or high-stakes, with block order randomly counterbalanced across participants. In games with low-stakes, the possible outcomes ranged from $\$ 0.01$ to $\$ 0.25$, while in high-stakes games, outcomes ranged from $\$ 0.01$ to $\$ 9.99$. The payoffs were drawn from a truncated normal distribution with mean $\frac{r_{\text {max }}+r_{\text {min }}}{2}$ and standard deviation $0.3 \cdot\left(r_{\text {max }}-r_{\text {min }}\right)$. Within each block, there were five low-dispersion trials and five highdispersion, ordered randomly. In low-dispersion trials, the probability of each of the four outcomes ranged from 0.1 to 0.4 , whereas in high-dispersion trials, the probability of the most likely outcome ranged from 0.85 to 0.97 .

Strategy identification We identified six different decision strategies, in humans and in simulations, using the following definitions: TTB was defined as inspecting all cells in the row corresponding to the most probable outcome and nothing else. SAT occurs when one gamble's payoffs are inspected for all four outcomes, potentially followed by the inspection of all outcomes of another gamble, and so on, but leaving at least one gamble unexamined. The hybrid strategy, SATTTB, was defined as inspecting the payoffs of 1 to 6 gambles for the most probable outcome and not inspecting payoffs for any other outcome. TTB2 was defined as inspecting all fourteen cells of the two most probable outcomes, and nothing else. WADD was defined as inspecting all 28 cells column by column.Random decisions mean zero samples were taken.

## Results

Our process tracing data confirmed that people do indeed use the SAT-TTB strategy discovered by our model. Table 1 shows the frequency of various decision strategies, for each of the four different types of trials. Out of 4000 trials across all participants, TTB was the most common strategy overall, accounting for $25.3 \%$ of all trials. SAT-TTB was the second most common strategy among those we examined: participants employed this strategy on $10.7 \%$ of all trials. In $8.0 \%$ of trials participants chose randomly without making any observations-mostly during low-stakes games. Interestingly, we also observed a second novel strategy that we call Take-The-Best-Two (TTB2). This strategy inspects all gambles' payoffs for the two most probable outcomes, and was used in $6.3 \%$ of trials. The WADD strategy occurred in 4.5\% of trials. Finally, the SAT strategy was used in $3.1 \%$ of games.

Consistent with our model's first prediction, people used TTB more frequently when the dispersion was high $\left(\chi^{2}(1)=\right.$ $897.9, p<0.0001)$. Consistent with our model's second prediction, participants used simple heuristics more frequently when the stakes were low: the frequency of the random choice-the simplest heuristic-increased significantly from $4.2 \%$ on high-stakes problems to $19.9 \%$ on low-stakes problems ( $\chi^{2}(1)=88.2, p<0.0001$ ), and so did the frequency of the second simplest heuristic, SAT-TTB $\left(\chi^{2}(1)=86.3, p<\right.$ 0.0001 ), and the third simplest heuristic, TTB $\left(\chi^{2}(1)=\right.$ $20.0, p<0.0001)$. The frequency of SAT also increased from high- to low-stakes games $\left(\chi^{2}(1)=3.4, p<0.05\right.$, one-

| :---: | :---: | :---: | :---: | :---: | :---: |
| Strategy | Total | HS-HD | HS-LD | LS-HD | LS-LD |
| TTB | 1012 | 392 | 64 | 449 | 107 |
| SAT-TTB | 412 | 68 | 54 | 140 | 150 |
| Random | 320 | 41 | 42 | 111 | 126 |
| TTB2 | 251 | 34 | 94 | 25 | 98 |
| WADD | 178 | 33 | 84 | 19 | 42 |
| SAT | 89 | 14 | 22 | 23 | 30 |

Table 1: Frequency of strategy types for each type of trial.
tailed). Finally, consistent with our model's third prediction, the frequency of the most effortful and most accurate strategy, WADD, increased with the stakes $\left(\chi^{2}(1)=19.3, p<0.0001\right)$.

Together, the strategies reported in Table 1 account for only about half ( $48.6 \%$ ) of all trials. To test our model's predictions on all of the trials, we quantified people's decision style by four metrics introduced by Payne et al. (1988): the number of inspected cells (acquisitions), the proportion of those inspections that pertained to the most probable outcome (prioritization), the degree to which subsequent acquisitions inspected the payoffs of different gambles for the same outcome versus the payoffs of the same gamble for different outcomes (outcome-based processing: $\frac{n_{\text {same outcome }}-n_{\text {same gamble }}}{n_{\text {same outcome }}+n_{\text {same gamble }}}$ ), and the average ratio of the expected value of the chosen gamble over the expected value of the optimal choice (relative performance). To further test our model's predictions, we ran a 2-way mixed-effects ANOVA for each of these four metrics.

As shown in Figure 2, the effects of the stakes and outcome probabilities on the four metrics confirmed the model's predictions. Our model's first prediction that high dispersion promotes the use of fast-and-frugal heuristics was confirmed by a decrease in the number of acquisitions $(F(1,3798)=$ $78.24, p<0.0001$ ) in conjunction with an increases in outcome-based processing $(F(1,3432)=68.31, p<0.0001)$ and prioritization $((F(1,3478)=280.1, p<0.0001))$. The increase in prioritization was especially striking: while only $40.4 \%$ of participants' clicks inspected the most probable outcome when dispersion was low, they focused $70.6 \%$ of their acquisitions on the most probable outcome when dispersion was high. Our model's second prediction that the higher stakes should decrease people's reliance on fast-andfrugal heuristics was confirmed by a significant increases in the number of acquisitions $(F(1,3798)=281.47, p<$ 0.0001 ) which was accompanied by a decrease in prioritization $(F(1,3478)=62.42, p<0.0001)$ and an increase in relative performance $(F(1,3798)=47.62, p<0.0001)$. Consistent with the model's third prediction, the average outcomebased processing metric was lower for high stakes but this effect was not statistically significant $(F(1,3432)=2.45, p=$ 0.06 , one-tailed). Our model's third prediction that highstakes increases time, effort, and performance, was confirmed by a significant increases in the number of acquisitions $(F(1,3798)=281.47, p<0.0001)$ and relative performance $(F(1,3798)=47.62, p<0.0001)$ with high stakes.

Figure 2: People's decision style by stakes and dispersion of the outcome probabilities.

Despite these qualitative agreements, there were quantitative differences. Most notably, our model predicted a more pronounced effect of the stakes on the number of acquisitions than we observed in people ( +19.6 vs. +3.4 ); the smaller effect in people might reflect their concave utility function.

## Discussion

In summary, our resource-rational theory of multi-alternative risky choice predicted some of the main strategies people use in the Mouselab paradigm and the conditions under which they are selected. In addition to automatically discovering known strategies and contingencies, our computational approach also discovered a novel, previously unknown heuristic that integrates TTB with satisficing (SAT-TTB), and our experiment confirmed that people do indeed use SAT-TTB on a non-negligible fraction of problems-especially when the stakes are low.

Tajima, Drugowitsch, and Pouget (2016) solved meta-level MDPs to derive boundedly optimal drift-diffusion models. The strategy discovery method presented here generalizes this approach to more complex decision mechanisms that can process and generate evidence in many different ways.

One limitation of the current work is that we do not know how closely our algorithm approximated the optimal policy, and it is possible that a more accurate approximation would yield somewhat different predictions. Future work will systematically evaluate the accuracy of our approximation method on smaller problems for which the optimal metalevel policy can be computed exactly. Another limitation of the present work is that the cost of computation had to be fit to the participants' responses. Future work will control the cost per click and measure it independently. This will enable a direct comparison of the time and effort people invest against the optimal amount of deliberation. However, a thorough answer to this question will require a more detailed model of people's cognitive architecture including a model of working memory. Another direction for future work is to characterize
the decision strategies the model employed on the vast majority of high-stakes problems where it did not use WADD.

Our proof-of-concept study suggests that formulating the problem of making optimal use of finite time and limited cognitive resources as a meta-level MDP is a promising approach to discovering cognitive strategies. This approach can be leveraged to develop more realistic normative standards of human rationality. This might enable future work to systematically evaluate the extent to which people are resourcerational. In the long term, our approach could be used to improve human reasoning and decision-making by discovering rational heuristics and teaching them to people.

# Sequential Effects in the Garner Tasks 

Deborah J. Lin (djlin@student.unimelb.edu.au)<br>Daniel R. Little (daniel.little@unimelb.edu.au)<br>Melbourne School of Psychological Sciences, University of Melbourne, Australia

#### Abstract

The distinction between integral and separable dimensions is of central importance to understanding how humans integrate information from multiple stimulus sources. One approach to characterizing stimulus integrality is through a set of speeded categorization tasks most closely associated with the work of Wendell Garner. These tasks demonstrate that integral dimensions result in marked speed up or slow down in responding when there is correlated or irrelevant variation, respectively, compared with a baseline task. Little, Wang \& Nosofsky (2016) recently found that the slow down or interference can be largely explained by a reduction in the number of direct repetitions in a modified Garner filtering task. In this paper, we examine a large sample of subjects tested on either separable or integral dimensions to determine the extent of and individual differences in the overall and sequential effects in the standard Garner tasks.

Keywords: Categorization; Response Times; Sequential Effects

## Introduction

In the study of perceptual decision-making, it is fundamental to understand the distinction between integrality and separability, as different processing architectures appear to underlie performance with integral and separable dimensions. Information from integral dimensions, which cannot easily be selectively attended to, is best explained as a pooling of information into a single, coactive processing channel (Little et al., 2013). On the other hand, separable dimensions, which can be easily selectively attended to, have been shown to be processed independently in serial or parallel (Fifić et al., 2010). Hence, the notion of integrality and separability must be taken into account in the formal model of categorization and decision making more broadly.

## Garner's (1974) Speeded-Categorization Tasks

One classic approach to understanding integrality is Garner's (1974) set of speeded-categorization tasks (see also Algom \& Fitousi, 2016, for a review). In these tasks, participants categorize stimuli into two categories as quickly and accurately as possible on each trial. Category membership in these tasks is determined by the stimulus' value on a single relevant dimension. The three major task conditions -control, correlated, and filtering - vary in the structure of the stimulus space, as shown in Figure 1.

Figure 1. Garner's (1974) control, correlated, and filtering conditions

In the control condition, there are two stimuli which only vary along the single relevant dimension (i.e., dimension X in Figure 1). In the correlated condition, there are two stimuli which vary along both the relevant dimension and a second irrelevant dimension. In the filtering condition, there are four stimuli with all possible combinations of relevant and irrelevant dimension values. In all conditions, participants should attend primarily to the relevant dimension while ignoring variation in the irrelevant dimension in order to perform the categorization task accurately and quickly.

For integral dimensions, a robust finding is that subjects have shortest response times (RTs) in the correlated task and the longest RTs in the filtering task. This suggests a correlated-facilitation and filtering- or Garner-interference effect, respectively (Garner, 1974). However, for separable dimensions, RTs across control, correlated, and filtering tasks are relatively invariant (Garner, 1974).

These patterns of RTs arise due to a difference in the ability to selectively attend and process information for integral and separable dimensions (Garner, 1974). When dimensions are separable, participants are easily able to selectively attend to relevant dimension, and as a result, the psychological representation of the stimulus space in all three conditions are collapsed to the single relevant dimension such that the correlated and filtering conditions are isomorphic to the control condition. However, when integral dimensions are used, participants are unable to selectively attend to the relevant dimension, and thus have different psychological representations of the stimulus space for each condition. For instance, as the stimuli vary along both dimensions in the correlated task, when the information from these dimensions are pooled and processed in a single channel, psychological discriminability between stimuli may be increased compared to when the stimuli only vary along one dimension in the control condition. With increased discriminability between stimuli, categorization becomes easier and more efficient resulting in
shorter RTs in the correlated task - the correlated-facilitation effect. There are several potential explanations for Garner interference. For one, there are more items in the filtering task than in the control task which may encourage more conservative responding, especially if the stimuli are highly confusable. Alternatively, the increase in the number of items might increase the perceived variability which would act to slow RTs (Nosofsky \& Palmeri, 1997).

In a recent paper using a modified version of the Garner task (see Figure 2), Little et al. (2016) showed that one explanation for filtering interference was the reduction of direct sequential repetitions in the filtering condition. That is, with more items, the probability of any one item repeating is reduced compared to the control condition. Repetitions have been show to produce very fast RTs; consequently, the reduction in repetitions results in slower responding (Fletcher \& Rabbitt, 1978; Krueger \& Shapiro, 1981). Investigations of decomposition (i.e., into sequential effects) of the standard Garner effects (Burns, 2016; Dyson \& Quinlan, 2010) have concluded that repetition effects can not be the sole explanation for Garner interference. However, two limitations of these papers are that only a small number of participants was tested ( $\mathrm{N}=16$; Dyson \& Quinlan (2010); $\mathrm{N}=30$; Burns (2016)) and there was no comparison to sequential effects in separable dimension stimuli in either case. Given that the sequential effects in our modified task were highly pronounced (Little et al., 2016), were also present for separable dimensions in the same modified task (Lin \& Little, 2017), and that we found considerable individual variability in our modified task, we sought in the present paper to conduct a larger replication of the standard Garner task to examine this decomposition using both integral and separable dimensions.

## Sequential Effects

Sequential effects arise due to a reliance on a relative comparison of the current stimulus to the preceding stimulus (or stimuli). These types of effects have been observed in a large variety of categorization tasks (Stewart et al., 2002, see e.g.,) but also in identification (Brown et al., 2007, see e.g.,) and simple choice tasks (Luce, 1986; Jones et al., 2013). One such effect that has been widely studied is the repetition effect, where subjects have higher accuracy and shorter RTs when the current stimulus is identical to the immediately preceding stimulus (Felfoldy, 1974; Lockhead et al., 1978). In their modified task, using integral dimensions, Little et al. (2016) showed that there are complex sequential effects that arise across the control, correlated, and filtering conditions.

1. Repetition Effect: Items which were adjacent to category boundary were categorized faster and more accurately when preceded by the same item than when preceded by another item.
2. Far same category pushing effect: When the near boundary item was preceded by a far item from the same category, RTs were slower and errors higher than when the near item was preceded by another item.

Figure 2. Schematic diagram of the modified Garner-task paradigm using stimuli varying on integral dimensions brightness and saturation - where the relevant dimension is brightness.
3. Adjacent opposite category pulling effect: When the near boundary item was preceded by an adjacent item from the opposite category, RTs were slower and errors higher than when the near item was preceded by another item.
4. Irrelevant dimension change: Finally, in the filtering task, the repetition effect was attenuated and the pushing and pulling effects were enhanced when the irrelevant dimension changed (i.e., when there was only repetition of the relevant but not the irrelevant dimension value). This effect emphasizes the role of previous item distance (i.e., from the current item) in determining the magnitude of the sequential effects. This was also evident in the attenuated pushing and pulling effects in the correlated condition (i.e., since the between category items are further apart in that category).

We have recently demonstrated with separable dimensions that the same repetition, pushing, and pulling effects arise even when there was no overall average RT difference between conditions (Lin \& Little, 2017). There is no effect of changing the irrelevant dimension in the filtering task with separable dimensions consistent with the notion that attention acts to collapse the separable conditions across the irrelevant dimension.

While there have been some investigations of sequential effects in the standard Garner task (Felfoldy, 1974; Lockhead et al., 1978), there have been few comparisons of sequential effects between integral and separable dimensions. Additionally, there is value in collecting a large replication sample in the standard Garner task, as the magnitude and variability of the standard Garner effects and sequential effect are currently unclear. For instance, not all subjects showed the standard Garner ordering (i.e., correlated RT ; control RT ; filtering RT) in a modified Garner task. Thus, the present study seeks to quantify the size and variability of the standard Garner effects and several decompositions of those effects (including sequential effects; from Dyson \& Quinlan, 2010) using a hierarchical Bayesian analysis.

## Method

Two sets of experiments following the general procedure outlined in Garner (1974) were conducted. Experiment 1 used integral dimensions; Experiment 2 used separable dimensions.

Participants In Exp 1, 100 University of Melbourne undergraduates were randomly assigned to either the brightness ( $N$ $=50)$ group or saturation $(N=50) .{ }^{1}$ One saturation participant was excluded due to an overwritten data file. In Exp 2, 99 students were randomly assigned to either the saturation ( $N$ $=49)$ or line-position $(N=50)$ group. All received course credit for participation.
Exp 1: Integral Stimuli Stimuli were color squares (100 $\times 100$ pixels each; Munsell hue 5R) that varied in brightness (value) and saturation (chroma). The set of four stimuli was created by combining two levels of brightness (values 5, 6) and two levels of saturation (chroma 6,8). The stimuli were presented on a monitor resolution of $1280 \times 1024$.
Exp 2: Separable Stimuli Stimuli were colored rectangles ( $170 \times 255$ pixels) with a black outline and with a small inset black vertical line positioned along the base of the rectangle. The color was selected from the Munsell hue 5R with a brightness value of 5 while the saturation was varied. The line varied by position along the base of the rectangle from the left side of the rectangle. The full set of stimuli was created by combining two levels of saturation (chroma 8,10 ) and two line positions ( 60,80 pixels from the left). The stimuli were presented on a monitor resolution of $1280 \times 1024$.

## General Procedure

In both experiments, participants each completed a one-hour categorization task. At the outset, participants were presented with an instruction screen with examples of the stimuli and were told to categorize each stimulus as accurately and quickly as possible. Participants then completed 5 blocks of 24 practice trials followed by 120 experimental trials, and a $6^{\text {th }}$ block of 120 experimental trials.

The control task and correlated tasks were presented over two blocks. In both tasks, only two stimuli of the full set were presented to the participant on each trial. For the subsequent block of the control task, the irrelevant dimension value was switched. For the subsequent block of the correlated task, the relevant and irrelevant dimension values of the two stimuli were both switched.

The filtering task was presented over two consecutive blocks without practice trials for the second block. The blocks of tasks were counterbalanced and the order of presentation of individual stimuli on each trial was randomized anew within each block.

On each trial, a fixation cross was presented for 1500 ms , followed by the stimulus. The participant then decided

[^130]whether the stimulus belonged to category A or B. Response choice and response time (RT) were recorded via button press of a customized RT box Li et al. (2010). The stimulus remained on screen until a button press was made or until the 5000 ms response deadline. Full feedback (i.e., "right", "wrong") was provided for the 24 practice trials; only incorrect response feedback was provided for experimental trials. If a response was not made before the response deadline, feedback "too slow" was given. The feedback remained on screen for 2000 ms .

## Data Analysis

We applied two hierarchical Bayesian models. For the first model, we found the posteriors for a single group distribution for each of the items in the control, correlated, and filtering task in each of the integral and separable experiments. For the second model, we found the posteriors for distributions of each sequential order for each condition across both experiments. That is, we estimated the posterior for when the relevant dimension value repeated and the irrelevant dimension value repeated (hereafter, RR), for when the relevant dimension changed but the irrelevant dimension repeated (CR), when the relevant dimension repeated but the irrelevant dimension change (RC), and for when both the relevant and irrelevant dimensions changed (CC). The control task only contains the RR and CR conditions, the correlated task contains the RR and CC conditions, and the filtering task contains all four conditions.

For each experiment $i$, each subject $j$, and each task (or sequence condition) $k$, we estimated the rt as a lognormal distribution, $r t_{i j k} \sim \log N\left(\mu_{i k}, \sigma_{i k}\right)$. The prior over the subject means was a normal distribution, $\mu_{i k} \sim N\left(M_{k}, S_{k}\right)$, and the prior over the subject precision $\left(1 / \sigma_{i k}\right)$ was a gamma distribution, $1 / \sigma_{i k} \sim \operatorname{Gamma}\left(a_{k}, b_{k}\right)$. Hyperpriors were relatively non-informative, $M_{k} U(0,7), S_{k} \sim U(0,500), a_{k} \sim$ $U(.5,100)$, and $b_{k} \sim U(.5,100)$, where $U(x, y)$ is a uniform distribution over the range $[x, y]$. The models were implemented in JAGS (Plummer, 2003) for which we collected 1000 samples after 1000 burn-in samples from two MCMC chains. Plots of these chains indicated good convergence.

## Results

The estimated rt means and variances are on a logarithmic scale and not the scale of the original RT data. Hence, to summarize the effects, we converted the posterior group logNormal distribution means, M, and standard deviation, to the RT scale using the following transformation:

$$
\begin{gathered}
\tilde{M}_{k}=\exp \left(M_{k}+\frac{S_{k}^{2}}{2}\right) \\
\tilde{S}_{k}=\sqrt{\exp \left(2 M_{k}+S_{k}^{2}\right) \exp \left(S_{k}^{2}-1\right)}
\end{gathered}
$$

## Overall Condition Analysis

We first analysed the overall difference between condition by taking the difference between the Control and Correlated posterior estimates (left panel, Figure 3) and between the Control

Figure 3. Posterior distributions for the difference between control and correlated overall mean RTs (left panel), and the difference between between control and filtering overall mean RTs (right panel). The solid line shows the distribution for the integral posterior and the dotted line shows the posterior for the separable condition.
task and the filtering task (right panel, Figure 3). We note that there were no strong qualitative individual differences; only quantitative variation.

For the comparisons to the correlated condition, positive values would indicate shorter RTs in the correlated condition than the control condition. Analogously, for the comparison to the filtering condition, negative values indicate longer RTs in the filtering condition than in the control condition. As shown in Figure 3, the posterior distributions for the separable conditions have substantial density over 0 indicating no overall effect of condition. For the integral conditions, the distributions had the most density over positive and negative difference values for the correlated and filtering comparisons, respectively. Hence, we've replicated the standard Garner result and have shown that all subjects in our experiment show this pattern of results.

## Sequential Item Analysis

Figure 4 shows the posterior distributions for each of the item conditions. For the separable dimensions condition, posterior distributions for item conditions appear to be relatively invariant across the control, correlated, and filtering tasks, indicating little or no sequential effects. The posterior distributions for the integral dimension condition reveals a more complex pattern of item condition effects. In the control task, the posterior distributions for RR and CC indicate no sequential effects. In the correlated task, the posterior distribution for RR lies slightly lower than CC, suggesting a repetition effect. In the filtering condition, posterior RTs are markedly slower for irrelevant dimension changes (i.e., RC and CC), and quickest when the stimulus is repeated (i.e., RR).
We summarized these distribution by computing several effect decompositions derived by Dyson \& Quinlan (2010).

Filtering interference Note that overall filtering interference can be decomposed into sequential components as: $\left[R R_{\text {filt }}+R C_{\text {filt }}+C R_{\text {filt }}+C C_{\text {filt }}\right] / 4-\left[R R_{\text {cont }}+C R_{\text {cont }}\right] / 2$,

Figure 4. Posterior distributions for the transformed $\operatorname{logNor}$ mal groups means for the Control condition (RR \& CR; Left panel), Correlated condition (RR \& CC; Middle panel), and Filtering condition (CC, CR, RC, CC; Right panel)

Figure 5. Posteriors distributions for irrelevant feature variation (left panel) and stimulus uncertainty (right panel) components of filtering interference for both integral and separable dimensions.
which "filt" refers to the filtering condition and "cont" to the control condition. This overall measure can be further decomposed into the following two components:

1. A measure of irrelevant feature variation, which is positive if there is a cost when the irrelevant dimension changes:
$\left[R R_{\text {filt }}+R C_{\text {filt }}+C R_{\text {filt }}+C C_{\text {filt }}\right] / 4-\left[R R_{\text {filt }}+C R_{\text {filt }}\right] / 2$
2. A measure of stimulus uncertainty, which is positive if there is a cost associated with having more stimuli in the filtering condition controlling for changes in the irrelevant dimension: $\left[R R_{\text {filt }}+C R_{\text {filt }}\right] / 2-\left[R R_{\text {cont }}+C R_{\text {cont }}\right] / 2$

These two effects are shown in Figure 5. For these figures, negative values indicate RT benefits (i.e., shorter RT) while positive values indicate RT costs (i.e., longer RT) for the respective effect. The posterior distribution for both effects for separable dimensions have substantial density over zero, indicating no irrelevant feature variation or stimulus uncertainty effects. In contrast, the posterior distributions for integral dimensions have substantial density over positive values, indicating RT costs as a result of irrelevant variation and stimulus uncertainty. Furthermore, stimulus uncertainty appears to contribute to filtering interference more than irrelevant variation for the integral dimensions condition.

Correlated benefit In the correlated condition we conducted a corresponding decomposition (again following

Figure 6. Posterior distributions for redundancy repetition (left panel) and redundancy change (right panel) components of correlated facilitation for both integral and separable dimensions.

Dyson \& Quinlan 2010) as: $\left[R R_{\text {corr }}+C R_{\text {corr }}\right] / 2-\left[R R_{\text {cont }}+\right.$ $\left.C R_{\text {cont }}\right] / 2$.

