity ratings on Same trials would be significantly greater than those on Different trials, consistent with re-representation of the Standard.

In sum, the relevant stimuli included six relevant items sets, each containing one Standard sentence, two analogous examples of Structure A (one for potential use in the Base comparison and one for the second Test comparison), and one example of Structure B (for potential use in the Base comparison).

Figure 2: Results from Experiment 1

Each participant completed three Same trials and three Different trials. The condition (Same vs. Different) of each of the six Test trials was assigned randomly for each participant. The presentation order of the six comparison pairs also varied randomly between participants. Additionally, participants completed six filler comparisons-one at the beginning of the task, and one following each of the Test trials except the lastfor a total of 18 comparisons.

Results and Discussion A paired-samples t-test revealed a significant difference between conditions (see Figure 2; $t(29)=$ 4.99, $p<.001, d=1.17$ ), with Same trials ( $M=9.59, S D=2.41$ ) receiving considerably higher similarity ratings than Different trials ( $M=6.40, S D=2.99$ ). To ensure that these effects were not driven by a small subset of the materials, we also analyzed the data across items. Similarity ratings for all of the six items were higher during Same trials than Different trials, and there was a significant difference between the ratings at the item level $t(5)=$ 4.13, $p=.009, d=2.23$ ). Because the sentences in these Test trials were identical for all participants, these systematic differences must reflect the influence of the Base comparisons that preceded them, the sole variation between conditions.

The observed pattern is consistent with a process of rerepresentation. According to this explanation, the structure and content of the mental representation of the Standard sentence was altered during the Base comparison in order to maximize its similarity to its paired sentence. When the resulting representational structure was also a good match for the sentence in the subsequent Test trial, a straightforward mapping would have been possible and comparison would proceed smoothly. However, when the initial re-representation left the Standard with a structure that mismatched the paired sentence in the Test trial, the perceived similarity between the sentences would be poor unless the participant devoted the additional processing effort necessary to alter the Standard yet again.

## Experiment 2

Changes in perceived similarity represent a straightforward, low-level means of assessing participants' mental representations. However, while our data is consistent with the proposed explanation of re-representation, there is a salient alternative explanation that must also be considered. Our
approach suggests that the changes in similarity ratings were the result of persisting changes in the mental representations of the Standard sentences themselves. However, our data could also be explained by the activation of more abstract representations that are external to the individual sentences, through a process of relational priming.

Consider the example stimuli discussed in the Introduction, with Nicole escaping from her bad relationship, and the python escaping from its enclosure at the zoo. In the course of comparing these situations, participants may be activating an abstract representation of the relation ESCAPED_FROM. In fact, there is considerable empirical evidence that comparison can promote the generation or activation of abstract knowledge structures (e.g., Catrambone \& Holyoak, 1989; Gentner, Loewenstein \& Thompson, 2003; Gick \& Holyoak, 1983). If so, that representation could presumably still be active and influential during the subsequent Test comparison. As such, it would be in a position to alter the perceived similarity in that trial in at least two different ways. First, it could serve to influence and bias the interpretations of each of the comparison sentences independently. For example, prior research has shown that when individuals are primed with traits such as brave and adventurous, they tend to develop more positive impressions of a character who attempts dangerous, exciting tasks, relative to participants who were primed with traits such as reckless and foolish (Higgins et. al, 1977). In other words, the mental availability of a concept appears to bias people's interpretation of novel, ambiguous stimuli. In our example case, priming of a general relational concept such as escape could be biasing participants to interpret subsequent sentences as examples of that schema.

At the same time, priming of the ESCAPED_FROM relation could be influencing participants' assessments of the relationship between the sentences in the Test trial. A large body of literature has shown that individuals give higher ratings on a variety of measures to a stimulus when it is processed more fluently (e.g., Mandler, Nakamura \& Van Zandt, 1987; Whittlesea, 1993). This fluency may be the result of a variety of factors, including physical properties of the stimulus itself, but it is most commonly associated with prior exposure to a stimulus. In our study, all participants might have been able to recognize the relevant relationship between the sentences in the Test trials. However, if that particular relationship was already primed and strongly available, the commonalities might have become easier to process, and this ease of processing may in turn have led to a heightened sense of relevance or meaning. If so, prior research suggests that this sense of fluency (or disfluency, in the Different trials) could have influenced participants' similarity ratings in a pattern similar to that observed in our data. Some prior research is consistent with the idea that relational priming may influence comprehension and interpretation (e.g., Estes, 2003; Estes \& Jones, 2006).

In some ways, the distinction between an explanation based on re-representation and an explanation based on relational priming is subtle. At a theoretical level, however, this distinction is crucial. As discussed, structure mapping theory is a highly influential model that has had a great deal of explanatory success. However, its viability depends upon its ability to accommodate
matches between relationships that are similar but not identicaland this ability depends upon the process of re-representation: structural and/or conceptual changes in one or both of the mental representations. An explanation based on relational priming would not require any changes in the representation of the Standard itself, and therefore would provide no evidence that rerepresentation was occurring. In order to draw any meaningful support for our hypotheses, we therefore need to either rule out a priming explanation, or to demonstrate that re-representation is exerting an influence over and above that of simple priming. In Experiment 2, we add a control condition in order to assess the independent contributions of re-representation.

Participants Sixty participants were recruited through Amazon's Mechanical Turk in return for $\$ 1.00$ payment.

Materials and Design Experiment 2 included two betweenparticipants conditions. In the Repeated Standard condition ( $n=$ 30), the materials and procedure were identical to those used in Experiment 1. The Relational Priming condition ( $n=30$ ), which served as a control, was identical to the Repeated Standard condition with the exception that each of the Standard sentences was compared only once, during the Test trial, rather than in two consecutive trials (the Base and the Test). During the Base trials, participants in this condition were presented with two sentences that were each an example of one of the two relevant relational structures. That is, each participant compared either two examples of Structure A or two examples of Structure B.

For instance, two consecutive trials in the Relational Priming condition might include the following two comparisons:

- When the instructor turned around to write something on the board, Eric slipped out of the boring lecture.
- The rabbit had been cornered by a fox for several minutes, but finally lunged through the weeds and got away safely.
- As the zoo keeper was busy cleaning its habitat, the Burmese python was able to escape its open cage.
- Nicole finally got out of the bad relationship that had prevented her from pursuing her own interests.
Unlike Experiment 1, and unlike the Repeated Standard condition in this experiment, participants in this condition did not see the Standard sentence (about the python at the zoo) until the Test comparison. There was therefore no opportunity for prior re-representation of that situation. There was, however, still an opportunity for relational priming. The two sentences in the Base trial are each unambiguous examples of escape, and that is the most salient commonality between them. According to a priming explanation for our data, that relation would have been highlighted and made more accessible during the Base trial, and would therefore be in a position to influence subsequent comparisons.

If the differences in Experiment 1 were solely the result of relational priming, we would expect no differences between the Repeated Standard and Relational Priming conditions, because the priming effects should be equivalent. If, on the other hand, re-
representation is influencing perceived similarity, effects should be greater for participants in the Repeated Standard condition.

Results and Discussion There were three primary goals in Experiment 2. First, it gave us an opportunity to attempt a replication of the findings from Experiment 1, which is important given the novelty of those results. Second, it allowed us to assess whether relational priming may exert an influence in simple consecutive similarity judgments. This is an interesting question in its own right, as we will explore in the General Discussion. Finally, and most importantly, this experiment allowed us to compare the two between-participants conditions, one of which provided the opportunity for re-representation and one of which did not. Because the two conditions should have been equivalent in terms of potential relational priming, any observed advantages for the Repeated Standard condition would provide strong evidence that re-representation had taken place.

We again found an overall advantage for ratings on the Same trials $(M=8.81, S D=2.49)$ relative to the Different trials ( $M=$ $\left.6.47, S D=2.36 ; F(1,58)=46.17, p<.001, \eta_{p}^{2}=.44\right)$. However, because this includes both of the between-participants conditions, we performed a separate analysis of the Repeated Standard condition (which was identical to Experiment 1) to determine whether the basic pattern from the first study had been replicated. This revealed a pattern of results very similar to Experiment 1 (see Figure 3). Similarity ratings for the Same trials ( $M=8.89$, $S D=2.48$ ) were significantly higher than those for Different trials $(M=5.66, S D=2.46 ; t(29)=5.72, p<.001, d=1.31)$, replicating our initial finding. This pattern also held in a separate analysis across items $(t(5)=7.16, p=.001, d=1.94)$.

Next, we examined whether relational priming might have had an influence on participants' ratings. In a separate analysis of the Relational Priming condition, Same trials ( $M=8.63, S D=2.53$ ) received higher similarity ratings on average than Different trials ( $M=7.28, S D=1.98$ ), across participants $(t(29)=3.67, p=.001$, $d=0.59$ ) and items $(t(5)=3.00, p=.03, d=1.00)$, suggesting that relational priming was indeed having a measurable effect.

Figure 3: Results from Experiment 2

Most important for our theoretical interests, a 2 (Repeated Standard vs. Relational Priming) $\times 2$ (Same vs. Different trials) ANOVA showed a significant interaction between participant condition and item condition $\left(F(1,58)=8.16, p=.006, \eta_{p}^{2}=\right.$ .12). This interaction reflected the fact that the advantage of Same over Different trials was significantly greater in the Repeated Standard condition (mean difference $=3.81, S D=$ 3.84) than the Relational Priming condition (mean difference $=$ $1.36, S D=2.03$ ). This advantage was seen for all six items sets individually, and confirmed by an interaction in an analysis across items $\left(F(1,10)=4.08, p=.021, \eta_{p}^{2}=.43\right)$.
(To ensure that the materials were equally apt in both conditions, we confirmed that ratings for the Base comparisons did not differ between conditions $(t(59)=1.22, p=.23)$. In fact, there was a small numerical advantage for the Relational Priming condition: $M=10.23, S D=1.52$, vs. $M=9.74, S D=1.55$.)

## General Discussion

The results of these two studies are informative in several ways. First and foremost, they provide important evidence for a process of re-representation during comparison. As the dominant model of analogy and structured comparison, structure mapping theory has been used to explore and explain a wide variety of cognitive phenomena. However, its ability to scale up to even very basic real-world situations depends on its ability to flexibly find connections between related but non-identical structures. Re-representation has historically been cited as the underlying explanation for this ability. Despite its theoretical importance, however, direct evidence for re-representation has remained scarce. In our studies, comparing a standard case to one situation systematically changed its perceived similarity to new cases. The pattern of these changes indicates that the representational structure and content of the original standard had been altered in a way that made it more compatible with its compared situation-in other words, it had been re-represented. This effect held even when controlling for potential relational priming effects. By adding support to this critical but under-explored area, our results are able to further bolster the viability of structure mapping theory in general.

Although it was not our primary research focus, another informative contribution of these studies is that Experiment 2 demonstrates a novel form of relational priming. The idea of relational priming - that processing a particular semantic relation in one situation may make it easier to process in the futureseems reasonable, and perhaps even obvious given what we know about priming in other contexts. However, finding evidence to support this phenomenon has not always been straightforward. In one of the earliest experimental attempts, Spellman and colleagues (2001) found no indication of relational priming between word pairs in a lexical decision task, even when participants were explicitly told to focus on the relationships between the presented words. Only when individuals were told to notice that consecutive trials might involve the same relationship was a modest effect observed. Subsequent research has been more successful in finding examples of relational priming, through the use of more tightly controlled stimuli and by having participants engage in tasks that more naturally
involved the activation of relations, such as the interpretation of two-word phrases (e.g., Bendig \& Holyoak, 2009; Estes, 2003; Estes \& Jones, 2006; Gagné, 2001). However, our control condition in Experiment 2 is the first example to our knowledge that demonstrates relational priming through changes in perceived similarity, and the first to find large effects with such naturalistic stimuli.

Finally, our experiments introduce a novel method for assessing mental representation more generally. As with most studies of this type, the stimuli for the present experiments were coded by the authors largely as a function of our intuitions about the semantics of the situations involved. However, as history has repeatedly shown, researcher intuitions can often be wrong. Furthermore, intuitions can vary markedly between individuals. Consider the following two situations: (1) X was victorious over Y, and (2) Y was defeated by X. In our stimuli, we assumed that these reflected two distinct representational structures. Another researcher, however, might reasonably argue that they are simply two different ways of expressing the same underlying proposition. Our experimental method provides a direct way to address this issue. In our studies, comparing a sentence to a clear example of the DEFEAT structure made it subsequently seem significantly less similar to an unambiguous example of VICTORY. In this case, the intuition that these reflect distinct mental representations appears to have been correct, although until that point it was an open empirical question. Examination of the similarity changes resulting from re-representation offers us an intriguing tool for exploring and answering questions about the semantics of mental relations, and therefore provides a potential window into a variety of important mental processes.

Martinos Center for Biomedical Imaging, Massachusetts General Hospital

#### Abstract

When semantic information is activated by a context prior to new bottom-up input (i.e. when a word is predicted), semantic processing of that incoming word is typically facilitated, attenuating the amplitude of the N400 event related potential (ERP) - a direct neural measure of semantic processing. This N400 modulation is observed even when the context is just a single semantically related "prime" word. This so-called "N400 semantic priming effect" is sensitive to the probability of seeing a related prime-target pair within experimental blocks, suggesting that participants may be adapting the strength of their predictions to the predictive validity of their broader experimental environment. We formalize this adaptation using an optimal Bayesian learner, and link this model to N400 amplitudes using an information-theoretic measure, surprisal. We found that this model could account for the N400 amplitudes evoked by words (whether related or unrelated) as adaptation unfolds across individual trials. These findings suggest that comprehenders may rationally adapt their semantic predictions to the statistical structure of their broader environment, with implications for the functional significance of the N 400 component and the predictive nature of language processing.

Keywords: language; prediction; rational adaptation; semantic priming; EEG/ERP; word processing; information theory; Bayesian modeling; surprisal

## Introduction

How a word is processed fundamentally depends on the context. Predictable words are processed more quickly than unpredictable words (Fischler \& Bloom, 1979), with shorter fixations (and more frequent skips) during reading (see Staub, 2015 for review). A similar facilitation pattern is found on the N400 component (Kutas \& Hillyard, 1984), an event-related potential (ERP) that reflects semantic processing (Kutas \& Federmeier, 2011). The degree to which any particular word is facilitated is proportional to the probability of encountering that word given the context (DeLong, Urbach, \& Kutas, 2005; Smith \& Levy, 2013).

Semantic facilitation is observed even when the preceding context is only a single word. For example, the processing of a "target" word is facilitated when it is preceded by a semantically related (versus an unrelated) "prime" word: the so-called "semantic priming effect" (Neely, 1991). Semantic priming is also apparent on the N400 component, with more predictable words eliciting a
smaller (less negative) N400 amplitude than less predictable words (Bentin, McCarthy, \& Wood, 1985).

Importantly, the strength of the behavioral semantic priming effect is sensitive not only to the degree to which the prime and target are semantically related, but to the probability of receiving a related trial in the first place (Brown, Hagoort, \& Chwilla, 2000; Grossi, 2006). This has also been found with ERPs: experimental blocks with a higher proportion of related trials elicit a larger N400 semantic priming effect (Lau, Gramfort, Hamalainen, \& Kuperberg, 2013; Lau, Holcomb, \& Kuperberg, 2013). The semantic priming effect is likely sensitive to predictive validity because participants implicitly track and adapt to changes in the statistical contingencies over time.

Here we utilized data from Lau and colleagues (Lau, Holcomb, et al., 2013) to build and test a quantitative hypothesis of what drives this effect of predictive validity on the N400 semantic priming effect. Specifically, we asked whether the larger N400 priming effect in the high predictive-validity block could have been achieved through a "rational" probabilistic model of trial by trial adaptation. Although there are an infinite number of ways to build such a model, there are some particular theoretical constraints we can start from. Current evidence suggests that (a) prediction in language processing is probabilistic in nature, (b) predictions incrementally adapt to new information (where adaptation should be rapid when the environment changes), and (c) the brain calculates something like prediction error.

## Probabilistic Prediction in Language Processing and Semantic Priming

The role of prediction in language has long been debated, with differing definitions of what a "prediction" actually entails (see Kuperberg \& Jaeger, 2016 for discussion). Here, we view probabilistic prediction as a central feature of language comprehension (DeLong et al., 2005; Federmeier, 2007; Smith \& Levy, 2013), which does not necessarily need to be strategic or even conscious in nature. For any given context, there exists a probability distribution over the words that could be encountered next. A "prediction" is simply the presence of this probability distribution. While there is evidence for probabilistic prediction at multiple different levels of representation (Kuperberg \& Jaeger, 2016), here we focus only on prediction at the lexical level.

Note that, defined in this way, prediction exists even in the absence of a local context. Consider an experiment where words are being serially presented to participants at random. The "prediction" that participants make in such an experiment could be expressed as a probability distribution over words given an average context. This is functionally identical to word frequency, where high frequency words are more probable given a random/average context and low frequency words are less probable given a random/average context (Norris, 2006).

Given these assumptions about the nature of linguistic predictions, we can view the semantic priming effect as a type of probabilistic prediction. If a participant knows that a prime informs the target, they will implicitly generate a probability distribution over possible targets given that prime. Target processing is facilitated proportional to its probability. Though these prime-target transition probabilities are not easy to estimate from corpus studies (people don't often write in prime-target pairs), it can be estimated using production tasks like word association.

## A Rational Model of Adaptation

Probabilistic prediction is only beneficial if it actually approximates the statistical structure of the environment. Bad predictions aren't helping anybody. A number of recent language studies suggest that people rapidly adapt local models based on changes in their environment (Kleinschmidt \& Jaeger, 2015). For example, an environment with a high proportion of typically dispreferred syntactic parses can attenuate or even reverse the so-called "garden-path" effect in ambiguous sentences (Fine, Jaeger, Farmer, \& Qian, 2013). At the phonemic level, participants change their perception of ambiguous phonemes if one of the two competing options was locally repeated (Kleinschmidt \& Jaeger, 2016). And across longer periods, people show signs of adaptation to foreign accents that can generalize between different speakers with that accent (Bradlow \& Bent, 2008).

We can view the predictive validity manipulation in Lau et al (2013) through a similar lens. In experimental contexts with a higher proportion of semantically related word-pairs, participants will rely relatively more on the prime (versus relying more on a random/average context) to inform their predictions of the target. This means that the probability mass assigned to any particular target word depends not only on the associative strength of its prime, but also the likelihood that the prime provides information about the target in the first place (i.e. the predictive validity effect). When the proportion of semantically related and unrelated trials within a block changes, people adapt.

Although there are many ways to quantify adaptive learning, one attractive theoretically motivated implementation is Bayesian updating. This assumes that adaption is "rational" in nature (Anderson, 1990). Here, initial belief about the probability of obtaining a particular
type of trial (i.e. a related versus unrelated prime-target pair) is denoted by the prior probability $\mathrm{p}(\mathrm{h})$. Upon receiving a trial, this prior belief is updated using Bayes Law. This "posterior" is then used as the prior belief for the next trial.

Applying this rational, Bayesian framework to the predictive validity effect (on semantic priming) has a number of advantages. It would allow for prior beliefs from an initial lower predictive validity block to influence expectations for a subsequent higher predictive validity block in a principled way (i.e. the prior). It would adapt incrementally across trials. It would adapt more quickly near the change point, when evidence is low. And beliefs would slowly asymptote to the known true probability of receiving a related trial.

In the present investigation, we will use this type of Bayesian framework as the starting point for explaining how the brain adapts to changes in the statistical contingencies of incoming language input. We will refer to this as a Rational Adapter model.

## The N400 Measures Information Content

So our model should be probabilistic, and it should adapt, but a third component of this model is required before it can be tested: a linking function to actual brain activity. It is not necessarily the case that N400 amplitudes - the brain activity we are attempting to model - need be linearly dependent on the probability of a word given a context. Here, we argue that the N400 is best thought of not as a measure of probability, but as a measure of information (see Rabovsky \& McRae, 2014 for discussion).

In information theory (Shannon \& Weaver, 1949), the amount of information conveyed by an event is "whatever was not known ahead of time". An input that was perfectly predicted does not convey any new information. In contrast, messages that are not very predictable convey a lot of information. The amount of information (in units of "bits") that was not predicted ahead of time is called "surprisal", quantified as $-\log _{2}[p($ word $\mid$ context $)]$. One bit is the amount of information provided by flipping a fair coin once. A halving of the probability (e.g. conveying a sequence of two coin flips instead of one) corresponds with a 1 bit increase in surprisal.

This simple transformation has proved tremendously powerful in explaining language processing data (Hale, 2001; Levy, 2008). Smith and Levy (2013) provide empirical evidence that reading times relate to word probability logarithmically (e.g. as with the surprisal transformation) across six orders of magnitude. More recently, Frank and colleagues (Frank, Otten, Galli, \& Vigliocco, 2015) discuss ERP evidence that the N400 component is sensitive to word surprisal. Given this evidence, for the present investigation, information-theoretic surprisal will be our linking function between the Rational Adapter model and N400 amplitude, rather than probability.

In the present investigation, we aim to build and test a Rational Adapter model of semantic priming against neural N400 component data. Specifically, we use data from Lau and colleagues (2013). Here, the N400 semantic priming effect was measured first in block 1 where $10 \%$ of the trials were related, and then in block 2 where $50 \%$ of the trials were related. We use the block 1 only to inform the prior, which is then fed into the Rational Adapter model to predict N400 amplitudes in block 2, as participants' beliefs about the predictive validity of the prime adapt.

We hypothesize that this Rational Adapter surprisal model will better account for the N400 data than a nonlearning model of N400 data. Specifically, we hypothesize that the size of the N400 effect (the difference in amplitude of the N400 evoked by related and unrelated target words ) will increase rapidly near the beginning of block 2 , as the Rational Adapter shifts from a " $10 \%$ related" prior towards a " $50 \%$ related" asymptote.

## Methods, Modeling and Results

## ERP Data collection

We used data from Lau and colleagues (Lau, Holcomb, et al., 2013). Briefly, 32 right-handed participants (13 men) between age 19-24 were shown sequential prime-target pairs as event-related potentials (ERPs) were recorded and timelocked to the onset of the target. Participants were asked to perform a semantic monitoring task that was not directly related to the experimental manipulation. All participants saw an initial 400 trials (block 1) where $10 \%$ of the stimuli were related (e.g. "ladder... climb"), followed by 400 trials where $50 \%$ of the stimuli were related (block 2 ). The blocks were separated by a short break, but participants were not explicitly told about any changes in the experiment.

80 of the trials in block 2 ( 40 related, 40 unrelated) were critical prime-target pairs that were matched and counterbalanced across participants, alongside 320 fillers. Primes were presented with an SOA of 600 ms and targets had a duration of 900 ms . The N400 component was averaged across a time window of $300-500 \mathrm{~ms}$ over the average of three centro-parietal channels. Extreme outliers in N400 measures were removed (4 standard deviations or more from the mean).

Visualization Lau et al originally reported that the N400 semantic priming effect was larger in block 2 than block 1. For the present investigation, we plotted how the N400 amplitudes of these critical trials changed over the course of block 2, as shown in Figure 1. This was estimated using a loess local regression over N400 amplitudes for related and unrelated words across the ordinal position of critical items in the experiment (this local regression was necessary because not every participant saw critical targets in the same place). As can be seen here, N400 amplitudes for related and unrelated words are initially similar, but then diverge as participants are exposed to more and more of the block.

Figure 1: Block 2 N400 amplitudes over trials.

## The Rational Adapter Word Surprisal Model

Our Rational Adapter model consists of three primary components: a) a Bayesian belief about the probability of receiving a related vs. an unrelated prime-target pair at any given point, b) a mixture of $p$ (word|prime) and $p$ (word|average context) given these beliefs about the trial types, and c) a conversion from these probabilistic predictions to word surprisal (as a linking function to the N400 component). The whole model takes the form:

$$
\begin{gathered}
\text { Word surprisal }=-\log _{2}\left[\lambda * p(\text { word } \mid \text { prime })+(1-\lambda)^{*}\right. \\
p(\text { word } \mid \text { average context })]
\end{gathered}
$$

where $\lambda$ is a point estimate of the probability with which a rational adapter expects a related trial at that point in time.

We use a beta-binomial model to estimate a participant's belief about the probability of seeing related versus unrelated trials. To set a prior on the beta distribution, we assume that participants enter block 2 assuming the proportion will be the same as block 1: a $10 \%$ chance of receiving a related trial. This prior is expressed using a 1:9 ratio of related:unrelated pseudocounts. Though participants see 400 trials in block 1, participants will likely discount their previous experience somewhat (reflecting some uncertainty). As a best-guess approximation, we set the prior going into block 2 at $\operatorname{Beta}(5,45)$, i.e. pseudocounts equivalent to having seen 5 related and 45 unrelated trials. In other words, participants were assumed to put more weight on their experience with the new block (vs their prior given the old block) after about 50 trials.

After each new trial, this Beta distribution is updated by adding the observed trial counts to the prior pseudocounts. For example, after 5 related and 5 unrelated trials in block 2, a participant's beliefs would be modeled as $\operatorname{Beta}(10,50)$. We took the mean of this beta distribution just before each critical trial to reflect the point probability $\lambda$ with which that participant expects a related trial for that event.

This probability, $\lambda$, then provides a weighting term for a mixture model between the two ways that participants might generate more specific predictions about the upcoming target word at any given trial. Given a related trial, we
model these within-trial predictions as p (word|prime), estimated using "forward association strength" (FAS) from the Florida Word Association Norms (Nelson, McEvoy, \& Schreiber, 2004), and then we weight this probability by $\lambda$. Given an unrelated trial, we model these within-trial predictions as p (word|average context), as estimated by word frequency from the SUBTLEX corpus (Brysbaert \& New, 2009), and then we weight this probability by $1-\lambda$.

The mixture of these two terms yields a "word probability", given the prime and beliefs about whether or not it will inform the target at any point in the experiment.

Finally, this word probability is transformed into "word surprisal", or the amount of information that was not predicted ahead of time (in bits), given by $-\log _{2}[\mathrm{p}$ (word probability)].

## Word Surprisal and N400 Amplitudes

To numerically test whether our estimate of surprisal explains variance in the N400 amplitudes evoked by each target word, we conducted a linear mixed-effects regression using the lme4 package in R, with word surprisal as a predictor and centro-parietal N400 amplitude for each trial in block 2 as an outcome. Word surprisal was standardized. The maximal random effects structure across (crossed) subjects and items was used (Barr, Levy, Scheepers, \& Tily, 2013).

Results We found that word surprisal significantly accounted for variance in N400 amplitudes $(\beta=-1.14, t=-$ $5.24, \mathrm{p}<0.001$ ). As word surprisal increased, N400 amplitudes tended to be more negative (i.e. larger).

## Word Surprisal Explains Trial-by-Trial Variance

There is an important caveat to this "rational adapter" word surprisal effect, however: by definition, unrelated words tend to have high surprisal, while related words tend to have low surprisal. As such, the word surprisal effect in block 2 could potentially be attributable to the categorical "Relatedness" effect already reported in the initial study.

To address this possibility, we ran a second linear mixedeffects regression that included both categorical Relatedness and word surprisal as predictors. This would show whether our rational adapter estimate of word surprisal could account for variance in N400 amplitudes above and beyond what could already be explained by the main effect of related vs unrelated trials. Again, the maximal random effects structure for word surprisal was used.

Results We found that word surprisal significantly accounted for variance in N400 amplitudes ( $\beta=-2.21, \mathrm{t}=-$ $2.76, \mathrm{p}=0.006$ ) above and beyond the main effect of Relatedness. This indicates that the surprisal difference between related and unrelated words was not sufficient to account for the way that word surprisal related to the N400 in the first model.

We caution that given the multicollinearity between word surprisal and the relatedness effect (the primary motivation
for running this test in the first place), this $\beta$ estimate is likely inflated. We limit our conclusions to the explanatory power here, not the regression coefficient.

## The "Rational Adapter" Word Surprisal Model Outperforms its Constituent Elements Alone

Another potential concern is that the model we used to estimate word surprisal simply includes more information about the trials. Namely, the word frequency and FAS of each trial are inputs to the Rational Adapter model calculations. These could have explained items-level variance in N400 amplitudes without resorting to adaptation, given that the N400 component is already known to be sensitive to both these factors. In short, perhaps the explanatory power of our rational adapter model is primarily due to the inclusion of trial-specific frequency and FAS information, rather than prediction and adaptation.

To address this possibility, we ran a third linear mixedeffects regression that includes not only word surprisal as a predictor, but also Frequency, FAS, and Relatedness predictors for each trial. This tests whether the particular arrangement of inputs into the "rational adapter" word surprisal model explains variance in N400 amplitudes marginal to the stationary main effect of Relatedness and to its constituent items-level elements. Again, the maximal random effects structure for word surprisal was used (across both items and subjects), and all continuous predictors were standardized.

Results We found that word surprisal significantly accounted for variance in N400 amplitudes $(\beta=-2.30, t=-$ 2.11, $p=0.036$ ) above and beyond Frequency, FAS, and Relatedness. This indicates that the particular way itemslevel features were combined into the our model is an important source of explanatory power, and that the increased fit is not simply due to the fact that our model included additional information about items-level features.

## Finding the Optimal Prior

Our model assumed that the rational adapter should approach $\lambda=0.1$ (the actual block 1 proportion) as they go through the first 400 trials of block 1, regardless of what their expectations were coming into the experiment. Given that our model is explicitly a rational one, we kept constant this 1:9 related:unrelated ratio for the prior for block 2. However, that still leaves the prior strength (i.e. number of pseudocounts) as an assumption that can be explored. For hypothesis testing above, we assumed that participants entered block 2 with a $\operatorname{Beta}(4,45)$ prior, i.e. that participants believed it would have the same $10 \%$ relatedness proportion as block 1 with a weight of 50 pseudotrials. This 50 pseudocount prior weighting, however, was essentially guesswork (we didn't want to bias our hypothesis tests by interrogating many models and selecting the best one). Here, we sought to ensure that our results were not idiosyncratically dependent on having made a "lucky" guess.

Figure 2: Deriving the optimal prior strength.
A low pseudocount prior like $(1,9)$ would cause rational adaptation to proceed very quickly, while a high prior pseudocount like $(40,360)$ would cause rational adaptation to proceed much more slowly, as participants enter block 2 with much more certainty about the environmental statistics. The pseudocount (and thus speed of adaptation) that best explains variance in N400 amplitudes is thus an empirical question: what is the optimal prior strength?

To find the optimal prior, we calculated the word surprisal (for all trials for all participants, as above) for every integer "prior strength" from 1 to 800 pseudocounts. We then ran a separate linear mixed-effects regression model for each prior strength with word surprisal and Relatedness as predictors and a maximal random effects structure. After fitting these 800 regression models, we extracted the loglikelihood of each.

Results These data are shown in Figure 2. The single maximum log-likelihood was obtained with a $\operatorname{Beta}(7.7$, 69.3) prior, a "prior strength" of 77 pseudocounts. However, all pseudocounts between 70 and 85 yielded similar model fits, and performance degrades smoothly on either side.

This indicates that, on average, participants began giving more weight to the new block's data than the previous block's data 70-85 trials into block 2. A rational adapter with a very weak prior (below $\sim 50$ pseudocounts) does not account for N 400 data well because it adapts too quickly. Similarly, a rational adapter entering block 2 with a very strong prior (above $\sim 200$ pseudocounts) also does not account for the N400 data well because it adapts too slowly.

We note that some models had poor fit because they did not converge. None were within the 70-85 range capturing the maximum.

## Discussion

Previously, Lau and colleagues (2013) found that the N400 semantic priming effect shows evidence that adaptation occurred when the predictive validity of the local context changed. In the present investigation, we explored the nature of the adaptation process as it unfolded. Figure 1 shows the trial-by-trial nature of this adaptation over ordinal position in block 2. Our Rational Adapter model provides a
theoretically-grounded quantitative account of how that adaptation may have occurred on an incremental trial-bytrial basis. It was built using three foundational considerations: that contexts can probabilistically inform lexico-semantic expectations for upcoming stimuli, that these expectations adapt rationally (in an optimal Bayesian manner), and that the N400 component is sensitive to units of information rather than units of probability (after the present analyses, we tested this assumption and found that word surprisal significantly accounted for variance in N400 amplitudes $[\mathrm{t}=-2.57, \mathrm{p}=0.011]$ above and beyond word probability and the categorical Relatedness effect.).

In a re-analysis of the original study, we provide empirical evidence that this model is consistent with how brain activity evoked by target words changed over the course of block 2 . We showed that it accounted for variance in N400 amplitudes above and beyond the stationary effect of related versus unrelated trials, suggesting that it was capturing trial-by-trial differences within block 2. Further, we showed that this particular formulation of the rational adapter model accounted for significant variance in N400 amplitudes above and beyond even its own constituent elements, suggesting that the additional explanatory power was not simply due to the inclusion of items-level information (our single trial approach to ERP analysis). These findings extend previous work on rational adaptation to demonstrate that it can account for changes in predictions during lexico-semantic processing.

In addition, we used the rational adapter model to derive the rate of adaptation that best accounted for the ERP data. Even though participants saw 400 trials in Block 1, we estimate that participants adapted as if they had only seen $70-85$ trials of bock 1 by the time they entered block 2 . Although participants were not informed of the changing environmental statistics (and the manipulation was not overtly task-relevant), we speculate that the conspicuous block boundary may have prompted participants to adapt at a faster rate. Additionally, there may be a decay or filtering that occurs for distant exposures, which dynamical models of prediction and adaptation may be able to account for.

While the present study included data from a semantic priming paradigm, we suggest that a similar pattern may hold in comparable experiments with more expansive contexts, like sentences or discourses, as the theoretical underpinnings are functionally the same. For example, in experimental contexts with a high proportion of highly constraining sentences, we might expect participants to learn to predict more strongly. Finally, these data have implications for the functional significance of the N400 component. The N400 is often discussed as being sensitive to probabilities. We suggest that its sensitivity to probabilistic measures like cloze probability, forward association, and even frequency may be best conceptualized it as reflecting units of information rather than probability alone (see also Frank et al., 2015; Rabovsky \& McRae, 2014; Smith \& Levy, 2013).

# The Role of Imagination in Exemplar Generation: The Effects of Conflict and Explanation 

Tammy M. Dennis (tdennis@student.unimelb.edu.au)<br>Daniel R. Little (daniel.little@unimelb.edu .au)

Melbourne School of Psychological Sciences, The University of Melbourne, VIC 3010, Australia

#### Abstract

Structured imagination refers to reliance upon prior knowledge when generating novel examples of a provided category. Yet studies supporting this tenet use experimental designs where the stimuli themselves cue exemplars based on culturally relevant items. The present study combined exemplar generation with abstract stimuli as a means of attenuating instructional bias. Participants were shown a group of abstract shapes identified as a single category and instructed to generate another member of this category. We additionally examined whether the introduction of a cognitive conflict (by including an anomalous category member) and self-explanation during generation affected the level of imaginative responses. Contrary to expectations, the presentation of a conflicting category member did not result in more imaginative responses when compared to more homogenous stimuli sets. However, a significantly greater degree of imaginative responses was observed from participants who were required to explain their thinking prior to and whilst constructing their exemplars.

Keywords: imagination; exemplar generation; cognitive conflict; self-explanation; reflective abstraction.
[Ramanujan's equations] must be true because no one would have the imagination to invent them.

G. H. Hardy

## Introduction

How does imagination impact the generation of novel ideas? Theories of structured imagination assert that the generation of ideas, concepts, and objects depends on and is constrained by prior knowledge (Ward, Patterson \& Sifonis, 2004). Prior knowledge limits the set of features, dimensions, relations, functions, and so on under consideration. However, support for this position comes from experimental paradigms where instructions reference prior concept knowledge or examples that cue prior knowledge. Consequently, the influence of prior knowledge on the role of imagination in, for instance, an exemplar generation paradigm remains somewhat unclear.

The exemplar generation paradigm requires participants to generate new category members that could plausibly belong to some presented set (e.g. Jern \& Kemp, 2013; Ward, 1994). The paradigm anticipates that imagination behaves like other cognitive processes in requiring reasoning about the rules (or other requirements) for category membership. The empirical evidence supporting the role of prior knowledge has countered romantic views that imagination stems from some unique unobservable process. For example,

Ward (1994) asked participants to draw an animal from another planet. Most responses contained features typical of Earth animals, (e.g., bilateral symmetry). Hence, knowledge from existing concepts was projected onto the generated exemplars. Evidence for the constraining effect of prior knowledge also comes from the study of cognitive biases in innovation. For instance, functional fixedness (Duncker, 1945) refers to a tendency to focus on an object's most common use. By contrast, McCaffrey \& Krishnamurty (2014) argue that more novel ideas are generated when attention shifts to less frequently noticed attributes of a problem (or in our case, of the stimulus).

In the present study, we attempt to limit reliance on prior knowledge by using sets of abstract stimuli drawn from a continuous multidimensional space. The use of abstract stimuli should increase the reliance on identification of similarity between stimulus features (Tversky, 1977). For example, new exemplars generated to belong to a presented category (see Figure 1) should tend to be similar on features such as color and shape. If only perceptual features are accessible, participants would be prone to adopt feature matching strategies such as replication (e.g., copying one figure directly) or averaging (e.g., generating the mean of the presented examples; see Figure 1). Hence, although the use of abstract stimuli may lessen reliance on prior knowledge, the use of feature matching strategies will likely be enhanced.

The extent to which participants merely replicate or copy one of the presented category members may also depend on whether participants adopt a strong sampling assumption (i.e., that the category members were deliberately chosen as positive examples; perhaps as the only members of that category; Navarro, Dry \& Lee, 2012). Under a weak sampling assumption, participants may view the presented

category as being sampled with no restrictions; hence, the presented objects may have implicit or hidden dimensionality with unknown support (i.e., the range of values that exist for a dimension). Our first goal was to examine how variability in the presented set affected the novelty of the generated exemplars.

Ward and Sifonis (1997) varied instructions across three experimental conditions: participants were told to generate (1) an alien animal, (2) an animal wildly different from Earth animals, or (3) a living thing. The second condition produced more unusual creatures than the first condition; while diversity was largest in the third group where many responses did not adhere to standard animal features. The authors' suggested that this was encouraged through ambiguity in the instructions and by participants describing their creature prior to drawing it. A second goal of the present study was to examine whether self-explanation leads to more imaginative exemplars.

The present study aimed to examine the effects of: (i) variability of the presented category, (ii) inclusion of a conflict item, and (iii) prospective explanation and thinking aloud on exemplar generation. We compared a baseline condition to a condition which contained an anomalous exemplar and to a further condition which additionally required participants to engage in self-explanation during the generation process. Cognitive conflict is recognized as a reliable method for promoting the search for new knowledge (e.g. Limon, 2001). For example, a study conducted by Kang, Scharmann and Noh (2004) found conflict recognition promoted the invention of alternative concepts and explanations to account for the disparity caused by a conflicting stimulus. Consequently, presentation of a conflicting item may act to stimulate imagination, highlighting potential options for a new category member. For instance, an anomalous category member could highlight new dimensions from which an exemplar could be sampled.

If the underlying category rules are unclear, selfexplanation may allow for exploration of alternative hypotheses through which to understand the presented

Figure 3. Example of a Single Trial. A) presented category examples, B) black box for drawing generated exemplar, C) color bar and saturation and brightness cube. The online version is in color.
category (Williams \& Lombrozo, 2010). Self-explanation, has a direct influence on how objects are mentally represented and understood. Verbalisation of thought processes during an activity can enable access to cognitive processes which are not directly observable (e.g. Ericsson \& Simon, 1980). Self-explanation can also override the influence of similarity, facilitate generalisation, and promote the integration of novel information with existing knowledge (Lombrozo, 2006). Similar to its influence on intelligence observed in educational psychology models which aim to accelerate cognitive development (Adey, 1992), selfexplanation, therefore, affords a means of engaging imagination in order to resolve conflict.

## Method

## Participants

Participants were 129 University of Melbourne students who received course credit for participation. Of the participants, 16 were excluded as a result of missing data, leaving a total of 113 (91 females, $\mathrm{M}=19.9,3.11$ ). Participants were randomly assigned to one of three conditions; baseline ( $\mathrm{n}=$ $35)$, conflict $(\mathrm{n}=43)$ or self-explanation $(\mathrm{n}=35)$.

## Stimuli

The stimuli were "blob-shaped" radial frequency curves, which varied in shape and color. Four shapes were presented, and participants were asked to generate a new member of the same category by drawing a shape using the mouse and selecting a color. In the baseline condition, the shape of the objects could vary with color identical across all of the category members; the color of the objects could vary with shape fixed, or both shape and color could vary (see Figure 2). The shape was determined by convolving three sine waves of different angles; two degrees, four degrees, and a third angle randomly generated from a normal distribution with a mean of zero and a standard deviation of 10 (low), 12.5 (medium), or 15 (high) ${ }^{1}$.

The color was determined by selecting a starting hue from a set of fully saturated and fully bright hue values between

zero and 255．These values were converted to RGB values using a look－up table．If color varied，then the hue was adjusted by a normally distributed random adjustment with a mean of zero and standard deviation of 20 （low）， 40 （medium），or 60 （high）${ }^{2}$ ．

In the conflict and self－explanation conditions，three of the items had low levels of variability（as in the baseline condition），and one study item varied markedly from the other three items on shape，color，or on both dimensions（see Figure 2）．The levels of conflict variation were determined in the same way as the baseline condition but with much larger standard deviations．

## Procedure

Participants completed 27 trials．Each trial consisted of presentation of four items displayed on a computer monitor， with instructions indicating that the four items all belonged to a single category．Participants were instructed to use the computer mouse to draw another member of this category in the provided box and to select its color．Colors were selected by choosing a hue from a color bar and then adjusting the saturation and brightness by selecting from the shading box （see Figure 3）．

In the baseline and conflict conditions，after completion of all trials，participants were instructed to provide a retrospective explanation for each trial．For the self－ explanation condition，participants were asked to provide a prospective explanation and then to think aloud whilst drawing their exemplar．Prospective and retrospective verbalizations were recorded on a digital recorder．

Shape and Color Similarity Scoring To provide an objective measure of how closely the generated objects

[^55]matched the presented category exemplars，we developed two measures：（1）The first method used translation，rigid shape rotation，and scaling to find the maximum proportion of overlap between the generated object and each presented exemplar．This measure ranged from 0 and 1 ，with 1 indicating perfect overlap．The shape similarity scores were approximately normally distributed with a mean of 61 （sd＝ 0.13 ）．（2）The second method extracted the color of the generated object and computed the Delta E color difference between the drawing and each of the presented examplars （Wyszeck \＆Stiles，1982）．These scores were positively skewed with a lower bound at 0 （perfect color match）．We log transformed these scores and adjusted the range to 0 and 1 ， and finally subtracted the scores from 1 so that 1 indicated a perfect color match．The final score was the minimum score across all four presented category members．The color similarity scores had a mean of $.18(\mathrm{sd}=.07)$ ．

Expert Coding Note that our shape overlap similarity measure does not really capture the extent of creativity in the generated exemplars；nor does it capture other potentially interesting patterns of exemplar generation．To capture these patterns，we had two experts（one was the first author） classify each drawing into whether the generated object replicated one of the presented exemplars，whether the generated object appeared to be an average of the presented exemplars，or whether the generated object exhibited imaginative characteristics．This latter rating category was further broken down into cases which used the perceptual features of the presented shapes（termed explicitly imaginative；i．e．，imaginative responses which utilized variations in blob－shape or color；e．g．，a butterfly which is blob－shaped）or whether the generated exemplar drew on implicit characteristics（we term this rating category

All values were selected based on pretesting to ensure perceptibly low，medium，and high levels of variation．
implicitly imaginative; i.e., response which utilize features other than blob-shape or color; e.g., a drawing of a space ship - which may have been justified as necessary to interact with

Figure 5. Average shape similarity (top panel) and color similarity (bottom panel) as a function of dimensionality and variability in the baseline condition.
the alien shapes that had been presented as part of the category). There was an $86 \%$ agreement between our expert raters; disagreements were then clarified between raters by drawing on the recordings generated by participants. Figure 4 shows exemplars representative of each response strategy.

## Results

## What is the effect of variability in the presented category on the generated exemplars?

We first examined the effects of dimensionality and variability within the baseline condition on both shape and color similarity. Dimensionality refers to what aspects of the presented category exemplars varied within the presented set (e.g., shape could vary with color fixed across all four category members, color could vary with shape fixed, or both
could vary). Variability refers to the level of variability applied to the dimensions which were not fixed in the presented set. We examined only the baseline condition because variability in the conflict and explanation conditions was instantiated via the anomalous items and is not comparable.

Figure 5 shows that there was little effect of dimensionality or variability on the shape similarity scores. On the other hand, the color similarity scores systematically decreased with increasing variability whenever color varied in the presented set. That is, whenever the presented category exemplars varied in color, people generated colors which were more dissimilar (to the presented colors) than when color was fixed or of lower variability.

A two-way Dimensionality $x$ Variability ANOVA confirmed these results. The largest F-ratio for the shape scores was the effect of variability, $F(2,882)=1.45, p=.23$. For the color scores, there was a main effect of dimensionality, $F(2,882)=151.33, p<.001$, a main effect of variability, $F(2,882)=27.35, p<.001$, and an interaction, $F(4,882)=11.06, p<.001$.

Figure 6. Average shape similarity (top panel) and color similarity (bottom panel) scores in the baseline, conflict and explanation conditions. Error bars are $+/-1$ standard error.

## Does conflict or explanation lead to less similar generated exemplars?

Automated Scores We compared the average shape and color scores for each participant across the baseline, conflict, and explanation conditions. There was a general decreasing trend across these conditions for both shape and color
similarity (see Figure 6). Both effects were significant using a one-way ANOVA: (Shape: $F(2,110)=3.2, p=.044$; Color: $F(2,110)=64.05, p<.001)$.

Expert Ratings The proportion of each drawing type is shown in Figure 7. It is immediately obvious that the main strategy for exemplar generation was to simply replicate one of the presented category members. While all conditions showed some evidence of generating imaginative exemplars, the level of implicitly imaginative exemplars appears to be higher (with a co-occurring decrease in replication) in the explanation condition. This was confirmed by a significant chi-squared test for independence across all three groups, $\mathrm{X}^{2}$ (6) $=63.46, p<.001$, and for the baseline vs explanation comparison, $\mathrm{X}^{2}(3)=49.11, p<.001$, the conflict vs explanation comparison, $\mathrm{X}^{2}(3)=34.59, p<.001$, but not the baseline vs conflict comparison, $\mathrm{X}^{2}(3)=3.02, p=.15$.

Figure 7. Expert rating proportions for the shape of the generated objects for each strategy type: replication, averaging, explicit imaginative, and implicit imaginative.

## Discussion

This experiment examined the effects of stimulus variability, which included adding a conflict item to the presented category set, as well as the impact of prospective selfexplanation and thinking aloud on exemplar generation.

We first showed that variability on a color dimension leads to more novel generation of values for that color dimension. We did not find an effect of variability on shape. There are a few potential explanations for this difference between shape and color similarity. For one, our operationalization of shape similarity as overlap did not adequately capture the more creative responses that were identified by our raters (see Figure 4, for examples). Second, color was easier to generate in our experiment than shape. Shape had to be hand-drawn but color could be selected from a color palatte. Hence, a third difference was that the range of color options was presented to the participant, but the range
of possible shapes was unbounded. The use of a mouse instead of a stylus may have restricted the shapes that were generated; we leave this as a goal for future experiments.

We next showed that including an anomalous exemplar and allowing self-explanation, led to responses which were less similar to the presented category members. Our rating analyses clearly showed that in all conditions, replication was the most utilized strategy. Examination of the drawings revealed that most subjects drew blob like objects and that typically these blobs looked primarily like one of the presented objects. The predominant application of replication strategies in all conditions in this study may have been anticipated through our use of abstract stimuli. The use of abstract stimuli promoted the predilection toward perceptual features of the presented stimuli (Tversky, 1977), and the absence of feedback on task performance made category comprehension more ambiguous. Consequently, a replication strategy represented the simplest approach to meet task parameters, whilst requiring the least amount of cognitive effort. This result may also indicate that participants adopted a strong sampling assumption (Navarro et al., 2012) and simply sampled from the presented set.

Despite stimuli having no direct links to prior conceptual knowledge, some responses drew on knowledge external to the perceptual features of the manufactured categories. This was more prevalent when participants were encouraged to self-explain. This implies that the method of instruction, along with the method of response, plays an active role in both understanding category membership and the subsequent exemplar generation process.

Presentation of a conflicting category member did not result in more or less imaginative exemplars. The implication is that the conflict item proved difficult to assimilate, resulting in replication being favoured as a strategy. The importance of delivering a conflict at the appropriate level so as to sustain interest has been demonstrated in previous research in learning. As noted by Limon (2001), the presentation of contradictory data can only result in a meaningful conflict if it presents a challenge to existing held beliefs. If the basis of the conflict is not understood, it fails to engage the person, and therefore the conflict may be ignored or explained away (Adey, 1992). Our results suggests that conflicting items which maintain the same explicit dimensional structure might limit the recruitment of imagination. We leave it for future research to examine conflicts which signal the implicit dimensionality of the concept.

On the other hand, prospective self-explanation promoted greater use of imaginative strategies. This indicates that cognitive interaction via self-explanation can foster imaginative responses to category conflicts. It appears that self-explanation provided a mechanism for reflective abstraction of the conflict (Adey et al, 2007), and encouraged imagination to resolve the problem. In line with studies into the influence of self-explanation in dealing with anomalous data (e.g., Williams, Lombrozo, \& Rehder, 2011), selfexplanation encourages the greater use of imaginative
strategies in response to a category conflict. It is the combination of both a conflict and a mechanism to explore the reasons behind the conflict which increases the use of imagination.

A limitation of the current study is that it failed to address whether self-explanation increases the likelihood of imaginative responses without the involvement of a conflict category member. It remains unclear whether highly imaginative responses would have arisen if a more complete range of feature variation had not been revealed by the conflict item. Therefore, repeating the current study allowing explanation in the baseline condition would facilitate a better understanding of the importance of self-explanation in promoting imaginative responses. Future studies should also explore the role of self-explanation in the use of replication. When a conflict category member was presented amongst similar stimuli, participants following a replication strategy either chose to replicate one of the three similar items or the minority conflict item. Understanding the patterns which underlies this decision making is important, as it represents the starting point for imaginative responses.

The motivation for the present study was to better understand the role of imagination in exemplar generation. To address the gap in the literature about the impact of instructions on structured imagination, abstract stimuli were used as a means of reducing access to prior knowledge when generating exemplars. Although participants favoured a strategy which leveraged perceptual features, the current study provides evidence of imaginative responses leveraging implicitly related prior knowledge. In addition, selfexplanation was shown to be an effective mechanism in generating imaginative exemplars in the presence of category conflict. This experiment confirms that self-explanation makes structured imagination more flexible when interacting with unexpected categorisation tasks, and represents the starting point for greater exploration into how imagination responds to cognitive challenges.

It is worthwhile to consider how one might develop a computational model of exemplar generation. Clearly an essential mechanism is the ability to retrieve instances or features from members of stored categories and then to combine these retrieved features. This type of mechanism is reminiscent of the echo content mechanisms in Minerva (Hintzman, 1984). Our results suggest a mix of strategies which direct retrieval of one of the presented category members being the most common. The fact that replication is increased in the conflict condition suggests a role for selective attention in determining retrieval. However, in some cases, there appears to be probabilistic sampling not only of the physically presented shape and color dimensions, but also of dimensions which are implicit to the presented category and likely more conceptual than physical (see Figure 4). McCaffrey \& Krishnamurty (2014) propose a taxonomy of different feature types that ranges from physical features such as size, shape, mass, weight, to the identification of object parts, to the types of functions or uses an object has, its super- and subordinate categories,
associated concepts, aesthetic values, and causal relations. In this taxonomy, only certain types of features (or dimensions) are immediately available to sensory perception. Selfexplanation seems to result in an increased probability of sampling from more implicit dimensions.

#### Abstract

Participants wore a smartphone, which collected GPS, audio, accelerometry and image data, in a pouch around their necks for a period of two weeks. After a retention interval of one week, they were asked to judge the specific day on which each of a selection of images was taken. To account for people's judgements, we proposed a mixture model of four processes - uniform guessing, a signal detection process based on decaying memory strength, a week confusion process and a event confusion process in which the sensor streams were used to calculate the similarity of events. A model selection exercise testing all possible subsets of the processes favoured a model that included only the event confusion model. GPS similarities were found to be the most significant predictors, followed by audio and accelerometry similarities and then image similarities.

Keywords: memory, experience sampling, hierarchical Bayesian model

## Introduction

Friedman $(1993,2004)$ argued that people typically employ one of four strategies to identify when events occurred. On some occasions, people can directly retrieve declarative knowledge about the event. For instance, many people can recall that the attacks on the Twin Towers occurred on September 11th 2001. Friedman argues, however, that such declarative knowledge is quite rare and is reserved for events of global or personal significance. On other occasions, people have relative order information that they can use to make a judgement. If one were asked when George W. Bush initiated military action in Afghanistan, one may not know the date, but one can make an inference. The military action in Afghanistan occurred as a consequence of the September 11th attacks and therefore was most likely to have been in late 2001. There is a natural order in which these events occurred and provided someone has the order information and access to the time of the
original event they can deduce the timing of the subsequent event. Again, Friedman argues that judgements based on relative order information are rare.

More common, according to Friedman, are judgements made using location-based strategies. Location-based processes rely on the retrieval of information associated with the cues that can be used to draw inferences about the timing of an event. For instance, suppose you are asked when you last saw your friend Mary. You might recall that you share a Psychology-101 class with Mary. Furthermore, you know that Psychology-101 occurs on Mondays and Wednesdays at 2 pm . It is now Saturday, so you infer that it was Wednesday at 2 pm when you last saw Mary.

Sometimes, however, the necessary knowledge to make an inference is not available. In these circumstances, Friedman argues one resorts to a distance-based strategy. Distance-based strategies rely on some quality of the memory that changes as a function of time. For instance, one might judge strong memories as having occurred more recently.

There is a substantial literature that has asked people to report on the time at which events occurred (see Friedman, 1993 and Thompson, Skowronski, Larsen \& Betz, 1996, for reviews). Much of this literature has involved the memory for events that occurred outside of the laboratory, but which can be dated because they are part of the public record or have been recorded in personal diaries (Kemp, 1999). Generally, people are very poor at identifying when events occurred showing a bias to report events as being too recent when they occurred remotely in time - forward telescoping (Huttenlocher, Hedges, \& Prohaska, 1988) or too remote when they occurred recently - backward telescoping (Hinrichs \& Buschke, 1968).

Early distance-based theories proposed that the psychological representation of time was logarithmically compressed, much as other psychophysical dimensions are
(Ferguson \& Martin, 1983). These theories are able to account for the decrease in accuracy that occurs with retention interval, but have been discounted because well-known remote events are often dated accurately. If it were the time axis itself that was compressed, dating accuracy should always be directly related to recency (Huttenlocher et al., 1988). Alternatively, the accessibility of the memory trace could be used to infer the time of occurrence. Some evidence suggests that better known events are dated more recently (Brown, Rips \& Shevell, 1985). However, there is substantial subsequent evidence that this does not occur (Thompson et al. 1988). Again, better known events are reported more accurately. Furthermore, people are often capable of accurately reporting the day of the week an event occurred, while struggling to faithfully retrieve the month or year (Friedman \& Wilkins, 1985). If people were using distance-based strategies, accuracy at smaller temporal scales ought to be worse than at larger temporal scales. The existing literature has tended to conclude that location-based strategies are far more commonly employed than distance-based strategies (Friedman, 1993; Thompson et. al. 1996).

There are two main models of time reporting that have been proposed (Huttenlocher, Hedges \& Prohaska, 1988; Kemp, 1999). The first of these, by Huttenlocher, Hedges, and Prohaska (1988), proposes that events are associated with time information, which is unbiased but subject to error that increases with time. Bias is introduced because answers are constrained to lie within the reference period either implicitly or explicitly defined by the memory query thus generating forward and backward telescoping. In addition, the theory posits that memory units are organized hierarchically - (e.g. day, month, year) and that events may be associated with any of these levels. The model provides a good quantitative fit to data they collected on judgements of when movies that were part of a campus initiative were shown.

Kemp's (1999) theory is similar to Huttenlocher's in that the representation of time is not systematically distorted and that reconstruction of this time information is the basis of memory judgements. Rather than suggesting that temporal information is distorted with age, Kemp (1999) proposed that when time information is available it is accurate regardless of age. However, only a small number of memories have stored time information. Events of a similar kind are associated with each other and retrieval proceeds by retrieving similar events until one is found for which time information has been stored. An inference is then made on the basis of this information.

Both the Huttenlocher and Kemp theories are typically construed as location-based theories because they rely on the retrieval of time information (i.e., a location in time) and inference proceeds on the basis of that information. However, another possibility is that the time information to which they refer evolves in a continuous fashion on multiple
time scales simultaneously. This kind of model is commonly employed to account for grouping effects in short term serial recall (e.g., Henson, 1998). Furthermore, it is possible that what is retrieved from memory is a combination of specific content on which conscious inferences can be drawn (location-based) and this more graded hierarchical form of context (distance-based).

Although it has long been argued that memory research that is focused solely on laboratory work is futile (Neisser, 1976), the difficulty has been how to proceed when the experience of the participant before they enter the laboratory cannot be rigorously captured. Today, however, technology provides us with entirely new options. Easy to carry and able to monitor multiple sensor streams, smartphones can provide a convenient and ubiquitous window into the events of the life of an individual. We had participants wear a phone around their necks for two weeks and collected image, audio, GPS and accelerometry data. We then developed a hierarchical Bayesian model to capture distance and location based processes.

## Method

## Participants

A total of 18 adult participants were recruited from flyers posted at the University of Newcastle and received \$100 compensation.

## Procedure

In prior work, we built a system that consists of an Android app, server infrastructure and user interfaces. The app acquires image, time, audio (obfuscated), GPS, accelerometer and orientation information at approximately five minute time intervals. The app runs in the background as a service and users carried the phone in a pouch attached to a neck strap from morning till evening (see Figure 1). Participants could turn off the app anytime they needed privacy. When the phone detects WiFi and is charged, it sends the stored data automatically to a remote server. This usually happened once per day at the end of the day when users charge the phone overnight.

Participants were instructed to wear the phone for two weeks. They returned to the laboratory on the Friday of the 3rd week and were presented with images one at a time and were required to determine on which of the week days each image was taken (participants were informed that the images only came from the week days). Each participant's test was based on images drawn from their own lifelogs. We selected images that came from distinct episodes as much as possible, and also avoided using images that were blurred due to excessive motion. The number of stimuli varied between participants since the available data depended on individual lifestyles. A presented image remained on the screen while they made the day judgment and they could use as much time as they needed to respond.

Figure 1. Android phone worn by a participant during the experience sampling phase of the study.

## Modeling

To account for people's judgements, we proposed a mixture model of four processes - (1) random (uniform) guessing, (2) a signal detection process based on decaying memory strength (distance), (3) a week confusion process (location) and (4) a event confusion process (location) in which the sensor streams were used to calculate the similarity of events. We start by describing the distance and location (sensor) models and then outline the mixture model incorporating all four processes.

## Distance model

Figure 2 depicts the distance based model we employed. Mean memory strength $(\mu)$ elicited at retrieval was assumed to decay exponentially with scale, $\alpha$, asymptote, $\beta$, and rate, $\lambda$. Variability around this mean was assumed to be Gaussian with standard deviation, $\sigma$. The probability of a response occurring given that the presented stimulus was taken on a given day, is given by the probability density that falls between criteria that separate it from the neighbouring days.
The nine criteria that determined the response probabilities for each day were fixed to the mid-point of $\mu$ values of each neighbouring day (to alleviate sampling issues that resulting from attempting to estimate these as free parameters). We used Bayesian hierarchical modeling to fit the model, with each individual's parameters being constrained by a group level distribution. All parameters were sampled on a double infinite scale, meaning that we sampled the inverse Probit of $\alpha$ and $\beta$, and the natural logarithm of $\lambda$ and $\sigma$, and that all group level distributions were, therefore, normal.

Figure 2. The distance based model.

## Location (sensor) model

The location (sensor) model assumed that events were stored in memory and that the likelihood of confusing the representation of the correct event with the stored representation of another event is determined by the similarity of those events. Each day was divided into hour periods and image, GPS, audio and accelerometry representations of those events were calculated. For a given sensor stream the distance of an image's event to a given day for a given stream was taken to be the minimum Jenson Shannon distance from the event to the events of that day (see Figure 3).

Figure 3. The sensor model.
These distance scores for each of the streams entered into a conditional logit model to determine the probability that the participant would respond with a given day. Missing data
were assumed to have a prior of a truncated normal distribution.
Like the distance model, the parameters were estimated in a hierarchical fashion, with the natural logarithm of the weights being estimated, making the group-level distributions normal.

## Mixture model

To estimate the probability of a participant's response we assumed a mixture model of the distance and location (sensor) models described previously as well as a random (uniform) guessing model and a location (week) model that assumed that participants correctly inferred the day of the week on which the event occurred, but had a certain probability of incorrectly determining the week (the kind of model that one might assume if people are relying on their schedules to make judgements).

A model selection exercise testing all possible subsets of the processes was conducted using the common model selection metric WAIC, which attempts to weigh both the goodness of fit to the data and the complexity of the model, in order to approximate the leave-one-out cross validation metric. The preferred model was the location (sensor) model although the location (sensor) + random model also performed well (see Table 1).

Table 1: Models tested and corresponding WAICs

| Model | WAIC |
| :--- | :---: |
| Location (sensor) | -1544 |
| Location (sensor) + Random | -1546 |
| Location (sensor) + Distance | -1557 |
| Location (sensor) + Distance + Random | -1565 |
| Distance + Random | -1649 |
| Location (week) + Random | -1958 |
| Distance + Location (week) | -2161 |
| Random | -2544 |
| Distance | -2688 |
| Distance + Location (week) + Random | -2812 |
| Location (week) | $-\infty$ |

To understand the performance of the models, it is useful to compare the posterior confusion matrices they produce to the data. Figure 4 shows the confusion matrix of responses accumulated over participants. The x -axis show the days on which the events actually occurred, and the $y$-axis shows the participants' responses. The diagonal represents correct responses, while responses off the diagonal are errors. The matrix is dominated by correct responses, with cells close to the major diagonal (representing adjacent days) showing significant mass particularly in week one.

Figure 4. Data confusion matrix

Figure 5. Distance only confusion matrix
The distance only model is able to explain the structure off the diagonal by estimating a large standard deviation for the strength distributions (see Figure 5). However, a large standard deviation prevents the model from capturing the proportion of correct responses on the diagonal.
The distance model performs much better when it is mixed with the uniform distribution (see Figure 6). The structure off the diagonal is captured by the uniform component, while the structure on and adjacent to the diagonal is captured by the distance model. The observation that counts adjacent to the diagonal are larger in week one is accommodated naturally by the model because in the first
week the gradient of the strength is small, which makes it more difficult to distinguish between adjacent days.

Figure 6. Distance + Random confusion matrix

The week only model does poorly. The model assigns no probability to cells that are neither on the diagonal nor exactly a week out (the off diagonals five above and below the main diagonal). As there are observations in those cells, the WAIC is negative infinity. When mixed with the random model, the model does better, but still has a tendency to predict more week out responses than appears in the data (see Figure 7).

Figure 7.: Week + Random confusion matrix

Figure 8. Sensor confusion matrix

The best model is the sensor model (see Figure 8). Unlike the distance and week models the sensor model did not require the random component in order to provide a good fit to the data. In fact, adding the random component decreases the WAIC slightly as the model is penalized for additional complexity (i.e. the mixture probability). While the distance and week models are informed only by the day on which the event occurred, the sensor model constructs a representation of the event that captures where the participant was (GPS), what the participant was hearing (audio), what the participant was doing (accelerometry) and what the participant was seeing (images) and compares it with representations of all other events. The importance of these features can be inferred from the weights associated with each of the data streams.

Figure 9. The posterior distributions of the sensor weights.

Figure 9 shows the posterior distributions of these weights. The GPS stream has the strongest weights followed by the audio stream and the accelerometry stream, which are approximately equal. The image stream has the lowest weights. That the image stream should have the lowest weights is counter intuitive. The participants are presented with the image as a retrieval cue, and so one might have expected the visual information to be salient.

There are multiple possible interpretations of this result. It may be that the image representation that we chose (GIST; Oliva \& Torralba, 2001) does not carry the information that participants rely upon when making memory judgements. Another possibility is that it is the static nature of the images or the fact that they are not synchronized with the direction of gaze that compromised this stream. While head mounted video technologies exist they are currently difficult to deploy for the duration of recording required for the time scales we explore here. Furthermore, they introduce additional ethical hurdles that need to be considered. A third possibility is that the result is not artifactual, but is a reflection of the information employed by the memory system. While the visual domain seems salient perhaps it is other aspects of experience that drive the retrieval and inferential systems that people employ to make location based judgements.

## Conclusions

When people are asked to determine when an event occurred, Friedman (2004) argues that people use a combination of distance based and location based processes, with location based processes being the most common. The current work supports this assertion.

Furthermore, we have demonstrated that it is possible to predict the responses people will make to images taken from their personal experience in the world outside the laboratory on a stimulus by stimulus basis. We believe this work establishes a new benchmark for what models of episodic memory should achieve and provides the promise of a more quantitatively rigorous, ecologically valid and translationally relevant memory science.

# Refixations gather new visual information rationally 

Yunyan Duan (yduan@u.northwestern.edu) and Klinton Bicknell (kbicknell@ northwestern.edu)<br>Department of Linguistics, Northwestern University<br>Evanston, IL 60201 USA

#### Abstract

The standard model is that word identification in reading is a holistic process, most efficient when words are centered in the visual field. In contrast, rational models of reading predict word identification to be a constructive process, where readers efficiently gather visual information about a word, and may combine visual information about different parts of the word obtained across multiple fixations to identify it. We tease apart these accounts by arguing that rational models should predict that the most efficient place in a word to make a second fixation (refixation) depends on the visual information the reader has already obtained. We present evidence supporting this prediction from an eye movement corpus. Computational model simulations confirm that a rational model predicts this finding, but a model implementing holistic identification does not. These results suggest that refixations can be well understood as rationally gathering visual information, and that word identification works constructively.

Keywords: eye movements; reading; word identification; rational analysis; refixation

## Introduction

Reading is a complex information processing task with a goal usually related to comprehending the text. In general, accurate text comprehension requires the identification of many (if not most) of the words in a text. It is not surprising, then, that decades of research on eye movements in reading have established that word identification can be seen as the primary driver of eye movements (Rayner, 1998). A substantial body of work has studied the role in this process of many information sources relevant to word identification in reading, including especially word frequency and in-context predictability, among others. However, although visual information is the primary source of information used to ultimately identify a word, the fundamental way in which visual information is used in word identification remains unresolved.