This overall measure can be further decomposed into:

1. The effect of redundancy repetition, which indexes the effect of changing both dimensions: $\left[R R_{\text {corr }}-R R_{\text {cont }}\right] / 2$
2. The effect of redundancy change, which indexes the effect of additional irrelevant dimension variation in the correlated condition compared to the control condition: $\left[C_{\text {corr }}-\right.$ CR $\left._{\text {cont }}\right] / 2$.

These effects are shown in Figure 6. For separable dimensions, the posterior distributions for both redundancy repetition and redundancy change have substantial density over zero, indicating no overall correlated facilitation effect. For integral dimensions, both redundancy repetition and redundancy change have substantial value over negative values, indicating RT benefits. In addition, the components appear to contribute approximately equally to the overall correlated facilitation effect.

Repetition Effect Finally, for all three conditions we computed the effect repeating an item compared to switching an item (i.e., in the control and correlated conditions; in the filtering condition, we compared repetition to the average of the other three item RTs). ${ }^{2}$ This repetition measure is computed as:

$$
\begin{aligned}
\text { Control Repetition } & =R R_{\text {cont }}-C R_{\text {cont }} \\
\text { Correlated Repetition } & =R R_{\text {corr }}-C C_{\text {corr }} \\
\text { Filtering Repetition } & =R R_{\text {filt }}-\left[C R_{\text {filt }}+R C_{\text {filt }}+C C_{\text {filt }}\right] / 3
\end{aligned}
$$

This measure can also be interpreted to indicate a repetition effect (i.e., shorter RTs as a result of repetition in both dimensions). A negative value indicates a repetition effect

In the control condition, the distributions for both integral and separable dimensions are centered around zero, suggest-

[^131]

Figure 7. Posterior distributions for the repetition effect in control, correlated, and filtering tasks for both integral and separable dimensions.
ing no repetition effect. In the correlated condition, the posterior distributions for both integral and separable dimensions have a substantial density over negative values, indicating a slight repetition effect. The repetition effect for integral dimensions also appears to be marginally stronger than for separable dimensions; though even here, both distributions have $95 \%$ highest posterior density intervals which overlap 0 . In the filtering condition, the distribution for separable dimensions has substantial density over zero, indicating no repetition effect. However, the distribution for integral dimensions lies mainly over negative values, indicating the presence of a strong repetition effect.

## Discussion

Overall, the hierarchical Bayesian approach in the present study revealed reliably strong standard Garner effects, showing correlated facilitation and filtering interference with integral dimensions but not with separable dimensions. A further decomposition of the Garner effects into sequential item conditions, following Dyson \& Quinlan (2010), provide further insight into the underlying mechanisms of perceptual decision-making. Notably, we found little evidence for any individual differences.

One notable finding is that no sequential effects were found with separable dimensions in the standard Garner task. This result is in contrast to the sequential effects found with separable dimensions in the modified Garner task (Lin \& Little, 2017). One potential explanation could be that the presence and magnitude of sequential effects depends on task complexity. For example, Bentin \& McCarthy (1994) found that immediate repetition provides a relatively larger advantage in lexical decision and face recognition tasks compared to simpler discrimination tasks, as it eliminated the need for more complex processes such as accessing semantic memory. Similarly, as the standard Garner task has a much smaller stimulus space compared to the modified Garner task, repetitions may provide a large benefit for the modified task but a much smaller or no RT benefit, and as a result, no sequential effects arise in the standard task. On the other hand, we have only examined the effects of a single preceding item; in simple RT tasks (i.e., with two stimuli), there are complex sequential ef-
fects extending up to five items back reflecting the influence of repetitions and alternations (Jones et al., 2013).

Another important result is that stimulus uncertainty contributes to filtering-interference more than irrelevant feature variation. An explanation could be that the lack of interference from irrelevant feature variation can be attributed to the integrality of dimensions. If dimensions are less integral and easier to selectively attend to, then the irrelevant variation would not contribute to interference, for example, in the separable dimensions case. It should also be noted that it is difficult to isolate stimulus uncertainty and irrelevant feature variation in the standard Garner task, as an increase in the number of irrelevant dimensions is associated with a larger number of stimuli. Even though these measures attempt to isolate trials where only stimulus uncertainty or irrelevant variation changes, it is unclear whether the larger context of the task has no impact. Burns (2016) attempted to disentangle these two components by introducing a 3-dimensional Garner task where irrelevant variation could be increased without affecting stimulus uncertainty, and demonstrated that irrelevant variation alone can increase interference substantially. In order to further evaluate the components underlying filteringinterference, promising avenues for future work might be to measure these decomposition effects with a variety of different dimensions varying on integrality or to carefully manipulate stimulus uncertainty and irrelevant variation within Burns's (2016) 3-dimensional Garner task.

# Error-Based Learning: A Mechanism for Linking Verbs to Syntax 

Yi Lin (yilin5@illinois.edu)<br>Department of Psychology, 603 E. Daniel Street<br>Champaign, IL 61820 USA

#### Abstract

Children and adults are guided by verb-specific syntactic likelihoods, or verb bias, in language comprehension and production. Recent reports showed that verb bias can be altered by new linguistic experience. We investigated the mechanisms underlying this verb bias learning or adaptation. Specifically, we asked whether verb bias learning, like abstract syntactic priming, is driven by error-based implicit learning. We report three experiments in which we altered the biases of familiar dative verbs in children's and adults' sentence production, via training trials that induced participants to produce each verb consistently in either double-object or prepositional-object dative structures. Participants' syntactic choices in later test trials reflected the expected adaptation of verb bias to the training experience. In addition, the magnitude of the training effect varied with the likelihood of each sentence structure and with pre-existing verb bias: Unexpected verb-structure combinations resulted in larger training effects, suggesting the operation of error-based implicit learning.

Keywords: language acquisition; verb bias; implicit learning; error-based learning; surprisal

## Introduction

Verbs are choosy about the sentence structures they occur in. Transitive but not intransitive verbs can appear in transitive sentences, with two noun-phrase arguments (She saw Sue; *She slept Sue); only certain verbs permit dative structures, with three arguments (She showed the book to Sue; *She saw the book to Sue). In addition to these all-or-none licensing restrictions, the linking of verbs with syntax is constrained by syntactic likelihoods. Most verbs license multiple structures, but may occur much more often in one structure than another. To illustrate, many dative verbs license both the prepositional-object (PO: He showed/passed the book to her) and the double-object dative structure (DO: He showed/passed her the book), but the verb show occurs much more often in the DO structure than does pass. These verbspecific likelihoods are known as verb bias. Verb bias knowledge guides language processing in children and in adults, affecting how we link verbs and syntax in production, and online expectations about likely sentence structures in comprehension (e.g., Peter et al., 2015; Snedeker \& Trueswell, 2004).

Verb bias effects emerge early in acquisition (Peter et al., 2015; Tomasello, 1992), but continually adapt to ongoing linguistic experience in children and adults. Recent reports show that the biases of even well-known verbs can be altered by
new linguistic experience (Coyle \& Kaschak, 2008; Lin \& Fisher, 2016; Qi, Yuan \& Fisher, 2011; Ryskin, Qi, Duff \& Brown-Schmidt, 2016). For instance, Lin and Fisher (2016) asked children and adults to describe videos by repeating and completing sentence stems provided by an experimenter. Training stems (10 per verb) induced participants to produce one verb only in DO structures (Dora gave Boots__), and another verb only in PO structures (Minnie showed the clock___). Test stems ended at the verb, allowing participants to choose either dative structure (Piglet gave__ The teacher showed___). This brief training changed the biases of a wide range of familiar verbs in adults' and 4-year-olds' sentence production. In unconstrained test trials, participants produced more DO descriptions with verbs trained in DO than in PO structures. Similar verb-bias training effects have been found in children's and adults' comprehension of sentences with a prepositional phrase attachment ambiguity (e.g., Tickle/choose the frog with the feather; Qi et al., 2011; Ryskin et al., 2016). These findings tell us that learners keep track of the statistics of verb-structure combinations in the linguistic environment, and adapt their language-processing systems accordingly.

In the present study, we explored error-based learning as a potential mechanism for verb bias learning. To do so, we explored parallels between verb bias learning and abstract syntactic priming. Syntactic priming is the tendency to reuse a previously encountered syntactic structure. For example, a talker who has recently read a sentence in the DO structure (The governess made the princess a pot of tea) is more likely to choose the same structure to describe an unrelated picture (The boy is handing the singer a guitar; Bock, 1986). Syntactic priming is abstract-it spans different verbs, as in the example just given. Syntactic priming can be measured in children and adults, and in comprehension and production (Rowland et al., 2012; Thothathiri \& Snedeker, 2008). The priming effects are long-lasting (Bock \& Griffin, 2000), suggesting that they reflect long-term learning about abstract syntax. Taken together, the literature on syntactic priming, and recent reports of verb-bias learning, suggest that learners adapt to the statistics both of abstract syntactic structures, and of verbstructure combinations (e.g., Wonnacott, Newport, \& Tanenhaus, 2008).

Of particular interest here, syntactic priming shows 'inverse preference' or 'surprisal' effects (e.g., Bernolet \& Hartsuiker, 2010; Jaeger \& Snider, 2013; Peter et al., 2015).

That is, priming effects are larger if the structure of the prime sentence is unexpected. To illustrate, Bernolet and Hartsuiker (2010), in a study of adult sentence production, reported that (a) DO prime sentences exerted a larger priming effect (relative to baseline) than did prime sentences in the more frequent PO structure, and (b) the magnitude of syntactic priming depended on verb bias: The effect of a DO prime was larger if a PO-biased verb (one that rarely appears in this structure) appeared in the prime sentence. Children show similar effects of verb bias on the magnitude of syntactic priming (Peter et al., 2015). This pattern points to error-based implicit learning as a mechanism for syntactic priming: We expect likely structures, and thus learn more from the unexpected, continuously adapting the language-processing system to a changing linguistic environment (Chang, Dell, \& Bock, 2006; Jaeger \& Snider, 2013).

Could verb bias learning result from the same error-based learning mechanisms that support syntactic priming? If so, then verb bias training effects should vary with training-sentence surprisal. We tested this prediction by adapting the materials of Lin and Fisher (2016) to vary both training structure (DO- vs. PO-training) and pre-existing verb bias (DO-biased vs. PO-biased verbs).

In three experiments, participants watched videos depicting simple transfer events, and were prompted to describe each one by repeating and completing a sentence stem provided by an experimenter (Fig-1). As before, each participant received training trials that induced them to produce DO structures with one verb (DO-training), and PO structures with a second verb (PO-training). Crucially, one of the restricted verbs was chosen to be already DO-biased (e.g., show), while the other was PO-biased (e.g., pass). The assignment of verbs to training conditions varied between subjects, resulting in two list conditions: In the with-bias list, both verbs were trained in the structure that matched their pre-existing biases (e.g., PO-training for PO-biased pass, DO-training for DO-biased show). In the contra-bias list, both verbs were trained in the structure that mismatched their preexisting biases (PO-training for DO-biased show, DO-training for PO-biased pass). Following this training, participants received test trials in which the sentence stems to be completed ended at the verb. Participants' structural choices in these unconstrained test trials provided our measure of verb

Figure 1. Example of contra-bias training in Experiment 1a.
bias learning.
We work through our predictions for test-trial performance in Fig-2. Each panel shows the expected rate of DO-structure responses (as a proportion of DO and PO responses) under different experimental outcomes, plotted by within-subjects training condition (PO-training vs. DO-training) and be-tween-subjects list condition (with-bias vs. contra-bias).

Based on previous results we expected pre-existing verb bias to affect the rate of DO responses at test. Fig-2a shows the data pattern that would result from baseline verb bias alone: DO responses should be much more common for the DO-biased than for the PO-biased verb. Assuming no training effect, the difference between the two verbs (indicated by the equal-sized arrows in Fig-2a) would not vary with training condition.

We also expected to find a training effect. Fig-2b shows the data pattern that would result if a uniform verb-bias training effect, one that does not vary with training-sentence surprisal, were added to the effect of pre-existing verb bias. As Fig-2b shows, PO-training would decrease the rate of DO responding (relative to baseline), and DO-training would increase the rate of DO responses. Given a uniform training effect, the difference between the two verbs, reflecting pre-existing verb bias, would again remain unchanged.

Fig-2c shows the predicted data pattern if verb bias training effects vary with training-sentence surprisal. Trainingsentence surprisal should reflect both the likelihood of the training structure itself, and its fit with the pre-existing bias of the verb. We expected DO-training to exert a larger effect

Figure 2. Predicted rate of DO responses, by training condition (PO- vs. DO-training) and list condition (with-bias vs. contra-bias). Fig-2a shows an effect of baseline verb bias only; Fig-2b shows the influence of both pre-existing verb bias and a uniform training effect; Fig-2c shows the key surprisal predictions. In 2c, the rate of DO responses reflects preexisting verb bias, and an effect of training that is influenced by training-sentence surprisal.
than PO-training, because the DO structure is a non-canonical structure. For example, the DO structure imposes discourse constraints on its use: It is typically used to place dis-course-given recipients in post-verbal position (Show her the picture; Stephens, 2015). The PO structure, in contrast, has no strong discourse constraints (Brown, Savova, \& Gibson, 2008). In our task, without a discourse set-up establishing the recipient as given, the DO structure should be an unexpected choice. We also expected the training effect to vary with preexisting verb bias: the effect of DO-training should be strongest for PO-biased verbs, those that rarely occur in the DO.

Accordingly, as shown in Fig-2c, DO-training should considerably increase the rate of DO responses for the PO-biased verb (e.g., pass), but should have relatively little effect on the rate of DO responses for an already DO-biased verb (e.g., show). In the PO-training condition, we should see relatively little change due to training for either verb, preserving the large difference between verbs that reflects their baseline biases. Notice the key difference between Fig-2b and Fig-2c: A training effect that varies with training-sentence surprisal should reduce the difference between the two verbs in the DO-training condition relative to the PO-training condition.

We tested this prediction with 4- and 5-year-olds in Experiments 1a and 1b, and with adults in Experiment 2.

## Experiment 1a

## Methods

Participants Forty-eight four- and five-year-old children (Mean $=4 ; 8$; Range $=4 ; 0-5 ; 11$ ) participated; all were native speakers of English. Data from 4 additional children were excluded due to low training compliance (see below).

Materials and Procedures The materials were 46 5-s animated video clips depicting transfer events designed to be described by dative verbs, and 49 filler videos that did not depict transfer events. Children watched and described all 95 (critical and filler) videos by repeating and completing a sentence stem (Fig-1). The task was adapted from Lin and Fisher (2016), described in the Introduction. The task took about 30 to 40 minutes, and was made engaging for children by embedding it in a scavenger hunt for which game-tokens were discovered at intervals.

The task included a training and a testing block, with no boundary between them from the child's perspective. The key manipulation involved artificially restricting particular verbs to particular dative structures (only DO or PO) in training. As shown in Fig-1, training stems ended with a post-verbal noun, biasing children to produce either a DO or a PO sentence. Test stems ended at the verb. Show and pass were the two verbs that were restricted in training. These verbs differ in their pre-existing biases, as revealed in a separate norming study. Show is used more often in the DO, and pass in the PO dative structure. Children were randomly assigned to the with-bias or the contra-bias condition. Recall that in the withbias condition, both verbs were trained in the structure that matched their pre-existing bias, whereas in the contra-bias
condition, both verbs were trained in the structure that mismatched their pre-existing bias.

A third dative verb, give, was unrestricted, appearing equally often in the DO and PO structures during training. Unrestricted give (a DO-biased verb) was included to increase children's baseline rate of DO responses in the task; note that children tend to prefer the PO structure in tasks like ours (Peter et al., 2015; Stephens, 2015).

Children received 10 training trials per verb ( 30 training trials total) in the training block. In the test block children received 4 unconstrained test trials per restricted verb (show, pass), and 8 test trials for the unrestricted verb give. The three verbs were interleaved in training and test, and each child heard equal numbers of DO and PO training stems across verbs, ensuring that any effect of training reflected verb-bias learning rather than abstract syntactic priming.

The main task was preceded by a naming game in which children named the familiar characters and objects involved in the events. The video-description task then began with two filler trials to demonstrate the task.

Children's responses were transcribed and coded as DO, PO, or Other, following Rowland et al.'s (2012) criteria. Children who produced fewer than $80 \%$ training-compliant responses in each training condition (e.g., $80 \%$ DO responses for their DO-trained verb) were replaced. The 48 included children showed a compliance rate of $94 \%$ in training.

Our main analyses concerned the responses in the 8 test trials with experimentally restricted verbs. Of the 384 test responses, 8 were Other responses, leaving 376 . The dependent measure was the proportion of DO responses (out of DO and PO responses only), compared across the training and list conditions.

## Results and Discussion

Fig-3a shows children's proportion of DO responses in the test trials with restricted verbs, by within-subjects training condition (PO- vs. DO-Training) and between-subjects list condition (with- vs. contra-bias). As predicted, children showed a training effect, producing more DO responses in the DO-training condition ( $38 \%$ ) than in the PO-training condition (27\%). They also showed a clear effect of pre-existing verb bias, producing more DO responses with the DO-biased verb show (43\%) than with the PO-biased verb pass (22\%), averaged across training conditions.

Crucially, the effect of training varied with the likelihood of the training structure and its fit with pre-existing verb bias. Fig-3a shows that DO-training dramatically increased the rate of DO responses for the PO-biased verb pass, but had little effect on the rate of DO responses for the already DObiased verb show. This asymmetrical training effect reduced the difference between the two verbs in the DO-training condition relative to the PO-training condition. In the PO-training condition, Fig-3a shows a large difference in the rate of DO responses for the PO-biased verb pass, versus the DObiased verb show; this difference straightforwardly reflects

Figure 3. Mean (se) proportion DO responses (out of DO and PO responses) in the test phrase of Experiment la (Figure 3a), Experiment $1 \mathrm{~b}(3 \mathrm{~b})$ and Experiment $2(3 \mathrm{c})$, by training condition (PO vs. DO-training) and list (with-bias vs. contra-bias).
the verbs' baseline verb biases. The effect of training was larger for DO- than for PO-training, reflecting the likelihood of each structure; the effect of DO-training was larger for a PO-biased verb, reflecting the likelihood of verb-structure combinations. This pattern of responses closely resembles the predictions shown in Fig-1c, suggesting both an effect of training and an influence of training-sentence surprisal on the magnitude of the training effect.

This pattern was supported by a two-way mixed-model ANOVA on the proportion of DO responses (arcsine transformed) that revealed a main effect of training $(F(1,46)=$ $5.24, p<.05)$, and an interaction of training and list $(F(1,46)$ $=12.22, p<.01)$. Separate t -tests revealed that the difference between the two verbs was significant in the PO-training condition $(t(47)=3.32, p<.01)$ but not in the DO-training condition $(t(47)<1)$, consistent with our surprisal predictions.

In Experiment 1a we reproduced the verb-bias training effect in young children's language production documented in prior work (Lin \& Fisher, 2016). Experience producing a verb repeatedly in one syntactic structure modified the structural biases of that verb, rendering children more likely to use the verb in the same structure in later sentences. We also found the first evidence that the magnitude of this training effect depends on the likelihood of the training sentences. In Experiment 1 b we sought to extend this effect to different verb sets, exploring the robustness of the surprisal effect.

## Experiment 1b

## Methods

Participants A new group of forty-eight four- and five-yearold children (Mean $=4 ; 7$; Range $=4 ; 0-5 ; 8$ ) participated, all native English speakers. Data from 4 additional children were excluded due to low training compliance (3), or too few dative responses in the test trials (1).

Materials and Procedures Materials and procedures were identical to those of Experiment 1a, except that send was the PO-biased verb for half of the children and throw for the other half. We chose send and throw, two other PO-biased verbs, to seek evidence of surprisal effects with different verb sets. We retained show as the DO-biased verb to avoid reducing
the verb-bias difference between our restricted verbs in Experiment 1 b : Given children's overall preference for the PO structure, our norming study with children identified few strongly DO-biased verbs. As in Experiment 1a, each participant was randomly assigned to the with- or contra-bias list.

Children who produced fewer than $80 \%$ training-compliant responses in each training condition were replaced. We also excluded one child who did not produce at least one dative response in the test block for each restricted verb. The included children produced training-compliant responses in $95 \%$ of training trials. Of the 384 possible responses in the test trials with restricted verbs, 7 were coded as Other trials, leaving 377 DO and PO responses.

## Results and Discussion

Fig-3b shows children's proportion of DO responses in the restricted-verb test trials, by within-subjects training condition (PO- vs. DO-Training) and between-subjects list condition (with- vs. contra-bias). The pattern of responses closely resembles that found in Experiment 1a. Children showed a training effect, producing more DO responses in the DOtraining condition (35\%) than in the PO-training condition (20\%), and an effect of pre-existing verb bias, producing more DO responses for the DO-biased verb show (34\%) than for the PO-biased verbs ( $21 \%$ ).

As before, the effect of training varied with the likelihood of the training structure and its fit with the pre-existing bias. In Fig-3b, DO-training greatly boosted the rate of DO responses for the PO-biased verbs, but had little effect on rate of DO responses for the DO-biased verb show. As a result, the difference between the two verbs in the DO-training condition was much smaller than in the PO-training condition. In the PO-training condition, Fig-3b shows a large difference in the rate of DO responses for the PO-biased verbs versus the DO-biased verb, reflecting these verbs' pre-existing verb biases. Therefore, as before, the data bear out our surprisal predictions: the effect of training was larger for DO- than for PO-training, reflecting the likelihood of each structure, and the effect of DO-training was larger for a PO-biased than for a DO-biased verb. The same pattern emerged for both verb sets (not shown in the figure).

These observations were borne out by an ANOVA on the proportion of DO responses (arcsine-transformed) that again
revealed a main effect of training $(F(1,46)=8.16 ; p<.01)$ and an interaction of training and list $(F(1,46)=5.83 ; p<$ .05 ). Separate $t$-tests revealed that children produced significantly more DO responses for the DO-biased verb show than for the PO-biased verbs send or throw in PO-training $(t(47)=$ 2.7, $p<.01$ ) but not in DO-training $(t(47)<1)$.

Experiment 1 b thus reproduced the key findings of Experiment 1a, varying the verb sets. Again, the pattern of results suggested that the magnitude of verb-bias training depended on training-sentence surprisal. In Experiment 2 we sought evidence of the same surprisal effect in adults, again varying the verb sets.

## Experiment 2

## Methods

Participants Forty-eight college-aged adults participated, all native English speakers. Data from 2 additional adults were excluded due to low training compliance (1), or too few dative responses in the test block (1).

Materials and Procedures Materials and procedures were identical to those of Experiment 1a, except that send and hand were the restricted verbs for half of the participants and pass and show were the restricted verbs for the other half. Send and pass were both PO-biased verbs in our norming data; hand and show were both DO-biased. As in Experiment 1a, each participant was randomly assigned to either the withbias or the contra-bias list condition.

Adults who produced fewer than $80 \%$ training-compliant responses in each training condition were replaced. We also excluded one adult who did not produce at least one dative response in the test block for each restricted verb. The included participants produced training-compliant responses in $99 \%$ of training trials. Of the 384 possible responses in the test trials with restricted verbs, 8 were coded as Other responses, leaving 376 DO and PO responses.

## Results and Discussion

Fig-3c shows adults' proportion of DO responses in the re-stricted-verb test trials, by within-subjects training condition (PO- vs. DO-Training) and between-subjects list (with- vs. contra-bias). Adults, like children, showed an effect of training, producing more DO responses in the DO-training condition (54\%) than in the PO-training condition (34\%). They also showed effects of pre-existing verb bias, producing more DO responses with the DO-biased verbs ( $53 \%$ ) than with the PO-biased verbs ( $35 \%$ ), averaged across training conditions.

The pattern of data shown in Fig-3c again suggests that the effect of training varied with the likelihood of the training structure and its fit with the pre-existing verb bias. The difference between the (pre-experimentally) PO- vs. DO-biased verbs was reduced in the DO-training condition relative to the PO-training condition. This is just what we would predict based on training-sentence surprisal: DO-training strongly increased the rate of DO responding for the PO-biased verbs.

As in Experiment 1b, the same pattern emerged for both verb sets (not shown in the figure).

This pattern was supported by an ANOVA on the proportion of DO responses (arcsine transformed) that revealed a main effect of training $(F(1,46)=16.73, p<.001)$ and an interaction of training and list $(F(1,46)=12.92, p<.01)$. Separate t -tests revealed that the difference between the two verbs was significant in the PO-training condition $(t(47)=$ 2.35, $p<.05$ ) but not in the DO-training condition $(t(47)<$ 1 ), consistent with the surprisal predictions.

## General Discussion

In three experiments, we found that children and adults produced more double-object (DO) sentences for verbs trained in the DO structure than for verbs trained in the PO structure. This difference between training conditions replicates previous reports that the biases of familiar verbs can be altered by new verb-structure patterns in the input (Coyle \& Kaschak, 2008; Lin \& Fisher, 2016).