In the standard model of word identification in reading, word identification is hypothesized to be a holistic process, during which visual information about the word as a whole constrains the efficiency of identification. Eye movement studies have shown that a word presented in isolation is most rapidly identified when fixating approximately at its center (O'Regan, 1990, 1992). It has also been found in natural reading that the fixation position that minimizes gaze duration (the total amount of time spent fixating a word in first pass) and refixation probability (the probability of making more than one fixation on a word in first pass) is on average at or slightly left of the center (Rayner, Sereno, \& Raney, 1996). One explanation for these results is that when the word center is directly fixated, the largest possible part of the word falls in the central high-acuity portion of the visual field (the fovea), yielding the highest-quality visual input of the whole word; as the fixation deviates from the center, more letters of the word fall out of
the fovea and suffer from a rapid drop in acuity, leading to poorer visual information about the overall word. Following this interpretation, it is hypothesized that visual processing efficiency of a word is maximized when fixating at word center, and decreases with increasing distance between word center and fixation position. This standard holistic account is incorporated in dominant eye movement models of eye movement control in reading (e.g. E-Z Reader, Reichle et al., 2009; and SWIFT, Engbert et al., 2005).

Alternatively, word identification may not utilize visual information holistically, especially in natural reading. Unlike in isolated word identification where information about a word comes only from visual input obtained by directly fixating it, in natural reading information about a word comes from more sources. These include contextual information from the preceding text and visual information obtained from fixations close to but not on the current word, which may still yield some visual preview of the word's initial letters. As a result, the most efficient positions from which to obtain useful new visual information about the word can vary from trial to trial, dependent on the information already obtained. Even in such an account, it is still possible that, on average, the most efficient positions are located near the center (as has been found in prior work). This account of word identification is implemented in rational models, which consider reading as a process of combining information from various sources to identify words and making eye movement decisions to maximize identification efficiency (Bicknell \& Levy, 2010, 2012; Legge et al., 1997, 2002). For example, if a reader in this framework is working to identify a particular word, considering all the information that has already been gathered, there may be parts of the word that the reader has already identified relatively well and parts that are still relatively uncertain. It is intuitive in such a situation that identification efficiency will be maximized by moving the eyes next to the part of the word about which the reader is still relatively uncertain. This is because such fixations would obtain fine-grained visual information of a particular part of the word, which can be combined with visual information obtained from previous fixations (as well as linguistic contextual information), and identify the word in a constructive manner. Thus, contrary to the holistic account's view that any fixation landing on a non-central position slows identification efficiency relative to a central fixation, the view from rational models is that the position in the word to move the eyes next to maximize identification efficiency will vary from trial to trial and depend on information already obtained.

A phenomenon that can be used to tease apart these two accounts is that of refixations, cases in which a word is fixated more than once during first-pass reading. The goal of an in-
tended refixation is assumed to be moving the eyes to a position that will maximize identification efficiency of the current word. Despite previous experiments showing that refixation rate varied on average as a quadratic function of the distance between word center and the fixation position (McConkie, Kerr, Reddix, Zola, \& Jacobs, 1989) and was influenced by linguistic properties such as word frequency (Rayner et al., 1996), few studies shed light on where refixations go. The two accounts of word identification make different predictions for this question. The rational model predicts that refixations target the part of the word about which sufficient information has not yet been obtained. Which part of the word this is depends on the visual information already available. ${ }^{1}$ In contrast, the standard model of word identification predicts that refixations should always target the center to maximize the holistic visual processing efficiency of the word, independent of information obtained about different parts of the word.

Naively, then, we could tease apart these two hypotheses by analyzing the relationship between the position of the initial fixation on a word (the 'landing position') and the refixation position. The rational account would predict that if the landing position is at the beginning of the word, a refixation should be at the end, and vice versa, whereas the standard model would predict that all refixations cluster around the center, regardless of the landing position. Empirically, this prediction of the rational models is borne out (Rayner et al., 1996), but the standard model explains this phenomenon in a different way. Specifically, there is a concept of systematic error (McConkie et al., 1988), which suggests that intended saccade sizes become biased toward the overall average saccade size. This means that refixation saccades intended to be short and target the center of the word in the standard model will tend to overshoot their target, landing on the opposite end of the word. Thus, both the standard model combined with systematic error and the rational model predict the effect of landing position on where refixations go.

Analyzing where refixations go as a function of the location of the previous fixation made before fixating a word (the 'launch site'), however, can tease apart these two accounts, when controlling for effects of landing site. If a reader's first eye movement to the word is launched from a position close to the word, then more visual information about the word's beginning should be available (relative to the launch site being further away), holding constant the landing site. Therefore, rational models predict that for closer launch sites, a refixation should be less likely to move the eyes back toward the beginning of the word (Fig. 1, right panel). In contrast, the standard model would not predict such an effect, but predict that an intentional refixation that follows a fixation on the left half of a word should always go forward, while one that follows a fixation on the right half should always go backward, always targeting the word center (Fig. 1, left panel).

[^56]

Figure 1: The standard model and the rational model make different predictions for where refixations go. For the standard model, refixations always target the center of the word, regardless of launch site. For the rational model, refixations target positions where character identity has low confidence (here represented by hypothetical $m(j)$ values). Therefore, closer launch sites, which provide more visual information about the word's initial letters (schematically represented here by grey rectangle) predict refixations are more likely to move forward. The refixation decisions here are based on eye movement policy parameters of $\alpha=.9$ and $\beta=.7$. (See Eye movement policy section for more details.)

In this paper, we empirically evaluate these two competing predictions by performing a statistical analysis of where refixations go in a large eye movement corpus, and we compare these results to simulations from computational models of both accounts. In the next section, we report the results of our statistical analysis of human refixation data, showing that it is as predicted by the rational account. We then confirm that an eye movement model that implements the standard model cannot accommodate this finding by performing simulations with E-Z Reader (Reichle et al., 2009). After that, we describe our rational model of refixations. Finally, we confirm that simulations using it show the same qualitative pattern as the human data, and then conclude.

## Experiment 1: Human data in Dundee corpus

This analysis aims to tease apart the predictions of the rational model and the standard model on where refixations go. Specifically, we use the English part of the Dundee corpus (Kennedy, 2003) of eye movements during natural reading, and analyze the direction of refixation as a function of launch site, statistically controlling for landing site.

## Methods

Data The English part of the Dundee corpus contained eye movement records from 10 native English-speaking participants as they read through newspaper editorials (see Kennedy \& Pynte, 2005 for further details.) We first did a set of screening procedures, according to criteria that are generally applied to eye movement data, to remove fixations involving blinks, non-first-pass fixations, and the first/last two fixations
of the line. After this procedure, the corpus contained 23,854 fixations that were followed by a refixation during first-pass reading ( $18.9 \%$ of first-pass fixations). These data then underwent screening procedures excluding: (a) extremely far launch sites ( $1 \%$ ), leaving the launch sites of fixations in the range $[-16,-1]$ (in terms of number of characters from word beginning); (b) fixations that landed on the space right before the word ( $25.5 \%$ ) or on the last character of the word (4.7\%) to ensure the variability of refixation directions; and (c) fixations on words of which the previous word was skipped to eliminate possible overshootings of the previous word ( $20.9 \%$ ), since these can be followed by corrective saccades. In the end, the data consisted of 7,667 fixations.

Statistical analysis A logistic generalized linear mixedeffects model (GLMM) was used to analyze the direction of refixations (forward vs. backward). Fixed effects included launch site and combinations of word length and landing site, which controlled for arbitrary effects of word length and landing site on refixation direction. Random effects included a random intercept and slope of launch site by subjects. Significance testing was via likelihood ratio test. All statistical analyses were implemented in the R environment, using the glmer function from the lme 4 package (Bates, Mächler, Bolker, \& Walker, 2015) for GLMM implementation. In order to ensure model convergence, word length-landing site pairs for which all refixations (or all but 1 ) moved in the same direction were excluded, leaving 6714 fixations ( $87.6 \%$ ).

## Results and discussion

Fig. 2 shows the effect of launch site on the probability that refixations move forward for each word length-landing site pair. The GLMM showed that nearer launch sites predicted significantly more forward refixations, $\hat{\beta}=0.15, S E=$ 0.03, $\chi_{1}^{2}=13.98, p<0.001,95 \%$ confidence interval (CI) $=[0.10,0.20]$. As reported in the following section, the standard model can accommodate this effect only for landing sites on the right half of the word. To see whether this was also true of the human data, separate analyses were carried out for fixations with landing sites on the left and the right half of the word. For the left half ( 4790 fixations), launch site predicted more forward refixations, $\hat{\beta}=0.16, S E=0.03, \chi_{1}^{2}=$ 10.91, $p<0.001,95 \% C I=[0.09,0.22]$, and the same was true for the right half ( 1362 fixations), $\hat{\beta}=0.14, S E=0.04$, $\chi_{1}^{2}=7.40, p<0.01,95 \% C I=[0.05,0.22]$. These observations that closer launch sites predicted more forward-moving refixations confirm the rational model's predictions. The separate analyses of fixations on the left and right halves of the word indicated that this effect generalized across both.

## Experiment 2: E-Z Reader

This section aims to show that the standard model does not predict the effect of launch site on direction of refixations. To this end, we carry out the same analyses as the previous section on simulation data from E-Z Reader, a computational model of eye movements in reading that incorporates the stan-

Figure 2: Effect of launch site on proportion of forwardmoving refixations on data from Dundee corpus. Each panel contains data from a combination of word length and landing position, and shows a GAM smoother.
dard holistic model of word identification, and always targets refixations to the center of words. In principle, then, all intentional refixations following a fixation on the left half of the word should move forward and those following a fixation on the right half should move backward. Simulations with an implemented version of this model help to ensure that unintentional refixations - saccades intended for another word that happen to become a refixation due to motor error - do not in general change these predictions.

## Methods

Data We used E-Z Reader 10 (Reichle et al., 2009) to generate eye movement data for 100,000 virtual readers reading sentences from the Schilling corpus (Schilling, Rayner, \& Chumbley, 1998) of single English sentences typical of reading experiments. Each virtual reader was a simulation completed using a Monte Carlo run of the model.

The data cleansing procedure was the same as that in Expt. 1. Out of the 20, 189,603 first-pass fixations, $3,417,999$ ( $16.9 \%$ ) of them were followed by a refixation. Excluding extreme launch sites, fixations landing on initial or final letters of a word, and skipping of the previous word left $1,029,801$ fixations. Launch site ranged between $[-15,-1]$.

Statistical analysis A generalized linear model (GLM) with the same fixed effects as that in Expt. 1 was adopted to analyze the effect of launch sites on refixation direction. Random effects were removed from the GLMM used for Expt. 1 since the virtual readers were simply different Monte Carlo runs with no systematic differences. Excluding word length-landing position pairs where all refixations (or all but 1) moved in the same direction left 899,838 fixations ( $87.4 \%$ ).

## Results and discussion

Fig. 3 shows the effect of launch site on the probability for refixations moving forward. The GLM showed that nearer
launch site predicted significantly more forward refixations, $\hat{\beta}=0.08, S E=0.004, \chi_{1}^{2}=386.66, p<0.001,95 \% C I=$ [ $0.07,0.09]$. However, this effect was driven by fixations landing on the right half of the word, $\hat{\beta}=0.10, S E=0.004$, $\chi_{1}^{2}=542.99, p<0.001,95 \% C I=[0.09,0.11]$, while fixations landing on the left half had $99 \%$ refixations moving forward and yielded an opposite effect, $\hat{\beta}=-0.33, S E=0.03$, $\chi_{1}^{2}=147.37, p<0.001,95 \% C I=[-0.39,-0.27]$.

Therefore, E-Z Reader does not in general predict that closer launch sites should lead to refixations being more likely to go forward, contrary to our observations on the human data, although it can accommodate such a prediction for fixations on the right half of the word. Although this effect on the right half of the word may seem surprising, we note that the predictions we described above for this account only hold for intentional refixations. We believe that this effect on refixations on the right half of the word arises from unintentional refixations. Specifically, for a fixation position on the right half of a word, the E-Z Reader model will generally execute one of two behaviors: initiating a saccade to refixate the word or initiating a saccade to move on to the next word. In this case, an intended refixation will target a leftward position (since the center of the word is to the left of fixation) and an intended saccade to the next word will target a rightward position. Which of these two behaviors occurs depends on how quickly the identification (or more technically, $L_{1}$ ) is completed for the current word. Closer launch sites mean that identification of the word will be completed more quickly, which in turn will lead to a greater chance of making a forward saccade intended for the next word. Assuming some of these forward saccades become unintentional forward refixations, this creates exactly the predicted relationship between launch site and refixation direction. For the present purposes, however, the main conclusion here is that the standard model cannot reproduce a general effect of launch site on refixation direction.

## Rational models of reading

In this section, we describe an implemented rational model of refixations, which we will use in the next section to confirm that the intuitively-derived predictions of the rational account for the relationship between launch site and refixations are actually produced by an implemented rational model. Rational models of reading use Bayesian inference to combine visual information with language knowledge (e.g., contextual information). Based on the posterior distribution, eye movements are selected to maximize identification efficiency. The rational model of refixations we describe in this paper also follows this idea, and can be viewed as an application of the more general-purpose rational models of eye movements in reading to the specific situation of refixations. This section introduces the framework of our model.

## Word identification as Bayesian inference

Word identification consists of Bayesian inference, in which a prior distribution over possible identities of the text given by

Figure 3: Effect of launch site on proportion of forwardmoving refixations in data from E-Z Reader simulation. Each panel contains data from a combination of word length and landing position and shows a GAM smoother.
its language model is combined with a likelihood term given by 'noisy' visual input at the position of fixation to form a posterior distribution over the identity of the text given all information sources. Formalized with Bayes' theorem,

$$
\begin{equation*}
p(w \mid \mathcal{I}) \propto p(w) p(\mathcal{I} \mid w) \tag{1}
\end{equation*}
$$

where the probability of the true identity of the word being $w$ given uncertain visual input $\mathcal{I}$ is calculated by multiplying the language model prior $p(w)$ with the likelihood $p(\mathcal{I} \mid w)$ of obtaining this visual input from word $w$, and normalizing.

In general, the prior $p(w)$ represents reader expectations for words conditioned on the context, but for the present paper, we ignore context and use only a word frequency model for simplicity. The visual likelihood is computed similarly to in Bicknell and Levy (2010): each letter is represented as a 26-dimensional vector with a single element being 1 and the rest being 0s. Visual input about each letter is accumulated iteratively over time by sampling from a multivariate Gaussian distribution centered on that letter with a diagonal covariance matrix $\Sigma=\lambda^{-1} I$, where $\lambda$ is the reader's visual acuity for that letter. Visual acuity depends on the location of the letter in relation to the point of fixation, which is a function of the letter's eccentricity $\varepsilon$. In our model, we assumed that acuity is a symmetric, exponential function of eccentricity:

$$
\begin{equation*}
\lambda(\varepsilon)=\int_{\varepsilon-.5}^{\varepsilon+.5} \frac{1}{\sqrt{2 \pi \sigma^{2}}} \exp \left(-\frac{x^{2}}{2 \sigma^{2}}\right) d x \tag{2}
\end{equation*}
$$

with $\sigma=3.075$, the average of two $\sigma$ values for the asymmetric visual acuity function ( $\sigma_{L}=2.41$ for the left visual field, $\sigma_{L}=3.74$ for the right visual field) used in Bicknell and Levy (2010). In order to scale the quality of visual information, we multiply each acuity $\lambda$ by the overall visual input quality $\Lambda$, which is set to 12 in our simulation (see Expt. 3 below).

## Eye movement policy

Based on the posterior distribution on possible identities of the word, eye movement decisions are selected to maximize reading efficiency. For example, the first rational model of reading, Mr. Chips, used this optimizing principle: the model reads input text sequentially, without error, in the minimum number of saccades (Legge et al., 1997, 2002). Specifically, saccades were made to minimize the expected entropy of the current word after the next fixation.

In a more recent rational model of eye movements in reading (Bicknell \& Levy, 2010, 2012), eye movement decisions depend on the uncertainty of the posterior distribution about each letter position. Specifically, given a fixation landing on an unknown character $c$ in position $j$, the marginal probability $m$ of the most likely character under the posterior is

$$
\begin{equation*}
m(j)=\max _{c} p\left(w_{j}=c\right) \tag{3}
\end{equation*}
$$

where $w_{j}$ indicates the character in position $j$. A high value of $m(j)$ indicates relative confidence about the character's identity, and a low value relative uncertainty. The model then decided between four possible actions based on $m(j)$ : continuing to fixate the current landing position, moving backward, moving forward, and ending the reading process.

We use a similar eye movement policy in our refixation model. If the value of the aforementioned statistic $m(j)$ is less than a parameter $\alpha$, the model chooses to continue fixating the current position. Otherwise, if the value of $m(j)$ is less than the parameter $\beta$ for some leftward position, the model initiates a saccade to the closest such position. If no such positions exist to the left, then the model initiates a saccade to the closest position to the right for which $m(j)<\alpha$. Once a refixation is executed, the simulation ends. If all $m(j)$ values to the right (left) are above $\alpha(\beta)$, we decide this word is identified with a satisfactory uncertainty level, and the identification of this word ends. In such a situation, we expect that the eyes move to the next word, which is beyond the current paper's scope of studying refixations.

The actual landing position is the intended fixation position with random motor error: the actual landing position $\ell_{i}$ is sampled from a Gaussian centered on the intended target $t_{i}$ with standard deviation given by a linear function of the intended saccade distance

$$
\begin{equation*}
\ell_{i} \sim \mathcal{N}\left(t_{i},\left(\sigma_{0}+\sigma_{1}\left|t_{i}-\ell_{i-1}\right|\right)^{2}\right) \tag{4}
\end{equation*}
$$

for some linear coefficient $\sigma_{0}$ and $\sigma_{1} .{ }^{2}$ In Expt. 3 in this paper, we follow the SWIFT model in using $\sigma_{0}=0.87, \sigma_{1}=0.084$. A refixation occurs if the actual landing site of the next fixation falls on the same word.

## Experiment 3: Rational model

In this section, we analyze simulated data from our rational model of refixations to verify that it does indeed make the

[^57]prediction that we derived from it intuitively: that refixations would be more likely to move forward for closer launch sites. As described in the previous section, the rational model of refixations we use combines information from previous fixations (including the launch site) to form a posterior distribution on the identity of a word through Bayesian inference. It then makes refixation eye movements to parts of the word about which it is uncertain.

## Methods

Model parameters For the language model component of the word identification model (the prior), we used word frequency information (a unigram model) from the Corpus of Contemporary American English (COCA) (Davies, 2016). For this simulation, we did not optimize the behavior policy parameters to maximize reading efficiency as in Bicknell and Levy (2010), but set them manually to what we surmised might be reasonable values of $\alpha=0.9$ and $\beta=0.7$. Future work will optimize them, but we do not expect the qualitative predictions relevant to this analysis to change.

Data Eye movement data were generated to identify a word. All words were in the most frequent 5,000 words in COCA, and word lengths ranged between [ 3,10$]$. Launch site had a range of $[-10,-1]$. For each word length, each possible landing position, and each launch site, 200 trials were run to model the word identification process as when a fixation landed on that landing position, preceded by a fixation on that launch site. In each trial, a word was randomly selected uniformly from words with the same length.

Procedure Each trial began with a fixation with a duration of 200 time steps on the launch site, in order to represent the visual information obtained prior to fixating the word. Then, the fixation at the landing site began. On each timestep of that fixation, visual information was obtained and integrated with prior information to update the posterior, and then a behavior decision was made: whether to continue fixating, make a refixation, or stop reading (see model description).
Statistical analysis A GLM with the same fixed effects as that in Expt. 2 was adopted to analyze the effect of launch site on refixation direction. Excluding word length-landing position pairs where all refixations (or all but 1) moved in the same direction left 25,636 fixations.

## Results and discussion

Fig. 4 shows the effect of launch site on the probability for refixations moving forward. As expected, the GLM showed that nearer launch site predicted significantly more forward refixations, $\hat{\beta}=0.07, S E=0.005, \chi_{1}^{2}=187.62, p<0.001$, $95 \% C I=[0.06,0.08]$. The same pattern held for both data with landing positions on the left half of the word, $\hat{\beta}=0.04$, $S E=0.008, \chi_{1}^{2}=28.85, p<0.001,95 \% C I=[0.02,0.06]$, and the right half, $\hat{\beta}=0.12, S E=0.009, \chi_{1}^{2}=179.38, p<$ $0.001,95 \% C I=[0.10,0.14]$. These results confirm that an implemented rational model does indeed make this predic-

Figure 4: Effect of launch site on proportion of forwardmoving refixations in data from rational model simulation. Each panel contains data from a combination of word length and landing position and shows a GAM smoother.
tion, which we observed in Expt. 1 to hold of human data.

## General discussion

In this paper, we investigated how visual information is used for word identification during natural reading. We compared two accounts: (1) the standard holistic model, in which visual information about the word as a whole is used in word identification, and processing is always most efficient from the center; and (2) a rational model, in which readers combine information from many sources to identify a word constructively, and the fixation location that maximizes identification efficiency depends on what prior information has been obtained. We suggested that these two models make divergent predictions for the possible effects of launch site on where refixations go. Specifically, only the rational model should predict that refixations are more likely to go rightward for closer launch sites. An analysis of a large human eye movement corpus confirmed that this prediction of the rational account holds in human data. Model simulations confirmed that a rational model does indeed predict it, and that at least one of the implementations of the standard model (E-Z Reader) could not accommodate this finding.

These findings seem strongly inconsistent with models in which all intentional refixations target the center of a word, which in turn suggests that the standard holistic model of word identification in reading may be incorrect. However, it is possible to imagine that other refixation targeting schemes could be used even if the holistic model of word identification in reading is correct. For example, even under the standard model, it might be a useful strategy to target a refixation further forward in a word when that word is closer to being identified. Even if there is an efficiency penalty for being away from the center while that word is finished being identified, that penalty might be outweighed by the benefits of being closer to the next word when the reader's attention
(soon) turns to it.
While it's possible that such eye movement models could be constructed while maintaining the standard model of word identification, our findings are completely consistent with the predictions of rational models of reading, and suggest that these models should be more fully explored. Here, we focused specifically on how visual information already obtained about a word influences where refixations should go, but rational models predict that the interaction of visual and linguistic information is what should ultimately matter. Future work should test these more complex predictions.

#### Abstract

We present a rational analysis of curiosity, proposing that people's curiosity is driven by seeking stimuli that maximize their ability to make appropriate responses in the future. This perspective offers a way to unify previous theories of curiosity into a single framework. Experimental results confirm our model's predictions, showing how the relationship between curiosity and confidence can change significantly depending on the nature of the environment.

Keywords: curiosity; rational analysis; computational model

## Introduction

In 1928, upon returning from a vacation, Alexander Fleming, who was a professor of Bacteriology at St. Mary's Hospital in London, noticed how a mold floating in one of his dirty petri dishes held the surrounding bacteria at bay. This peculiar event led him to develop a hypothesis that would be a prelude to the development of penicillin. The history of science abounds with incidents in which an event piqued the curiosity of a scientist thereby leading to important discoveries (other examples include Curie, Faraday, and Planck). For this reason, intellectual curiosity has long been recognized as the essence of science. In fact, Herbert Simon famously titled a 1992 talk given at Carnegie Mellon as 'The cat that curiosity couldn't kill' and described curiosity to be not only the beginning of all science, but also its end (Gobet, 2016).

Considering how important curiosity is to scientific discoveries and many other aspects of cognition, it is surprising that our understanding of curiosity as a psychological phenomenon remains quite limited (Simon, 2001; Gottlieb et al., 2013; Kidd \& Hayden 2015). Encouragingly, the field has seen a revived interest in curiosity in recent years with psychologists and neuroscientists beginning concentrated efforts to study curiosity systematically (Kang et al, 2009; Gruber, Gelman, \& Ranganath, 2013; Law et al., 2016; Walin, O’Grady \& Xu, 2016). However, much previous work on curiosity has either focused on defining a taxonomy for curiosity or providing a mechanistic explanation of curiosity (Kidd \& Hayden, 2015). This means that while we have made some progress describing the psychological processes involved in human curiosity, we have not satisfactorily provided an explanation of the purpose and function of curiosity. For example, a commonly held notion about the function of curiosity is that it motivates learning (Loewenstein, 1994; Kidd \& Hayden, 2015). Although it is easy to say that learning is the goal of curiosity, this is not very precise in its meaning. How does curiosity facilitate learning? Why does it do so?

In light of this, in this paper we present a rational analysis of curiosity in the spirit of Anderson (1990) and Marr
(1982) with the goal of providing a purposive explanation of curiosity. Our work shows that a rational analysis can predict many aspects of curiosity without making assumptions about its mechanisms. We start by defining an abstract representation of the problem that curiosity solves and making a small number of assumptions about the nature of the environment. Following that, we explore the optimal solution to this problem in light of these assumptions. Our theory posits that people are curious about stimuli that maximally increase the usefulness of their current knowledge. Depending on the structure of the environment, the stimuli that maximize this value can either be ones that are completely novel or that are of intermediate complexity. As a consequence, our rational analysis provides a way to unite previously distinct theories of curiosity into a single framework.

The rest of the paper is structured as follows. We first review previous theories of curiosity and then introduce our rational model of curiosity. Following that, we show how our model offers support to previous distinct accounts of curiosity thereby unifying them in a single model. We then conduct a behavioral experiment to test our model's predictions and evaluate how our model accords with human curiosity. We close with a discussion of the implications of our results.

## Models of curiosity

A number of theories have been proposed in the past to describe the psychological processes involving curiosity. In this section, we describe these theories in brief and provide their individual strengths and weaknesses.

Curiosity based on novelty. Several psychological theories have linked curiosity with novelty by hypothesizing that gaining information about novel stimuli is intrinsically rewarding (Berlyne, 1950; Smock \& Holt, 1962). Berlyne (1960) called this "perceptual curiosity" and described it as a driving force that motivates an organism to seek out novel stimuli which diminishes with an increase in exposure. This has also been supported by some neuroscientific studies that show that novel stimuli activate reward-responsive areas in the brain (Ranganath and Rainer, 2003; Düzel et al., 2010). However, a severe limitation of this theory is that it assumes that it is optimal for an individual to explore novel stimuli in all environments. A novel stimulus doesn't necessarily mean that it contains information that is useful or generalizable to an individual. This is also pointed out by previous studies that show that exploration based only on novelty could lead agents to be trapped in unlearnable situations (Gottlieb et al., 2013).

Curiosity based on information-gap. One of the most popular theories of curiosity is the information-gap hypothesis proposed by Loewenstein (1994). According to the information-gap hypothesis, curiosity arises whenever an individual has a gap in information prompting it to complete its knowledge and resolve the uncertainty. Thus, curiosity peaks when one has a small amount of knowledge but it diminishes when one knows too little or too much about the stimuli. A number of studies have supported this prediction and showed that curiosity is an inverted $U$-shaped function of confidence, with people showing the highest curiosity for topics that they were moderately confident about (Kang et al., 2009; Baranes, Oudeyer, \& Gottlieb, 2015). Berlyne (1960) called this form of curiosity "epistemic curiosity" and described it as a drive to acquire knowledge. While this theory has considerable strengths, it is also constrained in that an individual can only be curious about stimuli in known contexts. Thus, if an individual has no prior knowledge about stimuli in the environment then it is not clear how curiosity will function in that environment (as one will not be curious about any stimuli in an environment that it has no prior knowledge of).

Curiosity based on learning progress. A third theory concerning curiosity is guided by the hypothesis that learning progress generates intrinsic reward (Schmidhuber,1991; Schmidhuber, 2010). This hypothesis proposes that the brain is intrinsically motivated to pursue tasks in which one's predictions are always improving. Thus, an individual will not be interested in tasks that are too easy or too difficult to predict but will rather focus on tasks that are learnable. Based on Schmidhuber's framework, a number of papers in developmental robotics have supported this idea showing how an agent can explore in an unknown environment (Oudeyer \& Kaplan, 2006; Oudeyer, Kaplan, \& Hafner, 2007). While this theory can probably describe some forms of curiosity, it is again constrained in explaining curiosity in certain environments. For example, if an agent is ever present in an environment that has many difficult tasks then it is not clear how curiosity will work (as an agent will not be curious about anything within that environment).

Summary and prospectus. While each of these theories have their strengths, we first note that all the above theories are concerned with describing how curiosity functions and how it relates to different psychological factors. However, none of these theories satisfactorily provide an explanation as to why curiosity works the way it does. Second, we believe that all these theories need not be in contention but are all rather special cases of curiosity. As we will describe in the rest of the paper, our rational model supports each of these theories and unifies them in one common model.

## Rational model of curiosity

In this section, we detail our rational model of curiosity. We first consider the abstract computational problem underlying curiosity and then formally derive an optimal solution to this problem.

## Computational problem underlying curiosity

Suppose that an agent is in an environment with $n$ stimuli, each of which provides a reward if the appropriate response is produced. The goal of the agent is to decide what to explore in the environment in order to maximize its knowledge and hence maximize rewards in the future.

The environment determines the probability with which each stimulus occurs in the environment. Let $p_{k}$ denote the "need probability" that a stimulus $k$ will occur in the future (Anderson, 1990). Given this, the agent assigns a confidence value $c_{k}$ to each stimulus in the environment. $c_{k}$ denotes the probability the agent knows the correct response to the $k$ th stimulus. This probability increases at a decreasing rate with respect to the number of exposures $h_{k}$ with that stimulus. $h_{k}$ denotes the number of times the agent has been exposed to the $k$ th stimulus. For convenience, we describe the relationship between $c$ and $h$ by a bounded growth function,

$$
\begin{equation*}
c_{k}=1-e^{-h_{k}} \tag{1}
\end{equation*}
$$

However, our predictions hold for any monotonically increasing function.

Next, the agent computes the value of its overall knowledge. The value, denoted as $V$, is a function of the need probability $p$ and the confidence factor $c$ and is given as follows:

$$
\begin{equation*}
V=\sum_{k} p_{k} \cdot c_{k} \tag{2}
\end{equation*}
$$

According to this equation, the value of an agent's knowledge is simply the chance of successfully responding to the next stimulus computed by summing over all stimuli in the environment.

The goal of the agent is to increase the value of its current knowledge $V$, which it can do so by taking actions to increase $h$ for the various stimuli in the environment. So the computational problem that the agent has to solve is choosing which stimulus to explore further i.e. deciding which stimulus $k$ to increase $h_{k}$ for.

## Deriving an optimal solution

To solve the problem of choosing which stimulus to explore further, the agent can evaluate the change in $V$ as it explores each stimulus in the environment. Thus for every stimulus $k$ in the environment, the agent should compute the change in its knowledge that would result from exploring that stimulus. The stimulus that causes the largest increase in the overall value should be explored first. This computation can be done simply by differentiating $V$ with respect to $h_{k}$,

$$
\begin{equation*}
\frac{\mathrm{d} V}{\mathrm{~d} h_{k}}=p_{k} \cdot \frac{\mathrm{~d} c_{k}}{\mathrm{~d} h_{k}} . \tag{3}
\end{equation*}
$$

An agent operating according to this model will explore stimuli that have a high rate of change of value w.r.t exposure associated with them. This rate of change, i.e. $\frac{\mathrm{d} V}{\mathrm{~d} h_{k}}$, is simply the curiosity the agent has for knowing the $k$ th item, which we

Figure 1: Relationship between need probability $p_{k}$, exposure $h_{k}$, and confidence $c_{k}$ in different environmental structures. Graph 1 shows an environment in which need probability is related to exposure and subsequently confidence. Graph 2 shows an environment in which need probability is independent of exposure and confidence.
denote as $\Omega_{k}$. The agent will explore stimuli in the environment that it is most curious about. In this way, curiosity helps the agent to achieve its goal of maximizing its knowledge.

Under the choice of the form of $c_{k}$ given in Equation 1, we calculate this derivative as follows:

$$
\begin{equation*}
\Omega_{k}=p_{k} \cdot \frac{\mathrm{~d}\left(1-e^{-h_{k}}\right)}{\mathrm{d} h_{k}} . \tag{4}
\end{equation*}
$$

Upon differentiation, we get the relationship of curiosity $\Omega_{k}$, with respect to need probability $p_{k}$ and exposure $h_{k}$ as follows:

$$
\begin{equation*}
\Omega_{k}=p_{k} \cdot e^{-h_{k}} \tag{5}
\end{equation*}
$$

## Relationship to previous models

Having a formal account of curiosity, we now describe how our model relates to previous theories of curiosity.

First, we note that in our rational model framework, two different forms of environmental structure can exist. The first form comes in when the agent is an environment where $p_{k}$ is related to $h_{k}$ (as described in Graph 1, Figure 1). In this environment, stimuli frequently encountered by an agent are more likely to be needed in the future. Thus, the probability that the agent will require a stimulus in the future determines the number of times the agent is exposed to the stimulus which in turn determines the confidence of the agent in knowing that stimulus. The second form comes in when the agent is in an environment where $p_{k}$ and $h_{k}$ are independent of each other (as described in Graph 2, Figure 1). In this environment, the agent can encounter any stimulus in the future regardless of their previous occurrence.

Novelty based curiosity. According to theories that are based on curiosity driven by novelty, an agent is most curious
about stimuli that it is least confident about:

$$
\begin{equation*}
\Omega_{k}=1-c_{k} . \tag{6}
\end{equation*}
$$

According to our rational model, when the agent is in an environment where $p_{k}$ and $h_{k}$ are independent of each other (as described in Graph 2, Figure 1), the relationship between curiosity and exposure will be the one described in Equation 5 where $p_{k}$ is simply a constant value. Thus, curiosity is highest when exposure is lowest and it decreases as exposure increases i.e. curiosity is highest for novel stimuli. The relationship between curiosity and confidence can be rewritten as

$$
\begin{equation*}
\Omega_{k}=p_{k} \cdot\left(1-c_{k}\right) \tag{7}
\end{equation*}
$$

If $p_{k}$ is equal for all $k$, this reduces to Equation 6. Thus, when need probability and exposure are not related to each other, our rational model is similar to the previously proposed novelty based curiosity theory.

Information-gap hypothesis. When the agent is in an environment $p_{k}$ and $h_{k}$ are related to each other (as in Graph 1, Figure 1), then $p_{k}$ is proportional to $h_{k}$ and the relationship between curiosity and exposure given in Equation 5 reduces to

$$
\begin{equation*}
\Omega_{k} \propto h_{k} \cdot e^{-h_{k}} \tag{8}
\end{equation*}
$$

Subsequently, using Equation 1, confidence will be related to curiosity as

$$
\begin{equation*}
\Omega_{k} \propto-\log \left(1-c_{k}\right) \cdot\left(1-c_{k}\right) . \tag{9}
\end{equation*}
$$

Interestingly, this relationship between curiosity and confidence is highly similar to the one described by the information gap hypothesis. Loewenstein used Shannon's (1948) entropy formula to describe the relationship between curiosity and confidence as below:

$$
\begin{equation*}
\Omega_{k}=-\log \left(c_{k}\right) \cdot\left(c_{k}\right) \tag{10}
\end{equation*}
$$

Both the information-gap theory and our model predict that an inverted U-shape relationship exists between curiosity and confidence. In this view, when an agent exists in an environment where need probability is related to exposure, our rational model relates to the information-gap theory.

Relationship to curiosity based on learning progress. According to the learning progress hypothesis, an agent is intrinsically motivated to pursue tasks in which predictions are constantly improving thereby avoiding boring or extremely complicated tasks. An agent operating under this model ends up exploring stimuli of "intermediate complexity".

Our model proposes that an agent will explore stimuli that maximize the value of its current knowledge. In an environment where need probability and exposure are related to each other, then curiosity is highest for stimulus with moderate exposure i.e. intermediate complexity (Equation 8 and 9). Thus,

Figure 2: Relationship between a) curiosity and exposure, and b) curiosity and confidence in an environment where need probability is related to exposure (Graph 1, Figure 1).
in this environment, an agent that aims to maximize its knowledge behaves similarly to an agent whose curiosity is driven by learning progress.

Summary. Whereas previous theories associated curiosity to factors such as novelty, knowledge gap, and learnability, our model shows that depending on the structure of the environment, an agent's curiosity can be driven by any of these factors. In this way, our rational model allows to bridge previous theories related to curiosity in a single framework. In an environment where need probability and exposure are related, our rational model associates with the information gap and learning progress hypothesis. In an environment where need probability and exposure are not related, our model is akin to the novelty-based theory of curiosity.

## Empirical predictions

The rational model presented above makes two different empirical predictions.

Prediction 1. The first prediction arises when the agent is in an environment where the relationship between $p_{k}$ and $h_{k}$ holds true (as in Graph 1, Figure 1). The relationship between curiosity and exposure can be described using Equation 8 and between curiosity and confidence using Equation 9. Thus, Equation 8 predicts that an inverted $U$-shape relationship will exist between curiosity and exposure and Equation 9 similarly predicts that curiosity will be highest when the agent is moderately confident about a stimulus (see Figure 2). We test

Figure 3: Relationship between a) curiosity and exposure, and b) curiosity and confidence in an environment where need probability is independent of exposure (Graph 2, Figure 1).
this prediction in the confidence sampling condition of our behavioral experiment.

Note that this prediction fits the information gap and learning progress hypothesis which also predict an inverted Ushape curve between curiosity and confidence. While several studies have supported the existence of this U-shaped relationship, our model also predicts how to make this effect go away as described in our second prediction.

Prediction 2. Our second prediction comes in when the agent is in an environment where the relationship between $p_{k}$ and $h_{k}$ no longer holds true (as described in Graph 2, Figure 1). Then the relationship between curiosity and exposure will be the one described in Equation 5 and the relationship between curiosity and confidence will be that given in Equation 7. Equation 5 predicts that curiosity is highest when exposure is lowest and it decreases as exposure increases. Similarly, Equation 7 predicts that curiosity will be highest when confidence is the lowest (also shown in Figure 3). We test this prediction in the uniform sampling condition of the behavioral experiment.

While this prediction accords with the prediction of the novelty based hypothesis, that hypothesis can't explain our model's first prediction. On the other hand, while the information gap and learning progress hypothesis were in line with our model's first prediction, both of these theories fail to explain our model's second prediction.

## Testing the model predictions

This section details the behavioral experiment that was conducted in order to test our model predictions. The experiment used two different scenarios - confidence sampling and uniform sampling - to assess whether people's curiosity is affected by changes in the relationship between need probability and confidence. In the confidence sampling condition, we created an environment such that need probability was related to confidence (Graph 1, Figure 1) and in the uniform sampling condition they were independent of each other (Graph 2, Figure 1). Based on our model predictions, we hypothesize that an inverted U-shape relation will exist between confidence and curiosity in the confidence condition and a decreasing relation will exist in uniform sampling condition.

## Participants

We recruited 298 participants from Amazon Mechanical Turk. They earned $\$ 1.50$ for participation with the option of earning an additional bonus of $\$ 0.80$. Participants in the experiment were randomly assigned to one of two conditions: confidence sampling condition (163 participants) and uniform sampling condition (135 participants). Informed consent was obtained using a consent form approved by the institutional review board at Berkeley.

## Stimuli

The stimuli used in the experiment were 40 trivia questions on various topics that were taken directly from Experiment 1 in Kang et al. (2009). According to the authors, these questions
were designed to measure curiosity about semantic knowledge and evoke a range of curiosity levels.

## Procedure

The experiment was divided into two phases - the main round and bonus round. The main round was used to elicit and measure curiosity in participants. Participants were shown 40 trivia questions one after another and were asked to rate their confidence (i.e., probability that they know the correct answer) and curiosity in knowing the correct answer. Curiosity ratings were on a scale from 1 to 7 and the confidence scale ranged from 0 to $100 \%$. Following Kang et al.'s methodology, the raw curiosity ratings were individually normalized and confidence was rescaled to range from 0 to 1 . The order of trivia questions was randomized for each participant. Thus, the main round of the experiment followed the procedure of Kang et al.'s design closely. This part of the experiment took approximately 7-8 minutes to complete.

After the main round, the bonus round began which consisted of two parts. In the first part, all 40 questions from the main round were shown one after another and participants could choose to reveal the answer to those questions. However, each time they chose to reveal an answer, they had to wait an extra 10 seconds for the next question to appear. Findings from Experiment 3 of Kang et al. (2009) showed that participants were more likely to spend time, to wait longer, for the answers that they were more curious about. Thus, requiring participants to spend time to obtain information served as a proxy to measure their curiosity.

In the second part, participants attempted to answer 10 questions that were sampled from the main round ( $\$ 0.08$ bonus for each correct answer). To discourse participants from using Google or other search engines, they were only given 2 minutes in total to answer the questions.

At the beginning of the experiment, participants were randomly assigned to two conditions - the confidence and the uniform condition. Both the conditions had the same main round as described above but used different sampling methods for the bonus round. In the confidence condition, the sampling in bonus round was done based on the confidence ratings provided by the participants i.e. the questions for which participant's confidence rating was higher were more likely to appear in the second part of the bonus round. In the uniform condition, this sampling procedure was completely random i.e. each question was equally likely to appear in second part of the bonus round. Critically, participants were informed about the sampling procedure for their respective condition before the beginning of the bonus round. In a sense, the confidence condition creates a situation in which confidence is related to need probability (Graph 1 in Figure 1) and the uniform condition breaks this relationship (Graph 2 in Figure 1).

According to our model's predictions we should see an inverted U-shape between curiosity and confidence for both the conditions in the main round. However, the curiosity of participants (i.e. the answers they revealed) should be different for both conditions in the bonus round. For the confi-

Figure 4: Relationship of curiosity and confidence in the main round for a) confidence condition and b) uniform condition. The markers indicate mean curiosity at each confidence level and the solid curve is the regression line. Curiosity is an inverted-U function of confidence for both conditions.
dence condition participants' probability of revealing an answer should be highest for questions which they were moderately confident about. On the other hand, in the uniform condition, participants should be most curious about questions for which they were least confident about.

## Results

For all analyses that follow, we removed participants that revealed either too little $(<3)$ or too many answers $(>37)$ in the bonus round. 78 participants were excluded based on this criterion and our final data consisted of 220 participants (118 in the confidence condition and 102 in the uniform condition).

Main Round. Consistent with our prediction, an inverted U-shape exists between curiosity and confidence for both

Figure 5: Probability of participants revealing an answer as a function of confidence in the bonus round. Consistent with our model's prediction, an inverted U-shape exists between curiosity and confidence in the confidence condition and a decreasing relationship exists in the uniform condition.
conditions (Figure 4). Following the method of Kang et al., we fitted curiosity with confidence and uncertainty i.e. confidence $\times$ (1-confidence) for both conditions. For the confidence condition, the model provided $r=0.2$ and a significant coefficient for uncertainty (estimate $=2.01, p<0.001$ ). For the uniform condition, the model provided similar results with $r=0.2$ and significant coefficient for uncertainty (estimate $=2.12, p<0.001$ ). Thus, for both conditions, the model provided a significant quadratic coefficient thereby demonstrating the prevalence of an inverted U-shape between curiosity and confidence for both conditions.

Bonus Round. We first computed the probability of participants revealing an answer conditioned on the confidence rating for both the conditions. As per our model's predictions, an inverted $U$-shape exists for the confidence condition and a decreasing relationship exists for the uniform condition (Figure 5). Similar to the previous analysis, we fitted confidence and uncertainty to both the conditions. For the confidence condition, the model provided $r=0.9$ and a significant coefficient for both confidence and uncertainty (estimates $=-0.15$ and 0.53 respectively with $p<0.05$ for both) thereby showing a U-shape relationship. For the uniform condition, the model provided $r=0.91$ but the coefficient for uncertainty was not significant $(p=0.09)$. On the other hand, the coefficient for confidence was significant (estimate $=-0.23, p<$ 0.001 ), implying a decreasing relationship of curiosity with confidence for the uniform condition.

## Discussion

Curiosity is one of the hallmarks of human intelligence and is crucial to scientific discovery and invention. Models of curiosity have previously explained human curiosity by linking it to various psychological factors such as novelty, information-gap, and learning progress. We have shown that these different models are all special cases of curiosity - depending on the environment, curiosity can be driven by any of these factors. Along with providing a way to unify previous distinct mechanistic accounts of curiosity, our rational model explains human curiosity in various settings.

Our results suggest that human curiosity is not only sensitive to the properties of the stimuli but it is also affected by the nature of the environment. If people are in an environment where need probability influences exposure, then their curiosity is highest for stimuli for which they are moderately confident about. On the other hand, if need probability and exposure are independent of each other then curiosity is highest for novel stimuli, i.e. stimuli for which people have little confidence. This can have important implications in the context of education where researchers are concerned with ways to pique curiosity in students. If we want to make people curious about tasks or activities for which they have little confidence in, perhaps subtle changes in the structure of the environment might be a step towards achieving that. We intend to explore such possibilities in future work, building upon the foundation established in this paper and working towards a
better understanding of how to make people more curious especially in pedagogical settings.

#### Abstract

Distributional models of semantics assume that the meaning of a given word is a function of the contexts in which it occurs. In line with this, prior research suggests that a word's semantic representation can be manipulated - pushed toward a target meaning, for example - by situating that word in distributional contexts frequented by the target. Left open to question is the role that order plays in the distributional construction of meaning. Learning occurs in time, and it can produce asymmetric outcomes depending on the order in which information is presented. Discriminative learning models predict that systematically manipulating a word's preceding context should more strongly influence its meaning than should varying what follows. We find support for this hypothesis in three experiments in which we manipulated subjects' contextual experience with novel and marginally familiar words, while varying the locus of manipulation.

Keywords: distributional semantics; vector space models; discriminative learning; word frequency; semantic priming

## Introduction

In the study of human conceptual knowledge, a central theoretical question concerns how semantic representations are learned from the environment. How do speakers acquire knowledge of the meaning of a word and the precise contexts of its use? How are they able to make principled inferences about its senses and its similarity to other words? Inquiries in this domain have focused on two types of converging information sources that are thought to underpin these representations - perceptual and distributional (Andrews, Vigliocco, \& Vinson, 2009; Bruni, Tran, \& Baroni, 2014). Perceptual data derives from experiencing words in relation to the world, in connection with objects, events, and affordances in the immediate physical environment. Distributional data, by contrast, derives from experiencing words in relation to other words. While it is clear that neither data stream alone suffices to explain semantic representation, there appears to be considerable redundancy between them (Louwerse, 2007; Riordan \& Jones, 2010).

Distributional models operate on the assumption that the similarity between two words is a function of the overlap between the contexts in which they occur, a principle commonly known as the distributional hypothesis (Firth, 1957; Miller \& Charles, 1991). For instance, encountering the word violin in the same context as classical and strings supports the inference that these words are semantic neighbors. Such an inference will also be supported for words that occur in closely related musical contexts, such as cello, but not for those that occur in unrelated contexts, such
as jaguar. One of the key advantages of the distributional approach is that it provides an objective and replicable method of quantifying meaning, based solely on the statistical regularities found in large bodies of text.

Since the introduction of Latent Semantic Analysis (LSA; Landauer \& Dumais, 1997) to the cognitive sciences, a variety of different distributional models have been proposed to account for semantic phenomena. Within this class of models, there is considerable variation in implementation (for the latest class, see Baroni, Dinu \& Kruszewksi, 2014). Nevertheless, they share the same core architectural assumption that word meaning is derivable from lexical co-occurrence patterns. Words are represented as vectors within a high-dimensional semantic space, and word meanings as points located within that space. Whereas distributionally similar words tend to cluster together, words that occur in more distinctive contexts are more dispersed. The similarity relations derived from these models can then be used to account for phenomena as diverse as semantic priming (Jones, Kintsch, \& Mewhort, 2006), semantic categorization (Bullinaria \& Levy, 2007), and visual search (Huettig, Quinlan, McDonald, \& Altmann, 2006).

Implicit in these models is the notion that the lexicon is a highly interconnected system. The representation of a given word is neither static nor modular, but changes as a function of lingustic experience, both with that word in particular, and with others within the lexicon. As a demonstration of this principle, McDonald and Ramscar (2001) manipulated readers' semantic representations of marginally familiar and novel words by situating them in paragraph contexts that also contained close associates of a target meaning. For instance, subjects who read about a samovar in paragraph containing words like boil and electric rated it as closer to the meaning of kettle than subjects who read a modified version of the paragraph, which contained associates of an alternative meaning, urn. Even though subjects never directly observed the word kettle in training, their representation of the critical item-samovar-was moved closer to it, simply by virtue of encountering samovar in a similar linguistic context.

## Learning in Time

One question that arises from this, is the extent to which distributional learning about a particular item is influenced by the sequential structure of the context in which it is embedded (Elman, 1990; Jones \& Mewhort, 2007). Language unfolds in time, with one word following another in succession. Thus, the influence that the local context exerts on the critical item might depend on whether it helps predict the occurrence of that item, or is, in turn, predicted
by it - that is, whether the context is encountered before or after the item.

This framing maps naturally onto the the convergent and divergent learning hierarchies described by Osgood (1949). These abstract schemas capture asymmetries in how information is structured in time (Figure 1). In associative learning, convergent hierarchies label a situation in which a variety of cues are associated with a functionally identical outcomes ( $C_{1}, C_{2}, \ldots C_{\mathrm{x}} \Rightarrow O$ ), while divergent hierarchies label the inverse scenario, in which a single cue is associated with varied outcomes $\left(C \Rightarrow O_{1}, O_{2}, \ldots O_{\mathrm{x}}\right)$. Convergent hierarchies have been found to result in greater facilitation and positive transfer in learning, whereas divergent hierarchies yield interference and negative transfer.

Figure 1: Sequential relationships between linguistic regularities. The left side of the figure shows a convergent hierarchy; the right, a divergent one (Ramscar, 2013).

The temporal asymmetries captured by these schemas appear to be ubiquitous in word learning (Ramscar et al., 2010). Consider the problem of learning the relation between a class of things in the world - say, the category [ cat ] - and the word that denotes it - cat. Clearly, a sizable discrepancy exists between the rich array of perceptual features that belong to the class and the comparatively sparse acoustic features of the verbal label. Whereas the flesh and blood exemplars of the category exhibit a wide variety of discriminable features, across various perceptual modalities, the label itself comprises a simple sequence of sounds, which are likely to be perceived categorically (Kuhl, 2000). Accordingly, in a standard category learning paradigm, in which a category exemplar precedes its verbal label, a convergent hierarchy results. However, simply reverse the timing - by placing the label before the exemplar -and the structure becomes divergent.

The terminology used to describe this pair of temporal structures varies by research domain. In the study of categorization, a distinction is commonly drawn between classification, in which subjects predict the class to which an exemplar belongs based on its features, in line with a convergent schema, and inference, in which subjects predict an exemplar's feature values based on its class, in line with a divergent schema (Yamauchi \& Markman, 1988). Likewise, in the study of causal reasoning, predictive reasoning licenses inferences from a variety of possible causes to a shared effect-both rain and sprinklers make grass wet-in line with a convergent schema, whereas diagnostic reasoning licenses inferences from a common cause to its possible effects-rain makes grass wet and
green-in line with a divergent schema (Waldmann \& Holyoak, 1992; Waldmann, 2000).

Learning algorithms can help provide a mechanistic account of how the structure of information in time affects what is learned in these tasks. A critical assumption shared by most models of learning, ranging from classical conditioning to perceptrons, is that learning is scaffolded by the predictions we make about our environments, and powered by the surprise we experience whenever there is a mismatch between expectation and reality. Learning proceeds as a continual process of updating and refining expectations, selectively weighting the most informative predictors to relevant outcomes, while eliminating redundant or potentially misleading cues. When our predictions align with reality, learning asymptotes (Rescorla, 1988).

To examine how convergent and divergent structures affect word learning, Ramscar and colleagues (2010) simulated supervised category learning with the RescorlaWagner rule, while manipulating the sequencing of category exemplars and verbal labels. The findings were striking: The same algorithm, run over the same task, produced remarkably different representations of the learning environment, depending on the temporal sequencing of information: While convergent structures yielded predictive representations, divergent structures yielded veridical ones. Specifically, convergent schemas facilitated competition between the available perceptual features for associative weight, resulting in abstraction of the informative dimensions that best predicted the category label. By contrast, divergent schemas facilitated learning of the actual feature probabilities given the label. (For a closely related result in a different model architecture, see Yamauchi, Love, \& Markman, 2002).

The differences in these representations can be mapped onto the differences between discriminative and generative classifiers in machine learning ( Ng \& Jordan, 2002). In learning a verbal category, the problem is to establish the likelihood of a category label $L$ given some set of perceptual features $F$. To solve this problem, discriminative classifiers learn a direct mapping between features and labels, which yields $\mathrm{p}(L \mid F)$. Generative classifiers solve the same problem indirectly, by learning the joint probability of $\mathrm{p}(L, F)$ and relying on Bayesian inference to calculate the posterior likelihood of $\mathrm{p}(L \mid F)$. While discriminative classifiers are more efficient and better at minimizing error, generative classifiers operate with a more complete picture of the probability space (Levering \& Kurtz, 2014). Convergent schemas yield $\mathrm{p}(L \mid F)$; divergent schemas $\mathrm{p}(L, F)$.

The resultant representations appear to be optimized for different tasks. In studies of human category learning, convergent schemas benefit the learning of categories that require information-integration (Ashby, Maddox, \& Bohil, 2003; Yamauchi et al., 2002), which likely form the majority of natural kinds (Rosch \& Mervis, 1975). However, there are notable drawbacks to categorical responding. As a category structure becomes better learned, stimulus dimensions that are relevant to a particular categorization are selectively attended, such that they acquire distinctiveness, while irrelevant dimensions are
ignored, or down-weighted, maximizing intra-category similarities and inter-category differences (Goldstone, 1994; Lawrence, 1949; Nosofsky, 1986). Accordingly, while convergent schemas support accurate categorization across an array of perceptual domains, they can also systematically alter similarity relations, impairing memory for exemplars seen in training (Davis \& Love, 2010; Dye \& Ramscar, 2009) and distorting judgements of the underlying featural space (Yamauchi \& Markman, 1998). Likewise, in causal inference, whereas predictive reasoning is susceptible to blocking effects, diagnostic reasoning is not (Waldmann \& Holyoak, 1992). The optimal information structure at encoding thus depends on the demands imposed at retrieval (Tulving \& Thomson, 1973).

Previous research has examined the effect of these asymmetric information structures on category learning and causal inference. This paper addresses itself to distributional learning, where what is learned is not the relation between words and physical referents, but rather that of words in relation to each other.

## Studies

In the following three experiments, our aims were first, to build on the original findings of McDonald and Ramscar (2001)-which demonstrated that a pair of words can be moved closer together in semantic space even if they have never been encountered together-and second, to investigate whether readers would attach more weight to the associates that occurred before a word of interest, rather than after, as predicted by previous simulations (Ramscar et al. 2010).

The three studies presented here are all variations on the same principal design. In training, subjects read short passages containing critical words. These passages had been constructed such that the contexts occurring before the critical item were designed to encourage one set of inferences about its meaning, while the contexts occurring after it were designed to encourage a different, competing set of inferences. This design allowed us to measure the relative influence of preceding and succeeding contexts on semantic representation.

Variations on this design were devised to investigate the robustness of the predicted effects of training, and included (e.g.) the choice of cover story, the semantic proximity of
the topic meanings to the critical item and to each other, and the precise organization and length of training and test blocks (Table 1). Detailed descriptions of each experimental design, including counterbalancing and randomization, timing procedures, and lexical controls, are available in the Supporting Materials.

The training phase of each study required a set of critical items, competitor topic meanings, and a set of close lexical associates of each topic. From these materials, a set of triplets was created, each of which consisted of a critical word and two different topic meanings. One of these topic words was designated the preceding topic, and the other, the succeeding topic (Table 2).

| Triplet | topic1 | critical | topic2 |
| :--- | :--- | :--- | :--- |
|  | dream | fugue | music |

Table 2: An example of a training triplet taken from Study 2, in which the critical word fugue has been paired with the competing topics dream and music.

For each topic in a given triplet, corpus data were used to generate a ranked list of its lexical associates. These were used to construct training trigrams, which consisted of the critical item and a pair of its topics' close associates on either side of it (Tables $3 \boldsymbol{\&}$ ). These training trigrams were embedded into larger strings, which subjects were incidentally exposed to in training. The precise number of training trials varied by study.

| Condition 1 |  |  | Condition 2 |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: |
| T1 <br> associate1 | critical | T2 <br> associate1 | T2 <br> associate1 | critical | T1 <br> associate1 |

Table 3: Abstract representation of the training trigrams for a given critical word and its two topic meanings.

| \{DREAM, critical, MUSIC \} |  | \{MUSIC, critical, DREAM\} |  |  |  |
| :---: | :--- | :---: | :---: | :--- | :---: |
| chasing | fugue | listening | listening | fugue | chasing |
| lucid | fugue | classical | classical | fugue | lucid |
| worthy | fugue | primal | primal | fugue | worthy |

Table 4: Partial training sets in Study 2 for the critical item fugue and its topic synonyms dream and music. In Condition 1 (right), the ordering of associates is reversed from Condition 2 (left).

Post-training, two tests were administered. In the first, a semantic priming task, a prime word was briefly presented on-screen, and subjects were asked to determine whether the following word was a real word in English. Each critical item was tested in combination with its two competitor topics, alternating its position as a prime or target (Table 5).

Subsequently, in a semantic similarity rating task, subjects were asked to rate the similarity of various word pairs on a numerical scale, ranging from "unrelated in meaning" to "identical in meaning". Each critical item was alternately paired with its two topics (Table 6).
$\left.\begin{array}{|l|c|c|c|c|}\hline \text { Semantic }\end{array} \begin{array}{c}\text { topic1 } \rightarrow \\ \text { critical }\end{array} \quad \begin{array}{c}\text { critical } \rightarrow \\ \text { topic1 }\end{array} \quad \begin{array}{c}\text { topic2 } \rightarrow \\ \text { critical }\end{array} \quad \begin{array}{c}\text { critical } \rightarrow \\ \text { topic2 }\end{array}\right]$

Table 5: Example test trials from the semantic priming task.

| Semantic <br> Similarity | topic1 $\mid$ critical | topic2 $\mid$ critical |
| :--- | :---: | :---: |
|  | music $\mid$ fugue | dream $\mid$ fugue |

Table 6: Example test pairs from the semantic rating task.
A key point of difference between studies was the frequency of the critical item: Study 1 employed pseudowords, Study 2, low frequency items, and Study 3, a mix of high (HF) and low frequency (LF) items.

## Hypotheses

Priming Semantic priming is a classic paradigm for studying representation in semantic memory (Neely, 1991). A general finding is that a target item will be processed more efficiently when it is preceded by a semantically related prime, with the degree of facilitation depending on the relatedness of the pair. For instance, bread will be processed more quickly and accurately when it is preceded by butter than when it is preceded by nurse (Meyer \& Schvaneveldt, 1971). When what is studied is the extent to which recently trained associations can facilitate primingas is the case here-the priming is classed as episodic (Hayes \& Bissett, 1998; McKoon \& Ratcliff, 1979). When those associations are indirectly trained, it can be further classed as mediated (Lowe \& McDonald, 2000).

In our studies, a key consideration is that lexical processing is sensitive to temporal contingencies (Deese, 1965). If subjects learn about both the associative and temporal relations between critical items and their topics, then they should be faster and more accurate on lexical decision trials that are consistent with the sequences observed in training. For example, in training sequences in which Topic ${ }_{1} \rightarrow$ Critical $\rightarrow$ Topic $_{2}$, Topic ${ }_{1}$ should be a better prime to the critical item than Topic2, and Topic2 should be better primed by the critical item than Topic ${ }_{1}$.
Similarity Similarity judgments can be affected by the dimensions of alignment that are currently deemed salient to the comparison (Nosofsky, 1986; Tversky, 1977). In the domain of perceptual learning, simulations of convergent and divergent schemas indicate that they develop different feature weights, resulting in correspondingly different representations of the similarity space among exemplars (Ramscar et al., 2010).

If distributional learning is also sensitive to how information is structured in time, then the associative relations the critical item develops with its topics over
training should similarly depend on the positioning of their associates. When multiple lexical associates serve to predict a critical item, the information structure will be convergent; when the critical item serves to predict multiple lexical associates, the structure will be divergent (see Figure 1).

In the convergent case, competition between the lexical associates present in the preceding context should preferentially weight the shared semantic features they have in common with their topic word. By contrast, in the divergent case, weights will be tuned according to cooccurrence rates, which may not select for the most predictive dimensions. Convergent learning should therefore bring the preceding topic into closer alignment in similarity space with the critical item (Dye \& Ramscar, 2009).

## Study 1

Subjects were told that scientists had intercepted an alien communication that they had managed to partially translate, but needed further help in order to fully decode. Participants were presented with a series of these cryptic messages, and instructed to learn as much as they could about the alien word in the middle. That critical item was always a nonsense word.

The experiment was designed such that each subject completed ten short experimental sessions, comprising both training and test, one after the other. This meant that participants learned about each critical item in individual blocks, rather than learning about multiple items simultaneously. The design was fully randomized, such that the specific pairing of topic meanings with a given critical item varied by participant. At the end of the experiment, results were aggregated across all sessions.

Participants Eighteen Stanford University undergraduates participated for course credit.
Results In the semantic priming task, lexical decision accuracy was at ceiling, averaging 98\%. However, differences in response time were apparent. A paired samples t-test revealed that when the critical item served as a prime to one of its topics, subjects were significantly faster at recognizing succeeding topic words than preceding topic words $[t(17)=2.30, p=0.017]$, with a mean 37 ms advantage. However, this advantage was mediated by the prime type: when the topic words themselves served as primes to the critical item, no difference was observed between the preceding and succeeding topics $[t(17)=0.25, p>0.5]$.

After completing the priming task, subjects rated the semantic similarity of each critical item and its competitor topics. A sequential learning account suggests that the preceding topic word should become more similar to the critical item over training. In line with this prediction, subjects rated the preceding topic word as significantly more similar to the critical item than the succeeding topic word $[t(17)=2.27, p=0.018]$. Non-parametric analyses of the data, with the Wilcoxon signed-ranks test, yielded the same pattern of results.

## Study 2

Subjects were told they were taking part in a study testing their ability to distinguish human from artificial intelligence.

On each trial, they were presented with a trigram sequence (Table 4), and asked to judge whether those words had come from a text generated by a human or a computer. In this study, critical items were LF words, whose potential topic meanings were plausible synonyms (e.g., the critical item abscond was matched with the topic words hide and flee). The design was counterbalanced such that the position of each topic word was split evenly across participants. Testing was conducted at the end of the full training session.

Participants 43 undergraduates at Indiana University, Bloomington participated for course credit.

Results The test results of Study 2 replicate the pattern of results in Study 1. In the priming task, lexical decision accuracy averaged $86.4 \%$ overall and $81.8 \%$ for critical items. A dependent samples t-test revealed that when the critical item served as a prime to one of its topics, subjects were faster $[t(42)=-1.73, p=0.046]$ and more accurate $[t(42)=2.45, p=0.009]$ at recognizing topic words that had followed that item, compared to those that had preceded it. A by-items analysis produced a similar pattern for speed $[t(27)=1.53, p=0.068]$ and accuracy $[t(27)=1.85, p=0.038]$. This facilitation pattern was not evident when HF topic words primed LF critical items.

After completing the priming task, subjects rated the semantic similarity of each critical item and its competitor topics. Consistent with Study 1, a dependent samples T-test revealed that preceding topics were rated more similar to critical items, both by subjects $[t(42)=2.99, p=.002]$ and items $[t(13)=2.83, p=0.007]$. Non-parametric analyses, with the Wilcoxon signed-ranks test, confirmed the pattern of results.

## Study 3

Subjects were told they were taking part in a study on reaction time. Words were presented one by one, and subjects were instructed to make a keyboard response every time they saw an item that was either a fruit or a piece of furniture. Training trigrams (Figure 4) were pseudorandomly interspersed throughout this text sequence, with the design counterbalanced such that the position of each topic word was split evenly across participants.

To further assess the extent to which the frequency of the critical item might mediate the predicted effects, both HF and LF critical words were chosen, and each pair of topic meanings was assigned to a pair of unrelated critical items, one in each frequency band (e.g., the critical items jacket and repast were both assigned the same topic pair). Topic meanings were moderately semantically related to each other, but not to either critical item.

As with Study 2, testing was conducted at the end of the full training session.

Participants 26 undergraduates at Indiana University, Bloomington participated for course credit. Two subjects
were dropped from the similarity analyses for selecting the same number for every pair.

Results Study 3 largely replicated the pattern of results in Study 1 and 2. However, in the semantic priming task, the locus of the effect was different: Lexical decision accuracy was at ceiling when HF topic words served as targets ( $98.7 \%$ ). However, when topic words served as primes to the critical items, a 2 (training position) by 2 (critical item frequency) repeated measures ANOVA revealed main effects of item frequency for accuracy $[F(1,25)=16.86$, $p<0.001]$ and RT $[F(1,25)=29.49, p<0.001]$, and of training position for accuracy $[F(1,25)=3.82, p=.061]$ : Subjects were faster and more accurate at recognizing HF targets overall, and more accurate at recognizing critical items that had followed that topic in training, compared to those that had preceded it.

Analysis of the similarity ratings data revealed a main effect of training position $[F(1,22)=5.09, p=.034]$, a main effect of topic frequency $[F(1,22)=10.07, p=.004]$, and a marginally significant interaction between training position and critical item frequency $[F(1,22)=3.88, p=.062]$. Post hoc analyses (Tukey HSD) indicated that, as predicted, LF critical items became more similar to their topic words over training than did HF items. Further, the effect of the training manipulation was mediated by the frequency of the critical item: The preceding topic word was rated as significantly more similar than the succeeding topic word for LF items ( $p<.03$ ), but not for HF items.

## Discussion

Priming Results Speakers appear to be finely attuned to the statistical regularities of their language, allowing them to anticipate upcoming linguistic events based on the current input (Pickering \& Garrod, 2007). This notion is supported by our priming results in Studies 1 and 2, which indicate that when the critical items served as primes, subjects were significantly faster to respond to topic words whose associates had occurred after the critical items in training. This suggests that episodic priming is sensitive not only to temporal contiguity, but also to directionality. ${ }^{1}$

Interestingly, however, when the prime order was reversed, and the topic words served to prime the critical items, the effect disappeared in two of the three studies. The effect thus appears to be mediated by the frequency relationship between primes and targets.

At first blush, the results of Studies 1 and 2 may seem surprising. In semantic priming, a common finding is that while HF targets are responded to more efficiently overall, it is LF targets that typically show greater facilitation from semantically-related HF primes (Becker, 1979)-not HF targets, as in our studies. However, there are important differences between studies that test semantic memory (preexisting semantic associations in long term memory), and those that test episodic memory (associations developed over the course of study), like ours.