We also found the first evidence that the magnitude of the verb-bias training effect depended on the prior likelihood of the training sentences. The key result was that, as predicted, DO-training reduced the difference in DO responses between pre-experimentally DO- and PO-biased verbs. After DOtraining, a familiar PO-biased verb such as pass became almost as likely to be used in the DO structure as a familiar DO-biased verb such as show. In contrast, after PO-training, DO-biased verbs were still used much more often in the DO structure than were PO-biased verbs. This pattern supports the hypothesis that training-sentence surprisal affects verbbias learning. PO-training, which linked verbs with what is arguably the default dative structure, produced little change in the rate of DO responses relative to the verbs' pre-existing biases; DO-training, which linked verbs with a less canonical structure, led to sizable increases in the rate of DO responses, but did so mostly for PO-biased verbs, reducing the difference between the PO- and DO-biased verbs. This pattern was observed with 4 -year-olds (Experiments 1a and 1b) and with adults (Experiment 2).

These findings highlight a strong parallel between verb bias learning and syntactic priming. Prior evidence shows that the magnitude of syntactic priming depends on prime sentence surprisal: The largest priming effects are found when the prime structure is uncommon, or is unexpected given the verb in the prime sentence (Bernoulet \& Hartsuiker, 2010; Jaeger \& Snider, 2013; Peter et al., 2015). Here we saw strikingly similar effects for verb-bias learning. In both syntactic priming and verb-bias learning, children and adults learn more from unexpected sentences. This similarity suggests that syntactic priming, which involves learning about abstract syntactic structure, and verb bias learning, which involves linking verbs to syntax, depend on similar learning mechanisms and representations.

This conjecture fits well with the predictions of Chang, Dell and Bock's (2006) Dual-Path model of syntax learning. The model learns to link syntax and semantics without predefined syntactic representations, in a system that yokes a
syntactic sequencing system to a separate message system representing the meaning of input sentences. A key feature of the model is that the syntactic sequencing system is linked to abstract event-role slots in the message system, but not to the word-meanings bound to those event roles. This "Dual-Path" architecture keeps lexical semantics out of the syntax, ensuring that the model creates abstract syntactic representations. Accordingly, the model creates syntactic representations that support abstract syntactic priming, but the model can also learn about the syntactic biases of particular verbs under some circumstances (Chang, Janciauskas, \& Fitz, 2012). Because the model learns via error-based learning, it learns the most from input sentences that are unexpected given the model's prior experience. This model therefore provides one possible account of our findings-sentence surprisal affects verb bias learning as well as syntactic priming because the same error-based implicit learning mechanism underlies learning about abstract syntax and verb bias.

Our results leave open many questions for future research about the nature of the representations that were modified by verb-bias training. For example, participants could have strengthened the link between each verb and an abstract representation of sentence structure or between a verb and a thematic role ordering (Twomey, Chang, \& Ambridge, 2016). Training could have also highlighted the semantic difference between caused possession and caused motion, changing the prominence of recipient vs. theme. Note, though, that adapting the syntax and meanings of verbs are not mutually exclusive (Gleitman et al., 2005).

The verb bias learning studies reported here shed new light on a fundamental question in language acquisition: How do we coordinate abstract syntactic knowledge with our intricate knowledge of words? Our results suggest error-based implicit learning mechanisms help us track the likelihood of both abstract syntactic structures and the linking of those structures with particular verbs. The same learning mechanisms may underlie learning at both levels, creating both abstract and verb-specific syntactic knowledge throughout development.

# Repeated Interactions Can Lead to More Iconic Signals 

Hannah Little (hannah.little@mpi.nl), Marcus Perlman (marcus.perlman@mpi.nl)<br>Language and Cognition Department, Max Planck Institute for Psycholinguistics, 6500 AH Nijmegen, The Netherlands

#### Abstract

Previous research has shown that repeated interactions can cause iconicity in signals to reduce. However, data from several recent studies has shown the opposite trend: an increase in iconicity as the result of repeated interactions. Here, we discuss whether signals may become less or more iconic as a result of the modality used to produce them. We review several recent experimental results before presenting new data from multi-modal signals, where visual input creates audio feedback. Our results show that the growth in iconicity present in the audio information may come at a cost to iconicity in the visual information. Our results have implications for how we think about and measure iconicity in artificial signalling experiments. Further, we discuss how iconicity in real world speech may stem from auditory, kinetic or visual information, but iconicity in these different modalities may conflict.

Keywords: Iconicity; Modality; Artificial Language Experiment; Communication; Conventionalisation

## Introduction

Roughly 7000 languages are spoken around the world, and dozens more are signed. Over the course of human history, according to one rough estimate, hundreds of thousands of languages may have passed in and out of existence (Pagel, 2000). The number of words that have cycled through human languages, then, is enormous, perhaps in the order of billions. Imagine that we could trace these symbols back to their origins. How did people create the first words and signs?

One hypothesis is that the first words were created using iconicity (Fay, Ellison, \& Garrod, 2014; Imai \& Kita, 2014; Perlman, Dale, \& Lupyan, 2015; Perniss, Thompson, \& Vigliocco, 2010). Iconicity is a quality of a signal that, regardless of modality or medium, exhibits a degree of resemblance between its form and its meaning. For example, a person can communicate the idea of a 'rounded' shape by drawing a picture that resembles it, by molding their hands to reflect the shape, or by vocalising a 'round' word like "bouba". Iconicity can function to jump-start a new communication system because it enables a communicator to create new signals that are, to some extent, understandable to a partner without a shared system of conventional symbols.

The hypothesis that the first words were iconic improvisations is supported by evidence from natural signing systems. Traces of iconic creation are apparent in many of the signs of signed languages, and when signers lack a name for a referent, they tend to create an iconic sign for it (Klima \& Bellugi, 1979). Further, when deaf children are raised without native signers and deaf peers, they create iconic gestures that ground the development of home sign systems that they use with hearing adults (Goldin-Meadow, 2003). Experimental
studies where participants communicate using unfamiliar signalling systems also demonstrate extensive use of iconicity to ground novel signals, for example with drawing (Garrod, Fay, Lee, Oberlander, \& MacLeod, 2007), slide whistles (Verhoef, Roberts, \& Dingemanse, 2015), and non-linguistic vocalisations (Perlman et al., 2015).

In comparison to signed languages, the role of iconicity in the creation of spoken languages is obscure. It is widely assumed that spoken languages have markedly less iconicity than signed languages. Yet, it is unclear why this is the case. One widely argued reason is that the vocal-auditory modality affords little iconicity to represent a rich array of meanings (Armstrong \& Wilcox, 2007). This argument is supported mainly by comparing impressions of the iconicity of gesture and sign with vocalisations and speech, and also by experimental studies finding that gestures were more effective than non-linguistic vocalisations at communicating different meanings (Fay, Arbib, \& Garrod, 2013; Fay, Lister, Ellison, \& Goldin-Meadow, 2014). A second possible reason that spoken languages have so little iconicity is their extremely ancient origins. Over so many generations, the original iconicity of spoken languages has mostly degraded. This alternative assumes a process of conventionalisation in which the high level of iconicity characteristic of novel signals decays uni-directionally over time until it eventually disappears.

## Iconicity and conventionalisation

Is it actually the case that the iconicity of novel signals necessarily decays over time as the signal becomes conventionalised? In signed languages, the iconicity of signs does appear to fade over time as the forms become more regularised and systematic (Frishberg, 1975). Although mature signed languages are still iconic to a large extent, they are nevertheless much younger than spoken languages, and we do not know what might happen to their iconicity with further development. Graphic systems may provide a clearer case of how iconicity diminishes over time. For example, early records of written Sumerian, early Egyptian and ancient Chinese show that they originated from more detailed, iconic depictions that have became conventionalised into an increasingly abstract code (Gelb, 1952; Sampson, 1985; Vaccari \& Vaccari, 1964). A smaller-scale, but comparable, process for graphic systems has been demonstrated in the laboratory where drawings lose their iconicity and become more symbolic and arbitrary over repeated interactions (Caldwell \& Smith, 2012; Garrod et al., 2007; Theisen, Oberlander, \& Kirby, 2010).

However, recent experimental studies have found that sig-
nals may sometimes gain iconicity over repeated interactions, even as they otherwise show evidence of conventionalisation. In Perlman et al. (2015), pairs of participants took turns over ten rounds creating non-linguistic vocalisations for different meanings (e.g. big, rough, up). Accuracy within the game increased to ceiling, and vocalisations showed signs of conventionalisation, becoming shorter in duration and more stable in form. To measure how iconicity changed over this process, they tested the ability of naïve listeners to guess the meaning of vocalisations from rounds 1,5 , and 10 . Vocalisations from round 1 were guessed with the lowest accuracy, suggesting they were the least iconic, but in later rounds, vocalisations were guessed with higher accuracy. Verhoef, Kirby, and de Boer (2014) also found that signals increased in iconicity over repeated interactions and iterations. Participants used digital slide whistles to communicate different left or right facing animals. The results showed that participants only encoded the direction of these animals after 2 or 3 generations in an iterated chain.

On the surface, these findings may seem at odds with the idea that the function of iconicity is to bootstrap the formation of a conventional signal. How can signals become initially more iconic and then maintain their iconicity over time, even as they became more conventionalised? One explanation for this result is that the creation of iconic signals in vocalisation is more challenging than in modalities like drawing or gesture. Thus, partners may initially need to explore the signal space and negotiate their shared intuition for a meaningful vocalisation. Over interactions, as signals become streamlined, the strongly iconic features that are found to be effective in distinguishing its meaning tend to be enhanced, while more idiosyncratic features are shed.

## Experiments

## Stimuli

Stimuli for the experiments presented in this paper come from a previous experiment (Little, Eryılmaz, \& de Boer, in press). In this experiment, participants produced signals for meanings varying in shape, colour, and texture, which were designed to have no shared features (explained in Little et al., in press). Figure 1 shows the 15 meanings used in the experiment. Theremin-like signals were created using a "Leap Motion" controller: an infrared sensor that detects hand position (see Eryılmaz \& Little, 2016 for details of the paradigm). Participant's hand position determined the pitch of audio signals. Left to right hand-positions created low to high pitches respectively with a non-linear, exponential relationship between hand-position and pitch. Participants were given this audio feedback in real-time as they produced the signals and participants could not see each other as they produced signals. These signals were used because they share some qualities with speech: they are auditory, continuous and restrict the use of iconicity. At the same time, they are non-linguistic and so minimise possible interference from pre-existing linguistic knowledge and conventions.

Figure 1: The meanings used in the experiment.

The stimuli were created in two experimental conditions: an 'individual' condition, where one person produced signals and received their own signals in batches of 5, and a 'communication' condition where two participants took it in turns to produce and receive signals. When receiving signals, participants were asked to identify their referent from an array of 4 meanings. Feedback was given on the correct answer immediately after each response in both conditions.

The meaning space expanded throughout the experiment: by 5 meanings at a time in every block in the individual condition, and by 2 meanings at a time in the communication condition. In the communication condition, the meaning space only expanded once the participants had agreed on signals for existing meanings (by communicating them correctly twice).

For the experiments in this paper, signals from "early" in the individual condition were taken from the first phase (5 signals) and "late" signals were taken from the last phase (15 signals). In the communication condition, no pair managed to finish the experiment before time ran out, and so all of the data from the "last phase" in the current paper is referring to the last phase participants got to in their particular experiment. "Early" signals from the communication condition were for the first 2 meanings seen.

## Experiment 1: Audio playback experiment

We conducted a playback experiment to examine how the iconicity of signals changed over repeated interactions in the experiment above. Naïve listeners, without knowledge of a signal's development, guessed the meanings of the signals produced in the individual and communication conditions at both the beginning and end of the game. We took listeners' ability to match the signal with its intended referents as a measure of iconicity. This method for measuring iconicity has been used previously in a number of studies (e.g. Garrod et al., 2007; Perlman et al., 2015). The experiment tested two hypotheses, though it should be noted that both hypotheses could work in tandem, or represent different stages of emergence of a communication system.

Hypothesis 1 The first hypothesis is that in the communication condition, repeated interaction between two participants
will lead to initial signals that are high in iconicity, but then become less iconic over interactions. This would follow the results of experiments such as Garrod et al. (2007), that used drawings. Their results also suggest that we should not see a loss of iconicity in the individual condition as conventionalisation requires interaction between communicators.

Hypothesis 2 The second hypothesis is that iconicity will go up in the communication condition, in line with the findings of Perlman et al. (2015). If iconicity is not present from the beginning, or is very idiosyncratic, then interaction may act as a way for signals to adapt to be more transparently iconic. However, without an interlocutor, one would not expect there to be a pressure for transparency in any iconicity present, meaning signals in the individual condition should also not increase in iconicity under this hypothesis.

## Method

Procedure 391 participants were recruited on social media. Each participant was sent to a webpage which redirected randomly to one of several signal sets on its own webpage. A signal set was typically 15 signals. Signals were mp3 files which were playable by the participants by clicking on them. Under each mp3 file was a set of 4 images of possible meanings including the correct referent and 3 others chosen at random. Participants were asked to click on the meaning of the four that "you think the sound refers to". They could change their mind as many times as they liked, and their responses were only recorded after they pressed "submit" at the bottom of the page.

## Results and Discussion

The following results are all produced using a linear mixed effects analysis, from accuracy data that had been binnned by meaning. We included time phase (early or late) and condition (individual or communication) of production as fixed effects. The intended image was controlled for as a random effect with by-meaning random slopes for the effect of time phase and condition. Likelihood ratio tests were used to compare the model against a null model that did not include the variable of interest. The condition in which the signals were produced - individual or communication - did not appear to affect the iconicity of the signals $\left(\chi^{2}(1)=0.1, p=0.74\right)$. Listeners correctly matched signals with their referents with nearly the same level of accuracy in both conditions (around $35 \%$ ). The time phase in which the signal was produced also did not significantly affect guessing accuracy $\left(\chi^{2}(1)=2.3\right.$, $p=0.13$ ). However, there was a significant interaction between condition and time produced $\left(\chi^{2}(1)=5.9, p=0.015\right)$. In the graph (Figure 2), we show that naïve listeners were much better at matching signals that were produced later in the communication condition. In the individual condition, the signals went down slightly in their iconicity, though this difference was not significant.

The results from the audio playback experiment suggest that the iconicity of signals created at the start of the original

Figure 2: The percentage of signals correctly matched with their meanings by naïve listeners. The percentage for behaviour at chance levels is $25 \%$.
communication game is nearly the same in both the individual and communication conditions. Naïve listeners were able to guess their meanings with nearly equal accuracy. This is not indicative of participants not attempting to be iconic (indeed, accuracy was above chance), but it may be that their attempts to be iconic start as being relatively idiosyncratic. In further support of this account, in the individual condition, the iconicity of signals did not change from the early to the late phase of the communication game. It may be that with an individual participant, there is no selection pressure to enhance the strongly iconic features of signals or to discard more idiosyncratic ones.

In contrast to the individual condition, we found that in the communication condition iconicity increased significantly from the early to the late phase, confirming hypothesis 2. In media that afford less iconicity, the presence of another person might cause ongoing pressure to enhance the iconicity of signals, making them increasingly transparent to naïve listeners. However, because of the multi-modal nature of the signals in the initial experiment (i.e. gesture generating audio signals), it is also a possibility that participants were just becoming accustomed to being iconic using the audio feedback (the only thing transmitted between participants), rather than using iconicity in the visual modality.

In the original study, Little et al. (in press) found that signals in the individual condition became longer and more complex over the course of the experiment. However, there was no evidence of signals changing in complexity in the communication condition. Within the experiment, participants were better at correctly matching signals with their correct referent in the individual condition ( $85.6 \%$ correct) than in the communication condition ( $74.4 \%$ correct). In the individual condition, participants improved at recognising the signals correctly throughout the experiment, but they got worse in the communication condition.

## Experiment 2: Visual playback experiment

In this experiment, we look for evidence that participants were distinctly adapting the iconicity of their signals to be optimal for the communication modality. Many people's first instinct is to draw the shapes in the air, but this did not necessarily translate to an optimally iconic signal with respect to the auditory feedback that was generated. This auditory representation was the only information transmitted between participants as they could not see each other. Therefore, participants might have adapted their signals to be more iconic by sound, while at the same time discarding distracting features that turned out to be less iconic.

To examine more specifically how participants in the communication condition adapted their signals over the course of the experiment, we ran a second playback experiment where participants matched visual representations of the signals, instead of auditory ones. If signallers adapted their signals to enhance iconicity for the communication medium, but shed features that are less iconic, then naive guessing accuracy with the visual signals should not increase as it did for the auditory signals. Alternatively - as the visual signals include exactly that same information as the auditory signals, just mapped onto a spatial dimension - visual iconicity might increase along with auditory iconicity.

## Method

Stimuli The stimuli were the same signals used in the audio playback experiment for the communication condition but transformed into visual representations. Signals were small (200x200px) videos of the hand trajectory used to produce the audio signals. A black square moves left and right in real time with how participants' hands moved to produce the signals. These videos were produced using only information from the x -axis of the hand trajectory. We only used information from the x -axis because only the x -axis affected the pitch of signals. This gave the naïve participants in the visual playback experiment the same amount of information as in the audio experiment, making them more directly comparable.
Procedure 97 participants were recruited on social media. Again, each participant was linked to a webpage that redirected them to a webpage with one of several possible signal sets. The procedure was the same as in Experiment 1, except that the stimuli were presented as videos instead of as audio files. Participants were asked to watch 15 videos each and choose the meaning that "you think the video refers to" for each signal.

## Results and Discussion

We compared the results of the visual playback with the results from audio playback in Experiment 1. Again, these results are produced using a linear mixed effects analysis using data binned by meaning. For this experiment, time produced (early or late) and modality (audio or visual) were the fixed effects in the model. Meaning was controlled for as a random effect and the model had by-meaning random slopes for the
effect of time phase and modality. Likelihood ratio tests were used to compare the model against a null model that did not include the variable of interest.

Guessing accuracy in both modalities is shown in figure 3. The modality of the signals - visual or auditory - did not affect the overall accuracy of selecting the correct image $\left(\chi^{2}(1)=1.17, p=0.28\right)$. The time phase in which the signal was produced also did not significantly affect guessing accuracy across modalities $\left(\chi^{2}(1)=1.4, p=0.24\right)$. However, there was a significant interaction between modality and time phase ( $\chi^{2}(1)=5.9, p=0.015$ ). In the early phase, guessing accuracy was statistically equivalent in both modalities. However, in the later phase, while accuracy increased in the auditory condition, in the visual condition it dipped slightly (but not significantly).

Figure 3: The percentage of both visual and audio signals from the communication game matched with their meanings by naïve participants. The percentage for behaviour at chance levels is $25 \%$.

The results from the visual playback experiment demonstrate that signals produced at the beginning of the communication game exhibited a comparable level of iconicity in the auditory representations and the visual representations of the signals. However, as the iconicity appears to have increased in the auditory signals over the phases of the game, the iconicity of the visual transformations did not. This was the case even though the visual signals included the same information as the auditory signals. These results suggest that signallers in the communication game adapted their signals to be more iconic in ways that were particularly suited to the auditory communication channel. Features that may have been more iconic in a visual medium were not enhanced.

## General Discussion

In the first playback experiment, we found that naïve listeners were more accurate at guessing the meanings of signals produced in the later phases of the experiment, but only in the communication condition. The pressure to became more iconic was only present when signals were being negotiated in interaction between individuals. One possible confound
here was that the meaning space expanding more quickly in the individual condition. Given that the signal space has only a limited amount of information to iconically encode meanings without ambiguity, it may be the the expansion meant a loss of iconic information across the whole meaning space. However, this consideration does not account for the fact that the meaning space also expanded in the communication condition where iconicity rose.

In a second playback experiment, we found that iconicity appeared to be enhanced particularly for the auditory communication medium, for which participants may have had weaker intuitions for iconicity compared to a visual medium. Together our findings demonstrate how, under certain conditions, the iconicity of signals can increase over repeated interactions, perhaps especially in a modality that affords less potential for iconicity. This may happen as partners initially explore the signal space and negotiate their shared intuition for a meaningful signal. Over interactions, as signals becomes streamlined with conventionalisation, the strongly iconic features may be agreed upon and enhanced, while more idiosyncratic features are back-grounded. This may only be an initial step in grounding a communication system, in running the experiment for longer, the signals may very well tend towards losing their iconicity again.

The results of this study have implications for semiotics experiments using artificial communication modalities and how iconicity is understood and measured in these studies. Many studies now use continuous auditory feedback as a result of some kinetic input, such as slide whistles (Verhoef, Kirby, \& Boer, 2015), digital slide whistles (Verhoef, Roberts, \& Dingemanse, 2015) and the Leap Motion paradigm (Eryilmaz \& Little, 2016). Iconicity has been measured in signals generated from all of these paradigms, but not always in the same way. In Verhoef, Roberts, and Dingemanse (2015), the iconicity is measured by correlating the direction of stimuli (left or right facing animals) with the direction of pitch in a signal. Little, Eryılmaz, and de Boer (2015) measures iconicity by comparing the similarities between meanings with the similarities between signals, using information from the hand positions, rather than transformed values representing the auditory feedback. Verhoef, Kirby, and Boer (2015) asked naïve participants to rate how well signals "fit" the meanings they were paired with using auditory information alone. Importantly, none of these studies incorporate information from both the auditory and visual aspects of the signal in their measures for iconicity. Of course, there is a perfect correlation between movement and auditory feedback in all of these paradigms, but the results we present here suggest that iconicity may be perceived in very different ways depending on either the visual or auditory information. Some experiments using artificial continuous signal spaces do not have auditory feedback and are purely visual in nature (Galantucci, 2005; Verhoef, Walker, \& Marghetis, 2016). These visual signals are treated as a proxy for a human communication systems in the same way that the paradigms with auditory feed-
back above are. However, it may be important to examine whether the results from such paradigms may, in some cases, be modality-specific.

Of course, caution is required in considering how our findings might generalise to languages and other natural communication systems. There are several reasons for reservation: the linguistic knowledge of our participants, the constrained signal and semantic space, the limited nature of the interaction, and the short time-scale of the experiment. Nevertheless, one interesting point of comparison may be the multimodality of our signals. In real-world communication, multimodality comes not only in the combination of speech and gesture, but also in the auditory and visual information that is conveyed by speech alone (Massaro, 1998; McGurk \& MacDonald, 1976). This multi-modal nature of speech may impact how iconicity is encoded in speech. For instance, one common example of iconicity in spoken language is the /i/ phone for diminutive, as in words like teeny, itty-bitty (Ohala, 1994). This association has been found reliably across languages (Blasi, Wichmann, Hammarström, Stadler, \& Christiansen, 2016). But what features of the /i/ make it iconic? Is it that the high pitch of the second and third formants corresponds with the high-pitched vocalisations of small animals? Is it the kinesthetic feel of articulating the sound, which is produced by contracting the oral cavity? Or might it be the visual features of the vowel, such as the speaker's retracted lips which resemble a submissive facial expression? These are difficult questions to answer, but future experiments might examine multi-modal signals and how iconicity is differentially informative across different modalities.

## Further Work

The main reason for running the playback experiment with visual signals was the observation that participants were inclined to draw in the air as a starting point for novel signals. However, it is possible that this form of iconicity would only be evident from information from both the $x$ - and $y$ - axes. Though the $y$-axis did not affect the auditory feedback in any way, there was nothing to stop participants moving their hand vertically in the experiment. As a next step, we plan to create videos of participant's movements on both the $x$ - and $y$-axes to see if such representations would exhibit a higher level of iconicity as a starting point, which might then decay.

## Conclusion

In conclusion, we would like to challenge the oft-cited notion that languages consistently lose their iconicity over time. The work presented here and elsewhere (Perlman et al., 2015; Verhoef, Roberts, \& Dingemanse, 2015) demonstrates the dynamic nature of iconicity in the evolution of symbol systems, which may adapt to the communication modality and the context in which it is used. Thus the multitude of morphemes cycling through languages may not always be drifting towards arbitrariness. In some cases, words and signs may become more iconic with time. The lexicons of natural languages, whether spoken or signed, exist in a bal-
ance between iconicity and arbitrariness (Dingemanse, Blasi, Lupyan, Christiansen, \& Monaghan, 2015; Perniss et al., 2010).

## Acknowledgements

Thanks to Gareth Roberts for feedback on the first playback experiment that lead to the implementation of the second. The original experimental work was financed by the ERC starting grant project ABACUS, grant number 283435.

# What's worth the effort: Ten-month-old infants infer the value of goals from the costs of actions 

Shari Liu<br>Harvard University<br>Tomer Ullman<br>Massachusetts Institute of Technology<br>Josh Tenenbaum<br>Massachusetts Institute of Technology<br>Elizabeth Spelke<br>Harvard University

#### Abstract

Infants understand that people act in order to achieve their goals, but how can they tell what goals people find worthwhile? Here, we explore the thesis that human infants solve this problem by building a mental model of action planning, taking into account the costs of acting and the rewards actions bring. Consistent with this thesis, we found that 10 -month-old infants, after viewing an agent approach two objects equally often, inferred that the agent preferred the object whose attainment required a costlier action. Infants' responses generalized across changes in perceptual variables that distinguished one action from another (e.g. path length, angle of incline), suggesting that an abstract cost metric based on force or effort supported their judgments. These findings suggest that infants' knowledge about agents may be expressed as a generative model for action planning, which can then be inverted to identify the probable hidden causes for observed actions.

# Why Does Higher Working Memory Capacity Help You Learn?

#### Abstract

Algorithms for approximate Bayesian inference, such as Monte Carlo methods, provide one source of models of how people may deal with uncertainty in spite of limited cognitive resources. Here, we model learning as a process of sequential sampling, or 'particle filtering', and suggest that an individual's working memory capacity (WMC) may be usefully modelled in terms of the number of samples, or 'particles', that are available for inference. The model qualitatively captures two distinct effects reported recently, namely that individuals with higher WMC are better able to (i) learn novel categories, and (ii) flexibly switch between different categorization strategies.

Keywords: Bayesian inference; particle filter; working memory; category learning; knowledge restructuring

## Introduction

Humans often behave in a manner consistent with Bayesian principles (Chater \& Oaksford, 2008) yet how they achieve this is unclear. Though simple in principle, exact Bayesian calculations are frequently intractable in real-world settings, leading to a need for approximations. In statistics and computer science, this challenge has been met through the development of powerful, general-purpose techniques for approximate Bayesian inference, such as Monte Carlo methods, which allow practical application of Bayesian methods in complex domains. The practical success of these techniques has naturally prompted an interest in whether people deal with uncertainty in an analogous manner (Griffiths, Vul, \& Sanborn, 2012). Importantly, such algorithms can approximate probabilistic inference arbitrarily well when sufficient time and memory are available, thereby providing a benchmark for ideal performance, but also display systematic deviations from the normative solution when resources are limited. These latter 'qualitative fingerprints' may be particularly illuminating when considering human cognition, where constraints on information-processing capacity are typically assumed. A salient example is provided by limits on working memory capacity (WMC; Cowan, 2001). While the exact nature of these limits remain the subject of debate, one prominent conception is that they reflect a limited resource which is
shared across representations and processes in working memory (e.g., Just \& Carpenter, 1992).

In the current work, we consider WMC limits within the context of Bayesian inference, asking whether WMC may be usefully modelled as a constraint on inferential resources. In particular, we model the learning process as one of particle filtering, in which a series of probability distributions is represented by a limited set of samples ('particles') which are sequentially updated over time (Griffiths et al., 2012). Higher WMC is then assumed to be implemented as a greater number of particles. This approach is applied to two recent experiments which indicate positive effects of higher WMC on two distinct aspects of categorization: (i) the facility with which novel categories are learned (Lewandowsky, 2011); and (ii) the ability to flexibly switch between different category representations or response strategies, referred to as knowledge restructuring (Sewell \& Lewandowsky, 2012). We show that both of these effects are qualitatively captured by a single model in which WMC is equated with the number of particles available for inference - i.e., the number of hypotheses about category structure that an individual can concurrently entertain.

## WMC and Category Learning

Lewandowsky (2011) measured participants’ WMC before testing category learning performance on the six classical problem types of Shepard, Hovland, and Jenkins (1961) (henceforth 'SHJ'). Each involves learning to assign a set of stimuli to category $A$ or $B$ based on their values on binary dimensions, but the problem types vary in the number of stimulus dimensions required to correctly perform classification. Consistent with the classical results, participants generally learned the Type I problem fastest, Type VI the slowest, and Types II-V at an intermediate rate. Crucially, WMC score was found to be positively correlated with category learning performance: higher WMC individuals tended to make fewer errors across all problem types.

## WMC and Knowledge Restructuring

Sewell and Lewandowsky (2012) assessed the relationship between WMC and performance in a knowledge restructuring (KR) task. Participants were guided to use one particular categorization strategy in a binary classification task before being instructed to switch to an alternative, equally-effective strategy (Fig 1A). The stimuli, rectangles of varying height with a vertical bar located at different locations along their base, belonged to category $A$ or $B$ depending on their position in category space (Fig 1B). Crucially, training stimuli (filled circles) were clustered into two separate regions of category space (as indicated by different colours), with categories arranged so that partial category boundaries (solid lines) could not be integrated in a coherent manner; neither partial boundary could be extended so as to allow accurate classification of all stimuli in the other cluster. A third, binary 'context' dimension was systematically mapped onto the two training clusters so that stimuli belonging to distinct clusters appeared in different colours (see example stimuli, lower Fig 1B).

At the task outset, participants were given information designed to guide them towards using one of two different strategies for co-ordinating partial categorization rules: (1) a knowledge partitioning (KP) strategy was encouraged by imparting that the context variable (colour) could be used to determine which dimension to use (rectangle height or bar position) for categorization; (2) a context-insensitive (CI) strategy was instead encouraged by highlighting that bar position could be used to determine which partial boundary to apply (i.e., regardless of context). Both strategies could support perfect performance but predicted different patterns of generalization when applied to new stimuli (open squares, Fig 1B) in a transfer test, thereby revealing which strategy was in use (Fig 1C). A summary 'context sensitivity' (CS) measure was applied to participants' test patterns to quantify the degree to which they generalized in a manner consistent with the KP (high CS) or CI (low CS) strategy (Fig 1D).

Critically, Sewell and Lewandowsky found evidence that individuals with higher WMC were more adept at switching between these different categorization strategies when instructed to do so, as measured by how much their CS scores changed between tests. This was interpreted in terms of greater 'knowledge restructuring', i.e., ability to coordinate different category representations or response requirements.

## Modelling Approach

Our model comprises three parts: 1) assumptions about how participants represent categories, specified in terms of an explicit generative process; 2 ) a procedure by which participants are assumed to infer categories in light of prior assumptions and experimental stimuli; and 3) a means for translating participants' beliefs into choice (i.e., a predicted category label). Our description focuses on how the modelling approach is applied to the KR task; the SHJ tasks are simpler and easily modelled with only minor modifications.

Figure 1: (A) Knowledge restructuring (KR) task design. (B) Experimental stimuli, depicted in category space: position of a vertically-oriented bar ( $x$-axis) vs. height of rectangle ( $y$ axis). Filled circles denote training stimuli; open squares denote test stimuli; solid lines indicate the partial rule boundaries. Two example stimuli are shown underneath. (C) 'Ideal' predicted response profiles given exclusive use of a contextinsensitive (CI; top row) or knowledge-partitioning (KP; bottom row) strategy during test. Darker shading indicates a higher probability of classifying as category $A$. (D) Average context-sensitivity (CS) scores across participants during transfer tests, indicating use of CI (low) or KP (high) strategy. Figures B-D adapted from Sewell and Lewandowsky (2012).

## Category Representation

A number of representational formats for categories have been discussed in the literature. Here, we opted to use classification and regression tree (CART) models (Breiman, Friedman, Olshen, \& Stone, 1984). Firstly, these are well-suited to cases in which categories are readily described in terms of simple rules, particularly if an ordering on these rules is suggested (as in the KR task). Secondly, the classification boundaries generated by CART models lead naturally to 'axis-aligned' generalization patterns like those observed in the KR task (participants' response profiles were very similar to those shown in Fig 1C), whereas producing this behaviour is non-trivial for other category models.

Briefly, CART models provide a flexible method for specifying the conditional distribution of a binary category label $y$ given a $p$-dimensional stimulus feature vector $\mathbf{x}=$ $\left(x_{1}, x_{2}, \ldots, x_{p}\right)$. In the KR task, for a given stimulus on trial $t$, we have $y_{t} \in\{A, B\}$ and a 3-dimensional input $\mathbf{x}_{t}=$ $\left(x_{t, 1}=\right.$ bar position ${ }_{t} \in \mathbb{R}, x_{t, 2}=$ height $_{t} \in \mathbb{R}, x_{t, 3}=$ context $_{t} \in$ $\{0,1\})$. The models work by recursively partitioning the input space into axis-aligned cuboids (similar to the partial boundaries in Fig 1B) and applying a simple conditional model to each region (e.g., probability that category label $=$
A). The sequence of partitions can be represented as a binary tree (Fig 2).

Formally, a binary tree structure T consists of a hierarchy of nodes $\eta \in T$. Nodes with children are internal nodes, while nodes without children are leaf nodes (Fig 2A). Each node is associated with a block $B(\eta) \subseteq \mathbb{R}^{p}$ of the input space as follows: the root node is associated with the entire input space, while each further internal node splits its block into two halves by selecting a single dimension $\kappa(\eta)=\{1, \ldots, p\}$ and location $\tau(\eta)$ on which to split (Fig 2B). The block of input space associated with a node $\eta$ is determined by the ranges on each dimension $j$ which it covers, and we denote the corresponding range $R_{j}^{\eta}=\left[R_{j}^{\eta,-}, R_{j}^{\eta,+}\right]$. We call the tuple $\mathcal{T}=(\mathrm{T}, \kappa, \tau)$ the decision tree.

Figure 2: (A) Simple binary tree with (internal) root node $\eta$ which splits into two 'leaf' nodes, $\eta_{L}$ and $\eta_{R}$. (B) Corresponding split of a two-dimensional input space. The root node $\eta$ is associated with the full input space, $B(\eta)$. Here, node $\eta$ is split on dimension $1, \kappa(\eta)=1$, at a location $\tau(\eta)$. This splits the input space into two blocks, $B\left(\eta_{L}\right)$ and $B\left(\eta_{R}\right)$, associated with the leaf nodes $\eta_{L}$ and $\eta_{R}$.

In addition to a decision tree $\mathcal{T}$ with $K$ leaf nodes, a parameter $\Theta=\left(\theta_{1}, \theta_{2}, \ldots, \theta_{K}\right)$ associates parameter value $\theta_{k}$ with the $k$ th leaf node. If a stimulus $\mathbf{x}$ lies in the region of the $k$ th leaf node, then $y \mid \mathbf{x}$ has distribution $f\left(y \mid \theta_{k}\right)$ for some parametric family $f$. It is typically assumed that, conditional on $(\Theta, \mathcal{T}), y$ values within a leaf node are i.i.d. and that $y$ values across leaf nodes are independent. Thus, letting $n_{k}$ denote the number of observations assigned to the $k$ th leaf node and letting $y_{k, i}$ denote the $i$ th observation of $y$ assigned to leaf $k$,

$$
\begin{equation*}
p\left(y_{1: n} \mid \mathbf{x}_{1: n}, \boldsymbol{\Theta}, \mathcal{T}\right)=\prod_{k=1}^{K} \prod_{i=1}^{n_{k}} f\left(y_{k, i} \mid \theta_{k}\right) \tag{1}
\end{equation*}
$$

where $n=\sum_{k=1}^{K} n_{k}$ is the total number of observations.
Prior beliefs about category structure can be formalized as a prior distribution on decision trees, specified via a stochastic generative process. Following Chipman, George, and McCulloch (1998), we set the prior probability of a node $\eta$ in tree structure T being split into children nodes to

$$
\begin{equation*}
p_{\mathrm{SPLIT}}(\eta, \mathrm{~T})=\frac{\alpha}{\left(1+d_{\eta}\right)^{\beta}} \tag{2}
\end{equation*}
$$

where $d_{\eta}$ denotes the depth of the node, and $\alpha<1$ and $\beta \geq$ 0 are parameters controlling expected tree size. Under this specification, the probability $p_{\text {SPLIT }}$ is a decreasing function of node depth, and decreases more steeply for large $\beta$.

In addition to this prior on tree structure T , we generally
assume that the probability of splitting on each dimension is equal,

$$
\begin{equation*}
p(\kappa(\eta)=j)=1 / p, \quad j=1, \ldots, p \tag{3}
\end{equation*}
$$

and that split location is then drawn uniformly from the node's range,

$$
\begin{equation*}
\tau(\eta) \mid \kappa(\eta)=j \sim \mathcal{U}\left(R_{j}^{\eta,-}, R_{j}^{\eta,+}\right) \tag{4}
\end{equation*}
$$

However, in the KR task, participants were guided towards a particular strategy by being told in the first instance that stimulus colour (KP-first condition) or bar position (CI-first condition) reliably indicated whether height or bar position was diagnostic of stimulus category. To incorporate this additional information, we assume a bias term $b \leq 1$ which assigns higher probability to splitting the root node $\eta_{0}$ on the dimension $j^{*}$ highlighted by instruction:

$$
p\left(\kappa\left(\eta_{0}\right)\right)= \begin{cases}b & \text { if } \kappa\left(\eta_{0}\right)=j^{*}  \tag{5}\\ \frac{1-b}{2} & \text { otherwise }\end{cases}
$$

The generative model is completed by the conditional probabilities of stimulus labels given the tree structure, $p\left(y_{1: t} \mid \mathbf{x}_{1: t}, \mathcal{T}\right)$. We assume that the $k$ th leaf node has an associated probability $\theta_{k}$ of generating label $A$,

$$
\begin{equation*}
p\left(y_{t} \mid \theta_{k}, \mathbf{x}_{t}\right)=\theta_{k}^{y_{t}}\left(1-\theta_{k}\right)^{1-y_{t}} \tag{6}
\end{equation*}
$$

and that this probability is an i.i.d. draw from a Beta distribution, $\theta_{k} \stackrel{\text { iid }}{\sim} \operatorname{Beta}\left(a_{0}, b_{0}\right)$. Standard analytical simplification then yields the marginal likelihood
$p\left(y_{1: t} \mid \mathcal{T}, \mathbf{x}_{1: t}\right)=\left(\frac{\Gamma\left(a_{0}+b_{0}\right)}{\Gamma\left(a_{0}\right) \Gamma\left(b_{0}\right)}\right)^{K} \prod_{k=1}^{K} \frac{\Gamma\left(n_{k A}^{t}+a_{0}\right) \Gamma\left(n_{k}^{t}-n_{k A}^{t}+b_{0}\right)}{\Gamma\left(n_{k}^{t}+a_{0}+b_{0}\right)}$,
where $n_{k A}^{t}$ and $n_{k}^{t}$. are respectively the number of instances of category $A$ and the total number of data points in the partition of leaf $k$ up to trial $t$. Note that for a given tree, this likelihood is higher for leaves assigned observations with homogenous labels, and these are exactly the partitions that constitute 'good' solutions to the categorization problem.

## Inference

Participants are assumed to approximate the sequence of posterior distributions $\left\{p\left(\mathcal{T} \mid \mathbf{x}_{1: t}, y_{1: t}\right)\right\}_{t=1}^{T}$ over trials. Given the implausibility of enumerating all possible trees, participants are assumed to represent a relatively small number of samples, i.e. hypotheses, from these posterior distributions which can be updated over time. In other words, we assume participants perform particle filtering.

Two aspects of the inference process which we now describe draw parallels with working memory. Firstly, similar to the idea of a limit on the number of items that can be held in working memory (Cowan, 2001), we assume there is a bounded number of hypotheses about category structure in this case, the particles which correspond to specific tree structures - that can be entertained at a given time. Secondly, similar to the notion that working memory is active (Baddeley, 1992), involving manipulation rather than merely
passive storage of items, we assume that inference involves a continual process whereby local transformations to current hypotheses are proposed, and which may be accepted or rejected. The latter process promotes diversity in the hypothesis set and continuous exploration of the hypothesis space.

In detail, we assume that on trial $t$, a participant's beliefs are represented by a small set of $L$ possible trees $\left\{\mathcal{T}^{(l)}\right\}_{l=1}^{L}$ with associated importance weights $\left\{w_{t}^{(l)}\right\}_{l=1}^{L}$. This set of trees constitutes the limited set of hypotheses putatively maintained in a working memory of capacity $L$. With the observation of the stimulus and category label on the next trial $t+1$, a proper reweighting of the $l$ th tree is given by the following update (Chopin, 2002):

$$
\begin{equation*}
w_{t+1}^{(l)} \propto w_{t}^{(l)} p\left(y_{t+1} \mid \mathcal{T}^{(l)}, \mathbf{x}_{t+1}, y_{1: t}\right) \tag{8}
\end{equation*}
$$

As standard within particle filtering methods, this reweighting process is alternated with a resampling stage in which very unlikely trees, i.e., those with very low weights, are discarded and replaced by replicates of more probable trees. A simple way of doing this is to sample $L$ times with replacement from the set $\left\{T^{(l)}\right\}$ with probabilities proportional to the updated weights $\left\{w_{t+1}^{(l)}\right\}_{l=1}^{L}$ (Gordon, Salmond, \& Smith, 1993). Following this resampling step, all particle weights are equalized to $1 / L$.

Additionally, this resampled particle set can then be rejuvinated (Chopin, 2002), reintroducing diversity and allowing continuous exploration of alternative solutions. This is the 'active' step which, we suggest, recalls conceptions of working memory as involving active manipulation of currentlystored items. Specifically, we may, without altering the targeted posterior distribution, propose transformations of trees from a Markov chain transition kernel $q_{t+1}\left(\cdot \mid \mathcal{T}^{(l)}\right)$ with appropriate stationary distribution $p\left(\mathcal{T} \mid \mathbf{x}_{1: t+1}, y_{1: t+1}\right)$. Closely following the transition kernel suggested by Chipman et al. (1998), we consider the scheme where for each tree $\left\{\mathcal{T}^{(l)}\right\}$, a new tree $\mathcal{T}^{(l) *}$ is proposed by randomly choosing among 3 possible transformations: (1) grow: randomly select a leaf node, then draw a splitting dimension and location from the prior; (2) prune: randomly select an internal node, then turn it into a leaf node by deleting all nodes below it; or (3) change: randomly select an internal node, then reassign it a splitting dimension and location by a draw from the prior. The proposed tree $\mathcal{T}^{(l) *}$ is then accepted with probability
$\alpha\left(\mathcal{T}^{(l)}, \mathcal{T}^{(l) *}\right)=\min \left\{\frac{p\left(\mathcal{T}^{(l) *} \mid \mathbf{x}_{1: t+1}, y_{1: t+1}\right) / q_{t+1}\left(\mathcal{T}^{(l) *} \mid \mathcal{T}^{(l)}\right)}{p\left(\mathcal{T}^{(l)} \mid \mathbf{x}_{1: t+1}, y_{1: t+1}\right) / q_{t+1}\left(\mathcal{T}^{(l)} \mid \mathcal{T}^{(l) *}\right)}\right\}$,
as per the standard Metropolis-Hastings algorithm.
We also need to model the effect of an instruction to switch categorization strategy. We assume that the effect is to change the prior distribution over trees, which is then combined with past observations to produce an updated posterior distribution. This update can be implemented via a simple reweighting operation on the set of trees.

To see how this works, consider the specific example where a participant has initially been guided to use the CI strategy
and after $t$ training sessions has in mind the set of weighted trees $\left\{\mathcal{T}^{(l)}, w_{t}^{(l)}\right\}_{l=1}^{L}$ approximating the target distribution under the prior appropriate to the CI strategy. We denote this target distribution $p_{C I}\left(\mathcal{T} \mid \mathbf{x}_{1: t}, y_{1: t}\right)$. The experimenter then instructs the participant to change to using the KP strategy. Assuming that the set of trees remains fixed, the associated tree weights now need to be changed to reflect the new target distribution $p_{K P}\left(\mathcal{T} \mid \mathbf{x}_{1: t}, y_{1: t}\right)$. This can be achieved by an importance weighting step, treating $p_{C I}\left(\mathcal{T} \mid \mathbf{x}_{1: t}, y_{1: t}\right)$ as the importance distribution. In particular, denoting a particle's weight before and after the instruction to switch as $w_{t}^{(l)-}$ and $w_{t}^{(l)+}$, respectively, the relevant reweighting is

$$
\begin{equation*}
w_{t}^{(l)+} \propto w_{t}^{(l)-} \frac{p_{K P}\left(\mathcal{T}^{(l)} \mid \mathbf{x}_{1: t}, y_{1: t}\right)}{p_{C I}\left(\mathcal{T}^{(l)} \mid \mathbf{x}_{1: t}, y_{1: t}\right)} \tag{9}
\end{equation*}
$$

To switch in the reverse direction - from the KP to CI strategy - the appropriate reweighting instead uses the ratio $p_{C I}\left(\mathcal{T}^{(l)} \mid \mathbf{x}_{1: t}, y_{1: t}\right) / p_{K P}\left(\mathcal{T}^{(l)} \mid \mathbf{x}_{1: t}, y_{1: t}\right)$.

## Choice

Participants are assumed to predict category labels based on their current hypotheses. Assuming a newly-resampled particle set with equal weights $1 / L$, a sample-based approximation to the predictive probability that a stimulus $\mathbf{x}_{t+1}$ has label $y_{t+1}=A$ is given by

$$
\begin{align*}
p\left(y_{t+1}=A \mid \mathbf{x}_{1: t+1}, y_{1: t}\right) & \approx \frac{1}{L} \sum_{l=1}^{L} p\left(y_{t+1}=A \mid \mathbf{x}_{1: t+1}, y_{1: t}, \mathcal{T}^{(l)}\right) \\
& =\frac{1}{L} \sum_{l=1}^{L} \mathbb{E}_{\theta_{k} \mid \mathbf{x}_{1: t+1}, y_{1: t}, \mathcal{T}^{(l)}}\left[\theta_{k}\right] \tag{10}
\end{align*}
$$

Thus, an approximation to the predictive probability is given by an unweighted average of posterior means for $\theta_{k}$, where $k$ for the $l$ th particle is the index of the leaf node relevant to the input $\mathbf{x}_{t+1}$ in $\mathcal{T}^{(l)}$. In our case, the posterior mean is

$$
\begin{equation*}
\mathbb{E}_{\theta_{k} \mid \mathbf{x}_{1: t+1}, y_{1: t}, \mathcal{T}^{(l)}}\left[\theta_{k}\right]=\frac{n_{k A}^{t}+a_{0}}{n_{k}^{t}+a_{0}+b_{0}} \tag{11}
\end{equation*}
$$

## Results

## Rate of Learning

Lewandowsky (2011) found that WMC was positively correlated with category learning performance. We hypothesized that a greater number of particles, i.e. increasing $L$, would have a similar effect since, on average, one might expect the search for a 'good' (i.e., more probable) category structure to progress faster, and with less chance of getting stuck in local maxima, with a higher number of particles.

Figure 3 displays average simulated learning curves for the SHJ tasks when the number of particles is increased from 1 (Fig 3A) to 100 (Fig 3B). Though the effect is subtle, there is a general steepening of learning curves and a downward shift in initial error rate for problem Type I. A more systematic gauge of the effect is obtained by fitting exponential functions to such learning curves and comparing the size of the fitted coefficients as the number of particles is increased (a

Figure 3: Increasing the number of particles leads to faster category learning. Simulated learning curves for (A) 1 particle, and (B) 100 particles. Learning curves are averages over 100 simulations with other model parameters fixed ( $a_{0}=b_{0}=$ $1 ; \alpha=0.95, \beta=1$ ). (C) Learning rate as a function of number of particles. For each setting, the model is run 100 times and exponential curves fit to each individual learning curve. The resulting coefficients are averaged over both simulation runs and problem types to yield an aggregate 'learning rate'.
larger coefficient indicates a steeper learning curve). Figure 3C shows that the learning rate does increase with more particles, though the effect is small beyond $\approx 20$ particles.

Note that even without fitting the model parameters, the basic SHJ pattern of results - Type I easiest, Type VI hardest, and Types II-V clustered in between - is reproduced. Briefly, this results from the preference for simpler, or more parsimonious, hypotheses that arises naturally within the Bayesian framework. An advantage for the Type II problem relative to types III-V is not produced by the model here, but we note that any such advantage was extremely marginal in Lewandowsky (2011), and that the effect may arise only under specific conditions (cf. Kurtz, Levering, Stanton, Romero, \& Morris, 2013).

## Knowledge Restructuring

Sewell and Lewandowsky (2012) found a positive association between WMC and knowledge restructuring. In the model, increasing the number of particles also has a beneficial effect on the average degree of knowledge restructuring (Fig 4A), with an increased probability of being able to successfully switch strategy (Fig 4B).

This result arises from an enhanced ability to accurately represent the posterior distribution with a greater number of particles. Recall that strategy-switching was modelled by a change in posterior distribution, driven by the different priors underlying the distinct strategies; a simple way to track this change was by reweighting particles according to the new dis-

Figure 4: (A) In both the context-sensitive (CI)-first (left) and knowledge-partitioning (KP)-first (right) conditions, increasing the number of particles $L$ leads to a greater change in context sensitivity (CS) score on average when prompted to change strategy ( 1500 simulation runs per condition). (B) This is due to an increased probability $P$ (switch) of a successful switch ( $\Delta C S>0.5$ ). Lower inset: with fewer particles ( $L=20$ ), it will frequently occur that the model completely fails to switch $(\Delta C S=0)$. Upper inset: with more particles ( $L=100$ ), such failures are unlikely ( 3000 simulation runs; $b=0.9, a_{0}=b_{0}=1, \alpha=0.95, \beta=1$ ).
tribution (Eq. (9)). However, the success of this will depend on how well the particle set covers the support of the updated distribution. With a sufficiently large number of particles, at least some should be allocated to (previously) lower probability regions; if the new strategy corresponds to such a region, then appropriate reweighting can be applied. However, with a decreasing number of particles, representation of the posterior distribution may be so impoverished that such regions of low probability may not contain any particles at all, and so switching is not immediately possible.