[^58]While HF words outperform LF words in semantic tasks, and appear to be more broadly accessible in the lexicon, in episodic paradigms, it is LF words that tend to be better recognized and recalled (Gregg, 1976). This is due, at least in part, to the fact that HF words occur in many more contexts than LF words, making them less associable with any given experimental context (Anderson, 1974; Steyvers \& Malmberg, 2003).

The studies presented here examined the extent to which recently trained semantic and temporal associations facilitate priming. As with other episodic tasks, LF words should develop stronger associations to other experimental items than HF words (the similarity analyses in Study 3 attest to this). The key consideration is that these associations are directional: For a given item, its connections to other words may be distinct from its connections from other words (Nelson \& McEvoy, 2000). It follows sensibly then that in Studies 1 and 2, the LF critical items served as effective cue to the HF topic words, even when the reverse does not obtain (Ramscar et al., 2014).

Similarity Results Across three studies, critical items were rated as more similar to their preceding topics than their succeeding topics, a finding predicted by previous modeling simulations of convergent and divergent learning schemas. As with the priming results, the effect of this training manipulation was modulated by the frequency of the critical item (Study 3).

## General Discussion

Learning is a temporal phenomena, and it can produce asymmetric outcomes depending on how information is structured in time. Such asymmetries have been previously documented in causal reasoning (Waldmann \& Holyoak, 1992) and categorization (Ashby et al., 2002; Ramscar et al., 2010; Yamauchi et al., 2002), and are also attested in sequential learning in non-human animals (Chen et al., 2016). The goal of the present research has been to investigate whether these asymmetric effects might be similarly observable in distributional learning from reading. Across three experiments, our results affirm that they are. An obvious next step is to assess whether models that learn distributed semantic representations of words can replicate these findings (following Jones et al., 2006).

An additional theoretical possibility raised here is that linguistic regularities may play different functional roles depending on whether they participate in convergent or divergent schemas. Suggestive evidence has been offered in artificial language experiments: Whereas stable prefixes and their following nouns are better learned, stable suffixes increase the similarity among those nouns, helping them cohere better as a category (Ramscar, 2013; see also Valian \& Coulson, 1988). Biases toward prefixing or suffixing may thus represent a trade-off between ease of processing and learnability, with suffixes facilitating the discovery of grammatical categories among young learners (St. Clair, Monaghan, \& Ramscar, 2009), and prefixes serving to reduce uncertainty in online comprehension and production (Dye et al., 2017). This proposal is consistent with the finding that in child-directed speech, new words are
preferentially introduced in utterance-final positions (Fernald \& Mazzie, 1991), which appears to promote the best learning outcomes (Fernald, Thorpe, \& Marchman, 2010; Yu \& Smith, 2012). In future research, this framework might be extended to address broader typological questions on the forces at work in language change and evolution.

## Acknowledgments

This research was funded by an NSF graduate fellowship to MD. Many thanks to Colin Allen, Brendan Johns, the Shiffrin lab group, and three anonymous reviewers for comments and discussion.

#### Abstract

A central goal of typological research is to characterize linguistic features in terms of both their functional role and their fit to social and cognitive systems. One longstanding puzzle concerns why certain languages employ grammatical gender. In an information theoretic analysis of German noun classification, Dye et al. (2017) enumerated a number of important processing advantages gender confers. Yet this raises a further puzzle: If gender systems are so beneficial to processing, what does this mean for languages that make do without them? Here, we compare the communicative function of gender marking in German (a deterministic system) to that of prenominal adjectives in English (a probabilistic one), finding that despite their differences, both systems act to efficiently smooth information over discourse, making nouns more equally predictable in context. We examine why evolutionary pressures may favor one system over another, and discuss the implications for compositional accounts of meaning and Gricean principles of communication.

Keywords: prenominal adjectives; grammatical gender; language comprehension; language production; language evolution; information theory; typology; formal semantics; Gricean conversational maxims

## Introduction

Linguistic typologists work to define similarity and difference across languages, in an effort to establish what invariant 'universal' properties might underpin the fundamental human capacity for language, amidst remarkable diversity (Evans \& Levinson, 2009). This enterprise is complicated by the fact that language is a hybrid system, which is product both of a common biological endowment (shared across languages and peoples) and of a particular ecological niche (specific to a given language).

As languages evolve, they adopt communicative strategies in response to both social and cognitive pressures, strategies which are then refined over generations of cultural transmission (Becker et al., 2009; Tomasello, 2003; Boyd \& Richerson, 2005; Atkinson \& Gray, 2005). In seeking to understand the limits on variation, a typologist has the unenviable task of disentangling biological imperative (Christiansen \& Chater, 2008) from cultural and historical contingencies (Lupyan \& Dale, 2010), such as migrations or language contact.

Information theoretic approaches to language can help clarify this problem, by setting a goalpost that is explicitly functional, rather than biological or cultural (Ramscar \& Baayen, 2013). On this view, language is a communication system like any other, with the same fundamental purpose of
transmitting information. A language's structural features should thus be subject to the selection pressures that govern the design of efficient digital codes (Dahl, 2004). On this read, variation among languages is the result of selective adaptations to variable circumstances, with communicative efficiency the key measure of fitness.

This is not to imply that the solutions that different languages converge on are 'equally' optimal to some prespecified degree. Evolutionary processes achieve localrather than global-optima, and are chained to their particular historical lineage (Simon, 1989). Rather, the idea is to provide an overarching framework in which the host of interacting variables may be arrayed, so as to better understand how the system maintains and restores a functional equilibrium. In particular, it allows us to ask: How are the perturbations in one part of the system balanced by compensating forces in another?

For example, whereas more 'synthetic' languages, like German, rely heavily on morphological devices to convey information, others, like English, leave more to the surrounding context (Lupyan \& Dale, 2010). This mode of typological inquiry can help uncover how languages use different means to nevertheless achieve similar functional ends, and the potential trade-offs-in terms of complexity and efficiency-that these different strategies may incur (Pellegrino, Coupé, \& Marsico, 2011).

## Two Germanic Tongues

One longstanding puzzle for typologists concerns why certain languages employ grammatical gender, which assigns nouns to distinct classes and marks neighboring words for agreement. From a taxonomic standpoint, gender specification can often appear arbitrary, with little obvious correspondence between the semantic properties of a given referent and its noun class (Vigliocco et al., 2005). Historically, gender has thus been viewed as a useless ornament with little apparent rhyme or reason (Maratsos, 1979). In previous work, Dye et al. (2017) offered a possible solution to this puzzle, using an information theoretic lens to clarify the communicative function of noun classification in German.

On their account, grammatical gender marking serves to modulate nominal entropy, making nouns more equally predictable in context. This functionality benefits language processing in multiple ways: 1) by helping speakers avoid the peaks in uncertainty that would otherwise occur over nouns, smoothing entropy over the larger sequence; 2) by reducing competition between nouns that are highly confusable in context; and 3) by facilitating the use of a richer array of lexical items.

These findings raise a further puzzle: If gender systems are so beneficial to processing, languages should tend to maintain or expand them as they evolve. Yet a number of closely related Germanic tongues have followed precisely the opposite trajectory: Swedish, Danish, and Dutch have all consolidated their noun classification systems, while English has dispensed with gender altogether.

Like Modern German, Old English ( $\sim 750-1150$ AD) classified nouns according to three genders (masculine, feminine, and neuter) and all inanimate nouns belonged to one of the three classes (Curzan, 2003). However, in Modern English, aside from a few archaic exceptions, only nouns referring to males and females take gendered pronouns; inanimate nouns are neuter. The gender system in Modern English is thus far simpler than the noun class systems found in Old English and Modern German.

This raises the worrying possibility that English lacks the resources to accomplish the same specificity of expression available in German. However, another possibility, explored here, is that rather than employing a rigid grammatical device, English relies on a more graded, semantically transparent method of entropy reduction: namely, prenominal adjectives.

Like gender markers, adjectives may act to systematically delimit the space of following nouns. For example, massive and moist are likely to have markedly different following distributions. Yet even subtle differences, such as that between great big and very big, could be highly informative in English. To test this proposal, we use tools from information theory to compare gender marking in German (a deterministic system) to prenominal adjective use in English (a probabilistic one).

## Nominal Uncertainty Management

Languages appear to be organized to maintain relatively stable levels of uncertainty across discourse (Genzel \& Charniak, 2002), employing various strategies to make each lexical choice more equally predictable in context, and thereby reducing processing difficulties (Tily et al., 2009; Jaeger, 2010). In information theory, uncertainty is quantified in terms of entropy. Formally, the entropy H over a distribution of lexical items is a measure of the expected value of information ('surprisal') over the full range of items (Shannon, 1948):

$$
H(X)=-\sum_{x \in X} p(x) \log _{2} p(x)
$$

In many languages, like English and German, nouns are the most diverse part of speech. When prior context is ignored, uncertainty should thus be highest at points where a noun occurs. For example, in the following sequence, uncertainty over possible noun continuations (!) will be higher than for possible verb continuations (\#):
I would \# like a ! beer

Unsurprisingly, nouns are among the most common sites for disfluencies, incorrect retrieval, and mishearings (Clark \& Wasow, 1998; Vigliocco, 1997).

Nevertheless, speakers have various resources at their
disposal for making a particular lexical choice more or less predictable in context. One possibility is to rely on the preceding discourse as a form of scaffolding. Noun class is an efficient system for implementing this principle. Consider the German equivalent of (1):
Ich hätte gern ein ! Bier

Grammatical gender markers can significantly ease the lexical access problem by systematically narrowing the set of candidate nouns that follow (Dahan et al., 2000), thereby offloading some of the uncertainty about the upcoming noun onto the determiner.

To evaluate this hypothesis, Dye et al. (2017) examined the entropy of nouns in German, a language with a threeclass gender system. An analysis of the Stuttgart deWaC mega-corpus (Faaß \& Eckart, 2013) revealed that gender markers systematically reduced nominal entropy across all cases. Further, this appeared to benefit lexical diversity: German plurals, which are not gender-marked, showed a reduction in their type/token ratio, suggesting that the presence of a gender marker was catalyzing the use of a wider array of lexical items.

Yet English is not without its own entropy-smoothing resources. Compared to the sparse semantic context provided by (1), the noun beer should be more predictable following the comparatively constraining context provided by (3):

## I would like a nice cold ! beer

This raises an important question: Might prenominal adjectives in English serve a similar function to grammatical gender markers in German?

Suggestive evidence comes from the visual world paradigm, an experimental framework for studying online language processing in which subjects' eye movements over a visual display are monitored as they listen to a concurrent speech stream (Tanenhaus et al., 1995). A common finding is that listeners fixate semantically-related pictures as they become relevant, with patterns of eye movements timelocked to incoming speech. In studies of this kind, prenominal adjectives and gender markers have been shown to play similar functional roles: When French and Spanish speakers encounter a gendered determiner, they rapidly shift their gaze to gender-consistent referents in the display in anticipation of the upcoming noun (Dahan et al., 2000; LewWilliams \& Fernald, 2007). Similarly, when viewing an array of semantically plausible competitors, English speakers interpret prenominal adjectives contrastively, quickly homing in on likely candidates (Sedivy et al., 1999; Fernald, Thorpe, \& Marchman, 2010). Such findings suggest that both prenominal elements serve a predictive, discriminative function.

## Corpus Analysis

To more closely examine this apparent functional similarity between languages, we conducted a comparison of prenominal adjective and determiner usage in written English and German.

## Corpora

Analyses were initially run on manually annotated newswire corpora, and subsequently replicated on larger web-crawled mega-corpora. These corpus types trade off on scale and precision. Due to space constraints, we report one or the other, but not both; in each case, the qualitative nature of the results are the same.

The newswire corpora included the Negra II corpus of German newspapers, (Skut et al. 1997) and the New York Times Gigaword corpus (Graff et al., 2007). The webcrawled WaCky mega-corpus supplied the SdeWaC, a subset of the German section (Baroni, Bernardini, Ferraresi, \& Zanchetta, 2009), comprising more than 850 M word tokens and 1.1 M word types (Faaß \& Eckart, 2013), and the ukWaC, the British English subset, comprising nearly 2 billion word tokens and 3.8 M word types (Ferraresi et al., 2008). It is worth noting that these are collections of written language, which may not reflect the complexities of spoken production (Baayen, Milin, \& Ramscar, 2015).

Additional annotation for fine-grained part-of-speech categories and extraction was carried out with the RFTagger (Schmid \& Laws, 2008) and the Stanford Parser (Klein \& Manning, 2003).

## Determiners

Entropy Reduction In German, grammatical gender serves to subdivide the space of nouns that can legally follow each marker. By markedly reducing nominal entropy, gender facilitates the use of a more diverse-and more informative -set of nouns following gender-marked determiners. Consistent with this thesis, when Dye et al. (2017) compared singular nouns in German (which are marked for gender), with plural nouns (which are not), they found that singular nouns following determiners were significantly more lexically diverse than their plural counterparts.

By comparison, English determiners, which are neither gender nor case-specific, have less potential to be informative about their following nouns. Consider that while the determiner the in English is informative about the type of word that will follow (a noun, most likely), in German, the determiners der, die, das, den, dem, and des convey not only part of speech information, but also delineate the specific set of lexical items that can follow. This suggests that English determiners may not support the same level of lexical diversity available in German.

To examine this possibility, we first compared the conditional entropy of German nouns following articles (which are gender-marked) to that of English nouns following articles (which are not), in the Negra II and NYT Gigaword corpus, respectively. While the average uncertainty following the determiners was similar across languages, German determiners supported much greater entropy reduction than their English equivalent, a result that held across corpus types.

As Figure 1 illustrates, following a definite article, the conditional entropy of English nouns was similar to that of German nouns ( 10.17 vs. 10.55). However, whereas German provided a substantial entropy offset, English provided none at all. In German, removing information
about definite articles-and hence, about noun class-led to a significant increase in entropy (from 10.55 to 11.71 bits). In the simplified model corpus depicted in Figure 1, whereas the baseline entropy difference between marked English and German nouns suggests a usage rate of around $30 \%$ more nouns, the difference between marked and unmarked German nouns is the equivalent of more than $125 \%$ more nouns.

Lexical Diversity This finding suggests that compared to English, German noun usage must be more heterogeneous following determiners (Figure 1). To compare nominal usage across languages, we calculated the type/token ratio of noun lemmas in these contexts in the Negra II and NYT Gigaword corpus, following Dye et al. (2017), and normalizing for corpus size to make the results comparable. Conveniently, type/token ratio is the inverse of average frequency, which means that the greater the diversity of nominal usage, the lower the average frequency. We found that whereas the average frequency of the German noun lemmas in Negra II was 2.12, the average frequency of similar noun lemmas in the English ukWaC sample was 4.93 ( $p<0.001$ ).

These results suggest that noun class allows German speakers to use more 'informative'-and therefore, less frequent and less predictable-nouns after definite articles more often than English speakers do. Or, to put it another way, German speakers appear to use the entropy reduction provided by noun class to choose nouns that are more specific, resulting in greater nominal diversity.

Figure 1: To illustrate the relationship between entropy, probability, and frequency in a corpus of nouns, the $x$-axis above represents the entropy for a given noun as the size of a set of nouns of equal frequency ( $1, y$-axis) increases. As the size of the set of items increases linearly, entropy rises as an exponential function.

## Adjectives

While our results confirm that nominal usage following determiners is more diverse in German than in English, it does not therefore follow that English is lexically impoverished compared to German, or unable to achieve the same degree of specificity. In particular, definite articles are not the only type of word that typically precede nouns-
adjectives are also common prenominally, and may serve a similar function.

To further explore this idea, we compared the adjectivenoun sequences in the ukWaC and the SdeWaC corpora. Both the overall proportion of adjectives ( $t_{p}=1992.336 ; p<$ .0001 ) and the probability of a noun being preceded by an adjective ( $t_{p}=85.088 ; p<.0001$ ) were significantly higher in English than in German. While German nouns are significantly more lexically diverse than their English counterparts, precisely the opposite obtains for adjectives.

These results present us with two different theoretical explanations. One possibility is that English speakers use more adjectives overall to compensate for the use of less varied nouns in communication-i.e., that they make their messages more specific through adjectival syntagmatic choices. Alternatively, it might be that while German speakers use more varied nouns after articles, English speakers use an equally diverse set of nouns, but rely on adjectives-rather than determiners-to facilitate the use of more informative nouns. Fortunately, these accounts make competing predictions, allowing us to distinguish between them empirically.

The first account accords well with the taxonomic assumption that adjectives add semantic detail to nouns, or somehow "modify" their semantic content (Kamp \& Partee, 1995). On this assumption, adjectives should preferentially modify high frequency nouns, which are in greater need of semantic augmentation, over low frequency nouns, which tend to be more specific (Rosch, 1978). For example, dog is less informative than retriever, which is less informative than dachshund; accordingly, dog should be the most frequently modified, and dachshund the least.

However, if prenominal adjectives in English serve a similar role to gendered determiners in German, precisely the opposite prediction should be made regarding frequency. In German, the entropy reduction properties afforded by noun class facilitate the use of more informative (lower frequency) nouns. If, in English, at least some of this functionality is subsumed by prenominal adjectives, then it is low frequency nouns that should be preferentially "modified", not high frequency ones. The relationship between adjectives and noun frequency thus provides an important test case.

In line with the entropy smoothing account, our analysis reveals a negative correlation between a noun's log frequency and its likelihood of being modified ( $r=-0.17, p$ $<0.001$ ). Moreover, our investigation ${ }^{1}$ indicates that in English, adjectives redistribute the relative entropy of nouns, thus serving to balance the degree to which nouns can be predicted in context: More frequent nouns tend to be preceded by adjectives that are (on average) higher frequency and higher entropy ( $e d f=22.06$ : $F=32069$ : $p<$ 0.0001 ). Indeed, a nonlinear interaction between adjective entropy and adjective frequency accounts for fully $94 \%$ of the variance in noun frequency (Figures 3, 4).

Figure 3: Adjective maximum entropy, which provides an upper bound on uncertainty about the preceding adjective, accounted for almost $90 \%$ of the variance in noun frequency (Adjusted $R^{2}=$ 0.891 ), revealing that more frequent nouns are preceded by larger number of different adjectives.

Figure 4: To achieve greater precision, a second interactive model was run, which regressed noun frequency with the tensor product of adjective entropy by adjective average frequency. This interactive model accounted for fully $94 \%$ of the variance in noun frequency (Adjusted $R^{2}=0.941$ ), and achieved better goodness-offit than the max entropy model, as indicated by both the difference in AIC (28603.60), and the Chi-square test of fREML scores $\left(\chi^{2}=\right.$ 14274.832, edf difference $=3.000, \mathrm{p}<0.0001$ ).

## Discussion

In comparing English and German, two closely related Germanic tongues, we found that whereas German nouns are significantly more lexically diverse than their English counterparts, precisely the opposite obtains for adjectives. These results suggest that the difference between German and English does not lie in the 'specificity' of expression, per se, but rather in how specificity is achieved.

German uses gender marking to distinguish between likely lexical competitors, and adjectives to make rarer lexical items more predictable in context. By contrast, in English, which largely lacks gender, adjectives assume both roles. While these findings are compatible with discriminative accounts of language processing (Ramscar et al, 2010), they raise questions about the explanatory adequacy of traditional taxonomic theories.

[^59]
## General Discussion

## To Gender or Not

On an evolutionary scale, languages tend to become more codified over time, as frequently used sequences of words gradually crystallize into more rigid conventions, a process known as grammaticalization (Hopper \& Traugott, 1993). However, at a number of points in its history, English has taken the opposite developmental path.

One such turning point was the invasion and colonization of the British Isles in the 8th and 9th centuries by the Norse, followed by the Norman conquest of England in the 11th century. As a result of the extended interaction between Old English and Norse, much of the information that had been encoded in fixed aspects of the grammar became "optional" - expressed by words rather than fixed grammatical markers. Old English, the language of England at the beginning of this period, looks like Modern German, with relatively complex patterns of inflection for number, gender, and case. However, by the end of this period, Old English had been eclipsed by Middle English, which much more closely resembles the modern tongue: nouns are marked only for number, adjectives are no longer inflected, and demonstratives are reduced in kind (Dawson, 2003). What might explain this trajectory?

Evolutionary Pressures While it is well known that some languages are easier for adult learners to master than others, it is also the case that first languages are acquired at different rates-Russian children, for example, take several years longer than their Turkish neighbors to sort out nominal case marking (Slobin, 2006). However, what is difficult for a child to learn, may not be difficult for an adult, and vice versa; early language acquisition and adult second-language learning are qualitatively different, both in the nature of the task demands, and in the capacities of the learners themselves (Ramscar \& Gitcho, 2007; ThompsonSchill et al., 2009). Likewise, there may be tradeoffs between what is easy to acquire, and what is efficient to process (see Ramscar et al. 2010 on adjective ordering).

In line with this proposal, there is accruing evidence that the structural form of a language is coupled to its population (and history) of adult learners (Johnson \& Newport, 1989; Trudgill, 2002). Support for this comes from a series of indepth analyses of the World Atlas of Language Structures conducted by Lupyan and Dale (2010), who found that languages with "larger speaker populations, greater geographical coverage, and greater degree of contact with other languages" (p. 6) tend to be morphologically simpler, more transparent in their mappings between form and meaning, and more likely to express semantic distinctions through lexical or pragmatic means, rather than encoding them explicitly in the grammar.

On this account, languages strike a balance between early learnability and adult processing that is moderated by their social niche. Thus, while morphologically complex languages provide a rich set of additional cues to scaffold infant learning, this early advantage has significant drawbacks for adult speakers. The same marking
conventions that support young learners, prove nearly impossible for adult learners to master (Johnson \& Newport, 1989), particularly when extrapolating from noisy input (Hudson Kam \& Newport, 2009).

In languages spoken by large populations of adult learners, there is thus both impetus and imperative to simplify the obligatory aspects of the grammar. Moreover, adult speakers are instrumental to how languages evolve-it is skilled language users (not novices) who make and spread innovations (Labov, 1972; Trudgill, 2010), and adult learners readily adapt newly acquired grammars to better meet their communicative needs (Fedzechkina, Jaeger, \& Newport, 2011; Kirby, Cornish, \& Smith, 2010).
From this perspective, the distribution of Modern English can be seen as having developed in response to the selective pressures produced by the conflicting gender systems of Old English and Norse, combined with a large percentage of adults in the population of language learners. These conditions resulted in a shift away from the abstract, grammaticalized entropy management system of Old English gender marking, to the more probabilistic, semantically transparent system based on adjectives found in Modern English. In comparison to German and Old English, Modern English has thus traded efficiency-in communicative terms-for error tolerance, making it more amenable to later learning.

## Adjectives and Overspecification

From a certain perspective, languages with complex inflectional patterns can appear inefficient, in that they obligate the marking of certain distinctions-such as the temporal remoteness of an action or event-that may or may not actually be relevant to the topic at hand (Lupyan \& Dale, 2010). Yet languages with more transparent semantics employ much of the same apparent redundancy: Native English speakers, who are not grammatically obliged to be superfluous, still regularly produce overspecified utterances like "that's a cute little puppy" and "how about a nice cold beer?" (Deutsch \& Pechmann, 1982; Engelhardt et al., 2006) The logic of such productions has proved notoriously difficult to account for: For one, they appear to violate the Gricean Maxim of Quantity, which assumes that speakers provide just enough information to identify a referent, and no more; for another, their combinatorial meaning has defied systematic description (Lahav, 1989), relegated by formal semanticists to the realms of 'context dependence' and 'vagueness' (Kamp \& Partee, 1995).
However, productions like these only appear mysterious if their meanings are assumed to be compositional-i.e., constructed as a function of their syntax and the meanings of their constituent parts (Fodor \& Lepore, 2002; but see Baroni \& Zamparelli, 2010 for a novel approach). Under the alternative model suggested by information theory, utterances are produced so as to iteratively reduce uncertainty, and different languages employ more (or less) conventionalized means of streamlining that process (Baayen \& Ramscar, 2015). While the patterns of adjective use in English are difficult to account for in terms of formal semantics, their communicative function is strikingly clear from an information theoretic perspective.

## Future Directions

One straightforward extension of this work is to the ordering of prenominal adjectives in English. Violations of conventional adjective ordering can make interpretation difficult, as when we compare 'old French red wine crates' with 'red French old wine crates.' Yet adjective ordering cannot be explained by a simple syntactic rule, and while various elaborate semantic hierarchies have been suggested (Table 1), they are not consistent enough to be implemented computationally (Malouf, 2000).

|  | Modification zones for adjectives |  |  |  |
| :--- | :--- | :--- | :--- | :--- | :--- |
| Determiner | Specification | Description | Classification | Head noun |
| The | same | beautiful | italian | actress |
| Her | own | handsome | jazz | musician |
| The | next | big | guardian | dog |
| This | particular | tall | aboriginal | carving |
| The | same | gray | church | tower |

Table 1: A semantic account of adjective order, in which specifying adjectives "single out or quantify the referent", descriptive adjectives "characterize the referent along a variety of semantic parameters", and classifying adjectives "categorize the referent" (Kemmerer et al., 2007: 240).

Ziff (1960) proposed that adjective order was determined according to two closely related heuristics: the adjective's "privilege of occurrence" (i.e., the range of nouns it might modify) and its "definiteness of denotation" (i.e., the extent to which its interpretation depended on the noun being modified). On this account, adjectives that are more privileged and more definite should be slotted closer to the noun. In a related vein, Danks and Glucksberg (1971) argued that adjectives are ordered according to their "discriminative potential", with the most broadly discriminating being placed first. Both of these claims are amenable to further scrutiny in terms of information and prediction.

One possibility is that adjective chains follow the familiar branching structure seen in personal names (Ramscar et al., 2014), with set-size increasing as a function of proximity to the head noun. This would be consistent with the finding that more frequent adjectives tend to precede less frequent ones. However, given that adjectives' appear to smooth entropy, rather than simply reduce it, the precise chaining structure may be closely tied up with the frequency of the noun being 'modified'. This could explain apparent exceptions to this trend (like "witty young lawyer").

In addition to adjective order, similar analyses might help explain the cross-linguistic differences that have been observed in languages with postnominal adjective biases (Percy et al. 2009; see also Lambert \& Paivio, 1956). More ambitious extensions could be made to other parts of speech, such as verbs and adverbs, and for other languages, beyond those studied here.

#### Abstract

In the study of recognition memory, a mirror effect is commonly observed for word frequency, with low frequency items yielding both a higher hit rate and lower false alarm rate than high frequency items. The finding that LF items consistently outperform HF items in recognition was once termed the "frequency paradox", as LF items are less well represented in memory. However, recognition is known to be influenced both by 'context noise'-the prior contexts in which an item has appeared-and 'item noise'-interference from other items present within the list context. In a typical recognition list, HF items will suffer more interference than LF items. To illustrate this principle, we deliberately manipulated both the contexts in which critical items had been encountered prior to study, and the confusability of targets and distractors. Our results suggest that when noise sources are balanced, the mirror effect disappears.

Keywords: recognition memory; context noise; item noise; prior history; semantic similarity; orthographic similarity; list length; word frequency; mirror effect; differentiation

## Introduction

In a typical episodic memory experiment, subjects are introduced to a new item or list of items within the experimental context, and memory is then tested for that set. In an old-new recognition task, for example, subjects study a list of words, and then are asked to discriminate words seen at study (targets) from non-studied words (foils). What is potentially challenging about the task is that subjects must identify just those items seen at study from all other words encountered in everyday life. In other words, they must discriminate between pre-experimental familiarity with the test items and familiarity that is specific to the task context. Performance at test is assessed by the $d$ ' sensitivity index, common in signal detection, which computes the distance between the means of the hit-rate distribution (the probability of correctly identifying a target) and the false alarm-rate distribution (the probability of misidentifying a lure), normalized by the common standard deviation.

The study of recognition memory has been dominated by global matching models, which are variants on signal detection models. These capture the idea that recognition of a particular item depends not solely on the properties of the item itself, in isolation, but also on other items present in memory (for a review, see Clark \& Gronlund, 1996). When a particular item is tested, the available cues-such as item and context-form a joint probe of memory, which is accessed in parallel. This global search yields a numerical value, which prompts an 'old'response if it exceeds some criterion. The returned value is variously understood as the global familiarity of the test item, the match between the test item and the contents of memory, and the activation strength of memory for that test item. How the value is calculated also depends on the process specified by the model, ranging from the sum of retrieval strengths (Gillund
\& Shiffrin, 1984) to the match between vectors (Murdock, 1982).

A general assumption is that the distribution of familiarity values will have a higher mean for studied items than for unstudied lures. However, interference at retrieval can arise from two sources: item noise (McClelland \& Chappell, 1998; Shiffrin \& Steyvers, 1997) and context noise (Dennis \& Humphreys, 2010). Item noise refers to the probability of a chance match between an item at test and memory traces for other studied items. Context noise refers to the probability of a match between the experimental context and other contexts in which the tested item has occurred.

To study how noise arises in recognition, designs typically manipulate one or more variables of interest, such as the number of items on the list (list length), the number of repetitions or exposure duration of a particular item at study (item strength), and the number of repetitions of the list (list strength). The properties of the items may also be systematically manipulated: For instance, a list might be comprised of an equal proportion of randomly selected high (HF) and low frequency (LF) items (mixed list), or alternately, contain only items selected from one frequency band (pure list).

The study presented here was designed to investigate the extent to which item and context noise affect recognition processes, by systematically manipulating both the prior contexts in which critical items had been encountered (Kinsbourne \& George, 1974; Estes \& Maddox, 1997), and the similarity of items within the list (Hintzman, 1988; Shiffrin, Huber, \& Marinelli, 1995). There are a number of reasons to believe that these manipulations to item and context noise should differentially affect items as a function of their frequency, which we shall now review.

## Word Frequency Effects in Recognition

In studies of recognition memory, a mirror effect is commonly observed in subject performance with regards to item frequency: Compared to HF items, LF items are better discriminated, yielding a higher hit rate (HR) and lower false alarm rate (FAR) (Glanzer \& Adam, 1985; Glanzer et al., 1993). A similar effect is observed in forced-choice recognition paradigms that include (in addition to the usual old-new pairs) old-old and new-new pairs, for which there is no 'correct' answer. Subjects in these studies preferentially choose LF words over HF words for target pairs, and HF words over LF words for foil pairs (Glanzer \& Bowles, 1976).

In assessing word frequency effects (WFE), there are a few wrinkles to consider: For one, the mirror effect is not always perfectly symmetric; the performance gap is typically smaller for hits than false alarms, and there may be differences in criterion as well as sensitivity (Hintzman, Caulton, \& Curran, 1994). For another, recognition performance does not vary monotonically with word frequency. Instead, LF words only appear to benefit when subjects have some familiarity with them (Schulman, 1976; Zechmeister, Curt, \& Sebastian, 1978). Further, when frequency is considered as a continuous variable,

HR follows a U-shape, with the greatest decrements observable in the mid-frequency band (Hemmer \& Criss, 2013).

Clearly, differences in performance on high and low frequency items cannot be reduced to their differential repetition in prior history. Instead, there appear to be multiple, interacting factors at play in producing differences between frequency bands. Some of the key factors include: 1) how well a particular item is differentiated from other items in the lexicon given prior learning history; 2) how discriminable that item is from other items on the present list, given the specific list composition; and 3) the degree to which that item will be associated with the present task context, which should be inversely related to the number of distinct contexts in which it has previously appeared.

## Differentiation over Learning

How do these dimensions differ for high and low frequency items in a standard recognition experiment? A common theoretical assumption is that greater experience with an item over learning leaves it better differentiated in memory-the idea being that repeated exposure acts to increase similarity between the studied item and its memory trace, while decreasing the similarity between its trace and all others (Criss, 2006). This view of repetition falls naturally out of discriminative learning models (Rescorla, 1972; Ramscar et al., 2010), in which cue weights are tuned to produce ever more efficient responding. It is also common to the study of categorization, where it is well known that similarity relations among items change in systematic ways as a function of learning (Nosofsky, 1986).

Models of recognition memory formalize this notion in slightly different ways. In the Retrieving Effectively from Memory (REM) model, each time an item is encountered within a given context, its episodic memory trace is updated, accruing more complete and accurate feature information (Shiffrin \& Steyvers, 1997). Thus, more encoding opportunities lead to a higher probability of self-match and a lower probability of matching an unrelated item, leading to 'differentiation' of the trace. Likewise, in the subjective likelihood model (SLiM), initial experience with an item yields a noisy and underspecified representation of its features, which is refined over learning (McClelland \& Chappell, 1998). A logical inference from these models is that HF items-by virtue of having been experienced more often, and in more contextsshould be better differentiated from one another in long-term memory than are LF items.

If HF items are better learned, why do they not routinely outperform LF items in recognition, as they do in other memory paradigms, like lexical decision and recall? This is known as the frequency paradox (Gregg, 1976).

## Context Noise

To address this question, it helps to consider how memory for a word depends on the contexts in which it has been previously encountered. Events stored in memory are comprised of both information that was central to processing (the item itself) and information that was available in the peripheral environment (the broader context). The contextual information that is encoded may include aspects of the temporal or physical context in which an item is presented, the emotional state of the learner, and so on (Murnane, Phelps, \& Malmberg, 1999; Smith, Glenberg, \& Bjork, 1978).

Because contextual information is stored alongside item information, memory for an item is facilitated when there is a high degree of match between its encoding and retrieval
contexts, a principle known as encoding specificity (Tulving \& Thomson, 1973). However, similarity between contexts can also produce interference in tasks, like recognition, that require discrimination among encoding contexts. In making an accurate recognition judgment, one of the key challenges is in distinguishing between familiarity with the item from the study list and familiarity from previous experiences in everyday life. The more prior contexts in which an item has occurred, and the more confusable those contexts with the study list, the harder the problem.