## Discussion

Experiments suggest that higher WMC benefits learning of novel categories (Lewandowsky, 2011) and the ability to coordinate different category representations or response strategies (Sewell \& Lewandowsky, 2012). We framed such tasks in terms of inference, where individuals seek to infer the most probable category structure(s) given their prior assumptions and experimental observations/instructions. Further, we assumed that individuals approximate inference by representing and manipulating in working memory a relatively small number of hypotheses - samples, or 'particles' - about possible category structures. Our principal hypothesis was that by linking WMC with the number of such particles, we would observe similarly positive effects of higher WMC on performance. Simulation results were consistent with this hy-
pothesis: more particles in the model enhanced both category learning performance and the ability to switch between different categorization strategies.

These effects respectively arise due to increased search efficiency and what we might call 'representational adequacy'. Conceptualized in terms of search for more probable categories, the more resources (i.e., particles) available to search this space - i.e., the greater the number of hypotheses that one can entertain and manipulate within working memory - then the more likely it is that one will quickly discover good solutions, a process which draws natural parallels with the broader topic of problem-solving (Hambrick \& Engle, 2003; Newell \& Simon, 1972). Furthermore, a greater number of particles generally means that the posterior distribution over categories is more accurately represented - including those assigned lower probability - and this pluralism means that the model can more easily express alternative hypotheses when instructed to switch strategy, as operationalized by a reweighting of particles. This source of flexibility may also be relevant to so-called 'insight' problem-solving (Murray \& Byrne, 2005; Ohlsson, 1992).

The current work is preceded by a number of related lines of research. The HyGene model (Dougherty, Thomas, \& Lange, 2010; Thomas, Dougherty, Sprenger, \& Harbison, 2008), which emphasizes the importance of hypothesis generation and testing, includes the assumption that the number of hypotheses that can be entertained at a given time is limited by working memory constraints. Similarly, in their study of 'garden path' effects in sentence processing, Levy, Reali, and Griffiths (2008) suggested that difficulties in parsing such sentences correctly may be explained by constraints on the resources (i.e., number of particles) available for incremental parsing; their demonstration that a decreasing number of particles increases the probability of parse failure is exactly analogous to the mechanism suggested here in relation strategyswitching.

There are a number of avenues for future investigation. We have focused on qualitative effects here, but fitting the model to individual participants will be necessary for a more quantitative assessment; the obvious prediction is that highWMC individuals should tend to be fit best by a larger number of particles. Decomposing the relative contributions of particular features of the model, such as resampling, should also be explored, and quality of fit directly compared with 'single-particle' approaches (e.g., Bramley, Dayan, Griffiths, \& Lagnado, 2017). How the approach fares in domains beyond category learning is also of clear interest. More generally, Monte Carlo methods provide a rich source of ideas for psychological models - exploring how such methods may succeed or fail to illuminate aspects of human cognition is a substantial task for future research.

# Social Network Limits Language Complexity 

Matt Lou-Magnuson<br>Nanyang Technological University, Singapore, Singapore<br>\section*{Luca Onnis}<br>Nanyang Technological University, Singapore, Singapore

#### Abstract

Natural languages vary widely in the degree to which they make use of hierarchical composition in their grammars, in particular, the degree to which syntactic versus morphologi- cal means of composition are utilized. Languages historically spoken in small communities develop much deeper levels of morphological embedding than those spoken by larger groups, an observation confirmed by a statistical analysis of the World Atlas of Language Structures. However, beyond population alone, social networks change in topological structure as they grow, and it may be the pattern of connectivity rather than number of speakers driving these differences. To examine mechanistically this connection between social and linguistic structure, we propose an agent-based model of grammatical change using complex network methods. We identify global transitivity as a physical parameter of social networks critical for developing morphological structure, and hubs associated with scale-free networks as inhibitory, encouraging syntactic composition instead.

# Learning induced illusions: Statistical learning creates false memories 

Yu Luo (yuluo@psych.ubc.ca)<br>Department of Psychology<br>University of British Columbia

#### Abstract

The cognitive system readily extracts regularities in terms of object co-occurrences over space and time through statistical learning. However, how does learning such relationships influence the memory representations of individual objects? Here we used a false memory paradigm to examine the impact of statistical learning on memory representations of individual objects. Observers were exposed to a temporal sequence (Experiment 1) or spatial arrays (Experiment 2) of objects which contained object pairs (e.g., A-B). In a subsequent recognition phase, observers viewed a sequence or an array containing only one member of the original pair, and judged whether either the presented object or the missing object in the original pair was present. We found that statistical learning not only sharpened the detection of the presented object, but also induced a false memory of the missing object. This reveals a novel consequence of statistical learning: learning of regularities can create illusory memories.

Keywords: Statistical learning; false memory; implicit learning; regularities;

## Introduction

A remarkable ability of the cognitive system is to detect and learn the relationships among objects in the environment. Statistical learning is one mechanism that extracts the statistical relationships between individual objects in terms of object co-occurrences over space and time (Fiser \& Aslin, 2001; Saffran, Aslin, \& Newport, 1996). This process occurs incidentally, without conscious intent or explicit awareness, produces knowledge about object associations that people are not explicitly aware of (Turk Browne, Jungé, \& Scholl, 2005; Turk-Browne, Scholl, Chun \& Johnson, 2009), and can operate in multiple sensory modalities and feature dimensions (Conway \& Christiansen, 2005; Fiser \& Aslin, 2001; Saffran et al., 1996; Turk-Browne, Isola, Scholl, \& Treat, 2008). In addition, several cognitive consequences of statistical learning have been identified, such as the compressing of information (Brady, Konkle, \& Alvarez, 2009; Zhao \& Yu, 2016), attentional prioritization of cooccurring objects (Yu \& Zhao, 2015; Zhao, Al-Aidroos, \& Turk-Browne, 2013; Zhao \& Luo, 2017), and enhanced memory representation (Kim, Lewis-Peacock, Norman, \& Turk-Browne, 2014; Otsuka \& Saiki, 2016).

One important but unexplored question is: how does learning statistical associations influence the representation of individual objects? Initial evidence comes from studies on
false memories of semantically related objects. One pioneer work by Roediger and McDermott (1995) shows that after memorizing a list of words (e.g., nurse, sick, medicine, etc.) that are highly related to a target word that was never present (e.g., doctor), people falsely remember seeing the target word, and label it as an "old" word of the list in the recognition task. This finding was replicated using a visual paradigm, where participants viewed a stereotypical scene (e.g., classroom), and falsely recalled and recognized a target object that was never present (e.g., chalkboard, Miller \& Gazzaniga, 1998). One explanation for this phenomenon is that seeing one object can automatically activate other associated objects based on semantic memory (Roediger, Balota, \& Watson, 2001).

Here, we provide a new explanation behind this old phenomenon which focuses on a simpler mechanism: learning the co-occurrences of objects can create the false memories of non-present object when only its partner is present. We propose that the mere statistical co-occurrence of two objects can produce false memory, independent of semantic associations. Thus, the goal of the current study was to examine whether statistical learning alters the representations of individual objects.

## Experiment 1

This experiment examined how statistical learning alters the representations of individual objects in a temporal context, by first exposing participants to a sequence of paired objects and then testing them on whether seeing an individual object in the pair can produce the false memory of the non-present object in the pair.

## Participants

A total of 120 undergraduates ( 96 female; mean age $=20.6$ years, $\mathrm{SD}=2.8$ ) from University of British Columbia (UBC) participated in the experiment for course credit. Participants reported normal or corrected-to-normal visual acuity and provided informed consent. The protocol was approved by the UBC Research Ethics Board.

## Stimuli

The stimuli consisted of eight real-world objects (Fig.1a) which were selected from a stimulus set in a previous study
(Brady, Konkle, Alvarez, \& Oliva, 2008). All objects were converted to grayscale, and were adjusted to a mean brightness of 84 . Each object subtended $2.8^{\circ}$ of visual angle. The eights objects were randomly assigned into four pairs for each participant and remained constant throughout the experiment (Fig.1a). In each pair, the first object was always followed by the second object. The random assignment of objects into pairs ensured that there was no systematic semantic relation between two objects in a pair, but rather the two objects were associated with co-occurrences. Each pair was repeated 50 times to form a single continuous temporal sequence of objects in a pseudorandom order with a constraint where no single pair could repeat back-to-back.

## Apparatus

Participants in all experiments were seated 50 cm from a computer monitor (refresh rate $=60 \mathrm{~Hz}$ ). Stimuli were presented using MATLAB and PsychophysicsToolbox (http://psychtoolbox.org).

## Procedure

The experiment consisted of two conditions. In the structured condition, the eight objects were grouped into four pairs. In the random condition, the eight objects appeared in a random order in the sequence. Participants were randomly assigned to one of the two conditions ( $N=60$ in each). The experiment contained three phases: exposure phase, recognition phase, and test phase. During the exposure phase, one object appeared at the center of the screen for 500 ms followed by a 500ms inter-stimulus interval (ISI) in each trial (Fig.1b). Participants performed a 1-back task where they judged as quickly and accurately as possible whether the current object was the same as or different from the previous object (by pressing the "/" or " $z$ " key for same or different, respectively, key assignment counterbalanced). For the 1-back task, each object had a $20 \%$ chance of repeating the previous object, producing 480 trials in total. This 1-back task served as a cover task which was irrelevant to learning the object pairs, in order to conceal the true purpose of the study. This ensured that learning of the object pairs was incidental. Participants were not told anything about the object pairs.

After exposure, participants performed a recognition phase (Fig.1c). In each trial, participants viewed a continuous sequence of objects first and then judged whether a certain object was present in the sequence. In the structured condition, there were three types of trials. The first type was missing trials: the sequence contained all four pairs, except for one pair, one member was missing, and observers judged whether the missing member was present in the sequence. The missing trials measured the false alarm rate for the missing object. The second type was presented trials: the sequence contained all four pairs, except for one pair, one member was missing, but this time observers judged whether the presented member was present in the sequence. The presented trials measured the hit rate for the presented object. The third type was baseline trials: the sequence contained all four pairs, and observers judged whether one member in a
pair was present in the sequence. The baseline trials measured the hit rate for the presented object. In the missing trials, each member of an original pair was missing for once, resulting in 8 trials. In the presented trials, the presented object of an original pair was tested once, resulting in 8 trials. In the baseline trials, each member of a pair was tested once, resulting in 8 trials. The 24 trials were repeated twice, producing 48 trials in total (order of the trials was randomized). In the random condition, the trials were the same, except the objects in the sequence appeared in a random order, so the sequence contained no pairs. Each object was presented for 500 ms followed by a 500 ms ISI. After the sequence was presented, a 3000 ms blank screen followed. After the blank screen, an object was presented on the screen as a probe, and participants judged whether the object was presented in the previous sequence (by pressing the " 1 " or " 0 " key for "yes" or "no", respectively). The object remained on the screen until response.

## (a) Pairs

(b) Exposure phase: 1-back task over a sequence of pairs

(c) Recognition phase:

(d) Test phase: Which pair looks more familiar?

Figure 1. Experiment 1. (a) Four object pairs (e.g., A-B). (b) Exposure phase: 1-back task. (c) Recognition phase: missing trials, presented trials, and baseline trials. (d) Test phase: two-alternative forced-choice task.

To examine whether they had successfully learned the object pairs, participants in the structured condition completed a surprise two-alternative forced choice test phase following the recognition phase (Fig.1d). In each trial, participants viewed two sequences of objects. Each object appeared for 500 ms followed by a 500 ms ISI, and each sequence was separated by a 1000 ms pause. Participants judged whether the first or second sequence looked more familiar based on what they saw in the exposure phase (by pressing the " 1 " or " 0 " key for "first sequence" or "second sequence", respectively). One sequence was a pair (e.g., AB), and the other was a "foil" (e.g., A-D) composed of one object from an original pair (e.g., A-B), and the other from a different pair (e.g., C-D), while preserving the temporal positions in the pairs (Fig. 1d). Each pair was tested against each foil twice, which resulted in 16 trials in total (4 pairs $\times$ 2 foils $\times 2$ repetitions). Importantly, each pair and foil were presented the same number of times at test. Thus, to discriminate the pair from the foil, participants needed to know which two specific objects followed each other. The order of the trials was randomized, and whether the pair or foil appeared first was counterbalanced across trials. Participants in the random condition was not tested, since there were no pairs in the sequence.

A debriefing session was conducted at the end of the experiment, where participants were asked if they had noticed any objects that appeared one after another. For those who responded yes, we further asked them to specify which objects followed each other.

## Results and Discussion

At the test phase, pairs were chosen over foils on $60.0 \%$ ( $\mathrm{SD}=19.3 \%$ ) of the time, which was reliably above chance (50\%) $[t(59)=4.01, p<.001, d=0.52]$. Thus, learning of the object pairs was successful. During debriefing, 12 participants reported noticing the pairs, but none could correctly report which specific objects followed each other. This suggests that participants had no explicit awareness of the object pairs.

The false alarm rate (FA) and the hit rate in the recognition phase were presented in Fig. 2 and analyzed with a 2 (condition: structured vs. random; between-subjects) $\times 3$ (trial type: missing vs. presented vs. baseline; withinsubjects) mixed-effects ANOVA.

There was a main effect of condition $[F(1,118)=12.38$, $\left.p<.001, \eta_{p}{ }^{2}=.09\right]$ and trial type $[F(2,236)=425.06, p<.001$, $\left.\eta_{p}{ }^{2}=.78\right]$, but no reliable interaction between condition and trial type $\left[F(2,236)=0.73, p=.48, \eta_{p}^{2}=.006\right]$. Tukey's HSD post-hoc test showed that the FA rate of the missing trials was reliably higher in structured condition ( $27.9 \%$ ) than in random condition ( $20.4 \%$ ), $p=.03$; the hit rate of the presented trials was reliably higher in structured condition (72.5\%) than in random condition ( $62.60 \%$ ), $p<.001$; and a marginal difference in the hit rate of baseline trials between structured $(72.5 \%)$ and random condition ( $65.9 \%$ ), $p=.09$.

These findings suggest that statistical learning not only sharpens the memory of the object within the pairs, but also induces the false memory of the missing object.

Figure 2: The false alarm (FA) rate and the hit rate in recognition phase (error bars reflect $\pm 1 \mathrm{SEM} ;{ }^{\dagger} p<.1,{ }^{*} p<.05,{ }^{* * *} p<.001$ ).

To examine the relationship between statistical learning and recognition performance, we found that there were no correlations between learning of the pairs at the test phase and the FA rate or the hit rate. However, in structured condition there was a weak correlation between the FA rate in the missing trials and the hit rate in the presented trials. There was a moderate correlation between the FA rate in the missing trials and the hit rate in the baseline trials, but no correlations in random condition (Table 1).

Table 1: Correlations between learning of the pairs at the test phase and the false alarm rate or the hit rate

| Condition | Correlation | Correlation results |
| :--- | :--- | :--- |
| Structured | Learning vs. missing | $r(58)=-.15, p=.26$ |
| $(N=60)$ | Learning vs. presented | $r(58)=.21, p=.11$ |
|  | Learning vs. baseline | $r(58)=-.03, p=.79$ |
|  | Missing vs. presented | $r(58)=.28, p=.03$ |
|  | Missing vs. baseline | $r(58)=.31, p=.02$ |
|  | Presented vs. baseline | $r(58)=.48, p<.001$ |
| Random | Missing vs. presented | $r(58)=.17, p=.21$ |
| $(N=60)$ | Missing vs. baseline | $r(58)=.20, p=.12$ |
|  | Presented vs. baseline | $r(58)=.63, p<.001$ |

## Experiment 2

This experiment aimed to generalize the findings in Experiment 1 from the temporal context to a spatial context.

## Participants

A new group of 68 undergraduates ( 51 female, mean age $=20.2$ years, $\mathrm{SD}=2.4$ ) from UBC participated in the experiment for course credit.

## Stimuli

The stimuli were identical to those in Experiment 1, except that in structured condition the four pairs were grouped into horizontal, vertical, and diagonal spatial configurations (Fig.3a). Each array contained all four pairs, and was placed on an invisible $4 \times 4$ grid (subtending $8.2^{\circ} \times 8.2^{\circ}$ ) with the constraint that one pair was adjacent to at least another pair. This was to prevent participants from learning the pairs based on spatial segmentation cues other than object cooccurrences. In random condition, the eight objects were randomly assigned to one of cell on the grid, with the constraint that each object neighbored at least one other object. Thus, the only difference between structured and random condition was the presence or absence of the pairs.

## Procedure

As in Experiment 1, there were two conditions (i.e., structured vs. random, $N=34$ in each) and three phases (i.e., exposure, recognition, and test). In the exposure phase, participants in both conditions viewed arrays of objects, and performed a duplicate detection task where they judged as quickly and accurately as possible whether there were two identical objects in a single array (by pressing the "/" or "z" key for yes or no, respectively, key assignment counterbalanced, Fig. 3b). This duplicate detection task served as a cover task irrelevant to statistical learning, to ensure that learning of the object pairs was incidental. Participants were not told anything about the object pairs. Each array was presented on the screen for 1000 ms followed by a 1000 ms ISI in each trial. There were 480 trials in total, and $20 \%$ of the trials ( 80 trials) contained a duplicate object in the array.

The recognition phase was identical to that in Experiment 1, except that objects were presented all at once on the screen. In each trial, participants viewed an array for 800 ms followed by a 3000 ms pause, and judged whether the probe object was presented in the array. The display time was increased to 800 ms , as it required more time for participants to view all eight objects at once. As before, there were three types of trials: (1) missing trials, where one member in the pair was missing, and the missing object was tested; (2) presented trials, where one member in the pair was missing, but the presented object in the pair was tested; and (3) baseline trials, where all pairs were presented, and one object was tested (Fig. 3c).

After the recognition phase, participants in the structured condition completed the surprise two-alternative forced choice test phase to see whether they had successfully learned the object pairs (Fig. 3d). In each trial, one set of objects was presented on the left and another on the right side of the screen for 1000 ms . Participants judged whether the left or right set of objects looked more familiar based on what they saw in the exposure phase (by pressing the " 1 " or " 0 " key for "left" or "right", respectively). The foils were created following the same logic as in Experiment 1. Participants in the random condition was not tested, since there were no pairs in the array during exposure.

A debriefing session was conducted after test, where participants were asked if they had noticed any objects that appeared with one another. For those who responded yes, we further asked them to specify which objects appeared adjacent to each other.

## Results and Discussion

At the test phase, pairs were chosen over foils on $52.2 \%$ ( $\mathrm{SD}=10.3 \%$ ) of the time, which was not reliably above chance $(50 \%)[t(33)=1.25, p=.22, d=0.21]$. This suggests that participants failed to learn the spatial co-occurrences between the two objects in the pairs. During debriefing, four participants reported noticing the pairs, but none could correctly report which specific objects appeared with each other. This suggests that participants had no explicit awareness of the pairs.
(a) Pairs

(b) Exposure phase: duplicate detection task

(c) Recognition phase:

Figure 3. Experiment 2: (a) Four pairs in four different spatial configurations. (b) Exposure phase: duplicate detection task. (c) Recognition phase: missing trials, presented trials, and baseline trials. (d) Test phase: two-alternative forced-choice task.

The FA rate and the hit rate in the recognition phase were analyzed with a 2 (condition: structured vs. random; between-
subjects) $\times 3$ (trial type: missing vs. presented vs. baseline; within-subjects) mixed-effects ANOVA. There was a main effect of trial type $\left[F(2,132)=137.32, p<.001, \eta_{p}^{2}=.68\right]$, but no main effect of condition $\left[F(1,66)=0.004, p=.95, \eta_{p}{ }^{2}=.00\right]$ and no significant interaction between condition and trial type [ $\left.F(2,132)=0.45, p=.63, \eta_{p}{ }^{2}=.007\right]$. Tukey's HSD post-hoc test showed that the FA rate of the missing trials was not different between the structured condition $(30.7 \%)$ and the random condition ( $30.5 \%$ ), $p=.99$, the hit rate of the presented trials was not different between the structured condition (57.5\%) and the random condition ( $59.4 \%$ ), $p=.99$, and no difference in the hit rate of baseline trials between the structured $(66.7 \%)$ and the random conditions ( $64.3 \%$ ), $p=.97$ (Fig. 4).

Figure 4: The false alarm rate and the hit rate in recognition phase (error bars reflect $\pm 1$ SEM).

We found no correlation between learning of the pairs at the test phase and the FA rate or the hit rate. But in both the structured and random condition, there was a correlation between the FA rate, and the hit rate in the presented trials and in the baseline trials (Table 2).

Table 2: Correlations between learning of the pairs at the test phase and the false alarm rate or the hit rate

| Condition | Correlation | Correlation results |
| :--- | :--- | :--- |
| Structured | Learning vs. missing | $r(32)=.24, p=.17$ |
| $(N=34)$ | Learning vs. presented | $r(32)=.22, p=.22$ |
|  | Learning vs. baseline | $r(32)=.16, p=.35$ |
|  | Missing vs. presented | $r(32)=.66, p<.001$ |
|  | Missing vs. baseline | $r(32)=.57, p<.001$ |
|  | Presented vs. baseline | $r(32)=.40, p=.02$ |
| Random | Missing vs. presented | $r(32)=.44, p=.009$ |
| $(N=34)$ | Missing vs. baseline | $r(32)=.53, p<.001$ |
|  | Presented vs. baseline | $r(32)=.62, p<.001$ |

The lack of memory difference between the structured condition and the random condition could be due to the lack of learning of object pairs in the spatial context.

To further explore whether learning of spatial pairs changed the representation of individual objects in the pairs,
we separated participants who successfully learned the pairs (those who chose pairs over foil above chance, $N=15$ ), and those who failed to learn the pairs (those who chose pairs over foil at or below chance, $N=19$ ) in the structured condition. Among participants who showed learning, pairs were chosen over foils on $61.2 \%$ ( $\mathrm{SD}=6.8 \%$ ) of the time, which was reliably above chance (50\%) $[t(14)=6.44, p<.001, d=1.66]$. Only one participant reported noticing the pairs, but could not correctly report which specific objects appeared with each other. A 2 (group: learners vs. non-learners; betweensubjects) $\times 3$ (trial type: missing vs. presented vs. baseline; within-subjects) mixed-effects ANOVA revealed a main effect of trial type $\left[F(2,64)=68.40, p<.001, \eta_{p}^{2}=.68\right]$, but no main effect of group $\left[F(1,32)=1.25, p=.27, \eta_{p}{ }^{2}=.04\right]$ and no significant interaction between group and trial type $\left[F(2,64)=0.42, p=.66, \eta_{p}{ }^{2}=.01\right]$. Although the results were not reliably different between the two groups, the learners consistently showed numerically greater FA rate and hit rate than the non-learners (Fig.5), a pattern that was consistent with the findings in Experiment 1.

Figure 5: The false alarm rate and the hit rate of learners and nonlearners in recognition phase in the structured condition (error bars reflect $\pm 1$ SEM) .

## General Discussion

The goal of this experiment was to examine whether statistical learning alters the memory representations of individual objects. We found that after learning the temporal co-occurrences of objects, participants showed a reliably higher false alarm rate of seeing a missing object, and a reliably higher hit rate of seeing a presented object (Experiment 1). When the objects co-occurred over space, participants did not successfully express learning of pairs, and therefore did not show differential false alarm and hit rates (Experiment 2). However, with a more detailed analysis, participants who successfully learned the spatial pairs showed numerically higher false alarm rate of the missing object and numerically higher hit rate of the presented object than those who failed to learn the pairs. The current findings suggest that statistical learning not only sharpens the
detection of the objects within the pairs, but also induces a false memory of the missing object.

Induced false memory of the missing object can be explained by the automatic statistical association between the missing object and the presented object in the pair. Once the pairs were learned over repeated exposures even implicitly, one member in the pair could serve as a cue to signal the presence of its partner (Turk-Browne, et al., 2009). Thus, participants may have automatically brought the missing object to mind when seeing its partner in the sequence, thus false recalling that the missing object was present. This suggests that the automatic activation of the missing object was possible by merely co-occurring with its partner previously.

Alternatively, the two co-occurring objects may be unitized after learning. Previous studies have demonstrated that regularities compress information (Brady et al., 2009) and reduce perceived numerosity of the objects (Zhao \& Yu, 2016), which suggests that the co-occurring objects could be grouped and encoded as one single unit. Seeing a member of the unit could trigger the illusion that the entire unit was presented, and therefore inducing the false memory of the missing partner.

The enhanced hit rate of the presented member in the pair could be due to the possibility that statistical regularities automatically draw attention (Zhao et al., 2013). Given that attention plays an important factor in the recognition task, participants in the structured condition may have prioritized processing of the paired objects, and therefore showed a better hit rate compared to the random condition.