One way to demonstrate this is by incidentally exposing subjects to critical targets and lures in a familiarization phase prior to study, which shares many contextual features with the recognition task (e.g., the location, time of day, etc). Recognition for pre-exposed items is reliably impaired (Kinsbourne \& George, 1974; Tulving \& Kroll, 1995). Another method is to select list items that vary in their contextual diversity (CD)-i.e., the number of different pre-experimental contexts in which they have appeared. When CD varies, items with higher diversity scores are less well recognized overall, with a lower HR and higher FAR (Jones, Johns, \& Reccia, 2012; Steyvers \& Malmberg, 2003).

These findings establish context noise as an important source of interference at retrieval. Importantly, context noise is also a key dimension on which HF and LF items differ. Not only are HF words experienced more often than LF words, they are experienced in a more variable set of verbal contexts (Adelman et al., 2006; Jones, Johns, \& Reccia, 2012). Given their high frequency of occurrence in text and speech, they are also more likely to have been experienced more recently (Scarborough, Cortese, \& Scarborough 1977; Anderson \& Schooler, 1991). Relative to LF items, the contexts in which HF items are experienced will thus be more confusable with the study list, significantly increasing the difficulty of the recognition task for those items.

## Item Noise

Another clue to the "frequency paradox" concerns how memory for a single item depends on the composition of the surrounding list. As von Restorff (1933) demonstrated in a classic experiment, distinct items fare well on tests of recognition. For example, in a 10 item-list comprised of 9 nonsense syllables and 1 number, the number is recalled with far greater accuracy than the syllables. However, the extent to which a particular item benefits from its distinctiveness-i.e., its dissimilarity from other items-depends crucially on how dissimilar the rest of the items on the list are from each other.

To illustrate this idea, von Restorff placed the lone number on a list with several equally unrelated items, including "a syllable, a color patch, a single letter, a word, a photograph, a symbol, an actual button, a punctuation mark, and the name of a chemical compound" (as reported by Hunt, 1995, p. 109). Unsurprisingly, once all the items were similarly distinct, no advantage for the lone number was found. A benefit only obtained when the other items were clustered in similarity space relative to the critical item. That is, "similarity must establish a context in which difference functions" (Hunt, 1995).

The distinctiveness hypothesis proposes that memory for a given item should vary inversely with its featural overlap with other items at study (Hunt \& Mitchell, 1982). In line with this, when subjects are asked to remember a list of statements that are either congruent or incongruent with their expectations, incongruent-facts tend to be advantaged in recall-but only so long as they comprise a minority of the list (Hastie \& Kumar, 1979). Parallel results have been reported for word recall, where it has been found that orthographically or semantically
unusual items only benefit when presented with common ones (Hunt \& Eliott, 1980; see also Zechmeister, 1972). This is consistent with a surprisal-based account of the von Restorff effect (Green, 1956).

In recognition, it is clear that distinctiveness matters both at encoding and at retrieval. Researchers as far back as Postman (1951) have observed that performance on tests of recognition memory varies inversely with the similarity of items at study and at test, and thus, with the choice of distractor (Anisfield \& Knapp, 1968; Bahrick, Clark, \& Bahrick, 1967). For example, in face recognition, distinctive faces are better recognized than common faces when lures are selected at random, but recognized more poorly when the similarity of lures to targets is controlled (Davidenko \& Ramscar, 2005).

Importantly, distinctiveness is a feature on which low and high frequency items are bound to vary. LF words are, on average, more orthographically distinctive than HF wordscomprised of more rare letters, and more uncommon combinations of letters (Estes \& Maddox, 2002; Malmberg et al. 2002)—and belong to much sparser orthographic neighborhoods, with both fewer and rarer neighbors (Landauer \& Streeter, 1973).

In a random selection of words, LF items will also be more semantically distinctive than their HF counterparts. This is guaranteed by the distributional properties of the lexiconspecifically the fact that LF words are drawn from a much larger sample than their HF counterparts (using a 1 per million word cutoff, $80 \%$ of all words can be classified as low frequency; van Heuven et al. 2014). As a result, LF items will be less semantically similar to one another, on average, than HF items. A variety of measures of semantic richness attest to this: LF words have fewer closer associates (Deese, 1960; Balota et al., 2004), fewer close semantic neighbors (Pexman et al., 2008), and more sparse network connectivity (Steyvers \& Tenenbaum, 2005).

While HF items are better differentiated in memory, they are also drawn from a much more tightly clustered similarity space, both in terms of their surface and semantic features. When presented in a mixed lists of randomly selected items, they should thus be less distinctive at encoding and more confusable at test. ${ }^{1}$

## Study

In standard recognition experiments, there is a significant imbalance between frequency bands. When item selection is random, LF words should tend to be more orthographically and semantically distinctive than HF words, suggesting that they demand more attentional resources at encoding, and are less confusable with frequency-matched distractors at test. At the same time, their occurrence as a list item is less confusable with other, previous occurrences: LF items have been experienced in fewer, less diverse contexts, and are less likely to have been experienced recently.

In this study, our goal is to bring the sources of noise for high and low frequency items more in balance. To accomplish this re-balancing act, we manipulated two key variables: (1) recency of exposure ('context noise') and (2) inter-item similarity ('item noise'). When these noise sources are equalized, HF items, which are better represented in memory, should outperform LF items.

Design In the familiarization phase of the study, subjects completed a simple reading comprehension test in which they were incidentally exposed to a set of critical words. Following a short delay, subjects returned to complete a list recognition task in which they studied a list of words, and at test, were asked to distinguish between studied items (targets) and novel items (foils).

Context noise was manipulated by inserting previously encountered critical words at study and at test. To assess how recent exposure affected recognition, the study counterbalanced both whether a given word was encountered in reading, and whether it occurred as a target or foil. Item noise was manipulated by selecting control words for the recognition task from dense semantic categories (Figure 1). To assess for frequency effects, both critical and control words were evenly divided between high and low frequency bands.

Figure 1: The average semantic similarity of targets to distractors in lists randomly generated from the Exp. 1 control items, as compared to standard episodic word pools (see Dye et al., 2017 for methodology). Drawing items from semantic categories disproportionately increases similarity for LF items.

Participants 54 undergraduate students at Indiana University participated in the experiment for course credit. All were native American English speakers with normal or corrected-to-normal vision. 3 subjects were excluded from the analysis for performing at chance on the reading comprehension portion of the experiment.

Materials Two word lists were constructed (see Appendix), each of which comprised 40 critical words: 20 HF (165 occurrences/million) and 20 LF (1 occurrence/million), frequency matched across lists, using counts drawn from the Corpus of Contemporary American English (COCA: Davies, 2010).

In addition, an inventory of 240 control words was created, drawn from sixteen semantic categories (such as 'music' and 'time'). Half of these semantic categories were comprised of HF items, and half LF items. These control items were included to assess how item noise affects recognition. Introducing

[^61]semantic categories should disproportionately amplify item noise for LF items, by increasing the semantic and orthographic confusability of targets and distractors (Figure 1).

To create reading materials for the comprehension task, short passages were excerpted from the collected works of the notable Columbian author, Gabriel Garcia Marquez. Specifically, for each word on each of the lists, a passage containing that word was identified and paired with a true statement that synthesized the sentence in which the word had occurred. Affirming the statement as true relied on correct comprehension of the word. Additionally, 20 control passages, which contained no critical items, were selected and paired with a false statement. Each critical word appeared in only one of all possible paragraphs, and only once in that paragraph.

To gauge how pre-exposure affected recognition accuracy and response time, four counterbalanced conditions were created, such that across subjects, each critical item was presented as both a target and as a foil, and was either preexposed (encountered once previously in reading) or novel (occurring for the first time in the recognition task).

Study lists comprised 40 critical items and 120 control, and test lists comprised all 160 targets and an additional 160 foils, with the same 1:3 distribution between critical and control items. Here again, controls were evenly split between high and low frequency items, drawn from the same part of the frequency distribution as the critical words.

Procedure In the first stage of the experiment, subjects completed a self-paced reading comprehension task in which they read a series of short passages and, following each paragraph, were presented with a short statement and asked to determine whether it was true or false. Subjects then moved to a different experiment room to complete a 20 -minute distractor task, in which they solved a series of tangram puzzles. They then returned to the original room to complete the list recognition task.

At study, 160 words were presented on a computer monitor for 1 s each, separated by a 100 ms ISI. At test, subjects were presented with a new set of items, and asked to judge whether a given item had been presented at study. Testing consisted in 320 self-paced recognition trials, with up to 5 s to respond. Order of presentation for passages and for list items was randomized.

Results Looking first to the control items, which were drawn from tightly clustered semantic categories, but did not vary in their exposure history: Welch two-sample $t$-tests confirmed that -consistent with the typical finding-LF targets had a significantly higher HR than HF targets, both by items $[t(212.63)=-4.12, p<.0001]$ and by subjects $[t(99.34)=-3.20$, $p=0.002$ ]. However, the FAR for LF and HF foils was not significantly different ( $p>.5$ ), and the speed of correct rejections was slower for LF foils, both by items $[t(234.24)=-5.85, p<.0001]$ and (marginally) by subjects $[t(97.82)=-1.70, p<.0 .092]$.

Performance on control items thus shows a marked departure from the standard mirror effect: The typical FAR advantage for LF items disappears, and LF foils are more slowly rejected than HF foils (Figure 2). The trends captured here are robust over the course of testing (see Figure 6 for contrast). This finding is consistent with the notion that the introduction of semantic categories differentially increases item noise for low frequency items, diminishing the typical LF advantage. However, LF control items still outperformed HF control items overall-the increase in FAR was balanced by the sustained HR advantage.

Figure 2: Control item performance for correct RT (right panel) and $p$ (old) (left panel), shown by frequency and trial type. Error bars are SEM.

An identical pattern is observable for the critical items with no prior exposure (Figures 3, 4). However, for these items, the mirror effect disappears completely following exposure at reading, and overall performance for HF and LF items draws even (Figure 3). This is because while $p$ (old) increases overall, the LF FAR increases sharply, far outstripping that of the HF foils (Figure 4).

Figure 3. The effect of prior reading exposure on critical items, as measured by $d^{\prime}$ (using a $1 / 2 \mathrm{~N}$ correction).

Figure 4: The effect of prior reading exposure on $p$ (old), graphed by frequency and trial type. Error bars are SEM.

Performance on critical items (Figures 4, 5) can be broken down as follows: For targets, there was a main effect of item frequency on accuracy $[F(1,50)=28.42, p<0.001]$, and a main effect of exposure condition both on accuracy $[F(1,50)=3.35$, $p=.073$ ] and correct RT $[F(1,50)=14.36, p<.0005]$. Subjects were more likely to affirm LF targets overall, and to more quickly and (marginally more) accurately affirm targets that had previously been seen in reading.

For foils, the picture was somewhat more complicated, but no less consistent. For response time, there was a main effect of
item frequency on correct RT $[F(1,50)=5.87, p<0.02]$, but no effect of prior context. For accuracy, there were main effects of item frequency $[F(1,50)=3.98, p=0.052]$ and prior context $[F(1,50)=14.82, p<.001]$, modulated by a significant interaction between frequency and context $[F(1,50)=4.66, p<.05]$. Post hoc analyses (Tukey HSD) indicated that previous exposure significantly increased the FAR for LF items ( $p<0.001$ ) but not HF items ( $p>.5$ ), and that the FAR for pre-exposed LF items was significantly higher than for pre-exposed HF items ( $p<0.005$ ).

Figure 5: The effect of prior reading exposure on response latency, graphed by frequency and trial type. Error bars are SEM.

Figure 6: $P($ old $)$ to critical LF items as a function of test position for hits (top) and false alarms (bottom). Trend lines are generated by the glm smoothing method in ggplot2.

To summarize: For HF items, the primary effect of prior exposure was to increase the speed and accuracy of hits. This effect was also observable for LF targets, and the time to execute a hit was similar for HF and LF targets. However, with LF items, the recency manipulation led to an overall bias in $p$ (old), such that both the HR and the FAR were significantly higher than that of HF items. The dramatic increase in FAR, as a result of item and context noise, is mirrored by the finding that correct rejections were significantly slower for LF foils across both exposure conditions.

In this study, the magnitude of the performance drop for LF items is, in part, a function of testing (Annis, Malmberg, Criss, \& Shiffrin, 2013). At the beginning of testing, no effect of prior history was apparent: the HR for exposed and unexposed critical items was identical, as was the FAR. However, while
the HR for LF items uniformly declined over trials, the pattern of false alarms diverged depending on prior exposure (Figure 6): Whereas for unexposed items, the FAR showed a steady downward trend, for previously encountered items, precisely the opposite was true. This suggests that the ability to discriminate prior context decreased with continued testing. By contrast: For HF items, while a similar decline in HR is observable over testing, the FAR remains constant, and exposure condition does not appear to interact with these trends.

## General Discussion

This paper investigates the sources and robustness of the mirror effect for normative word frequency, finding that under the right set of experimental conditions, it disappears. In particular, when noise sources for high and low frequency items are balanced, LF items prove to be more confusable than better-learned HF items.

## Word Frequency Effects

The aim of the present study was to examine how item and context noise interact with word frequency effects. Item noise was manipulated by selecting control items from a small set of semantically cohesive categories, such as 'music' and 'cooking' (Shiffrin, Huber, \& Marinelli, 1995). Context noise was manipulated by incidentally exposing subjects to critical items prior to the recognition task (Kinsbourne \& George, 1974; Tulving \& Kroll, 1995). Both noise sources have been found to impair recognition in a similar fashion: While these manipulations lead to an overall increase in the probability of responding 'old', the increase in hits is slower than the concomitant increase in false alarms, leading to a general decline in discriminability. For instance, when categories of items are present within a recognition list, hits and false alarms increase monotonically with the number of items within each semantic category, such that discriminability decreases as a function of category size (Hintzman, 1988). Similarly, when items are incidentally exposed prior to study, confusability increases as a function of the number of prior exposures (Criss \& Shiffrin, 2004; Chalmers \& Humphreys, 1998), and as the delay between the familiarization and recognition phases decreases (Maddox \& Estes, 1997).

While previous research has tended to focus on how noise affects items from within a single frequency band, our experiment assessed how items were differentially affected as a function of their frequency. A close analysis of the mirror effect for recognition suggests that it derives from the distinctiveness of LF items relative to their HF counterparts. Specifically -in a random selection of items, LF targets will be more distinctive at study, and more distinctive at test compared to foils; in addition, the contexts in which they have previously occurred will be less confusable with the present study context.

In our study, these advantages are systematically mitigated. Introducing verbal categories entails that items will be sampled from a dense semantic space, rather than randomly from the lexicon at large. This selects for LF items that are more similar to each other than HF items, rendering them more confusable at test. Likewise, pre-exposing critical items guarantees that all such items, regardless of frequency, will have recently been experienced in a highly similar, confusable context. If the usual LF FAR advantage is mediated, at least in part, by the greater distinctiveness of randomly selected LF targets relative to potential lures, and by the greater distinctiveness of their prior contexts of occurrence, then these manipulations should diminish or reverse that advantage.

Our findings comport well with this proposal. The item noise manipulation disappeared the LF FAR advantage both for control items and for critical items with no prior exposures: LF foils attracted a similar number of false alarms as HF foils and were rejected significantly more slowly. (A similar result has been reported when orthographic similarity among items is controlled, and lures are orthographically matched to targets; Hall, 1979; Malmberg, Holden, \& Shiffrin, 2004).

The context noise manipulation amplified this effect, fully reversing the FAR advantage in favor of pre-exposed HF items, a trend that intensified over the course of testing. This occurred because while pre-exposure dramatically increased the LF FAR, it had a negligible effect on HF items. These manipulations thus vanished one half of the standard mirror effect, equalizing the overall discriminability of HF and LF items.

Nevertheless, LF items maintained a strong HR advantage. There are a number of possible theoretical explanations for this result: LF items may have garnered more attentional resources at study (Malmberg \& Nelson, 2003), been more easily associable with the present task context (Hirshman, Whelley, \& Palij 1989), or simply been a better match to their own memory traces at retrieval. All these explanations are potentially consistent with the results of the present study, but beyond its scope to establish; further experimental work is needed to distinguish among these accounts.

## Modeling Accounts

Empirical results like those presented here can provide important constraints on representational assumptions in modeling (Criss \& Shiffrin, 2004). For example, to account for the standard mirror effect, the REM model assumes that LF items possess more rare features than HF items, features that are more diagnostic (Steyvers \& Shiffrin, 1997). This implies 1) that LF targets will be a better match to their own memory traces than HF targets (resulting in a higher HR), and 2) that LF foils will be less likely to share features in common with targets than HF foils, resulting in less spurious matches (resulting in a lower FAR). REM thus correctly predicts that when targets are matched with highly similar foils, the FAR for LF items should substantially increase, diminishing or reversing the standard mirror effect. REM can also be modified to account for the finding that increasing the proportion of HF words on a list decreases the FAR for LF items, by assuming that the distinctiveness of the LF items at study leads to better encoding (Malmberg \& Murnane, 2002).

Likewise, virtually all models of recognition memory incorporate the idea that an item's prior contexts of occurrence are a critical source of interference (Dennis \& Humphreys, 2000). A common assumption is that both item and context information are stored at encoding and that similarity between the study context and prior experiences gives rise to interference at retrieval. What varies is how: In some models, the item and context on the current trial form a joint probe of memory (Gillund \& Shiffrin, 1984). In others, the context cue first acts to restrict the subset of activated memory traces to those that match the current context, prior to comparing the item cue to the resulting set (Shiffrin \& Steyvers, 1997).

In future work, it may be profitable to use item representations derived directly from the items themselves, by quantifying the lexical and semantic characteristics of a given list or word pool (Dye et al., 2017). Models can then be constructed and tested against the true properties of the stimulus set, permitting cleaner adjudication between competing accounts.

#### Abstract

We report the results of a large-scale ( $N=1571$ ) experiment to investigate whether spoken words can emerge from the process of repeated imitation. Participants played a version of the children's game "Telephone". The first generation was asked to imitate recognizable environmental sounds (e.g., glass breaking, water splashing); subsequent generations imitated the imitators for a total of 8 generations. We then examined whether the vocal imitations became more stable and word-like, retained a resemblance to the original sound, and became more suitable as learned category labels. The results showed (1) the imitations became progressively more word-like, (2) even after 8 generations, they could be matched above chance to the environmental sound that motivated them, and (3) imitations from later generations were more effective as learned category labels. These results show how repeated imitation can create progressively more word-like forms while retaining a semblance of iconicity.

Keywords: categorization; transmission chain; language evolution

People have long pondered the origins of languages, especially the words that compose them. For example, both Plato in his Cratylus dialogue (Plato and Reeve, 1999) and John Locke in his Essay Concerning Human Understanding (Locke, 1948) examined the "naturalness" of words-whether they are somehow imitative of their meaning. Some theories of language evolution have hypothesized that vocal imitation played an important role in generating the first words of spoken languages (e.g., Brown et al., 1955; Donald, 2016; Imai and Kita, 2014; Perlman et al., 2015); early humans may originally have referred to a predatory cat by imitating its roar, or to the discovery of a stream by imitating the sound of rushing water. Such vocal imitation might have served to clarify the referent of a vocalization and eventually establish a mutually understood word. In this study, we investigate the formation of onomatopoeic words-imitative words that resemble the sounds to which they refer. We ask whether onomatopoeic words can be formed gradually and without instruction through repeated imitation.

Onomatopoeic words appear to be a universal lexical category found across the world's languages (Dingemanse, 2012). Languages all have conventional words for animal vocalizations and various environmental sounds. Rhodes (1994), for example, documented a repertoire of over 100 onomatopoeic

Figure 1: The design of the transmission chain experiment. 16 seed sounds were selected, four in each category of environmental sounds. Participants imitated each seed sound, and then the next generation of participants imitated the imitations and so on for 8 generations.
words in English, which he notes exist along a continuum from "wild" to "tame". People often use more wild vocal imitations and other sound effects during demonstrative discourse, especially when producing quotations (Blackwell et al., 2015; Clark and Gerrig, 1990). Wild words have a more imitative phonology whereas tame words take on more standard phonology of other English words. In some cases, words that begin as wild imitations of sounds become fully lexicalized and integrated into the broader linguistic system, when they behave like more "ordinary" words that can undergo typical morphological processes. Examples are English words like "crack" or the recently adapted "ping".

However, not all researchers agree that vocal imitation has any significant role in language. For instance, Pinker and Jackendoff (2005) suggested that, "Humans are not notably talented at vocal imitation in general, only at imitating speech
sounds (and perhaps melodies). For example, most humans lack the ability (found in some birds) to convincingly reproduce environmental sounds ... Thus 'capacity for vocal imitation' in humans might be better described as a capacity to learn to produce speech." Nevertheless, experiments show that people can be quite effective at using vocal imitation. For example, Lemaitre and Rocchesso (2014) collected imitations and verbal descriptions of mechanical and synthesized sounds. When participants listened to these and were asked to identify the source, they were more accurate with imitations than descriptions. A subsequent study found that vocal imitations tend to focus on a few salient features of the sound rather than a high fidelity representation, which aids identification of the source (Lemaitre et al., 2016).

Thus humans can be effective at communicating with vocal imitation, it can play an important role in narration and discourse, and it appears to be the basis for substantial inventories of sound-imitative vocabulary across languages. But the process by which onomatopoeic words like "meow", "ping" and "buzz" emerge from vocal imitations has yet to be observed. Here we examine whether simple repeated imitations of environmental sounds become more word-like even in the absence of explicit communication intent or the intent to create a word-like token. Alternatively, repeating imitations might never stabilize on a particular wordform, or the limited fidelity of human vocal imitation may simply restrict the formation of stable words through iterated imitations.

To test this, we recruited participants to engage in a large scale online version of the children's game of "Telephone" in which an acoustic message is passed from one person to the next. After obtaining these imitations, we investigated how the imitations changed over generations to determine whether they became more word-like. We investigated the acoustic properties of the imitations as well as the orthographic properties once transcribed into English words. We find that by both measures the imitations become more stable through repetition. In addition to stability, we also find that the imitations can still be matched back to the original sounds at above chance levels for many generations. Finally, we measured how quickly the invented words are learned as category labels in a category learning experiment, and find that later generation imitations are easier to learn as category labels.

## General Methods

In Experiment 1 we collected iterated vocal imitations using the transmission chain design depicted in Fig. 1. We then assessed changes in these imitations over generations in the remaining experiments, which are listed in Table 1. In Experiment 2 we assessed the extent to which each imitation could be matched back to its originating sound. Experiment 3 involved collecting transcriptions of imitations, and these transcriptions were matched back to the original sounds in Experiment 4. In Experiment 5 we selected transcriptions taken from first and last generation imitations as novel labels in a simple category learning experiment.

Table 1: Experiment sample sizes. Participants in Experiments 1-4 were recruited via Amazon Mechanical Turk and paid to participate in an online study. Participants in Experiment 5 were University of Wisconsin-Madison undergraduates who received course credit in exchange for participation.

## Exp 1: Collecting imitations

In Experiment 1 we collected the iterated vocal imitations that served as the basis for the remaining experiments. Our hypothesis was that these vocal imitations would become more stable as they were repeated over generations of speakers.

## Methods

We selected inanimate categories of sounds because they were less likely to have lexicalized onomatopoeic forms already in English, and they were less familiar and more difficult to imitate. Nonetheless, it is possible that lexical knowledge still influenced imitation fidelity-a possibility to be explored in future work. The sounds used here were selected using an odd-one-out norming procedure ( $N=105$ participants) to reduce an initial set of 36 sounds in 6 categories to a final set of 16 "seed" sounds: 4 sounds in each of 4 categories. The four final categories included: water, glass, tear, zipper.

Participants were paid to participate in an online version of the children's game of "Telephone". The instructions informed participants that they would hear some sound and their task is to reproduce it as accurately as possible using their computer microphone. Participants listened to and imitated 4 sounds. Participants received one sound from each of the four categories of sounds drawn at random such that participants were unlikely to hear the same person more than once. Imitations were monitored by an experimenter to catch any gross errors in recording before they were passed on to the next generation of imitators, including blocking sounds that violated the rules of the experiment, e.g., by saying something in English.

Given large differences in recording quality resulting from conducting the experiment online, we were unable to use previously published techniques for calculating acoustic distance (cf. Lemaitre et al., 2016). Instead, we obtained subjective measures of acoustic similarity using a controlled, randomized norming procedure completed by research assistants. Five RAs listened to pairs of imitations while blind to generation and rated their similarity on a 7-point scale where a 1 meant the sounds could never be confused with one another and a 7 meant the sounds were nearly identical.

Figure 2: Increase in acoustic similarity over generations. Points depict mean acoustic similarity ratings for imitations in each category of environmental sounds. The predictions of the linear mixed effects model with random effects for rater and category are shown, with error bands denoting +/- 1 standard error of the model predictions.

## Results

We collected a total of 480 imitations, of which 115 were removed, leaving 365 imitations along 105 contiguous transmission chains for analysis. Imitations from later generations were rated as being more similar to one another than imitations from earlier generations, $b=0.09(0.02), t(4.5)=4.42, p$ $=0.009$ (Fig. 2), suggesting that the imitations are stabilizing through repetition.

## Exp 2: Matching imitations to seeds

Experiment 2 was conducted to determine if the imitations retained some resemblance to the original environmental sound that motivated it (i.e. the seed sound). Participants listened to imitations and guessed which seeds they came from. By varying the relationship between the imitation and the options presented to each participant, we were able to assess the extent to which the imitations retained categorical as opposed to specific, identifying information. On the view that repetition makes the imitations more word-like, we expected later imitations to be better indicators of categories of sounds as opposed to specific sounds within each category.

## Methods

All 365 imitations collected in Experiment 1 were tested in each condition depicted in Fig. 3. On each trial participants listened to an imitation and selected among four possible options as to which option sounded the most like the imitation. They did not receive any feedback on their performance. We tested three types of matching questions that differed according to the relationship between the imitation and the four seed sounds serving as the options in the 4AFC task (Fig. 3).

Figure 3: Types of matching questions depicted in relation to the 16 seed sounds. For each question, participants listened to an imitation (dashed circles) and had to guess which of 4 sound choices (solid circles) they thought the person was trying to imitate. (Top) True seed questions contained the actual seed that generated the imitation in the choices, and the distractor seeds were sampled from different categories. (Middle) Category match questions also used distractor sounds from different categories but the correct seed was not the actual seed, but a different sound within the same category. (Bottom) Specific match questions pitted the actual seed against the other seeds within the same category.

## Results

Matching accuracy for all question types started above chance for the first generation of imitations, $b=1.65$ ( 0.14 ) log-odds, odds $=0.50, z=11.58, p<0.001$, and decreased steadily over generations, $b=-0.16$ (0.04) log-odds, $z=-3.72, p<$ 0.001 . We tested whether this increase in question difficulty was constant across the three types of questions or if some question types became more difficult at later generations.

The results are shown in Fig. 4. Performance decreased over generations more rapidly for specific match questions than for category match questions, $b=-0.05$ ( 0.02 ) log-odds, $z=-2.53, p=0.012$, suggesting that category information was more resistant to loss through transmission. One explanation for this result is that the specific match questions are simply harder than the category match questions. However, performance also decreased more rapidly for the easiest type of question where the correct answer was the actual seed generating the imitation. The advantage for having the true seed among the options decreased over generations, $b=-0.07$ (0.02) log-odds, $z=-2.83, p=0.005$. These results indicate that later generation imitations were more likely to be recognized as identifiers of a particular category than they were of particular exemplars within each category.

Figure 4: Accuracy in matching imitations back to seed sounds. Performance is separated by question type based on the relationship between the imitation and the options in the question (see Fig. 3). Lines depict predictions from the generalized linear mixed effects model along with $+/-1$ standard error of the model predictions.

## Exp 3: Collecting transcriptions of imitations

In addition to assessing stability in the acoustic properties of the imitations, we also measured orthographic agreement. If imitations are becoming more wordlike we would expect orthographic agreement to increase over generations.

## Methods

We selected the first and final three imitations in each transmission chain to be transcribed into English orthography. Participants were instructed to write down what they heard as a word so that the written word would sound like the message.

## Results

We collected a total of 2182 or roughly 21 transcriptions per imitation. All transcriptions containing actual English words were excluded from analysis. Orthographic agreement was measured as the longest contiguous substring match between the most frequent transcription of an imitation and all other transcriptions. Analyzing changes in orthographic agreement over generations paralleled what was observed in the analysis of acoustic similarity: Transcriptions from later generation imitations were more similar to one another in terms of orthographic distance than transcriptions from earlier generations, $b=-0.12$ ( 0.03 ), $t(3.0)=-3.62, p=0.035$ (Fig. 5). This result supports our hypothesis that the imitations were becoming more stable in both acoustic and orthographic forms.

## Exp 4: Matching transcriptions to seeds

Experiment 4 tested whether the transcriptions could be matched back to the original seed sounds.

Figure 5: Average orthographic distance among transcriptions of imitations taken from first and last generations. Each point represents the average distance among all transcriptions for a single imitation. Error bars are +/- 1 standard error of the linear mixed effects model predictions.

## Methods

The top 4 most frequent transcriptions for each imitation transcribed in Experiment 3 were tested in Experiment 4. Participants completed a modified version of the 4AFC described in Experiment 2. Instead of listening to imitations, participants now read a transcription of an imitation, which they were told was an invented word. They were instructed that the word was invented to describe one of four presented sounds, and they had to guess which one. Specific match questions (see Fig. 3) were not collected for transcriptions.

## Results

Participants were able to guess the correct meaning of the transcribed word above chance even after 8 generations of repetition, $b=0.83$ ( 0.13 ) log-odds, odds $=-0.18, z=6.46, p$ $<0.001$ (Fig. 6). This was true both for true seed questions, $b$ $=0.75$ (0.15) log-odds, odds $=-0.28, z=4.87, p<0.001$, and for category match questions, $b=1.02(0.16)$ log-odds, odds $=0.02, z=6.39, p<0.001$. The effect of generation did not vary across these question types, $b=0.05$ ( 0.10 ) log-odds, $z$ $=0.47, p=0.637$.

## Exp 5: Transcriptions as category labels

In Experiment 5 we examined whether there was a learning advantage to the more word-like imitations emerging through iterated repetition as compared to direct imitations of the source of the sound. We hypothesized that transcriptions of the more word-like forms emerging through repeated imitation should be easier to generalize to new category members than transcriptions from direct imitations.

Figure 6: Matching accuracy for transcriptions of imitations taken from first and last generations. True seed questions contained transcriptions of the actual seed generating the transcribed word. Category match questions contained transcriptions of imitations of other seeds from the same category.

## Methods

To determine which transcriptions to test as category labels, we selected transcriptions which were matched above chance in Exp. 2. Of these, transcriptions with fewer than two unique characters or more than 10 characters in length were excluded. The final set comprised first and last generation imitations sampled to control for overall matching accuracy.

Participants learned, through trial-and-error, the names for four different categories of sounds. On each trial participants listened to one of the 16 environmental sounds used as seeds and then saw a novel word-a transcription of one of the imitations. Participants responded by pressing a green button if the label was the correct label and a red button otherwise. They received accuracy feedback after each trial.

The experiment was divided into blocks so that participants had repeated exposure to each sound and the novel labels multiple times within a block. At the start of a new block, participants received four new sounds from the same four categories (e.g., a new zipping sound, a new water-splash sound, etc.) that they had not heard before, and had to associate these sounds with the same novel labels from the previous blocks. The extent to which their performance declined at the start of each block serves as a measure of how well the label they associated with the sound worked as a label for the category.

## Results

When participants had to generalize the meaning of the novel label to new category members (new sounds), they were faster when the label came from transcriptions of later generation imitations than from transcriptions of first generation imitations, $b=-114.13$ (52.06), $t(39.9)=-2.19, p=0.034$ (Fig. 7A). Accuracy improved over generations but did not significantly differ between groups, $p>0.05$. The effect can be further localized within each block. Comparing RTs on the trials leading up to a block transition and the trials immediately after the block transition (6 trials) revealed a reliable interaction between block transition and the generation of the transcribed label, $b=-146.75$ (65.47), $t(1869.7)=-2.24, p=$

Figure 7: (Top) RTs on correct trials by block, showing faster responses when learning category labels transcribed from last generation imitations. (Bottom) RTs on trials leading up to and immediately following the block transition where new category members are introduced.
0.025 (Fig. 7B). This suggests that in addition to becoming more stable both in terms of acoustic and orthographic properties, imitations that have been more repeated may also be faster to learn as category labels.

## Discussion

We show that repeated imitation of an originally imitative vocalization gradually becomes more word-like as it is transmitted along the chain of a "Telephone" game. The first evidence provided showed that imitations became more stable over generations of repetition, both in terms of acoustic similarity as well as in orthographic agreement. But more than just becoming more stable over generations, the imitations also become more word-like in that they served as more effective category labels. Category information was more resilient to transmission decay than specific information identifying a particular exemplar within a category. This category information remained even when the imitations were transcribed into lexical forms, as participants were able to guess the categorical meaning of the word at above chance levels even after 8 generations of repetition. One such consequence of having words is that they make categorization easier. In support of this conclusion, we found that participants were faster and
not less accurate in learning category labels that had emerged through repeated imitation than those who learned from transcriptions of direct imitations of the environmental sounds, completing the transition from nonverbal imitation to a fully lexicalized word form and demonstrating the impact of this transition on communication.