Another account for the enhanced memory is that it may be easier to memorize the objects that were present in the sequence, because statistical learning increases the working memory capacity to encode objects (Brady et al., 2009). The better memory performance of the paired objects in the baseline condition was consistent with previous finding that statistical learning enhances memory of structured objects (Otsuka \& Saiki, 2016).

In conclusion, we discovered a novel consequence of statistical learning: it not only enhances the detection of the object within the regularities, but also creates a false memory of the missing object.

#### Abstract

Language comprehension in grounded contexts involves integrating visual and linguistic information through decisions about visual fixation. But when the visual signal also contains information about the language source - as in the case of written text or sign language - how do we decide where to look? Here, we hypothesize that eye movements during language comprehension represent an adaptive response. Using two case studies, we show that, compared to English-learners, young signers delayed their gaze shifts away from a language source, were more accurate with these shifts, and produced a smaller proportion of nonlanguage-driven shifts (E1). Next, we present a well-controlled, confirmatory experiment, showing that English-speaking adults produced fewer nonlanguagedriven shifts when processing printed text compared to spoken language (E2). Together, these data suggest that people adapt to the value of seeking different information in order to increase the chance of rapid and accurate language understanding.

Keywords: eye movements; language processing; information-seeking; American Sign Language

## Introduction

The study of eye movements during language comprehension has provided fundamental insights into the interaction between conceptual representations of the world and the incoming linguistic signal. For example, research shows that adults and children will rapidly shift visual attention upon hearing the name of an object in the visual scene, with a high proportion of shifts occurring prior to the offset of the word (Allopenna, Magnuson, \& Tanenhaus, 1998; Tanenhaus, Spivey-Knowlton, Eberhard, \& Sedivy, 1995). Moreover, researchers have found that conceptual representations activated by fixations to the visual world can modulate subsequent eye movements during language processing (Altmann \& Kamide, 2007).

The majority of this work has used eye movements as a measure of the output of the underlying language comprehension process, often using linguistic stimuli that come from a disembodied voice. But in real world contexts, people also gather information about the linguistic signal by fixating on the language source. Consider a speaker who asks you to "Pass the salt" but you are in a noisy room, making it difficult to understand the request. Here, comprehension can be facilitated by gathering information via (a) fixations to the nonlinguistic visual world (i.e., encoding the objects that are present in the scene) or (b) fixations to the speaker (i.e., reading lips or perhaps the direction of gaze).

But, this situation creates a tradeoff where the listener must decide what kind of information to gather and at what time.

How do we decide where to look? We propose that people modulate their eye movements during language comprehension in response to tradeoffs in the value of gathering different kinds of information. We test this adaptive tradeoff account using two case studies that manipulate the value of different fixation locations for language understanding: a) a comparison of processing sign vs. spoken language in children (E1), and $b$ ) a comparison of processing printed text vs. spoken language in adults (E2). Our key prediction is that competition for visual attention will make gaze shifts away from the language source less valuable than fixating the source of the linguistic signal, leading people to generate fewer exploratory, nonlanguage-driven eye movements.

## Experiment 1

E1 provides an initial test of our adaptive tradeoffs account. We compared eye movements of children learning ASL to children learning a spoken language using parallel real-time language comprehension tasks where children processed familiar sentences (e.g., "Where's the ball?") while looking at a simplified visual world with 3 fixation targets (a center stimulus that varied by condition, a target picture, and a distracter picture; see Fig 1). The spoken language data are a reanalysis of three unpublished data sets, and the ASL data are reported in MacDonald et al. (under review). We predicted that, compared to spoken language processing, processing ASL would increase the value of fixating on the language source and decrease the value of generating exploratory, nonlanguagedriven shifts even after the target linguistic item began unfolding in time.

To test this prediction, we present traditional behavioral analyses of first shift Accuracy and RT. We also present two model-based analyses. First, we use an exponentially weighted moving average (EWMA) method (Vandekerckhove \& Tuerlinckx, 2007) to categorize participants’ gaze shifts as language-driven or random. In contrast to the standard RT/Accuracy analysis, the EMWA allows us to quantify differences in the accuracy of gaze shifts as a function of when that shift occurred in time. Next, we use drift-diffusion models (DDMs) (Ratcliff \& Childers, 2015) to quantify differences in the underlying psychological variables that might drive behavioral differences in Accuracy and RT. For example, the DDM uses the shape of both the correct and incorrect RT distributions to provide a quantiative estimate of whether higher accuracy is driven by more cautious responding or by more efficient information processing.

Figure 1: Stimuli for E1 and E2. Panel A shows the layout of the fixation locations for all tasks: the center stimulus, the target, and the distracter. Panel B shows the five center stimulus items: a static geometric shape (Bullseye), a static image of a familiar object (Object), a person speaking (Face), a person signing (ASL), and printed text (Text).

## Method

Participants Table 1 contains details about the age distributions of children in all of four samples.

Spoken English samples. Participants were 80 native, monolingual English-learning children divided across three samples. Participants had no reported history of developmental or language delay.

ASL sample. Participants were 30 native, monolingual ASL-learning children (18 deaf, 12 hearing). All children, regardless of hearing status, were exposed to ASL from birth through extensive interaction with at least one caregiver fluent in ASL and were reported to experience at least $80 \%$ ASL in their daily lives. The ASL sample included a wider age range compared to the spoken English samples because this is a rare population.
Stimuli ASL linguistic stimuli. We recorded two sets of ASL stimuli, using two valid ASL sentence structures for questions: 1) Sentence-initial wh-phrase: "HEY! WHERE [target noun]?" and 2) Sentence-final wh-phrase: "HEY! [target noun] WHERE?" Two female native ASL users recorded several tokens of each sentence in a child-directed register. Before each sentence, the signer produced a common attention-getting gesture. Mean sign length was 1.25 sec , ranging from 0.69 sec to 1.98 sec .

| Task | Mean_Age | Min_Age | Max_Age | n |
| :--- | ---: | ---: | ---: | ---: |
| ASL | 27.90 | 16 | 53 | 30 |
| Face | 26.00 | 25 | 26 | 24 |
| Object | 31.90 | 26 | 39 | 40 |
| Bullseye | 26.10 | 26 | 27 | 16 |

Table 1: Age distributions of children in Experiment 1. All ages are reported in months.

English linguistic stimuli. All three tasks (Object, Bullseye, and Face) featured the same female speaker who used natural child-directed speech and said: "Look! Where's the (target word)?" The target words were: ball, banana, book, cookie, juice, and shoe. For the Face task, a female native English speaker was video-recorded as she looked straight ahead and said, "Look! Where's the (target word)?" Mean word length was 0.79 sec , ranging from 0.6 sec to 0.94 sec .

ASL and English visual stimuli. The image set consisted of colorful digitized pictures of objects presented in fixed pairs with no phonological overlap (ASL task: cat-bird, car-book, bear-doll, ball-shoe; English tasks: bookshoe, juice-banana, cookie-ball). Side of target picture was counterbalanced across trials.
Design and procedure Children sat on their caregiver's lap and viewed the task on a screen while their gaze was recorded using a digital camcorder. On each trial, children saw two images of familiar objects on the screen for two seconds before the center stimulus appeared (see Fig 1). Then they processed the target sentence - which consisted of a carrier phrase, a target noun, and a question - followed by two seconds without language to allow for a response. Participants saw 32 test trials with several filler trials interspersed to maintain interest.

Coding. Participants' gaze patterns were coded ( $33-\mathrm{ms}$ resolution) as being fixated on either the center stimulus, one of the images, shifting between pictures, or away. To assess inter-coder reliability, $25 \%$ of the videos were re-coded. Agreement was scored at the level of individual frames of video and averaged $98 \%$ on these reliability assessments.

## Results and Discussion

Analysis plan First, we present behavioral analyses of First shift accuracy and Reaction Time (RT). RT corresponds to the latency to shift away from the central stimulus to either picture measured from target-noun onset. Accuracy was the mean proportion of first gaze shifts that landed on the target picture out of the total number of shifts. We log transformed all RTs and used the lme4 R package (Bates, Maechler, Bolker, \& Walker, 2013) to fit mixed-effects regression models that included a random intercept for each participant and item. Since children's age varied across conditions, we included age in months as a covariate in all models. All analysis code can be found in the online repository for this project: https://github.com/kemacdonald/speed-acc.

Next, we present two exploratory model-based analyses to quantify differences in eye movements across the four samples. First, we use an EWMA method to model changes in accuracy as a function of increases in RT. For each RT, the model generates two values: a "control statistic" (CS, which captures the running average accuracy of first shifts) and an "upper control limit" (UCL, which captures the pre-defined limit of when accuracy would be categorized as above chance level). Here, the CS is an expectation of random shifting to either the target or the distracter image (nonlanguage-driven shifts), or a Bernoulli process with probability of success 0.5 .

Figure 2: First shift accuracy and RTs from E1. Panel A shows a boxplot representing the distribution of RTs for correct (orange) and incorrect (blue) shifts for each center stimulus type. Panel B shows the distribution of mean first shift accuracy scores for each center stimulus type. The solid lines represent median values, the boundaries of the box show the upper and lower quartiles, and the whiskers show the full range of the data excluding outliers.

As the RTs get longer, we assume that participants have gathered more information and should become more accurate, or a Bernoulli process with probability success $>0.5$. Using this model, we can quantify and compare: a) the cutoff point when the CS exceeds the UCL, indicating that participants started to generate language-driven shifts and $b$ ) the proportion of shifts that the model categorizes as language-driven vs. nonlanguage-driven.

Finally, we took the shifts that were categorized as language-driven by the EWMA and fit a hierarchical Bayesian drift-diffusion model (HDDM) to quantify differences in the speed and accuracy of language-driven eye movements. We chose to implement a hierarchical Bayesian version of the DDM using the HDDM Python package (Wiecki, Sofer, \& Frank, 2013) since we had relatively few trials from child participants and recent simulation studies have shown that the HDDM approach was better than other DDM fitting methods for small data sets (Ratcliff \& Childers, 2015). The model assumes that people accumulate noisy evidence in favor of one alternative with a response generated when the evidence crosses a pre-defined decision threshold. Here we focus on two parameters of interest that map onto meaningful psychological variables: boundary separation, which indexes the amount of evidence gathered before a response (higher values suggest more cautious responding) and drift rate, which indexes the amount of evidence accumulated per unit time (higher values suggest more efficient processing).

Behavioral analyses $R T$. Visual inspection of the Fig 2, panel A suggests that there was a speed accuracy tradeoff in the ASL, Face, and Bullseye conditions, with incorrect shifts tending to be faster than correct shifts. To quantify differences across the groups, we fit a linear mixedeffects regression predicting first shift RT as a function of center stimulus type, controlling for age, and including user-defined contrasts to test specific comparisons of interest: Log (RT) ~ center stimulus type + age + (1 | subject) + (1 | item). We found that (a) ASL learners generated slower RTs compared to all of the spoken English samples ( $\beta=-0.97, p<.001$ ), (b) ASL learners' shifts were slower compared directly to participants in the Face task ( $\beta=$ $-0.42, p<.001$ ), and (c) participants in the Face task shifted slower compared to participants in the Object and Bullseye tasks ( $\beta=-0.73, p<.001$ ).

Accuracy. Next we compared the accuracy of first shifts across the different tasks by fitting a mixed-effects logistic regression with the same specifications and contrasts as the RT model. We found that (a) ASL learners were more accurate compared to all of the spoken English samples ( $\beta=$ $-0.78, p<.001$ ), (b) ASL learners were more accurate when directly compared to participants in the Face task ( $\beta=-0.62$, $p=0.001$ ), and (c) participants in the Face task were numerically more accurate compared to participants in the Object and Bullseye tasks $(\beta=-0.73)$ but this effect was not significant ( $p=0.089$ ).
Model-based analyses $E W M A$. Figure 3 shows changes in the control statistic (CS) and the upper control limit (UCL) as a function of participants' RTs. Each CS starts at chance performance and below the UCL. In the ASL and Face tasks, the CS value begins to increase with RTs around 0.7 seconds after noun onset and eventually crosses the UCL, indicating that responses $>0.7 \mathrm{sec}$ were on average above chance levels. In contrast, the CS in the Object and Bullseye tasks never crossed the UCL, indicating that children's shifts were equally likely to land on the target or the distracter, regardless of when they were initiated. This result suggests that first shifts in the Bullseye/Object tasks were not language-driven and may instead have reflected a different process such as gathering more information about the referents in the visual world.

Next, we compared the EWMA output for participants in the ASL and Face tasks. We found that ASL learners generated fewer shifts when the CS was below the UCL ( $\beta=-1.61$, $p<.001$ ), indicating that a larger proportion of their initial shifts away were language-driven (see the differences in the red shaded area in Fig 3). We did not find evidence for a difference in the timing of when the CS crossed the UCL ( $\beta=$ $-0.04, p=0.387$ ), indicating that both groups began to generate language-driven shifts about the same time after noun onset.

HDDM. Using the output of the EWMA, we compared the timing and accuracy of language-driven shifts for participants
in the ASL and Face tasks 1 We found that ASL learners had a higher estimate for the boundary separation parameter compared to the Face participants (ASL boundary $=1.77, \mathrm{HDI}=$ $[1.64,1.9]$; Face boundary $=1.35, \mathrm{HDI}=[1.21,1.49])$, with no overlap in the credible values (see Fig 4). This suggests that ASL learners accumulated more evidence about the linguistic signal before generating an eye movement. We found high overlap for estimates of the drift rate parameter, indicating that both groups processed the linguistic information with similar efficiency (ASL drift $=0.64, \mathrm{HDI}=[0.44,0.83]$; Face drift $=0.57, \mathrm{HDI}=[0.33,0.83])$.

Taken together, the behavioral analyses and the EWMA/HDDM results provide converging support that ASL learners were sensitive to the value of eye movements, producing fewer nonlanguage-driven shifts and prioritizing accuracy over speed, but accumulating information at roughly the same rate. This behavior seems reasonable since the potential for missing subsequent linguistic information is high if ASL users shifted prior to gathering sufficient information. It is important to point out that these were exploratory findings and that there were several, potentially important differences between the stimuli, apparatus, and populations. In E2, we set out to perform a well-controlled, confirmatory test of our adaptive tradeoffs account.

## Experiment 2

In E2, we attempt to replicate a key finding from E1: that increasing the competition between fixating the language source and the nonlinguistic visual world reduces nonlanguage-driven eye movements. Moreover, we conducted a confirmatory test of our hypothesis that also controlled for the population differences present in E1. We tested a sample of English-speaking adults using a withinparticipants manipulation of the center stimulus type. We used the Face and Bullseye stimulus sets from E1 and added two new conditions: Text, where the verbal language information was accompanied by a word-by-word display of printed text (see Fig 1), and Text-no-audio, where the spoken language stimulus was removed. We chose text processing since, like sign language comprehension, the linguistic information is gathered via fixations to the visual world.

Our key behavioral prediction is that participants in the Text conditions should produce a higher proportion of language-driven shifts as indexed by the EWMA model output. We did not have strong predictions for the DDM parameter fits since the goal of the Text manipulation was to modulate participants' strategic allocation of visual attention and not the accuracy/efficiency of information processing.

## Method

[^132]

Figure 3: Output for the EWMA guessing model in E1. The black curve represents the evolution of the control statistic (CS) as a function of reaction time. The grey curve represents the upper control limit (UCL). The vertical dashed line is the median cutoff value (point when the control process shifts out of a guessing state). The grey shaded area represents the $95 \%$ confidence interval around the estimate of the median cutoff point. And the shaded areas represents the proprotion of responses that were flagged as guesses (red) and languagedriven (green).

Participants 25 Stanford undergraduates participated (5 male, 20 females) for course credit. All participants were monolingual, native English speakers and had normal vision.

Stimuli Audio and visual stimuli were identical to the Face and Bullseye tasks in E1. We included a new center fixation stimulus type: printed text. The text was displayed in a white font on a black background and was programmed such that only a single word appeared on the screen, with each word appearing for the same duration as the corresponding word in the spoken language stimuli.
Design and procedure The design was nearly identical to E1, with the exception of a change to a within-subjects manipulation where each participant completed all four tasks (Bullseye, Face, Text, and Text-no-audio). In the Text condition, spoken language accompanied the printed text. In the Text-no-audio condition, the spoken language stimulus was removed. Participants saw a total of 128 trials while their eye movements were tracked using automated eye-tracking software.

## Results and Discussion

Behavioral analyses $R T$. Visual inspection of Figure 5, panel A suggests that there was a speed-accuracy tradeoff for all conditions: incorrect gaze shifts tended to be faster than

Figure 4: Posterior distributions for the boundary and drift rate parameters for children in E1 (Panel A) and adults in E2 (Panel B).
correct shifts. We fit a linear mixed-effects regression with the same specification as in E1, but we added by-subject intercepts and slopes for each center stimulus type to account for our within-subjects manipulation. We did not find evidence that RTs were different across conditions (all $p>.05$ ).

Accuracy. Next, we modeled accuracy using a mixedeffects logistic regression with the same specifications (see Panel B of Fig 5). We found that adults' first shifts were highly accurate, and, in contrast to the children in E1, their responses were above chance level even in the Bullseye condition when the center stimulus was not salient or informative. We also found that participants tended to be less accurate in the Text conditions compared to conditions without text ( $\beta$ $=1.18, p=0.002$ ). We did find not any other statistically significant differences.
Model-based analyses $E W M A$. For all four conditions, the CS crossed the UCL (see Fig 6), suggesting that for all tasks some proportion of adults' shifts were language-driven. Interestingly, we found a graded effect of condition (see the shift in the vertical dashed lines in Fig 5) on the point when the CS crossed the UCL such that the Text-no-audio condition occurred earliest $\left(M_{\text {text-no-audio }}=0.39\right)$, followed by the Text and Face conditions that were not different from one another ( $M_{\text {text }}=0.44, M_{\text {face }}=0.45, p>.05$ ), and finally the Bullseye condition $\left(M_{\text {bullseye }}=0.54\right)$. We also found the same graded difference in the proportion of shifts that occurred while the CS was below the UCL (see the red vs. green shaded area in Fig 5), indicating a higher proportion of first shifts were language-driven in the Text conditions, with the highest proportion in the Text-no-audio condition when tested against the three other conditions ( $M_{\text {text-no-audio }}=3.88, \beta=1.74, p$ $<.001$ ). These results provide strong evidence for our key

Figure 5: Behavioral results from E2. All plotting conventions are the same as in Figure 2.
prediction: that increasing the value of fixating the language source reduces exploratory gaze shifts to the nonlinguistic visual world.
$H D D M$. Using the output of the EWMA, we fit the same HDDM as in E1. There was high overlap of the posterior distributions for the drift rate parameters (see Fig 4, panel B), suggesting that participants gathered the linguistic information with similar efficiency. We also found high overlap in the distribution of credible boundary separation estimates for the Bullseye, Text, and Text-no-audio conditions. Interestingly, we found some evidence for a higher boundary separation in the Face condition compared to the other three center stimulus types (Face boundary $=1.72$, $\mathrm{HDI}=[1.47,1.97]$; Bullseye boundary $=1.42, \mathrm{HDI}=[1.21,1.65]$; Text boundary $=1.38, \mathrm{HDI}=[1.16,1.6]$; Text-no-audio boundary $=1.36$, $\mathrm{HDI}=[1.15,1.58])$, suggesting that adults higher accuracy in this condition was driven by accumulating more information before generating a response.

Together, these results suggest that adults were sensitive to the tradeoff between gathering different kinds of information. When processing text, people generated fewer nonlanguagedriven shifts (EWMA results) but their processing efficiency of the linguistic signal itself did not change (HDDM results). Interestingly, we found a graded difference in the EWMA results between the Text and Text-no-audio conditions, with the lowest proportion of early, nonlanguage-driven shifts occurring while processing text without the verbal stimuli. This behavior makes sense; if the adults could rely on the auditory channel to gather the linguistic information, then the value of fixating the text display decreases. In contrast to the children in E1, adults were highly accurate in the Bullseye condition, perhaps because they construed the Bullseye as a center fixation that they should fixate, or perhaps they had better encoded the location/identity of the two referents prior to the start of the target sentence.

Figure 6: EWMA model output for E2. All plotting conventions are the same as Figure 3.

## General Discussion

Language comprehension can be facilitated by fixating on relevant features of the nonlinguistic visual world or on the speaker. But how do we decide where to look? We propose that eye movements during language processing reflect a sensitivity to the tradeoffs of gathering different kinds of information. We found that young ASL-learners generated slower but more accurate shifts away from a language source and produced a smaller proportion of nonlanguage-driven shifts compared to spoken language learners. We found the same pattern of behavior within a sample of English-speaking adults processing displays of printed text compared to spoken language. These results suggest that as the value of fixating on a location to gather information about the linguistic signal increases, eye movements to the rest of the visual world become less useful and occur less often.

Our work here attempts to synthesize results from different populations and stimuli in a single framework, but it has several limitations that we hope will pave the way for future work. First, we have not performed a confirmatory test of the DDM findings: both ASL-learners (E1) and adults processing language from a person (E2) prioritize accuracy over speed. So these findings, while interesting, are preliminary. Second, we do not know what might be driving the population differences in E1. It could be that ASL-learners' massive experience dealing with competition for visual attention leads to changes in the deployment of eye movements during language comprehension. Or, it could be that the in-the-moment constraints of processing a visual language cause different fixation behaviors. Finally, we used a very simple visual world, with only three places to look, and very simple linguistic stimuli, especially for the adults in E2. Thus it remains an open question how these results might scale up to more com-
plex language information and visual environments.
This work attempts to integrate top-down, goal-based models of vision (Hayhoe \& Ballard, 2005) with work on language-driven eye movements (Allopenna et al., 1998). While we chose to start with two case studies - ASL and text processing - we think the account is more general and that there are many real world situations where people must negotiate the tradeoff between gathering more information about language or about the world: e.g., processing spoken language in noisy environments or at a distance; or early in language learning when children are acquiring new words and often rely on nonlinguistic cues to reference such as pointing or eye gaze. Overall, we hope this work contributes to a broader account of eye movements during language comprehension that can explain fixation behaviors across a wider variety of populations, processing contexts, and during different stages of language learning.

# Preschoolers appropriately allocate roles based on relative ability in a cooperative interaction 

Rachel W. Magid (rwmagid@mit.edu), Mary DePascale (mdepascale@wesleyan.edu) \& Laura E. Schulz (lschulz@mit.edu)<br>Department of Brain and Cognitive Sciences, MIT<br>Cambridge, MA 02139 USA

#### Abstract

In cooperative activities, all parties have a shared goal but may not have the same set of skills. The current study considers whether preschoolers are sensitive to probable differences in individuals' competence when allocating roles. We found that 3.5 - to 5.5 -year-olds use relative competence, as indexed by the age of their intended partner, to determine who should do the harder and easier of two tasks in a cooperative interaction. A second experiment demonstrated that children allocate roles differently in a competitive context. Young children infer differences in others' ability and can divide labor efficiently to achieve their goals.

Keywords: cooperation; self/other knowledge; planning.

## Introduction

Cooperation is a foundation of human culture, observed in activities as diverse as governing, hunting, fishing, building, and playing (Tomasello, 1999). Young children begin cooperating in problem-solving tasks and social games by their first birthday, and the sophistication of their cooperative interactions increases over the first few years of life (Brownell \& Carriger, 1990; Cooper, 1980; Warneken, Chen, \& Tomasello, 2006). Children cooperate by sharing food and toys (Brownell, Svetlova, \& Nichols, 2009; Hay, 1979), pointing to inform others (Liszkowski, Carpenter, Striano, \& Tomasello, 2006; Liszkowski, Carpenter, \& Tomasello 2008), and assisting in goal-directed actions (Warneken \& Tomasello, 2007). Children also appear to expect cooperation: when adults disengage from cooperative interactions, they protest (Ross \& Lollis, 1987).

Across species, the most sophisticated forms of cooperation involve collaboration: cases in which individuals flexibly adjust their behavior to accomplish a goal - as in when some individuals pursue prey and others block its escape (Boesch \& Boesch, 1989). In laboratory tasks, children as young as 3.5 engage in this kind of collaboration, flexibly dividing labor, reversing roles when necessary, and coordinating on tasks involving different sub-goals (e.g., as when one child lifts a lever and another pulls a handle to achieve a joint goal; Ashley \& Tomasello, 1998; Fletcher, Warneken, \& Tomasello, 2012). Moreover, older preschoolers divide labor appropriately with respect to available
resources: when the participant has both the tools needed to achieve a joint goal while their partner has only one, five-year-olds (though not 3-year-olds) appropriately delegate to their partner the task corresponding to their partner's tool (Warneken, Steinwender, Hamann, \& Tomasello, 2014). Preschoolers also collaborate to achieve goals by considering what action the other partner has already selected (Warneken et al., 2014).

Critically, previous research has focused on cases in which both partners are, in principle, equally capable of performing both roles. However, people differ not just with respect to the availability of external resources, but also with respect to their physical, cognitive, and emotional resources. This is advantageous for living in social groups, given that collaboration among individuals with different skills might lead to more efficient and effective actions, and better problemsolving (e.g., Azmitia, 1988; Dyer \& Singh, 1998). However, to capitalize on diverse skills, role allocation should correspond to individuals' differing capabilities.

Dividing labor in this way requires integrating several pieces of information. Even in simple twoparticipant scenarios, the individual must represent both her own and her partner's ability to perform the different tasks or components of the task, compare the two, and allocate roles so the person relatively more capable of each task performs it. Thus an adept collaborator should take on a relatively easier task when partnered with someone she regards as more capable than she is, and a relatively more difficult task when partnered with someone she believes is less capable than she is. Here we ask whether preschoolers effectively allocate roles in collaborative tasks by considering their own abilities relative to a partner's.

Previous research, in addition to the work reviewed above, provides grounds for believing that children might succeed at this kind of division of labor. Three and four-year-olds acknowledge and comment on the fact that different people have different abilities (Mostache \& Bragonier, 1981), and are sensitive to differences in others' knowledge, competence and reliability (e.g., Jara-Ettinger, Tenenbaum, \& Schulz, 2015; Koenig, Clément, \& Harris, 2004; Sobel \& Kushnir, 2013). Such evaluations influence children's helping behavior; children as young as 3 who master a problem-solving task spontaneously tutor learners they
know are naïve (Johnson, Pynn \& Nisbet, 2002).
Preschoolers' ability to accurately represent their own strengths and weaknesses is somewhat more controversial. Some work suggests that preschoolers are (excessively) optimistic about their abilities (Cimpian, 2010; Smiley \& Dweck, 1994; Schneider, 1998), and thus resilient in the face of negative feedback (Boseovski, 2010; Droege \& Stipek, 1993; Ruble, Parsons, \& Ross, 1976). To the degree that children misjudge their own abilities, they would be relatively incapable of efficient division of labor.

However, other work suggests that children begin to regard themselves as good or bad at tasks even in very early childhood (e.g., Gunderson et al., 2013; Heyman, Dweck, \& Cain, 1992; Smiley \& Dweck, 1994). Moreover, children begin to evaluate their own performance relative to their peers as young as 3 (Butler, 1988; Cimpian, 2010; Magid \& Schulz, 2015; Rhodes \& Brickman, 2008). For the current purposes, note that even if children are relatively poor judges of their abilities in an absolute sense, they might be able to judge whether one task is easier for them than another, and whether they are more or less capable than a peer. If so, children might recognize that they should take the easier task if they believe their partner is more capable than they are, and the harder task if they believe their partner is less capable.

## Experiment 1

In the current study, we test this by introducing children to two carnival style games: a ring toss and ball toss. Each game had an easy and a hard version. (See Figure 1.) Any individual child got the easy version of one game and the hard version of the other (counterbalanced across participants). Children were not told that one game was "easy" and the other was "hard" but they were allowed to try each game four times to get a sense of their own ability to succeed on each task. Children were then told that another child was going to come to play with them. They were told that they should choose one game for their partner, and one game for themselves, and that if they both succeeded - so that a ring went on a pole and a ball went in the box-a special machine would light up.

How might children infer others' capabilities on a novel task? Considerable work suggests that children play differently with peers of different ages (Brody, Stoneman, \& MacKinnon, 1982; Edwards \& Lewis, 1979; French, 1984) thus here we manipulated the age of the (fictitious) peer to see whether children would use this to infer their peers' competence relative to their own and allocate roles accordingly. In one condition, children were told that the partner would be younger (Younger Other condition); in the other condition they were told that their partner would be older than the
participant (Older Other condition).
There are a number of possible results. If children are poor judges of task difficulty, they should choose at chance. If children judge the tasks accurately, but try only to maximize their own chances of success (and ignore the joint, collaborative nature of the task) they should always choose the easy task for themselves and the hard task for their partner. Alternatively, if children tend to overestimate themselves (or underestimate their partners) they should always choose the hard task for themselves and the easy task for their partner. However, if children's role allocation in cooperative tasks is sensitive to relative ability (as indexed by age), they should choose the easier game for their partner if their partner is younger, and the easier game to themselves if their partner is older.

Figure 1: Each participant saw only one setup (top or bottom). Participants practiced each game before allocating roles.

## Method

Participants and Materials. All procedures and the analysis plan for this study were pre-registered on the Open Science Framework (osf.io/aq246). Assuming a large effect size (Cramer's $\mathrm{V}=.50$ ), a power analysis indicated that 44 participants were required to reach a power of .90 . All participants were recruited from an urban children's museum and randomly assigned to one of two conditions: Younger Other or Older Other. Forty-four children (mean age $=54$ months; range 4366 months) were included in the final sample ( $n=22$ per condition). Ten additional children did not pass the inclusion criteria. (See Procedure for details). An additional five children were tested but excluded due to parental interference $(n=3)$ or failing to provide a response to the test question $(n=2)$.

A felt mat ( $132 \times 94 \mathrm{~cm}$ ) was placed on the floor for game play. The mat was marked with three tape Xs and a line ( 16 cm in front of the Xs) to indicate where participants should stand. Participants stood on the left and right Xs to play games and the center X to answer questions. Children played two games: a ring toss and a ball toss. Each game had two versions-one easier (Easy Rings, Easy Balls) and one harder (Hard Rings, Hard Balls). The ring toss used a plastic pole on a black circular plastic base. The easier version used a shorter pole ( 22 cm with a 5 cm red tip) and was closer to the tape line ( 13 cm away); and the harder version used a taller pole ( 40 cm with a 5 cm red tip) and was farther from the tape line ( 65 cm away). The ring toss game was played with blue rings ( 16 cm diameter). Each ball toss game used a gray fabric box placed on top of a blue plastic crate $(24 \times 24 \times 41 \mathrm{~cm})$ and was played with yellow plastic balls ( 26 cm circumference). The easier version used a larger box ( $29 \times 14 \times 10 \mathrm{~cm}$ ) with a cardboard backboard ( $17 \times 28 \mathrm{~cm}$ ) and was placed at the front of the crate, closer to the tape line $(53 \mathrm{~cm})$. The harder version used a smaller box ( $14 \times 14 \times 10 \mathrm{~cm}$ ) elevated on a black box of the same size, and was placed at the back of the crate, farther from the tape line ( 77 cm ). Half the participants played the Easy Rings and Hard Balls; half the Hard Rings and Easy Balls. Laminated cards $(23 \times 6 \mathrm{~cm})$ showed photographs of Older Other or Younger Other children. Children depicted in the photographs were either two-year-olds ( 10 cm tall) or six-year-olds ( 15 cm tall), based on the condition. A laminated card of the same size had the word "YOU" printed in the center and was used to represent the participant. A remote-controlled LED light machine $(12 \times 13 \times 12 \mathrm{~cm})$ was used for the joint task.

Procedure. All children were tested individually in a quiet room at a children's museum. Children were shown two games (either Easy Rings and Hard Balls, or Hard Rings and Easy Balls) and given the chance to practice each game four times. The game played first (rings or balls), the location of each game (right or left), and the version of each game (easy or hard) were counterbalanced across children. After children practiced, the experimenter introduced the light machine and explained that players of the two games could work together to achieve a single joint goal: if the ball went in the box and a ring went on the pole at the same time, then the machine would light up. The experimenter introduced the participant to the fictional Other child, named Jamie, by explaining that she had talked with the other child earlier that day and that $\mathrm{s} / \mathrm{he}$ wanted to come play the games together with the participant. The experimenter then showed children a card with a picture of the Other child and said that they were either a toddler (Younger Other) or a first-grader (Older Other). The experimenter then asked children
their own age, specifying that the Other child was younger or older, by condition. The Other child was matched by gender to the participant. For each category (Younger boy, Older boy, Younger girl, Older girl) two pictures were used to reduce the possibility that ancillary features of any picture might influence children's choices or perceptions of the Other child's abilities. The photographs represented a diversity of races and ethnicities. The experimenter then asked children to allocate roles by choosing which game the Other child should play, placing the Other child's picture next to the game chosen for them and a card with "YOU" written on it next to the game the participant chose for themselves. One game was designed to be easier than the other, however differences in motor skills or experience might lead different children to different conclusions, thus to ensure that the role allocation matched children's judgment of the relative difficulty of the two games, we asked children "Which game was easier?" As a followup, children were asked why they chose the game they picked for the Other child. Finally, we asked children if the Other child was older or younger to ensure that they had understood the task. This last question was used as an inclusion criterion: children who did not answer correctly were not included in the analysis. ${ }^{1}$ Following these questions, the experimenter left the room briefly ( $15-30$ seconds) and returned saying that she couldn't find the Other child. The experimenter then played the games with the child to turn on the light machine.

## Results

In response to, "Which game was easier?" 37 of the 44 children ( $84 \%$ ) responded that the game we had designed to be easier was easier for them. Children's self-reported judgment was used in all analyses (consistent with the pre-registered design).

As predicted, children's role assignments differed by condition $\chi^{2}(1)=7.62, p=.006, V=.462$. In the Younger Other condition, $64 \%$ of children assigned their partner the Easy Game. In the Older Other condition, only $18 \%$ of children assigned their partner the Easy Game. Collapsing across conditions, $73 \%$ of children assigned roles in a way corresponding to the difficulty of fulfilling each role in the joint task, $p=.004$ by binomial

[^133]test. Children allocated roles in a way most likely to their joint success. Given previous work showing that five-year-olds, but not 3 -year-olds allocate roles based on available resources (Warneken et al., 2014), we also asked whether the likelihood of participants allocating roles based on ability increased with age. We found no evidence of an age effect in the present task, $\beta=-$ $.004(.75), p=.995$, suggesting that even children as young as 3.5 years can allocate roles in a cooperative interaction given inferred differences in ability.

Although there was no significant difference in children's ability to allocate roles effectively in each condition, Fisher's Exact Test, $p=31$, it is intriguing that twice as many children (eight) in the Younger Other condition misallocated the hard game to the toddler whereas only four children in the Older Other condition misallocated the hard game to themselves. Both the Easy Game and the Hard Game were fairly difficult for the preschoolers. Children scored a zero out of four practice trials $32 \%$ of the time across both games. As such, the decision of some children in the Younger Other condition to allocate the Easy Game to themselves may make sense: given that a toddler is unlikely to do better, and the joint goal may thus seem out of reach, it is reasonable for children to choose the game at which they themselves are more likely to succeed. Indeed, when partnered with a younger child, the majority of preschoolers opted for a game that, while increasing the probability of achieving the joint goal, decreased the probability of their own success.

## Discussion

Results from Experiment 1 suggest that children appropriately consider their own and their partner's relative abilities in allocating roles in a cooperative interaction. However, the results raise questions about the extent to which preschoolers simply assign harder games to older children and easier games to younger children without regard for context in which they are making this decision. Here children's explanations provide some insight. Recall that we asked children why they chose one of the games for the Other child and the other for themselves. Nine children did not answer, and eleven gave uninformative answers. However, 24 children referred to the difficulty of the activities and/or alluded to relative ability (e.g., "She is older and can get the balls in"; "Because it's easier for him (in context, this meant "than the other game" rather than "easier for him than me"). Anecdotally, children's spontaneous behavior also provided some evidence that children think about role allocation dynamically: one child in the Younger Other condition who had assigned the Easy game to her partner asked to switch roles when she learned that the Experimenter, not a toddler, would be her partner in the interaction.

Figure 2: Proportion of children who chose the Easy Game or Hard Game for their partner by condition in Experiment 1: Joint Goal Context.

Figure 3: Proportion of children who chose the Easy Game or Hard Game for their partner by condition in Experiment 2: Competitive Context.

## Experiment 2

Testing the sophistication of children's role allocation requires seeing if children allocate the roles differently if they are not in a cooperative context. In Experiment 2 , we tested children in a competitive condition: in this context, children should assign their partner the harder game regardless of the other child's ability.

## Method

All participants were recruited from an urban children's museum and randomly assigned to one of two conditions: Younger Other or Older Other. Forty-four children (mean age $=54$ months; range 42-65 months) were included in the final sample ( $n=22$ per condition). Seven additional children did not pass the inclusion criteria. (See Experiment 1 for details). Two additional
children were tested but excluded due to parental interference. Materials were the same as Experiment 1.

Children were introduced to and practiced the two games as in Experiment 1. After children practiced, the experimenter introduced the light machine and explained that the person who gets a ball in the box or a ring on the pole before the other person wins and gets to turn on the machine to establish a competitive context. The introduction of other child, Jamie, and the questions (asking children which game Jamie should play, which game was easier, and how old Jamie is) were identical to Experiment 1.

## Results

In response to, "Which game was easier?" 34 of the 44 children $(77 \%)$ responded that the game we had designed to be easier was easier for them. As predicted, children's role assignments did not differ by condition $\chi^{2}(1)=1.03, p=.31, V=.204$. In the Younger Other condition, $64 \%$ of children assigned their partner the Hard Game, see Figure 3. In the Older Other condition, only $82 \%$ of children assigned their partner the Hard Game. Collapsing across conditions, $73 \%$ of children assigned the harder game to the Other child, $p=.004$ by binomial test. These results suggest that children do not allocate the harder game to the older child and the easier game to the younger child independent of context. Instead, participants took into account the competitive context of the interaction and assigned roles accordingly.

## Conclusions

In the current study we found that young children allocate roles appropriately in 1) a cooperative interaction, deciding that the less competent partner should take on the easier task while the more competent partner takes on the harder task and 2) a competitive interaction, deciding that the partner should take on the harder task. Note that we did not label the tasks as easy or difficult prior to when children allocated roles.

Past work looking at children's ability to use social comparison information has focused on how children compare themselves to others to evaluate their abilities, or to plan future actions (Butler, 1998; Magid \& Schulz, 2015; Rhodes \& Brickman 2008; Ruble, et al., 1994). The current study shows that relative ability appraisals are also involved in planning joint interactions. Although one could imagine that preschoolers would simply choose which games to play based on how much they like playing each game, these results suggest they consider the games as sub-goals in a cooperative task and consider their own and others’ competence in allocating roles. In future work, we plan
to ask how other contexts affect role allocation. Consider for instance that one goal of an interaction might be to allow the other partner to develop her skills. In this case, less competent, and younger individuals might be asked to do harder parts of a task. Note also that the current study asks a single child to allocate roles for herself and one other child, and to plan for a task occurring immediately. How children allocate roles among multiple individuals, in real time requires negotiating myriad other factors that influence successful cooperation. Additionally, we note that age is a coarse proxy of ability: younger individuals can be more skilled than older ones and in some contexts, most likely are. Moreover, individuals of exactly the same age may have special competencies and expertise in particular areas. Studies suggest that children are sensitive to these differences in ability and know who to ask for help for particular kinds of tasks (Koenig \& Jaswal, 2011; Kushnir, Vredenburgh, \& Schneider, 2013; Lutz \& Keil, 2002). Future work might ask whether children also use such knowledge to allocate roles appropriately. However, these results suggest that at least some of the core skills underlying teamwork and collaborative problem-solving are in place in early childhood.

# Intuitive psychophysics: Children's exploratory play quantitatively tracks the discriminability of alternative hypotheses 

Rachel Magid<br>Massachusetts Institute of Technology, Cambridge, Massachusetts, USA<br>Max Siegel<br>Massachusetts Institute of Technology<br>Josh Tenenbaum<br>Massachusetts Institute of Technology<br>Laura Schulz<br>Massachusetts Institute of Technology

#### Abstract

Studies suggest that children's exploratory behavior is sensitive to uncertainty; however, few have approached this with sufficient precision to model quantitatively. Across three experiments, children (mean age $=70$ months) were asked to shake a box to identify which of two sets of marbles, differing in numerosity, were hidden inside. The sets' numerosities varied in their discriminability indices - the degree to which listeners can distinguish the sets based on the acoustic information generated. The time children spent shaking the box varied systematically with the discriminability of the alternative hypotheses they were asked to distinguish, even though they heard only one set for each contrast. This suggests that children represent the uncertainty in their own perceptual discrimination abilities (an ability we refer to as an intuitive psychophysics) and their exploratory behavior is precisely calibrated to their degree of uncertainty about alternative hypotheses that might explain unobserved causes of perceptual data.

# Leveraging Response Consistency within Individuals to Improve Group Accuracy for Rank-Ordering Problems 

Brent Miller (brent.miller@vanderbilt.edu)<br>2301 Vanderbilt Place<br>Vanderbilt University<br>Nashville, TN 37240

#### Abstract

Averaging the estimates of a number of individuals has been shown to produce an estimate that is generally more accurate than those of the individuals themselves. Similarly, averaging responses from a single individual can also lead to a more accurate answer. How can we best combine estimates within and between individuals to create an accurate group estimate? We report empirical results from a general knowledge rankordering experiment and demonstrate that individuals that provide more consistent answers across repeated elicitations are also more accurate. We develop a consistency weighting heuristic and show that repeated elicitations within an individual can be used to improve group accuracy. We also develop a Thurstonian cognitive model which assumes a direct link between the process that explains the accuracy of an individual and response consistency and show how the model can infer accurate group answers.

Keywords: Bayesian Modeling; Rank Ordering; Knowledge; Recall; Wisdom of Crowds; Within; Expertise; Uncertainty; Coherence; Consistency.

## Introduction

There has been a lot of interest recently regarding how the judgments of individuals can best be combined to make group estimates that are as accurate as possible. When there is a ground truth - one single, verifiable correct answer the group average is often more accurate than most or all of its constituent individual judgments (Davis-Stober, Budescu, \& Broomell, 2014; Wallsten, Budescu, Erev, \& Diederich, 1997; Yaniv \& Foster, 1997) even if the correct answer is unknowable at the time of questioning (Lee, Steyvers, de Young, \& Miller, 2012). When repeated judgments are averaged within one individual as opposed to across individuals, a similar phenomenon occurs. For example, when a single person produces two estimates for the same underlying quantity, the average of the two estimates is generally less erroneous than the individual estimates (Vul \& Pashler, 2008; Herzog \& Hertwig, 2009; Ariely et al. 2000). A standard explanation for these averaging benefits is that random error associated with probabilistic mental representations and processes partially cancel out in the average. A larger averaging benefit is typically found when averaging judgments across as opposed to within subjects (Rauhaut \& Lorenz, 2011;

Müller-Trede, 2011) presumably because differences in mental representations and associated random error is larger across individuals.

In order to improve the accuracy of the group average, many approaches have been developed to identify and upweight more expert or accurate judgments in the group average, including performance or contributor weighting (Budescu and Chen; Cooke, 1991; Bedford \& Cooke, 2001; Aspinal, 2010), consensus (Shanteau et al. 2002; Wang et al. 2011; Batchelder \& Romney, 1988; Batchelder \& Anders, 2012; Lee, Steyvers, de Young \& Miller, 2012; Lee, Steyvers, \& Miller, 2014) as well as subjective confidence and metacognitive judgments (Koriat, 2012; Prelec, 2004).

We will focus on the role of response agreement within subjects as an indicator for expert judgment. Previous research has shown that expert judgments tend to be more consistent over time (Einhorn, 1972, 1974) and that intrasubject reliability can be used as a proxy for expertise (Shanteau, Weiss, Thomas, \& Pounds, 2002; Weiss \& Shanteau, 2003; Weiss, Brennan, Thomas, Kirlik, \& Miller, 2009). This work has focused on the idea of highly specialized expertise and across-question consistency for tasks such as perception and categorization (Weiss \& Shanteau, 2003; Weiss, Brennan, Thomas, Kirlik, \& Miller, 2009). As opposed to previous research, we focus on tasks where expertise may be question-specific; subjects may have knowledge for some questions, but not for others, making their question level consistency more informative about their expertise than the overall domain consistency.

One challenge for using intra-subject consistency as an indicator for expert judgment is that other factors can contribute to response agreement, including decision strategies and episodic recall (Vul \& Pashler, 2008; Hourihan \& Benjamin, 2010). For example, in Vul and Pashler's experiment, subjects were prompted for a second estimate either in the same experimental session or after a delay of three weeks. The intra-subject averages were most accurate after a delay of three weeks, suggesting that subjects were less likely to simply recall the first answer after a long delay. The requirement of a long temporal delay between repeated questions to avoid episodic recall might not be practical in scenarios where subject judgments need to be aggregated over a short interval.

In this paper, we focus on rank-ordering questions where the task is to rank-order a set items such as Presidents by terms in office or US cities by population size (Miller, Hemmer, Steyvers, Lee, 2009; Lee et al. 2012; Lee, Steyvers, Miller, 2014). In contrast to simple yes/no or percentage estimation question involving single quantities, rank-ordering questions involve the retrieval and coordination of many pieces of information, making it less likely that a subject can explicitly remember a previous response. In the absence of easily available episodic strategies, subjects can be asked for a second response almost immediately after their first, eliminating the need for multiple conditions and removing any question anchoring effects.

Our contribution in this paper is threefold. First, we show that the crowd within an individual effect observed by Vul and Pashler exists for rank-ordering tasks, indicating that there is a degree of statistical independence between repeated elicitations for rank-ordering judgments. Second, we demonstrate that the agreement between the first and second response is related to each subjects' response accuracy. We present a simple consistency weighting heuristic where rank-ordering judgments from individuals that are consistent across repeated questions are given larger weight in the group average. We demonstrate that this consistency weighting heuristic significantly improves group accuracy. Finally, we introduce a new repeatedelicitation variant of a Thurstonian model for rank-ordering that has been explored elsewhere (see Steyvers et al., 2009 \& Lee et al., 2012). We compare the performance of the repeated-elicitation model and the original variant, and demonstrate that accounting for the variance in an individual's responses improves overall group aggregation performance

## Experiment

## Method

The experiment was composed of 8 rank ordering questions, and an additional 3 distracter questions; the distracter questions were included to increase the delay between subject responses. Increased delay between responses has been shown previously to increase response independence and effect size (see Vul \& Pashler, 2008). Subjects were 120 undergraduate students between the ages of 18 and 22 at the University of California, Irvine who were compensated with course credit.

Selection for the non-distracter questions was based on difficulty, as determined by the accuracy of subjects in previous experiments (Steyvers et al., 2009; Miller et al., 2011). Approximately one third of questions were selected for being easier (U.S. Holidays, U.S. Presidents, Book Release Dates), three for being moderately difficult (Country Landmasses, U.S. Cities, European Cities), and one two for being particularly difficult (10 Amendments, World Cities). All were general knowledge questions that subjects were likely to have had exposure to. For the
distracter questions, subjects were asked to rank teams for the NFL and NBA based on what they thought their final season standing would be.

Subjects were given the eight knowledge questions in a random order, and items for each question were initially placed in random positions. Subjects were then given the distracter questions. Subjects were then prompted to give responses for the eight questions again, in the same order they appeared in the first elicitation, but with a new random initial placement of the items for each question.

All questions had a ground truth obtained from Pocket World in Figures and various online sources. An interactive interface was presented via a web browser on computer screens. Subjects were instructed to order the presented items (e.g., "Order these books by their first release date, earliest to most recent"), and responded by dragging the individual items on the screen using the computer mouse and "snapping" them into the desired locations in the ordering, as in previous experiments. Transitions between question blocks were marked by a holding page reminding subjects of the instructions for the tasks. At no point were subjects informed that they would be answering the same questions twice.

## Results

Assessing Accuracy Performance was measured relative to the ground truth using Kendall's tau distance $\tau$. This metric is used to count the number of pair-wise disagreements between the reconstructed and correct ordering (lower is better). The larger the distance, the more dissimilar the two orderings are. Values of $\tau$ range from: $0 \leq \tau \leq \mathrm{N}(\mathrm{N}-1) / 2$, where N is the number of items in the order (ten for all of our questions). A value of zero means the ordering is exactly right, a value of one means that the ordering is correct except for two neighboring items being transposed, and so on up to the maximum possible value of forty-five (indicating that the list is completely reversed). An average score of 22.5 is expected for random performance.
Averaged Responses We first evaluated whether or not averaging the responses within each individual reduced the error relative to the individual responses, indicating statistically independent error of the sort observed in the simple recall tasks of Vul and Pashler (2008). Table 1 shows the median Kendall's tau distance for individual rank-ordering problems for the first and second response as well as the combined first and second response using the Borda aggregation method (see modeling section for Borda details). Subjects' error on the first and second responses were not significantly different, on average, and varied according to question difficulty. The averaged first and second responses of each subject (combined column in Table 1) was less erroneous than the first and second responses $-\mathrm{t}(120)=2.16, \mathrm{p}<.05$ and $\mathrm{t}(120)=2.87, \mathrm{p}<.01$ respectively - replicating the findings of Vul and Pashler (2008) for rank ordering tasks.