One result that did not fit squarely with imitations becoming more word-like is that with transcriptions, there was no difference over generations between question types. If the results of matching transcriptions back to seed sounds would have mirrored the results of matching imitations we would have expected the difference between True seed questions and Category match questions to decrease over generations, but it did not. Although participants were able to match transcriptions to categories of sounds after 8 generations of repetition, it was easier for them to match a transcription to the actual seed that generated the transcription, meaning that individuating information was retained over and above category information. One possible explanation for this is that by converting the imitations into orthographic representations of phonemes, idiosyncratic features of the sound could become rendered as categorical phonological features. This process could exaggerate the features and facilitate identification of the source. To test this we need to collect match accuracy for transcriptions on Specific match questions to see if transcriptions are able to be matched within-category even when the imitations that generated those transcriptions are not.

Our study focused on the formation of onomatopoeia-sound-imitative words-but in addition to onomatopoeia, many languages have semantically rich systems of ideophones. These words comprise a grammatically and phonologically distinct class of words that are used to express a variety of sensory-rich meanings (Dingemanse, 2012; Voeltz and Kilian-Hatz, 2001). Notably, these words are often recognized by native speakers to be somehow imitative of their meaning. For example, in Japanese, the word 'koron' - with a voiceless [k] refers to a light object rolling once, the reduplicated 'korokoro' to a light object rolling repeatedly, and 'gorogoro' - with a voiced [g] - to a heavy object rolling repeatedly (Imai and Kita, 2014). The iconicity of ideophones was verified by an experiment that tested the ability of nave listeners to guess the meanings of words sampled from five different languages (Dingemanse et al., 2016). Although words for sounds were guessed more accurately than the rest, listeners were better than chance at guessing the synonyms of ideophones that expressed meanings from all five semantic categories tested - color/visual, motion, shape, sound, and texture. In addition, laboratory experiments show that people are able to generate imitative vocalizations for a variety of non-sound concepts, and that these are also understandable to nave listeners (Perlman et al., 2015). Thus vocal imitation has the potential to play a role in word formation that extends beyond just the imitation of sounds.

Our findings from an online game of Telephone suggest that the formation of words from vocal imitation can be a sim-
ple process. The results show how repeated imitation can create progressively more word-like forms while retaining a resemblance to the original sound that motivated it. This raises the possibility that onomatopoeic words can be created simply through repeated imitation.

# A Model of Event Knowledge 

Jeffrey L. Elman (jelman@ucsd.edu)<br>Department of Cognitive Science, 9500 Gilman Drive<br>La Jolla, CA 92093 USA

Ken McRae (kenm@uwo.ca)<br>Department of Psychology, Social Science Centre<br>London, ON N6A 5C2 Canada

#### Abstract

We present a connectionist model of event knowledge that is trained on examples of sequences of activities that are not explicitly labeled as events. The model learns co-occurrence patterns among the components of activities as they occur in the moment (entities, actions, and contexts), and also learns to predict sequential patterns of activities. In so doing, the model displays behaviors that in humans have been characterized as exemplifying inferencing of unmentioned event components, the prediction of upcoming components (which may or may not ever happen or be mentioned), reconstructive memory, and the ability to flexibly accommodate novel variations from previously encountered experiences. All of these behaviors emerge from what the model learns.

Keywords: events; schema; scripts; prediction; recurrent connectionist model

## Introduction

We know many things about the world. How that knowledge is organized, its content, and how it is stored, accessed, and learned have been the subject of semantic memory research for some time. A long and rich tradition of scholarship has produced a relatively stable set of theoretical constructs that are used for discussing this kind of knowledge, including categories, concepts, and features.

But people also possess another type of knowledge that has been long recognized as extremely important, although it is less clearly understood. This is knowledge about common situations and events, and has been referred to by a range of names, including pragmatic knowledge and world knowledge. Such knowledge appears to serve multiple purposes. It guides our behavior, and helps us interpret the behavior of others. We use this knowledge to anticipate the consequences of events as they unfold. We use this knowledge extensively in language understanding to make inferences about components of situations that may be unstated or incompletely described.

Bartlett (1932) was one of the first psychologists to talk about the role of such knowledge in memory. Later, in the 1970s and 1980s, cognitive psychologists such as Bransford and colleagues demonstrated that event knowledge is important in encoding and retrieving details about situations. Garrod and Sanford, among many others, showed that this kind of knowledge supports inferences in language
comprehension. One assumption that appears to be shared (though was often implicit) was that the use of world/pragmatic/event knowledge in language comprehension occurred at late stages in processing. In large part this reflected theoretical assumptions of the time in linguistics and psycholinguistics, but it is also true that the typical experimental tasks used at the time were off-line, and did not lend themselves to tracking real-time incremental processing.

Over the years, there have been a number of attempts to formalize this kind of knowledge, giving rise to mechanistic explanations involving frames (Minsky, 1974), scripts (Schank \& Abelson, 1977), schema (Norman \& Rumelhart, 1981), and stories (Mandler, 1984), among others. Although the core intuitions motivating these proposals were widely accepted, the actual implementations revealed a number of challenges. Templates were inherently rigid and inflexible. Yet most situations admit a large range of variation and novelty. Moreover, many situations involve blends of multiple events. Symbolic architectures did not lend themselves to dealing with such challenges. Thorny questions were raised and not satisfactorily answered: What is an event (and what is not)? What is the content and detail of event knowledge? Does event knowledge have a structure common across all event types? How is event knowledge accessed and used? How is event knowledge learned? These questions remain open to this day.

Several recent developments have encouraged cognitive scientists to focus more intensely on event knowledge and how best to model it. Our own interest arises from work in language processing using real-time measures to examine processing as comprehenders deal with incrementally presented input. There is now considerable evidence that event knowledge plays a significant role in comprehension very early in processing. Indeed, it guides expectations even in advance of input being received. The time course of how this knowledge is accessed and deployed is now not only of great theoretical interest (insofar as it may constrain our theories about the cognitive architecture underlying language understanding), but has become something that can be measured empirically.

A second development was the emergence of nonsymbolic computational frameworks that demonstrate the ability to capture behaviors that simultaneously reflect
awareness of global abstractions as well as sensitivity to ways in which those abstractions may be graded and affected by subregularities and even idiosyncracies. Connectionist models have these qualities (although Bayesian models often do as well). Our research uses a connectionist model because they exhibit key additional capabilities. They learn by example, and they allow us to probe in (simulated) real time the dynamics of the network's responses to incrementally presented input.

In the remainder of this paper, we present a model and report a set of simulations we have conducted. We begin by explaining the design criteria that guided model development. These criteria were chosen because we believe they are needed to model processes that reflect the use of event knowledge in human behavior. We conclude by discussing what we have learned from the model, and ways in which it might guide future research.

## The Model

## Design Criteria

The model's architecture was developed with the goal that it should have the following four properties.

Learn the components that comprise an activity. We make the assumption that events can be viewed as sequences of activities, where activities occur in the moment and are comprised of various participants, actions, and contexts. Rather than prespecifying a template for necessary or sufficient components, the model must learn which components occur and co-occur across contexts and sequences. These co-occurrences may be statistically variable, and the model must learn these (often high-order) statistical interdependences.

Learn the temporal structure of activity sequences. We also assume that the temporal structure of activity sequences that make up an event may be variable across instances of any given event type. The model must learn this temporal structure, including cases in which that structure is rigid and obligatory as well as cases in which there is a high degree of variability or optionality. The model should be able to use its knowledge of temporal structure to anticipate likely future activities given previously encountered sequences. These expectations should reflect both global contingencies as well as predictions that may reflect more idiosyncractic variants of an activity sequence. In human terms, the model should be able to make predictive inferences.

Learn to generalize from specific examples of events. Although the model will learn from multiple examples of a given event type, it must learn the (often graded) patterns that underly them. It must also learn subregularities and if possible, exceptions.

Fill in missing information. Both during learning and testing, the model may be exposed to activity descriptions in which some highly expected information is omitted. The model should be able to activate missing elements, as appropriate (pattern completion). In human terms, the model should be able to make elaborative inferences.

## Architecture

The architecture of the model is shown in Figure 1.

Figure 1
There is a single network, but the left and right portions play complementary roles. The left portion receives input from the world in the form of (localist) specifications of potential participants, actions, and contexts that might characterize the current activity under description. Each rectangle thus represents a number of possible inputs of the same category (agents, patients, etc.). It should be emphasized, however, that there is no representational status to these groups. As far as the network is concerned, every input node in all of these groups is orthogonal to every other node. If there are similarities in terms of behavior or statistics of privilege of occurrence, the network must discover them. Input nodes are fully connected to nodes in the Hidden Unit layer, and hidden units also connect (with different weights) back to input units. This use of recurrence allows the network not only to learn co-occurrence patterns among input units, but also to implement constraint satisfaction. This means that after the network has learned, it has the potential to activate missing elements in an input pattern, as appropriate. The Next Activity side of the network consists of units that are identical to the Current Activity units, but the job of the Next Activity units is to predict which activity will follow, given the sequence so far. Recurrent connections from the hidden units back to themselves are critical for this function because they provide the network with an internal representation (which must be learned) of the past that can be used for prediction. This architecture builds on elements of prior modeling that has provided a strong foundation for the present approach, including in particular Botvinick and Plaut (2004), Elman (1990), Rogers and McClelland (2004), Rumelhart, Smolensky, McClelland, and Hinton (1986), St. John and McClelland (1990), and Reynolds, Zacks, and Braver (2007).

## Training and Testing

Simulations were conducted using the $r b p$ package from the PDPtool simulator (McClelland, 2016). Weights in the network were initialized with random values between $\pm 0.1$ and adjusted gradually using backpropagation through time (Williams \& Zipser, 2004). Training stimuli were either artificially generated activity sequences (Studies 1-3) presented one activity at a time, or sequences obtained from human norming data (Study 4). After training, testing was conducted by freezing weights and presenting the network with input sequences designed as analogs of stimuli used in human experimental paradigms. Details of the general training regime can be found in http://tatar.ucsd.edu/jeffelman/EventModelTraining.html, and details relevant to each simulation are given below.

## Simulation Results

## Study 1: Pattern completion and elaborative and predictive inferences

Typical language use relies heavily on interlocutors' shared knowledge. This allows speakers to omit information that is assumed to be known by the comprehender, and allows comprehenders to infer unstated information. A frequent distinction is made between elaborative inferences, which involve unstated details regarding an activity currently described, and predictive (or forward) inferences, which involve expectations about what will occur next. Bridging inferences are those in which a comprehender draws on knowledge only as needed to understand a prior statement. The extent to which, and conditions under which, such inferences are drawn remains a topic of debate. Bridging inferences are largely uncontroversial. However, whether, and under which conditions, elaborative and predictive inferences occur is still debated (for review, see Murray, Klin, \& Myers, 1993). In Study 1, we first verify that the constraint satisfaction properties of the network do support inference under optimal conditions. We then examine the fragility or robustness of such inferencing because it has been claimed that discrepant data have arisen from stimulus properties and the sensitivity of behavioral measures.

Simulation 1.1. The network was trained on event sequences that ranged in length from three to six activities. The sequences might be glossed as (1) John goes to a fancy restaurant; (2) John is cutting wood in the forest, using an axe; (3) John (and other people) cut themselves accidentally with a knife, and he bleeds; (4) John (and other people) cut themselves accidentally with an axe and the wound is fatal; (5) Mary and Penny are in the library and Mary asks Penny a question, which Penny answers. Having learned these sequences, the model was then tested on novel sequences. The sequences were novel both in that they omitted critical information, and they involved new combinations of activities that the model had not encountered in the same event. Figure 2 shows activations in the Next Activity units
in response to the input sequence John is in a restaurant; John cuts himself; What happened to John? (the query takes the form of simply presenting John without any specified result, so the network must fill in the information). Figure 3 shows similar activations, but in response to the sequence John is in the forest; John cuts himself; What happened to John?

Figure 2

Figure 3
After receiving the input that John is in a restaurant, a knife is inferred to be present, whereas in the forest, axe is activated. These may be considered elaborative inferences. Then when John cuts himself, with no instrument mentioned, the network immediately begins to predict the result that is consistent with the instrument. These are predictive inferences. Such inferences have not always been found in humans, however. One possibility raised by Murray et al. (1993) is that failures to detect predictive inferences may result from experimental stimuli in which either the forward inference is disrupted, or it is not tested soon enough. In Figure 4, we see what happens when the discourse is disrupted by switching to a new topic, which is

Figure 4
a situation involving Mary, immediately after the cutting activity. The network begins to predict that John will bleed (because he is assumed to have cut himself with a knife, given the restaurant context). However, as soon as Mary is introduced, the activations of all consequences of cut
decrease sharply. Probing for the consequence of John cutting himself subsequent to this topic change would show little or no evidence of the predictive inference, consistent with Murray et al.'s findings.

Simulation 1.2. One open question concerns precisely how far into the future comprehenders predict when processing incrementally presented language. In much of the empirical literature focusing on prediction in language, there has been an implicit assumption that the next word in a sequence is anticipated by comprehenders, but nothing beyond that. However, more recent findings suggest that when language is used to describe an event, comprehenders anticipate event-relevant elements even at points in the discourse where they might not be appropriate (Metusalem, Kutas, Urbach, Hare, McRae, \& Elman, 2012). A simplified stimulus example is the short story: The crowd is in the stands. The crowd looks around. The skater goes to the podium. The audience applauds, The skater receives a $\qquad$ Participants' brain activity was measured while reading the final noun. When an event-appropriate word, such as medal, was presented, the N400 amplitude was small. A word that was completely anomalous (e.g., bleach) elicited a large N400. However, a word that was contextually anomalous but event-appropriate (e.g., podium) produced an N400 with intermediate amplitude. The authors interpreted this as evidence that event elements are activated and available even at times when they might not be expected immediately.
Figure 5 shows the network's activations in the Next Activity units throughout such a stimulus sequence.

Figure 5
By the second activity, the network has already activated two event-appropriate elements, podium and medal. Bleach is not activated at all. As the focus shifts in the fourth activity back to the crowd, both medal and podium are deactivated. However, near the end, the network re-activates both. The re-activation of medal is not surprising because it has been mentioned explicitly. However, the network has also learned that podium is the likely location for awarding a medal and so activates it as well, though at a lower level. There are two lessons from this simulation. First, behavioral evidence for the activation of putatively inferred event elements may depend on the timing of the probe. Second, it may be that only highly sensitive behavioral measures will reveal the presence of partially activated event elements. These elements, even if only partially activated, become more easily accessible should subsequent discourse make reference to them. This in fact was seen in Simulation 1.1.

## Study 2: Novel Events and Blending

In real life, events exhibit not only variability (which the model accommodates, as we see in Figures 1 and 2) but often are combined in novel ways. Fixed templates or rigid structures are ill suited for dealing with this. In the next simulation, we test the model's ability to flexibly respond when events are combined in unusual ways.

Simulation 2.1. The model was trained on sequences that included examples of going to a restaurant (as in Simulation 1.1), and activities corresponding to a romantic relationship between two people (John and Mary), with Mary being married to a third person (Bill). Furthermore, the model was exposed to examples of aggressive behavior between various people (but not including John or Bill). In many of the latter examples, weapons are used. Gun is a more typical weapon, but knives are used occasionally. After training, the model was tested on a sequence that might be glossed as John and Mary are at a fancy restaurant. John and Mary cut steak with a knife. Bill enters the restaurant. Bill attacks John. Activations of relevant nodes are shown in Figure 6.

Figure 6
Two things are apparent. First, as soon as Bill enters the restaurant, the model quickly adjusts its expectations about what it predicts will happen next. Second, and more interesting, is that although the model has learned that gun is the most common weapon used in aggressive behavior, the presence of knife that was established from the outset (even prior to its mention) leads to the knife being the predicted instrument in this new situation. Thus, the model not only adjusts to a change in sequence structure that it has not encountered before, but it also flexibly incorporates relevant components from the first event into the second event. That is, the model produces a novel response to a situation it has never encountered by drawing and integrating knowledge from different events.

## Study 3: Priming

Studies 1 and 2 illustrate examples of priming. There is a large literature showing that event relevant information facilitates processing target elements related to that event. These include typical agents, patients, and instruments priming their event-relevant verbs, priming between eventrelevant nouns, and verbs priming their event-related agents, patients, and instruments (for review, see McRae \& Matsuki, 2009). The model exhibits the same behavior, not shown here because of space limitations. Instead, we
demonstrate an example of priming involving second order dependencies between event elements. Bicknell et al. (2010) found that the patient that is expected to follow a given verb may depend on the agent carrying out the action. Thus, shopper saved... primes money, whereas the lifeguard saved... primes person. (Control conditions established that the priming was not directly between the agent or verb and the patient, but that it required the combination.)

Simulation 3.1. The model was trained on various examples of shoppers and lifeguards (and other people) in events in which saving was one of the activities. Typically, reflecting the corpus analyses carried out by Bicknell et al., shoppers save money whereas lifeguards save people. When probed with the partial description of an activity shopper + saved (Figure 7), the model predicted money as the most likely patient, compared to lifeguard + saved, which led to greater activation of person (Figure 8). However, we also see that that there is an asymmetry in the responses, such that at later stages in processing, lifeguard + saved results in an increased activation of money (though still lower than person).

Figure 7

Figure 8

This reflects asymmetries in the training data that mirror asymmetries in corpus analyses, that is, that save is overall more commonly associated with money than with people. We might test the model's predictions (to our knowledge, as of now untested) by testing whether the timing of the patient probe leads to different degrees of facilitation, depending on when the probe was presented.

## Study 4: Learning from Human Data

In the previous simulations, we used training sets that were designed by hand. The design of the training corpora was controlled to carefully probe the network's behavior under different learning situations. This strategy is similar to that used in many human behavioral experiments. But in real life, people's knowledge of events results from experiences that may involve considerably greater variability. Consolidating such experiences and making sense of commonalities, subregularities, and exceptions is a challenge. Furthermore, temporal structure may vary considerably not only between different event types but even within a single event type. For example, there may be some parts of an event in which the ordering of activities is consistent and even obligatory (eggs must be broken before they are fried), whereas activity sequences in other parts of the event may be optional (one might make coffee before making eggs, or after). To investigate these issues, we
conducted a norming study to sample people's knowledge of types of events.

Norming study 4.1 We used 81 events, drawing on prior literature that has used stimuli that describe events and situations. Some of these events have clear goals and outcomes (e.g., fixing a flat tire). Other events are more situation-like, in that things happen but the goal and outcome are less clear (e.g., going to a picnic). Using Mechanical Turk, participants were asked to list up to 12 activities for each event. Participants saw a random subset of $10-12$ of the 81 events, and each event was presented to 22-24 different participants. Table 1 shows responses from three participants for fixing a flat tire.

Table 1: fixing a flat tire

| Pull over | Get out of car | Pull over |
| :--- | :--- | :--- |
| Get out of car | Loosen lug nuts | Open trunk |
| Open trunk | Jack up car | Get tire iron |
| Get spare tire | Remove lug nuts | Get spare tire |
| Get jack | Remove flat tire | Put on hazard lights |
| Remove flat tire | Put on new tire | Jack up car |
| Put on new tire | Tighten lug nuts | Remove lug nuts |
| Tighten lug nuts | Remove jack | Take flat tire off |
| Put flat tire in trunk |  | Put on new tire |
|  |  | Tighten lug nuts |
|  |  | Lower car |

The data can be visualized using graph analysis, in which nodes represent activities and directed arrows show temporal sequence (size indicates frequency), as in Figure 9.

Figure 9
Some of the sequences are consistently ordered (e.g., jack up car $>$ remove flat tire $>$ put on new tire), undoubtedly reflecting causal constraints. Other sequences may be performed optionally at different times. How does the model deal with such data?
Simulation 4.1. The model was trained on the activity sequences provided by 23 participants for fixing a flat tire. Of particular interest is that although the model responds appropriately to the data it was trained on, its responses also incorporate what it has learned from other participants. The model thus does not slavishly reproduce the individual training data, but detects general patterns that are common across all the data.
Can the model generate activity sequences on its own? We tested this by seeding the model with a reasonable starting
activity, and then using the most strongly predicted elements as the subsequent input. This process iterated until the event was complete. The initial five activities in the network's self-generated sequence are shown in Figure 10 (presenting greater than five makes the figure unreadable). Notably, the network's self-generated activity sequence is not identical to any single participant's sequence. However, it is a completely reasonable abstraction of the sequencing across all participants' descriptions.

Figure 10

## Discussion

Our goal was to develop a model that could learn the structure and temporal dynamics of activity sequences, as well as the co-occurrence properties of participants, activities, and contexts in those sequences. Although we might call these sequences events, the concept of event is not a primitive in the model and events are not pre-defined templates. Rather, what we might call an event is an epiphenomenal consequence of having to learn about activity sequence structure. Having done this, the architecture of the model allows it to perform pattern completion, both in the moment (supporting elaborative inferences) and across time (supporting predictive inferences). The model replicates a wide range of behavioral studies (only a few of which are described herein) for which event knowledge has been hypothesized to play a role. It also produces unanticipated behaviors that can be tested empirically to assess the model.
A great deal remains to be done. The model's inputs serve as cues to event knowledge, but the model itself does not provide those cues. Those cues must come from perceptual or motor evidence from the world as well as a language processor. Nor does the model provide an account for how these various cues can serve to alter focus on different event elements, including adjusting how the temporal contour of the event is understood (e.g., by grammatical aspect). We are guardedly optimistic that these are tractable problems, and that the model we propose here provides a solid framework for understanding how people acquire, represent, and use knowledge of events in the world.

#### Abstract

Speakers of Mandarin, Spanish, and Yucatec Maya watched videos of two actors involved in a causal chain initiated by one of them. After watching each video, participants divided 10 tokens into piles indicating their assignment of responsibility for the resulting event. There was a significant interaction between intentionality and population: causer and causee intentionality made a significant difference only for the Spanish and Yucatec participants, but not for the Chinese participants. This is in line with previous findings suggesting that internal dispositions play a lesser role in responsibility attribution in societies in which attention to individual agency is far more common than attention to group agency.

Keywords: causality; agency; responsibility; intentionality; cultural mediation; linguistics; social psychology

## Introduction

Linguistic theories of the mapping between meaning and syntactic form in language have long recognized the key role of agency and causality. In verbal representations of causal chains, causality and agency determine the assignment of grammatical relations such as subject and object, voice (active/passive), case marking, and a host of other properties (e.g., Croft 1987; Dowty 1991; Foley \& Van Valin 1984; among many others). Yet, much of this work implicitly treats causality and agency as universal notions - even in crosslinguistic research (e.g., Comrie 1981; Dixon 2000; Shibatani 2002). Meanwhile, a growing body of work in the field of social psychology calls the universality of these notions very much into question.
Take, for example, the nexus between responsibility and intentionality. Much theoretical work on agentivity in language assumes that prototypical agents are volitional and that nonvolitional causers are either atypical agents or not agents at all (Dowty 1991; Lakoff 1977; Van Valin \& Wilkins 1996; inter alia). [We assume in the following that volitional actions require a choice on the actor's part and intentional actions require a plan; the latter are thus a subset
of the former (cf. Van \& Valin \& Wilkins 1996: 315-316)]. However, cross-cultural research since the 1990s has uncovered evidence suggesting that internal dispositions such as volition and intentions do not play the same role in attributions of causality across cultures. Much of this research has focused on a contrast (treated as binary) between two types of societies that are said to differ from one another in terms of the relative prominence of individual agency and group agency in their members' cognition. American culture has been said to downplay collective agency in favor of individual agency. We assume that our Spanish participants exhibit the same trait. In contrast, group agency is hypothesized to play a relatively more prominent role in Chinese culture.

For example, in one classic study, Morris \& Peng (1994) examined reports of similar crimes in Chinese- and Englishlanguage newspapers, showing that the former paid relatively more attention to explanatory factors in the situational context of the crime while the latter spent more time discussing the perpetrator's presumed disposition. Similar patterns have been reported, with varying theoretical conclusions, by Chiu et al (2000); Choi \& Nisbett (1998), Choi et al (1999), Maddux \& Yuki (2006); Menon et al (1999), and Peng \& Knowles (2003), inter alia.

If the attribution of responsibility and causality is indeed influenced by culture-specific folk theories of agency, then such folk theories may also influence the role of agency in the grammars of different languages. We are currently laying the groundwork for a large-scale crosslinguistic study of the representation of causality in the grammars of languages spoken around the world. In preparation for this effort, we decided to directly investigate the role of intentionality in causal attributions in three populations: Mandarin Chinese speakers from Mainland China, Spanish speakers from Spain, and Yucatec Maya speakers from Mexico. Mayans practice a traditional Mesoamerican horticulturalist society surrounded by a Western-dominated Spanish-speaking society and transitioning into the Age of

Globalization. Their inclusion in our study allows us to open up the investigation beyond the egocentric-sociocentric dichotomy of the debate on 'dispositionalism' and 'situationalism' in social psychology, but also to compare our findings to those reported in Le Guen et al (2015), whose sample includes Yucatecans as well.

Le Guen et al (2015) investigated the role of concepts of chance and coincidence in causal attributions among four populations, comparing Tseltal and Yucatec Mayans, urban Mexicans of non-indigenous descent, and Germans. They based their stimuli on Alicke's (2000) 'Culpable Control Model', which distinguishes three components of responsibility: whether the causer intended their immediate action (' $I \rightarrow A$ '), whether they intended the final outcome (' $\mathrm{I} \rightarrow \mathrm{O}$ '), and whether there is a causal relation between the action and the outcome (' $\mathrm{A} \rightarrow \mathrm{O}$ '). The distinction between $\mathrm{I} \rightarrow \mathrm{A}$ and $\mathrm{I} \rightarrow \mathrm{O}$ informed our stimulus design as well. Le Guen et al found that intentionality had a greater effect on the Mayan participants' attributions of causality than on those of the German and Mexican populations. By way of interpretation, they tacitly point toward the tradition of anthropological research identifying elements of 'magical thinking' in traditional non-Western cultures (e.g., EvansPritchard 1937).

## Method

Speakers of Mandarin, Spanish, and Yucatec Maya watched videos of two actors involved in a chain of events that culminates in a resulting event. In each case, the chain is initiated by one actor, dubbed the Causer in the following. The second actor is affected by the Causer's action and may or may not in turn affect a third, inanimate, entity. This second actor is labeled the Causee After watching each video, participants divided 10 tokens into piles indicating their assignment of responsibility for the resulting event. Piles represented 'Causer', 'Causee', and 'Neither'.

## Participants

12 speakers of Yucatec Maya, 16 Mandarin speakers, and 20 Spanish speakers were recruited from and tested at sites in Barcelona and Murcia, Spain, at Beihang University in Beijing, China, and in the village of Yaxley, Quintana Roo, Mexico. The Chinese participants included 8 women and 8 men aged 19-40 ( $M=27.46, ~ S D=4.98)$. Spanish participants included 12 women and 8 men aged 18-55 ( $\mathrm{M}=$ $28, \mathrm{SD}=12.92$ ). The Yucatec participants included 5 women and 7 men aged 18-76 ( $\mathrm{M}=44, \mathrm{SD}=16.83$ ). Participants completed the tasks in about 45 minutes and were compensated 100 pesos (approximately $\$ 5$ USD), 8 euros (approximately $\$ 9$ USD), and a cup of coffee, respectively (all Mandarin participants were students of the school of foreign languages at Beihang University).

## Materials

The experiment comprised a training phase involving 10 video clips and a test phase with 24 video clips. Four of the
training clips and three of the test items were cut from news reports, a home video show, and a movie. The remaining videos were taped with students and faculty of the University at Buffalo Linguistics Department staging the actions and events. The mean duration of the test videos was 8.05 seconds (SD 4.56s). They were shown to the participants on laptop computers.

The test items are described in Table 1 in terms of the action/event involving the Causee. These actions/events can all in one way or another be understood as caused by the Causer - in some cases via a physical impact on Causee; in others via a reflexive/uncontrolled or deliberate psychological response to the Causer's behavior or as a response to a gestural command by Causer. Three intentionality variables are represented as well: whether Causer intended their action $(\mathrm{I} \rightarrow \mathrm{A})$, whether Causer intended the outcomes of the chain $(\mathrm{I} \rightarrow \mathrm{O})$, and whether Causee acted intentionally/volitionally. ${ }^{1}$

Table 1: Test Phase Video Descriptions

| Clip Description | Causer |  | Causee |
| :--- | :---: | :---: | :---: |
| (CE=Causee) | intentional | intentional |  |
|  | $\mathrm{I} \rightarrow \mathrm{A}$ | $\mathrm{I} \rightarrow \mathrm{O}$ |  |
| CE breaks a plate | Yes | Yes | Yes |
| CE breaks eggs | Yes | Yes | Yes |
| CE collapses a cup tower | Yes | No | No |

[^62]

Figure 1: Causee leaves when causer sings poorly

Figure 2: Causee knocked into cups by causer with cart
Intentionality was indicated by obvious body language on the part of the actor, including whether or not they looked at the causee or touched them with their hands in a manner that appeared to be controlled. For example, in an 'unintentional' clip, a Causer walks into a room without looking at the causee and loudly sneezes, which causes a startled Causee to tear a piece of paper. In the contrasting 'intentional' clip, the Causer looks at the Causee and deliberately pushes them, causing them to tear the paper. Four of the training items featured scenes that fit the same parameters as the test items. The remaining six items featured actions on which the two actors collaborate, events that occurred without the involvement of either actor, and events in which one actor destroyed an object while the other looked on.

Participants were given 10 identical tokens, which consisted of small glass stones or other objects of similar size. To prevent confusion about the purpose of the task, no tokens resembling currency were used. These tokens represented total responsibility for end results in video clips observed during the task, where each token symbolized $10 \%$ of total responsibility. Participants were also given a sheet of paper with three circles drawn on it. The leftmost circle represented the actor who ended in the left-most position or final frame of the video clip, the center circle represented the other actor, and the right-most circle represented 'neither actor.' Circles were arranged in a horizontal row, or in two rows where the two circles representing actors were next to
one another in the top row and the 'neither' circle was drawn below them.

## Procedure

Preparation. Prior to working with participants, researchers established how to convey the concept of responsibility in the target language. A complication of concern was the potential for negative implications of 'blame'. To avoid participant confusion over assigning blame to a neutral event, researchers explained that participants should think of assigning responsibility in terms of explaining the events to someone who wanted to know what happened and why. For video clips depicting one character involuntarily initiating a causal chain, participants had to decide between prioritizing intentionality or control in the assignment of responsibility. This provided data on cross-cultural differences on how these two factors were weighed.

Before the training phase, the task was explained to participants in their native language. Participants were asked to indicate which actor in each video was responsible for the resulting event and reminded that they could distribute responsibility between all three piles, two piles, or just one pile so long as the distribution of tokens at the end of each trial was proportional to the amount of responsibility of each actor. After this explanation, the participant watched the 10 training videos.

Training. The purpose of the training phase was to allow the participants to gradually familiarize themselves with the rationale of the ratings procedure. For this reason, it was designed to initiate training with six scenes in which the assignment of responsibility seemed straightforward (collaborative action; no involvement of either actor; or one actor involved while the other was not), followed by four items similar in structure to the test items, where responsibility assignment is more competitive, at the end. For each of the first three videos, the experimenter would demonstrate by playing the video, and apportioning the tokens in the appropriate way, and then would explain why they did so. Next, the experimenter would invite the participant to use the tokens to rate responsibility in each of the remaining seven scenes. The experimenter would play a clip, establish which circle on the paper represented each actor in the video, replay the video and ask the participant to distribute the tokens. The experimenter would correct any confusion about allocating the tokens and verified that the participant understood the task.

Testing. The test items were presented in one of four pseudo-randomized orders. Participants were randomly and evenly distributed over these four orders.

During the test phase, participants watched the 24 test clips. After each clip, experimenter and participant established which circle would represent each actor in the video and then played the video a second time. The participant was then asked to distribute responsibility for the final outcome of the clip between the actors. Responses
were recorded in a spreadsheet. Experimenters did not question participant understanding of video clips or correct token distribution during this portion of the experiment. After watching the 24 clips, the participant viewed each clip again and provided a verbal description of the action in the video. The sessions were video recorded in their entirety.

## Results

## Exclusions

One response by a Mayan participant was accidentally omitted from recording. There are no further missing observations.

## Predictions

If it is the case that East Asians pay relatively less attention to internal dispositions of the causer and more to situational factors in their causal attributions compared to Westerners, as suggested by the line of research starting with Morris \& Peng (1994), both Causer intentionality and Causee intentionality should play a less predictive role in the ratings of the Chinese participants than in those of the Spanish participants. On the other hand, Le Guen et al's (2015) findings suggest that Causer intentionality may play an even greater role in the Yucatecans' responsibility assignments than in those of either of the other two groups.

## Analysis

Figure 3 shows the mean Causer responsibility ratings by population, suggesting small but significant differences (Mandarin $\mathrm{M}=7.37, \mathrm{SD}=2.09$; Spanish $\mathrm{M}=5.98, \mathrm{SD}=$ 3.14; Yucatec $\mathrm{M}=6.67, \mathrm{SD}=3.24$ ). Figure 4 presents a breakdown by Causer intentionality, suggesting that the Mayan and Spanish participants, but not the Chinese participants, assigned more responsibility to intentional than to unintentional Causers, as predicted.

Figure 3: Mean Causer responsibility rating by population

A linear mixed effects regression model was fitted, using the lme4 package in R and treating the Causer responsibility rating as dependent variable. The rating was treated as a continuous rather than ordinal (categorical) variable since the participants expressed it through the proportional allocation of the tokens rather than through labeled categories. As fixed factors were included Population, $\mathrm{I} \rightarrow \mathrm{A}$, $\mathrm{I} \rightarrow \mathrm{O}$, Causee Intentionality, and all binary interactions between Population and the intentionality variables. Random intercepts were added for participant and stimulus clip (formula: CR.Responsibility $\sim$ Population $+\mathrm{I} \rightarrow \mathrm{A}+$ $\mathrm{I} \rightarrow \mathrm{O}+$ Intentionality.of.CE + Population $* \mathrm{I} \rightarrow \mathrm{A}+$ Population * $\mathrm{I} \rightarrow \mathrm{O}+$ Population * Intentionality.of. $\mathrm{CE}+(1$ $\mid$ Participant.ID $)+(1 \mid$ Clip.Code $)$ ). The three intentionality variables were coded binarily.

Figure 4: Mean Causer responsibility rating by population and Causer intentionality
Table 2 summarizes the effects. Due to the multitude of models, the confidence level should be Bonferroni-adjusted to $\mathrm{p}<.001$. Effects outside this level should be ignored. There were main effects of population and causee intentionality and significant interactions between population and the $\mathrm{I} \rightarrow \mathrm{A}$ link and between population and causee intentionality. There was neither a main effect of the $\mathrm{I} \rightarrow \mathrm{O}$ link nor did it feature in any significant interaction. Collinearity of factors above . 6 occurred exclusively between the absence of $\mathrm{I} \rightarrow \mathrm{A}$ and the absence of $\mathrm{I} \rightarrow \mathrm{O}$ (to be expected, as in the design of the items, the former entails the latter, i.e., we did not include scenes in which an unintended action accidentally yielded an intended outcome; cf. Table 1) and between some of the interactions and either their component factors or interactions sharing a factor.

## Discussion

The presence of an unintentional (nonvolitional) Causee significantly boosted attribution of responsibility to the causer across populations. This is of course eminently plausible and thus can be seen as very basic support of internal validity.

In line with what Figure 1 suggests, the Spanish and Yucatec participants' ratings were significantly lower than those of the Chinese participants, although the differences
were quite small. This effect is plausibly attributable to the Spanish and Yucatecan participants having paid more attention to the intentionality/volitionality of the Causee than the Chinese participants, in line with the hypothesis that intentionality plays a lesser role in the Chinese participants' attributions.

Table 2. Significant factors in the regression model with

| Factor$(\mathrm{CE}=\text { Causee })$ | Baseline population Chinese Spanish Yucatec |  |  |
| :---: | :---: | :---: | :---: |
|  |  |  |  |
| Chinese | N/A | *** 5.1 |  |
| Spanish | ***-1.2 | N/A | **-1.1 |
| Yucatec |  | ** 1.2 | N/A |
| No I $\rightarrow$ O |  |  |  |
| No I $\rightarrow$ A |  | ***-3.6 | *-2.2 |
| CE unintentional | ** 1.7 | *** 2.8 | ** 1.6 |
| Chinese * No I $\rightarrow \mathrm{O}$ | N/A |  |  |
| Spanish * No I $\rightarrow$ O |  | N/A |  |
| Yucatec * No I $\rightarrow$ O |  |  | N/A |
| Chinese * No I $\rightarrow$ A | N/A | ***3.1 | * 1.8 |
| Spanish * No I $\rightarrow$ A | *** -3.1 | N/A | *-1.4 |
| Yucatec * No I $\rightarrow$ A | *-1.8 | * 1.4 | N/A |
| Chinese * CE unintentional | N/A | **-1.1 |  |
| Spanish * CE unintentional | ** 1.1 | N/A | ** 1.2 |
| Yucatec * CE unintentional |  | **-1.2 | N/A |

Crucial for the evaluation of our predictions are the interactions between population and the causer intentionality variables. In line with our predictions, we found that absence of the $\mathrm{I} \rightarrow \mathrm{A}$ link - i.e., an unintended action on the causer's part - strongly positively interacted with Chinese against Spanish as baseline and vice versa. In other words, the Chinese participants' responsibility scores for unintentional causers were significantly higher than the Spanish participants, in line with predictions. The relevant interactions with Yucatec were not significant by the Bonferroni criterion.

Turning to unintentional causees, this factor showed a significant positive interaction with Spanish against Chinese as baseline. The Spanish participants rated Causer intentionality higher than the Chinese participants when the Causee was unintentional. This suggests that the Spanish participants paid more attention to the intentionality of the causee than the Chinese participants did - again in line with predictions. When Spanish was the baseline, significant negative interactions with both Chinese and Yucatec were found (and when Yucatec was the baseline, of course the inverse positive interaction with Spanish materialized). This suggests that the Spanish participants rated Causer responsibility relatively higher when the Causee was acting involuntarily than did the Yucatec participants. It thus appears that Causee intentionality played a greater role for the Spanish participants than for the Yucatecans.

The difference between the populations was specifically located in scenes that lacked $\mathrm{I} \rightarrow \mathrm{A}$, in other words, scenes in
which an unintended action caused a certain result (which in our stimuli was likewise unintended). In all instances, the relevant actions of the Causer involved spontaneous bodily functions (yawning, sneezing, losing balance, fainting). Such acts caused the Spanish and Yucatec participants, but not the Chinese participants, to rate the Causer's responsibility lower. In contrast, we found no significant effect for scenes in which intended actions had unintended consequences (e.g., causing somebody to leave the room by singing poorly or causing somebody to knock down a cup tower by running into them while dragging a cart backwards into the room).

## General discussion

We did not find greater sensitivity to intentionality among our Mayan participants than among the other two groups. There is thus no apparent evidence of remnants of 'magical thinking' in our traditional non-Western population, contrary to the findings of Le Guen et al (2015). However, as predicted by a line of studies in social psychology, the Chinese participants in our experiment appear to have been less inclined to factor the intentionality of both the Causer and the Causee into their attributions of responsibility than the Spanish participants. To our knowledge, this has been demonstrated here for the first time in terms of relative responsibility distribution between competing actors.

## Future research

Whether our evidence of culture-specificity in causal attributions submits to the explanatory mechanisms in terms of folk theories of group agency vs. individual agency and/or context sensitivity invoked in research tradition that motivated the present study remains to be seen. A crucial test will be the extension of the investigation to other populations of the supposed 'egocentric' vs. 'sociocentric' types. We are currently preparing to test further populations.

A question we intend to take up in the next phase of our investigation is whether the apparent difference in causal attribution also manifests itself in the grammatical means used when members of the different groups talk about causality. It has often been observed that more agentive causal chains tend to be represented more compactly in language than less agentive ones. Thus, Sally made Floyd knock over the cup tower implicates, but does not entail, that Sally acted intentionally, whereas Sally bumped into Floyd and he knocked over the cup tower does not (McCawley 1976). This predicts that members of sociocentric societies may use relatively more compact representations of lowintentionality scenarios than members of egocentric societies. If confirmed, this could suggest a relationship between grammars and folk theories of agency.
For the treatment of agency in linguistic theories, two responses to our findings are conceivable: retain a universal notion of agency, which then plays a variable role in the grammars of different languages, or replace it with culturespecific concepts of agency, which then would stand a chance of playing a more uniform role across languages.

## Acknowledgments

The material presented here is based upon work supported by the National Science Foundation under Grant No. BCS153846 and BCS-1644657, ‘Causality Across Languages'; PI J. Bohnemeyer. We would like to thank the members of the University at Buffalo Semantics Typology Lab for assistance with the creation of the stimuli (in particular, Anastasia Stepanova, Alexandra Lawson, Randi Moore, and Karl Sarvestani) and the members of the Beihang Research Group for Event Representation and Cognition for their assistance in testing the Chinese participants (specifically, Enirile, Hongxia Jia, Fuyin Li, Jinmei Li, Sai Ma, Chenxi Niu , and Mengmin Xu ). We are grateful to Dare Baldwin, Sieghard Beller, Andrea Bender, and Bertram Malle for advice.

# Explaining Enculturated Cognition 

Regina E. Fabry (regina.fabry@psychol.uni-giessen.de)<br>Justus Liebig University, Experimental Psychology and Cognitive Science, Otto-Behaghel-Strasse 10 F 35394 Giessen, Germany

#### Abstract

Many of our cognitive capacities are shaped by enculturation. Enculturation is the temporally extended transformative acquisition of cognitive practices such as reading, writing, and mathematics. They are embodied and normatively constrained ways to interact with epistemic resources (e.g., writing systems, number systems). Enculturation is associated with significant changes of the organization and connectivity of the brain and of the functional profiles of embodied actions and motor programs. Furthermore, it has a socio-culturally structured dimension, because it relies on cumulative cultural evolution and on the socially distributed acquisition of cognitive norms governing the engagement with epistemic resources. This paper argues that we need distinct, yet complementary levels of explanation and corresponding temporal scales. This leads to explanatory pluralism about enculturated cognition, which is the view that we need multiple perspectives and explanatory strategies to account for the complexity of enculturation.

Keywords: enculturation; neural plasticity; neural reuse; embodied cognition; cognitive niche construction; cumulative cultural evolution; cultural learning; reading acquisition; explanatory pluralism

## Introduction

Many cognitive processes are shaped and facilitated by our successful acquisition of cognitive practices such as reading, writing, or mathematics. Cognitive practices are evolutionarily recent, embodied interactions with writing systems, number systems, and various other epistemic resources in our local environment (Fabry, 2017; Menary, 2015). Given the evolutionary recency of cognitive practices, with reading, writing, and mathematics dating back to approx. 3000 BC (Donald, 1991), the question arises how their acquisition can be explained from an empirically informed perspective. The purpose of the present paper is to sketch an explanatory framework that can help close the current gap in thinking about the phylogenetic and ontogenetic emergence of cognitive practices. The proposal is that competence in the performance of cognitive practices is the result of enculturation.

Enculturation is defined as the acquisition of cognitive practices during ontogeny. It is a temporally extended process that augments and transforms our overall cognitive capacities. There are two background assumptions that inform the conceptualization of enculturation. First, it is committed to a robust variant of embodied cognition (Menary, 2015). On this view, the embodied interaction with the local environment plays an indispensable functional role
in at least some cognitive processes. In the present context, embodiment is understood as the bodily manipulation of epistemic resources (Menary, 2010; Rowlands, 1999), e.g. by initiating and executing eye movements and hand movements. Second, the present account of enculturation rests on on the assumption that cognitive practices are cases of strong embedded cognition (Menary, 2015). This amounts to the idea that at least some cognitive processes are realized by the integration of cerebral, extra-cerebral bodily, and environmental components. We will see in the course of this paper that the theoretical commitments to strong embodied and embedded cognition are supported by empirical research.

## Shaping the Brain and the Rest of the Body

Enculturation is associated with significant changes to the organization and connectivity of the brain and to the functional profiles of embodied actions and motor programs. Learning driven plasticity (LDP) is a potent principle governing ontogenetic brain development, according to which structural changes of the organization and connectivity of brain areas lead to new neuronal functions (Ansari, 2012; Menary, 2015). LDP is not an open-ended process that leads to the unlimited realization of new neuronal circuits. Rather, it is constrained by the functional biases of certain cortical units that contribute to the development of new neuronal connections. This is suggested by empirical and conceptual work on neural reuse (Anderson, 2010, 2015) and neuronal recycling (Dehaene, 2005, 2010). The idea is that especially evolutionarily recent cognitive practices need to allocate and re-exploit already existing structural and functional connections of brain areas and integrate them into new neuronal circuitry. The scope of neural reuse in each particular case depends on the functional and structural biases of specific brain areas and on the functional proximity of uses to which these areas can be put (Anderson, 2015).

Neural reuse - and its component process of neuronal recycling that is associated with the acquisition of reading, writing, or mathematics - is a guiding principle of LDP. This is especially important in cases of enculturation. The reason is that it helps explain how cognitive practices can be acquired, given that there was not sufficient evolutionary time for the development of brain circuits unequivocally and exclusively dedicated to them.

The assumption that enculturation is defined as the acquisition of embodied cognitive practices gives rise to the idea that LDP is complemented by a genuinely bodily form of transformation. According to the principle of learning driven bodily adaptability (LDBA), new bodily ways to
interact with the socio-culturally structured environment emerge in the course of enculturation. LDBA guides the ontogenetic trajectory of skilled motor action. The resulting development of new motor patterns and action routines is constrained by extra-cerebral bodily biases, e.g., by the functional potential of the overall morphology of human bodies and their constitutive parts (Dounskaia, van Gemmert, \& Stelmach, 2000; Furuya \& Altenmüller, 2015; Phillips, Ogeil, \& Best, 2009). The employment and allocation of bodily resources available to the human organism bring about the embodied adaptation to new cognitive practices in close co-ordination with LDP. In this sense, the functional biases of brain areas are complemented by the biases of functional units of the rest of the body. It is important to note that the overall possibility space of cognitive practices is not only defined, but also delimited by the anatomical and physiological properties of the human body.

## Interacting with the Cognitive Niche

The present account of enculturated cognition is committed to the view that cognitive practices are distributed across the brain, the rest of the body, and the local environment. This leads to the assumption that our understanding of LDP and LDBA needs to be complemented by considerations of the embodied interaction of cognitive systems with the cognitive niche. The cognitive niche can be defined as the incrementally, trans-generationally structured socio-cultural environment that provides human organisms with epistemic resources for the completion of cognitive tasks (Bertolotti \& Magnani, 2016; Clark, 2006, 2008; Kendal, 2011; Sterelny, 2003, 2012; Stotz, 2010). Examples of resources in the cognitive niche include writing systems, number systems, and notational symbol systems. In addition, the cognitive niche is also characterized by socio-cultural institutions like kindergartens, schools, or universities. Cognitive practices are shared by a large number of individuals in the cognitive niche. Therefore, the skilful performance of cognitive practices is constrained by sets of cognitive norms. These norms regulate the interaction with epistemic resources (Menary, 2007, 2016). They need to be learned and automatized in the course of enculturation (Menary, 2013). Since cognitive practices are socio-cultural phenomena, their acquisition is itself a socio-culturally structured process. This process is characterized by scaffolded learning (Clark, 1997; Estany \& Martínez, 2014; Wood, Bruner, \& Ross, 1976). The notion of scaffolded learning refers to the idea that the acquisition of a cognitive practice is a systematic process of novice-expert interaction in the cognitive niche. This interaction is structured by the current developmental stage of the novice and a specific set of skills and knowledge that needs to be acquired in the long run (Vygotsky, 1978).

## Socio-Cultural Learning

It is conceivable that scaffolded learning is the result of evolutionary processes that have shaped specific types of
socio-culturally transmitted human cognitive capacities (Boyd, Richerson, \& Henrich, 2011; Henrich, 2016). According to Kline's (2015) recent framework for the investigation of teaching, direct active teaching is of vital importance for human scaffolded learning. It is defined by the "[...] manifestation of relevant information by the teacher to the pupil, as well as the pupil's interpretation of that information as generalizable" (Kline, 2015, p. 12). In contrast to other forms of teaching and learning that are ubiquitous in the animal kingdom, e.g., social tolerance or opportunity provisioning, direct active teaching is specific to humans. It is likely to have co-evolved with genuinely human ways of cognitive niche construction. If correct, cumulative cultural evolution and scaffolded learning, where the latter might be the result of trans-generationally emerged socio-cultural processes (Heyes, 2012), mutually influence and constrain each other.

In sum, enculturation is a complex phenomenon that requires the synthesis of several explanatory components targeting the cerebral, the extra-cerebral bodily, and the socio-cultural dimensions of cognitive practices. This leads the question how we can combine these components in such a way that we will end up with an explanation of enculturation that is both conceptually coherent and empirically plausible without running risk of committing mereological fallacies. The suggestion of the present paper is to analyse enculturation at three levels of explanation and corresponding time scales.

## Levels and Time Scales of Explanation

Levels of explanation are defined by the conceptual and/or empirical tools, by the research questions, and by the individuation and operationalization that are employed to account for (a component of) a certain target phenomenon (Dennett, 1969; Drayson, 2012, 2014; Metzinger, 2013). In this sense, levels specify the scope and the epistemic tools of explanation. Following Drayson (2012), it is reasonable to include Kim's distinction of the vertical and the horizontal into our meta-theoretical consideration of explanation: "The term 'vertical' is meant to reflect the usual practice of picturing micro-macro levels of a vertical array, with the micro underpinning the macro. In contrast, we usually represent diachronic causal relations on a horizontal line, from past (left) to future (right) [...]" (Kim, 2005, p. 36). This distinction adds a temporal dimension to the individuation of levels of explanation. Accordingly, levels of explanation correspond to specific temporal scales. For the present considerations, we can distinguish three levels of explanation and corresponding time scales.

First, on a sub-personal level of explanation, we can provide an account of the cerebral and extra-cerebral bodily functions that underlie the acquisition of cognitive practices. On this level of explanation, we focus on the corresponding physiological time scale. This temporal scale is defined by time intervals that have a duration of hundreds of milliseconds to several seconds. The time intervals are
determined by the full range of electrophysiological, neuroimaging, and eye-tracking paradigms and the resulting statistical analyses. This explanatory component is concerned with the consideration of LDP and LDBA.

Second, on a personal level of explanation, we can investigate the diachronic unfolding of specific changes of the human organism as a whole that characterize the ontogenetic process of enculturation. This level of explanation corresponds to an organismic timescale. First, we can develop an account of the temporal unfolding of the novice's ongoing interaction with experts in a particular domain. This helps specify the various stages of the acquisition of cognitive practices and the ways in which it relies on the scaffolding by other cognitive agents. Second, from this perspective we can provide an account of the properties of epistemic resources in the cognitive niche as they are relevant for the acquisition and on-going realization of cognitive practices. Finally, we can identify the set of cognitive norms that are acquired and applied in the course of the acquisition of a certain cognitive practice.

Third, the supra-personal level of explanation is also relevant for a full-fledged account of enculturation. The reason is that contemporary cases of enculturation are rendered possible by evolved biological principles and the inter-generational transmission of practices, skills, and epistemic resources. On this view, enculturation is constituted by the interdependence of evolved cerebral and extra-cerebral bodily biases and of the on-going large-scale process of cognitive niche construction. Therefore, it seems reasonable to introduce an additional type of diachronic explanation, namely a supra-personal level of explanation that focuses on an evolutionary time scale comprising hundreds to thousands of years.

## Reading Acquisition: A Paradigm Case of Enculturation

To illustrate the considerations, conceptual distinctions, and the meta-theoretical assessment of the account of enculturation, I will now consider reading acquisition as a paradigm case of enculturation. At first sight, reading poses a challenge to researchers, because it requires an explanation of how we are able to acquire reading, given that there was not sufficient evolutionary time for dedicated brain areas to develop. Dehaene (2010) refers to this as the "reading paradox."

On a sub-personal level of explanation and at a physiological time scale, this paradox can be solved by considering LDP and its guiding principle, i.e., neural reuse. There is now much empirical evidence suggesting that the brain undergoes significant plastic changes in the course of reading acquisition at times $\mathrm{t}_{1}, \mathrm{t}_{2}$, and $\mathrm{t}_{3}$. First, many studies

[^63]and theoretical evaluations emphasize the crucial importance of the left ventral occipito-temporal (vOT) area (Dehaene, 2005, 2010; McCandliss, Cohen, \& Dehaene, 2003; Price \& Devlin, 2003, 2004; Vogel, Petersen, \& Schlaggar, 2014). 1 Recent studies indicate that its activation level peaks in beginning readers and that its decrease, by way of comparison with the level of neuronal activation at $t_{1}$, is associated with reading proficiency (Ben-Shachar, Dougherty, Deutsch, \& Wandell, 2011; Brem et al., 2010; Maurer et al., 2006). Second, there is a significant increase of functional connectivity between the left vOT area and lefthemispheric frontal and temporal areas that are reliably associated with language processing and production (Dehaene et al., 2010; Gaillard, Balsamo, Ibrahim, Sachs, \& Xu, 2003; Turkeltaub, Gareau, Flowers, Zeffiro, \& Eden, 2003). It is in virtue of LDP that new structural and functional connections can be realized as a solution to new and challenging processing needs.

LDP is complemented by LDBA. In the case of reading acquisition, LDBA is mainly realized by the developmental trajectory of eye movements. In general, eye movement patterns in reading are constituted by the alternation between fixations and saccades (Rayner, 2009; Rayner et al., 2001, 2007). Eye movements are necessary because of the acuity limitations of the visual field. The functional biases of the ocular-motor system, e.g., the saccadic latency and the saccadic span, constrain the developmental trajectory of reading. Research paradigms employing eye-tracking methodologies are specifically interested in evaluating the span or amplitude of saccades, the duration of fixations, and the landing positions or locations of fixations with regard to certain target words embedded in syntactically and semantically structured linguistic items. Comparisons of novice and proficient readers reveal that proficient readers display a decrease of fixation durations, refixations (i.e., several fixations targeted at the same word), as well as an increase of saccadic amplitudes (Huestegge et al., 2009; Joseph \& Liversedge, 2013; Seasseau et al., 2013). These findings suggest that ocular-motor patterns adapt to the demands and requirements of processing structured linguistic material.

On a personal level of explanation and at an organismic time scale, reading acquisition is characterized by scaffolded learning and structured novice-teacher interactions. In the case of alphabetic writing systems, reading instruction puts a particular emphasis on phonics instruction (Rayner, Foorman, Perfetti, Pesetsky, \& Seidenberg, 2001). Phonics instruction conveys the alphabetic principle, according to which graphemic units of an alphabetic writing system correspond to phonemic units of the target language (Castles \& Coltheart, 2004; Dehaene, 2010; Snowling, 2000; Ziegler \& Goswami, 2006). In the vast majority of cases, the alphabetic principle can only be understood and applied if

Lipka, 2011). This provides further support for the idea of neural reuse, because it establishes that one particular brain area has a certain bias that makes it suitable to contribute to functionally distinct, yet partly overlapping neural circuits.
novices receive extensive instruction and scaffolded tutorials provided by teachers and other caregivers. These tutorials provide detailed information about the cognitive norms underlying reading, e.g., by progressively increasing the complexity of phoneme-grapheme correspondences in the training materials. In addition, there are other types of metalinguistic awareness that need to be made explicitly available to novice readers. Beginning readers are already proficient speakers of their native language and are able to apply fluently syntactic, semantic, and pragmatic norms in their everyday conversations. However, they usually lack the explicit insight that utterances are made up of sentences and that sentences are constituted by the combination of words (Frith, 1985; Rayner et al., 2001). To novices, these basic properties have to be made explicitly available in order to put them in the position to apply the knowledge about it automatically and fluently at later stages of reading acquisition. Furthermore, novices need to be acquainted with the norm that alphabetic writing systems are decoded from left to right and from the top to the bottom of a page (Dehaene, 2010). In sum, explicit reading instruction is a good example of scaffolded learning and of the socioculturally structured transmission of knowledge and skills.

The history of writing systems is a good example of cumulative cultural evolution (Henrich, 2016). This example needs to be approached on a supra-personal level of explanation and at an evolutionary time scale. The first writing system we know of is the cuneiform system. It dates back to approx. 3000 BC and was pictorial in origin. The cuneiform system was cumulatively refined in the service of an accurate representation of abstract ideas and relations that were especially relevant for trade and the organization of social communities. Furthermore, the functional biases of the brain and the rest of the body constrained the properties of symbols, e.g., the arrangement of lines or inter-letter spacing (Dehaene, 2010). Linearity, the grouping of symbols, and grammatical norms were not pre-given properties of early writing systems. Rather, they gradually evolved over hundreds of years. Tracing back the development of alphabetic writing systems, Donald characterizes the evolutionary trajectory as a "[...] progression from a primarily visual medium, inventing completely new representations like lists of numbers, to a medium which, increasingly, tried to map the narrative products of the language system" (Donald, 1991, 289). In sum, then, contemporary writing systems are the direct result of cumulative cultural evolution. They were afforded by the socially structured need of a system that can represent transactions, relations, genealogies, and so forth.

## Towards Explanatory Pluralism

The previous considerations suggest that we need at least three levels of explanation and corresponding temporal scales to unveil the complex dynamics that give rise to enculturation. This suggestion is at odds with explanatory monism, according to which there will always be one and
only one explanation of a certain target phenomenon or a specific set of target phenomena in the long run (Colombo \& Wright, 2017; Kellert, Longino, \& Waters, 2006). It is informed by unificationism and by reductionism. Unificationism is the idea that there will always be one set of principles that is able to unify previously distinct kinds of explanation targeted at a certain phenomenon. Reductionism about theory formation is the idea that we will gain new knowledge if we discover low-level principles to which previously entertained higher-level explanations can be reduced (Colombo \& Wright, 2017). The present analysis of enculturation and the distinction of complementary levels of explanation and corresponding time scales leads to the view that it is at least unlikely, if not impossible, that unificationism and reductionism are meta-theoretical principles that will lead to a complete and exhaustive account of enculturation. This is the reason why the present account of enculturated cognition is an example of explanatory pluralism about theory formation in the cognitive sciences. Explanatory pluralism is the view that there will always be more than one and only one explanation of a specific target phenomenon (Van Bouwel, Weber, \& de Vreese, 2011; Dale, 2008; de Jong, 2001). This stance towards enculturation promises to arrive at a better understanding of the complexity of the phylogenetic and ontogenetic development of cognitive practices and of the temporal unfolding of enculturated organism-niche interactions. Thus, the positive proposal is that the phylogenetic and ontogenetic components of enculturation on sub-personal, personal, and suprapersonal levels of explanation are required for the prospect of a full-fledged and complete account of enculturation. The consideration of reading acquisition as a paradigm case of enculturation can lend support to the idea that we need the pluralistic explanatory stance in order to account for the vast set of empirical results and empirically informed considerations applying to enculturation.

## Concluding Remarks

Enculturation is a temporally extended process that transforms our overall cognitive capacities. In this paper, I have argued that enculturation is a complex phenomenon that needs to be approached on at least three levels of explanation and corresponding time scales. The reason is that enculturation spreads across the brain, the rest of the body, and the cognitive niche. Explanatory pluralism allows us to do justice to these dynamics, because it provides us with an explanatory strategy that is able to track the ontogenetic and phylogenetic component processes of enculturation. The application of this strategy to the cases of reading acquisition shows that the present account of enculturation has the conceptual resources to connect initially disparate lines of empirical research. The suggestion is that the present account of enculturation promises to provide us with a better understanding of the ways in which our cognitive processes are shaped and re-shaped by the delicate interaction of the brain, the rest of the body, and the cognitive niche.

#### Abstract

We developed a cognitive-pharmacokinetic computational (CPC) model to understand how pharmacoactive substances, such as caffeine and toluene, modulate cognition. In this integrated model, dynamic physiological mechanisms are simulated to predict concentrations of the solvent toluene in the brain, which modulates specific cognitive systems in a doseresponse fashion over multiple hours. We used our CPC model to reanalyze the results from prior research that documented an increase in reaction time following exposure to toluene in several laboratory tasks with no change in accuracy. Our analysis provides tentative evidence that toluene affects motor execution, rather than attention or declarative memory.

Keywords: ACT-R; Toluene; Pharmacokinetic; Computational Models

## Introduction

In cognitive science, there has been a growing trend toward incorporating neurological, physiological, and bodily factors into theories of cognition to improve our understanding of cognition. van Rijn et al. (2016) argued that theories of cognition should span multiple levels of abstraction, such as the computational, algorithmic, and implementational levels proposed by Marr (1982). Integrative models have the advantage of explaining phenomena that are difficult to explain with models cast at a single level, constraining and informing cognitive models, demonstrating physiological/neural plausibility of cognitive models, and enabling prediction at multiple time scales (e.g., milliseconds and hours).

Integrative models take several forms. For instance, embodied cognition encompasses a diverse set of views with a common emphasis on the central role for perceptual-motor systems, bodily states, and the environment in cognition (Wilson, 2002). Many views of embodied cognition posit a reciprocal relationship between cognition and bodily states, or a tight coupling between perception and action, whereas some even consider the environment as part of the cognitive system (Wilson, 2002). Another integrative approach incorporates physiological moderators of cognition, such as circadian
rhythm, to explain changes in cognition due to sleep deprivation (Gunzelmann et al., 2009).

The benefits of integrated models have been demonstrated in several recent studies. For example, Turner et al. (2016) demonstrated that incorporating neural models into a sequential sampling model of inter-temporal decision making improved fit and cross-validation compared to the component models. Integrated models have also been used to understand how cognitive moderators, such as stress and fatigue, alter task performance. For example, Gunzelmann et al. (2009, 2012) developed integrated models to understand the detrimental effects of sleep deprivation on cognition. In the integrated models, the physiological dynamics of circadian oscillation and sleep homeostasis modulated specific cognitive mechanisms. One important insight gained from these integrated models was that sleep deprivation affects procedural memory in simple reaction time (RT) tasks (Gunzelmann et al., 2009) and declarative memory in arithmetic tasks (Gunzelmann et al., 2012). Dancy et al. (2015) used a similar approach to understand how the physiology of a startle response affects cognition. Their integrated model revealed that the startle response increases epinephrine and the behavioral consequences could be explained in terms of fluctuations in the level of noise in declarative memory.

Building upon these integrative approaches, we present a general model that we call a cognitive-pharmacokinetic computational (CPC) model to understand how pharmacoactive substances (PSs) modulate cognition. PSs include toxins (e.g., toluene), pharmaceuticals, and other chemicals (e.g., caffeine) that affect cognition. Although there is a robust literature showing that PSs impact behavior, there is little computational work investigating which cognitive mechanisms are affected by PSs. Cognitive models lack a theory detailing how PSs are metabolized across time, whereas physiological models lack a theory that can link physiological changes to behavioral and cognitive consequences.

By integrating these approaches, we can disentangle the
contributions of multiple cognitive systems to overall task performance and identify which cognitive system is affected by PSs. To test our CPC model, we focus on a chemical called toluene, a colorless and odorless solvent commonly found in products, such as paint and adhesives, and is present in many work environments. Several studies have shown that acute and chronic toluene exposure leads to performance deficits in terms of RT or accuracy on a wide array of cognitive tasks (Rahill et al., 1996; Tang et al., 2011). What remains unclear is which cognitive system is affected by toluene exposure. For example, RT could increase as a result of a slowdown in attentional processing, motor execution, or memory retrieval. We use our CPC model to distinguish between these competing explanations.

## Data and Tasks

We developed a CPC model of the toluene exposure experiment reported in Rahill et al. (1996). In that experiment, six subjects completed a battery of cognitive tasks, once without toluene exposure and again with toluene exposure. The experiment was conducted in a chamber where the atmospheric level of toluene was precisely controlled. A battery of seven cognitive tasks was administered three times throughout each 8 -hour condition: once upon entering the chamber, again at 150 minutes immediately following 15 minutes of exercise and 15 minutes of biological exposure analysis, and one last time at 330 minutes. In the toluene condition, the air concentration of toluene was maintained at 100 ppm for the first 6 hours, after which point no further toluene was released into the chamber. Rahill et al. (1996) found that toluene increased mean RT for six of the seven tasks without impacting accuracy.

We developed CPC models for a subset of the tasks that offered the greatest chance of differentiating between competing accounts of performance decrements due to toluene exposure. The tasks were the procedural memory task, the recognition memory task, and the arithmetic task. Collectively, these tasks form a discriminative test bed for evaluating competing explanations because each task engages cognitive mechanisms in the computational model to varying degrees and thus produce a different pattern of predictions depending on which mechanism is modulated by toluene. Furthermore, a viable model must meet the challenge of producing the following pattern of effects with a single mechanism: an effect of toluene on RT in the procedural and recognition memory tasks, but not the arithmetic task.

## Procedural Memory Task

On each trial of the procedural memory task, the number 1 , 2,3 , or 4 was presented on the screen. Participants were instructed to respond according to the following stimulusresponse mapping: press one button if the number was 1 or 2 and press another button if the number was 3 or 4 . The stimulus disappeared after a maximum of 600 ms . ${ }^{1}$

Figure 1: An illustration of the dose-response predictions of the motor CPC model for the procedural memory task. Toluene is rescaled in RT units for illustration.

## Recognition Memory Task

During the learning phase, participants studied a set of six letters displayed simultaneously on the screen until they were confident the letters were committed to memory. Next, on each trial of the test phase, participants indicated whether or not a memory probe was in the studied list. The stimulus disappeared after a maximum of 850 ms .

## Arithmetic Task

On each trial, a set of three single digit numbers were presented on the screen (e.g., $3+4-5$ ) and participants indicated with the appropriate button whether the solution was less than or greater than 5 . The stimulus disappeared after a maximum of $3,500 \mathrm{~ms}$.

## Cognitive-Pharmacokinetic Computational Model

The CPC model spans two levels of abstraction. At the physiological level, the physiologically-based pharmacokinetic pharmacodynamic (PBPK-PD) model describes the physiological dynamics that control the distribution and concentration of toluene. The output of the PBPK-PD model is the concentration level of toluene in the brain at a given point in time. At the cognitive level, the ACT-R cognitive architecture models the interplay of multiple cognitive systems during task performance. ACT-R and the PBPK models are integrated into a single model based on the assumption that toluene affects physiological and neural processes that support cognition, which in turn, affects performance. Figure 1 illustrates how mean RT for the motor CPC model tracks changes in toluene level in a dose-response fashion. We describe the submodels and model integration in the following sections.

## PBPK-PD Model

We used a PBPK-PD model to quantify the concentration of toluene in the brain throughout the exposure period (Tardif et al., 1997). The PBPK-PD model allows us to estimate the

[^65]amount of toluene in the brain and formulate dose-response predictions for task performance. A PBPK-PD model is an in silico representation of the movement of chemicals in the arterial blood, flowing to each major organ or lumped tissue compartment, including the brain.