Table 1: Subject response error (Kendall's tau) across individual rank-ordering problems.

| Problems | $1^{\text {st }}$ | $2^{\text {nd }}$ | Combined |
| :---: | :---: | :---: | :---: |
| Landmass | 9 | 10 | 8 |
| Holidays | 7 | 8 | 7 |
| Presidents | 7 | 7 | 6 |
| Books | 11 | 11 | 10 |
| Euro Cities | 15 | 16 | 14 |
| US Cities | 16 | 14 | 14 |
| World Cities | 21 | 21 | 20 |
| 10 Amendments | 16 | 15 | 15 |
| AVERAGE | 12.5 | 12.7 | 11.9 |

Response Consistency and Accuracy If subject response consistency is correlated to the precision of an individual's knowledge, then multiple independent responses should be further apart from each other the less knowledgeable a subject is. We quantified (inverse) response consistency as the Kendall's tau distance between subjects' responses. Subjects with a larger distance between their first and second judgment should show a higher tau distance to the ground truth. Figure 1 illustrates this relationship separately for the first and second response. The correlation between each subject's response disagreement, and the error of their first and second responses, is $\rho=.51$ and $\rho=.55$ respectively. This correlation is observed not only across all questions, but also for each individual question. The correlation between response disagreement and accuracy appears to scale linearly with overall subject accuracy for the problem.

## Modeling

While averaging across a given individual's responses yields answers that are more accurate, the improvement is far smaller than averaging two responses across subjects (Miller et al., 2011). Given a large number of subjects, it is unclear whether repeated elicitations would improve group responses aggregation if they are merely treated as extra subjects. Can within-subject response consistency be integrated into a between-subject aggregation model to improve overall accuracy? To test this, we evaluate two models - a heuristic approach based on Borda aggregation method and a Thurstonian cognitive model of subject behavior.

## Borda Aggregation

In order to assess if incorporating within-subject response consistency can improve between-subject estimates for rank ordering tasks, we used a modified version of Borda count aggregation that incorporates subject weighting. Borda aggregation is a representative aggregation heuristic that has been used widely elsewhere (see Miller et al., 2009). In traditional Borda count aggregation, all items are assigned

Figure 1: Correlation between response disagreement and accuracy for the first answer (top panel) and second answer (lower panel).
points based upon their location in a given response: 1 point for being in position 1, 2 points for being in position 2, up to 10 points for a list of 10 items. In a standard Borda aggregation method, the points are added across all rankorderings provided by subjects and the items are ordered according to the sum totals for each item. In our modified Borda aggregation method, we add a weighting factor for each individual subject in order to upweight subjects that are more consistent. Specifically, we calculate the point total $S_{k}$ for each item $k \in\{1, \ldots, K\}$ by:

$$
s_{k}=\sum_{j=1}^{N} r_{j, k} w_{j}
$$

where $r_{j, k}$ is the rank of item $k$ for subject $j \in\{1, \ldots, N\}$, and $w_{j}$ is the weight given to subject j . As in a standard Borda method, the sums of these points for each item are then ranked from smallest to largest to determine the final Borda aggregate rank ordering

For an unweighted aggregate rank-ordering, the subject weights were set to the same value for all participants. We used this as the baseline for comparison. For the aggregate rank-ordering weighted by response consistency, we use the inverse of the tau disagreement between the first and second rank-ordering:

$$
w_{j}=1 /\left(\tau_{j}+1\right)
$$

where we add one to the distance in order to avoid zero division. Therefore, the rank-orderings of participants with larger response consistency have a stronger influence on the aggregate rank ordering.

Figure 2 shows the aggregation results. As we found previously (Miller et al., 2009), unweighted Borda
aggregation outperforms the average subject for all eight questions. Additionally, the weighted Borda model performs as well as or better than the unweighted model for all but two of the questions. The weighted Borda model performed worse for the Presidents question because most subjects performed so well that weighting over-penalized the many subjects with near-correct responses. Similarly, the model performed poorly on the European Cities question because there were so few subjects that performed well. Aggregation for the unweighted Borda model was performed across both trials so as not to give the weighted model the advantage of extra subject responses. This superior performance in reconstructing the ground truth ordering demonstrates that response consistency can be used to improve group accuracy for rank ordering tasks. Next we explore whether a cognitive model of the rank-ordering task can better describe subject behavior and more accurately reconstruct the ground truth.

## Thurstonian Model

Given that subject response consistency is clearly related to accuracy in rank-ordering tasks, what kind of mechanism might be responsible for this observed behavior? We developed a probabilistic model based upon a Thurstonian approach. In a Thurstonian representation, the latent ground truth ordering for a specific problem is represented by coordinates on an interval scale. As Figure 3a illustrates, each item $k$ is represented as a latent coordinate $\mu_{k}$ on an interval dimension. Note that this represents not the actual ground truth but the latent truth as perceived by a group of individuals. The one-dimensional representation of items is appropriate as all problems in our study involve onedimensional relative judgments (e.g. the size of items and the timing of events).

Each individual $i$ is assumed to have access to all of the ground truth latent coordinates $\mu$, but without precise knowledge about their exact locations. This uncertainty is represented with normal distributions that are centered on the shared latent ground truth locations and with a subjectlevel $\sigma_{i}$ that represents the uncertainty of the individual about the item locations. Note that for a given subject, all items have the same standard deviation which is a strong assumption but simplifies the model considerably.

As Figure 3b shows, the subject draws mental samples from these item distributions. Repeated elicitations are modeled simply by repeating the sampling process which leads to a new set of samples. The rank-ordering produced by a subject is then based on the order of the mental samples.

As illustrated in Figure 3c, different subjects can have different uncertainty $\sigma_{i}$, and this influences not only the response accuracy but also the response consistency. For example, the larger uncertainty associated with the subject illustrated in Figure 3c leads to more transposition errors in the mental samples associated with a given response - it becomes more likely that samples of nearby distributions are out of order (relative to the latent ground truth) which

Figure 2: Aggregation performance of unweighted and weighted Borda aggregation across first and second responses, compared to the average subject performance.
lowers accuracy. In addition, the larger uncertainty also leads to increased differences in orderings between different responses. Therefore, the model assumes an inherent connection between response consistency and accuracy they are both driven by a latent parameter $\sigma_{i}$ that represents the (inverse) expertise level of a subject for a particular

## a. Latent Ground Truth

## b. Ranking Items via Distributional Sampling

Figure 3: Illustration of the Thurstonian Model for repeated elicitations. (a) The latent ground truth is represented as a set of coordinates on an interval scale (b) Uncertainty about the latent ground truth is represented by Gaussian noise and responses are created by sampling latent values from each item distribution (c) Example of a subject with larger uncertainty about the ground truth and larger variability in the item samples across the first and second response
question.
This multiple-elicitation model is different from previous Thurstonian models that we have presented, where subjects only give a single response per question (Steyvers et al., 2009; Miller \& Steyvers, 2011). This extended model allows us to examine whether accuracy and response consistency can be described with the same underlying mechanism.

We apply Bayesian estimation techniques to infer the group representation from individual orderings. Figure 4 shows the Thurstonian model for a single question across subjects using graphical model notation (see Koller, Friedman, Getoor, \& Taskar, 2007; Shiffrin, Lee, Kim, \& Wagenmakers, 2008, for statistical and psychological introductions). Each node represents a model variable, and the graph structure is used to indicate the conditional dependencies between these variables. Stochastic and deterministic variables are indicated by single-and doublebordered nodes ( $\mu, \sigma, x$ and $y$ respectively), and observed data are represented by a shaded node (y). The plate represents independent replications of the graph structure, which corresponds to multiple elicitations from each individual $i$ and across individuals for each question $j$.

To explain how these data are generated, the model begins with the underlying ground truth location of the items, given by the vector $\mu$. The latent ground truth $\mu$ is given a flat prior such that all item locations are equally likely a priori. Each individual has an associated uncertainty parameter $\sigma_{j} \sim \operatorname{Gamma}\left(\lambda \sigma_{0}, 1 / \lambda\right)$ where $\lambda$ is a hyperparameter that determines the variability of the expertise levels across individuals. We set $\lambda=3$ in the current model.

To determine the order of items for the $i$ th repetition, the $j$ th individual samples a location $x_{i j k}$ for each item $k$ where $x_{i j k} \sim \operatorname{Normal}\left(\mu_{k}, \sigma_{j}\right)$. The sample $x_{i j k}$ represents the realized mental representation for the individual at that particular time. The ordering for each individual is determined by the

Figure 4: Graphical model of the Thurstonian model for repeated elicitations.

Figure 5: Aggregation performance of weighted Borda, traditional Thurstonian, and repeated Thurstonian models.
ordering of all of their mental samples $y_{i j}=\operatorname{Rank}\left(\boldsymbol{x}_{i j}\right)$.
While the generative model is relatively straightforward, the inference is challenging because the observed data $y_{i j}$ is a deterministic ranking. We utilized MCMC procedures originally developed by Yao and Böckenholt (1999), which allowed us to estimate the posterior distribution over the latent variables $x_{i j k}, \sigma_{j}$, and $\mu$ given the observed orderings $y_{i j}$. We use Gibbs sampling to update the mental samples $x_{i j k}$, and Metropolis-Hastings updates for $\sigma_{j}$ and $\mu$.

Figure 5 shows the accuracy of three aggregation models, and demonstrates that the repeated elicitation Thurstonian model performed best overall. It outperformed the weighted Borda model and also outperformed a Thurstonian model that is given both the first and second response of participants but treats the second responses as coming from a new set of participants. Additionally, the repeated elicitation Thurstonian model matched or exceeded other models' performance for each individual question.

The advantage of the repeated elicitation Thurstonian model over the Thurstonian model where the first and second responses are not linked to the same subject is not due to the fact that it has access to additional response information (it uses the same set of subject responses), but because the model simultaneously infers a subject's uncertainty based upon their disagreement with other subjects and their disagreement with themselves. In this way, we have some confidence in the Thurstonian representation of individual-level uncertainty for subject item recall, both as a generative model and as a means of yielding more accurate group estimates for rank ordering tasks.

## Conclusions

In this paper, we have shown that repeated elicitations for general knowledge rank-ordering tasks exhibit statistically independent error, and the variance of that error is correlated to the accuracy of subject responses for easy and difficult questions. Additionally, we have shown that this response consistency can be used to improve group
aggregate accuracy in reconstructing the ground truth answer for rank ordering knowledge tasks. These findings might also be applicable to tasks that do not have a known ground truth, as we have discussed elsewhere (Lee et al., 2012). Finally, we introduced a cognitive model of rankorder judgement wherein a subject-level uncertainty parameter accounted for both subject response accuracy and response consistency, and found that it was best able to capture subject behavior and reconstruct the original ground truth ordering for each of our questions. This lends credence to the idea of a combined probabilistic mechanism for consistency and accuracy underlying the subject behavior observed in these complex knowledge recall tasks.

# A Rational Constructivist Account of the Characteristic-to-Defining Shift 

Francis Mollica, Shirlene Wade, Steven T. Piantadosi<br>\{fmollica | swade | spiantadosi\} @mail.bcs.rochester.edu<br>Department of Brain and Cognitive Sciences, University of Rochester, Rochester, NY 14627 USA

#### Abstract

A widely observed phenomenon in children's word-extensions and generalizations is the characteristic-to-defining shift, whereby young children initially generalize words based on typical properties and gradually transition into generalizing words using abstract, logical information. In this paper, we propose a statistically principled model of conceptual development grounded in the trade-off between simplicity and fit to the data. We run our model based on informant-provided family trees and the real-life characteristic features of people on those trees. We demonstrate that the characteristic-to-defining shift does not necessarily depend on discrete change in representation or processes. Instead, the shift could fall out naturally from statistical inference over conceptual hypotheses. Our model finds that the shift occurs even when abstract logical relations are present from the outset of learning as long as characteristic features are informative but imperfect in their ability to capture the underlying concept to be learned-a property of our elicited features.

Keywords: characteristic-to-defining shift; concept learning; development; computational modeling

## Introduction

Children can often comprehend a word and use a word without having a full grasp of its meaning. Consider the following scenario from Keil and Batterman (1984, pp. 226): "This smelly, mean old man with a gun in his pocket came to your house one day and took your colored television set because your parents didn't want it anymore and told him that he could have it." While adults have a strong sense that the man in the scenario is not a robber, young children are willing to label the man a robber. Across multiple domains, young children have been shown to initially privilege perceptuallyobservable, characteristic information in concept learning. Eventually, children transition to more abstract, conceptually-aligned-upon meanings. This phenomena has been termed the characteristic-to-defining shift (Keil \& Batterman, 1984).

Previous research has suggested that perceptual similarity (e.g., shape) plays a strong role in young children's early word-concept mappings (e.g. Landau, Smith, \& Jones, 1988). As children age, they begin to use deeper, relational properties for concept learning (Imai, Gentner, \& Uchida, 1994; Keil \& Batterman, 1984). For example, Keil and Batterman (1984) probed kindergartners', second graders', and fourth graders' definitions for several words using a scenario task. In some scenarios, characteristic features of a term were presented without the defining features of the term; whereas, other scenarios provided the defining features of the term without the typical characteristic features associated with the term. Younger children extended a word's meaning to more scenarios lacking defining features-but possessing many characteristic features-than older children.

While the characteristic-to-defining shift is commonly observed in concept acquisition, the process by which this occurs is unclear. One possibility is that the characteristic-todefining shift is a stage-like transition that occurs in the representational system (Werner, 1948; Bruner, Olver, Greenfield, et al., 1966). For example, the shift could be explained by a transition from representing concepts wholisticallyi.e., using all the features of objects, to representing concepts analytically-i.e., narrowing in specific relevant features of objects (Kemler, 1983). Neural network models of conceptual classification inherently capitalize on this idea when demonstrating a shift (e.g., Shultz, Thivierge, \& Laurin, 2008). Another possibility is that there is a change in the mechanism by which one learns concepts. For example, concept learning might change from storing exemplars to constructing prototype or rule-based representations. These hypothetical changes in representation or processing might be maturational in nature, such as the development of abstraction (Piaget \& Inhelder, 1969). Alternately, they may be driven by inductive inference mechanisms operating over observed data, a la rational constructivism ( $\mathrm{Xu}, 2007$ ).

From the outset we can narrow down this space of hypotheses. The conceptual to defining shift is most likely a function of data, not maturation (Keil, 1983). One prediction of a maturational-shift is that at a single time-point, children should represent all words using characteristic features or defining features, whereas a data-driven shift predicts that both adults and children should have more exemplar-based representations in unfamiliar domains, and more rule-based representations in familiar domains. The former does not explain children's behavior-children seem to possess characteristic representations and defining representations of different words at a single time point. The prediction of the latterthat individuals have more exemplar-based representations in unfamiliar domains and more rule-based representations in familiar domains, is observed in adults (Chi, Feltovich, \& Glaser, 1981) and in children (Chi, 1985).

All of the aforementioned hypotheses require a discrete shift in representation or process. However, it is unclear whether a representational or mechanistic shift is entirely warranted. To date, no model has tested whether a characteristic-to-defining shift could be a natural by-product of the continuous data-driven construction of concepts. We evaluate this proposal in the task of learning kinship concepts. While "mommy" and "daddy" are some of a child's earliest produced words, children actually spend many years mastering kin relations (e.g. Haviland \& Clark, 1974; Benson \& Anglin, 1987; Keil \& Batterman, 1984). For example, 7- and 8 -year-olds are still unable to provide adequate definitions for
a number of kinship terms (Haviland \& Clark, 1974).

## The Acquisition of Kin Terms

Kinship is an ideal domain for studying the characteristic-todefining shift because it easily lends to logical representations (e.g. Kemp \& Regier, 2012); the domain of kinship is familiar to young children; and the characteristic and defining features behind kinship terms are fairly intuitive and straightforward. Furthermore, several semi-structured interviews attempting to uncover children's knowledge of kinship demonstrate considerable variation in children's definitions. For example, the following is an interview with a six-year-old from Benson and Anglin (1987, p. 48):

I: What is an uncle?
S: A man that's related to ya.
I: Tell me everything you know about an uncle.
S: He knew you when you were a baby...Sometimes they work to build houses... Sometimes they join in for the army.
I: Can you tell me anything else about an uncle?
S: They help you. That's all I know.
I: What kind of a thing is an uncle?
S: A man that's related to you.
Based on children's definitions, researchers have proposed theories weighing the importance of conceptual simplicity (Haviland \& Clark, 1974) and the role of sufficient data (Benson \& Anglin, 1987) in the acquisition of kinship terms. To explain the order of acquisition of kinship terms, Haviland and Clark (1974) proposed a semantic complexity hypothesis. In this account, the simplicity of a concept is defined as the fewest number of base relations (e.g., up one node on the family tree) required to explain a relationship on a kinship tree with a penalty on the variety of base relations used. Children use these base relations to build concepts in a piecewise fashion. By this logic, adult-like kinship concepts are acquired for semantically simpler terms before semantically complex terms. Haviland and Clark (1974)'s original hypothesis is a learning model whereby children first develop perceptual features to construct a concept and only over time develop abstract, relational features. This formalism is entirely consistent with the formalisms used in Mollica and Piantadosi (2015), which we also adopt and describe below. Furthermore, simplicity, in general, is an empirically grounded principle underlying concept construction (Feldman, 2000). More specifically, the role of simplicity and communicative efficiency in kinship terms has been demonstrated across a variety of the world's languages (Kemp \& Regier, 2012).

In addition to simplicity, researchers have proposed that the amount and quality of the observed data drive word learning and conceptual development both in kinship (Benson \& Anglin, 1987; Danziger, 1957) and in other domains (e.g., Weisleder \& Fernald, 2013). For example, Benson and Anglin (1987) found that the order of acquisition of kinship terms was best predicted by children's experience with their relatives. In his rejection of stage theories, Danziger (1957) proposed that conceptual development is primarily driven by opportunities provided by the environment. To account for the influence of data, we incorporate assumptions about plausible data distributions in our model. Further, we trade off
the influence of data with semantic complexity by placing a simplicity weighted prior against a data-driven likelihood.

## Our Approach

We approach this problem at the computational level of analysis (Marr, 1982) to demonstrate how an ideal learner would manifest a characteristic-to-defining shift. We start with the model of Mollica and Piantadosi (2015), which demonstrates how a learner could use cross-situational word-referent occurrences to infer the concept that licenses how a word should be extended. We extend the Probabilistic Context-Free Grammar (PCFG) in their model to construct both characteristic and defining hypotheses for kinship terms. We then collected data about the characteristic and logical relationships from two naive informants' own family trees. This is important because the characteristic and logical relationships of real people allows us to test if natural data will contain perceptual and experiential features informative enough to observe a characteristic to defining shift. We ran the model on the informant-provided trees and a simulated tree to generate possible characteristic and defining hypotheses for four kinship concepts: BROTHER, GRANDMA, MOTHER and UNCLE. These hypotheses were then scored using Mollica and Piantadosi (2015)'s Bayesian model according to their simplicity and ability to explain simulated word-referent data. We analyzed (1) whether an ideal learner is most likely to entertain characteristic or defining hypothesis given an amount of data and (2) the accuracy of the hypotheses in explaining the data as a function of the amount of data observed.

We expect that an ideal learner (without any maturational factors) should demonstrate a characteristic-to-defining shift only if the elicited features (both perceptual and experiential) are informative but imperfect in their ability to capture the underlying concept. If the elicited features accurately capture a concept, an ideal learner should never shift from generating characteristic hypotheses to defining hypotheses. On the contrary, if the elicited features are uninformative, and thus poor at capturing a concept, an ideal learner might predominately generate defining hypotheses, predicting either no shift or an implausibly rapid shift from characteristic to defining hypotheses. Therefore, it is crucial that we collect data about the characteristic and logical relationships of real people to test if natural data will contain features within the range of informativity that will show a characteristic-to-defining shift.

## Data Collection

To simulate data for the learning model, two informants, who were blind to the experiment, drew their family tree, ranked each member in terms of how frequently they interacted with them as a child (e.g., see Figure 1), and provided ten oneword adjectives for each family member. For each informant, the unique adjectives were used to construct a binary feature matrix (adjective by family member; e.g., see Figure 2). Each informant was presented with the feature matrix and asked to indicate if each feature applied to each family member. Informants made a response to every cell of the matrix: zero if

Table 1: The Probabilistic Context Free Grammar used to generate kinship concepts
the feature did not apply; one if the feature did apply. The informants provided 109 and 88 unique features respectively including both experiential features (e.g., strict) and perceptually observable features (e.g., blonde). Additionally, we simulated data from the extended family tree used in Mollica and Piantadosi (2015). To sample from the extended tree, we ranked distance using Euclidean distance and constructed a feature matrix for the tree based on 29 perceptually observable features following the principles of Mendelian genetics ${ }^{1}$.

## Extending the model

The model incorporates a PCFG prior with uniform rule probabilities to measure the simplicity of any composition of logical or perceptual features. In the PCFG (see Table 1), we include set theoretical primitives-i.e., union, intersection, set_difference and complement-for both characteristic and defining hypotheses. For defining hypotheses, we include gender primitives-i.e., male and female-and graph theoretical primitives that mimic the abstract primitives proposed by Haviland and Clark (1974): up_node, down_node and lateral_node. The terminal for a defining hypothesis is an argument for the speaker $X$, as we assume that the kinship term should be processed relative to the speaker. For characteristic hypotheses, we include a primitive for each feature, which takes a binary indicator variable and returns the set of family members with or without that feature. Using a PCFG as a prior penalizes complex hypothetical meanings and, thus, builds in a simplicity bias as discussed above. It is important to note that our PCFG generates characteristic hypothesesi.e., only containing characteristic information, and defining hypotheses-i.e., only containing logical information (and gender). We leave the exploration of a hybrid characteristicdefining hypothesis space for future research.

Data for the learning model was noisily sampled from a

[^134]family tree such that $90 \%$ of the time the data reflected accurate use of the true concept and $10 \%$ of the time the data was entirely random. To construct a data point, which took the form of a speaker-referent pair $\{s, r\}$, we first sampled a speaker $s$ from a Zipfian distribution over all members of the family tree ordered by reported distance from the learner. Consequently, data from speakers ranked closer in distance to the learner were more likely to be sampled than data from speakers ranked distant to the learner, which is in line with the intuition that most input a child receives comes from her immediate family. We then sampled a referent $r$ from the Zipfian distribution conditioned on the speaker and word. Given all possible referents the speaker could be correctly referring to when using the word, referents that are closer to the learner are more likely to be talked about than the learner's more distant relations. This reflects the intuition that a child is more likely to hear about her immediate family than distant relatives. Both intuitions are supported by Benson and Anglin (1987)'s survey of children's experience with kinship terms and relations. During learning, we compute the likelihood of the data under the same model used to simulate the data.

Together the prior and the likelihood specify a model for all possible hypotheses constructed from the PCFG:

$$
\begin{equation*}
P\left(h \mid\{s, r\}_{i}^{N}\right) \propto \prod_{i}^{N} P\left(r_{i} \mid s_{i}, h\right) \cdot P(h) \tag{1}
\end{equation*}
$$

With this model we can score the probability of a hypothesis conditioned on simulated data. We then investigate the conditions under which a characteristic-to-defining "shift" will naturally emerge as children learn kinship concepts without positing discrete change.

## Methods

Discovering the most likely hypotheses considered by an ideal learner according to Equation 1 is a complex inference problem because the PCFG specifies an infinite set of possible hypotheses. We solved this problem with Markov-Chain Monte-Carlo (MCMC) methods, which provided us with samples from the posterior distribution by walking around the space of hypotheses. In the limit these walks provably draw samples from the true posterior distribution $P\left(h \mid\{s, r\}_{i}^{N}\right)$. We implement our model using LOTlib (Piantadosi, 2014).

At different amounts of data, we expected an ideal learner to favor different hypotheses. Therefore, we explored the space varying the amount of data between 10 data points and 250 data points by 10 point increments. At each increment of data, we ran eight chains per hypothesis type for one million steps. We stored the top 1000 hypotheses from each chain and combined the hypotheses discovered across chains to form a finite hypothesis space representing the posterior distribution over hypotheses. We normalized all hypotheses by calculating the likelihood over the same set of 1000 data points generated using the same procedure used to generate data for individual chains. We then divided this value by the amount of data (i.e., 1000) to get a measure of each hypothesis' average log likelihood per data point.

## Results

The upper panels of Figure 4 show the posterior probability of entertaining either a characteristic or defining hypothesis ( y -axis) as a function of the amount of data observed ( x -axis). For all of the words, we observe the characteristic-to-defining shift-i.e., the probability of entertaining a characteristic hypothesis is initially greater than the probability of entertaining a defining hypothesis. This means that a simple conceptual learning model shows a characteristic-to-defining shift when given real data about logical relations and characteristic features.

The lower panels of Figure 4 show the posterior weighted $F_{1}$ score conditioned on hypothesis type (characteristic or defining). The $F_{1}$ score is the harmonic mean of precision (i.e., the pressure to extend without over-extending) and recall (i.e., the pressure to extend to all the correct referents). An $F_{1}$ score of 1 reflects perfect performance. Notably in Figure 4, the model successfully learns BROTHER, GRANDMOTHER, and MOTHER-i.e., posterior weighted $F_{1}$ scores all reach 1. With 250 data points, the model does not successfully learn UNCLE yet there still is a shift from characteristic to defining hypotheses on a larger timescale ${ }^{2}$ (Note the $x$-axis in the upper panels).

To help build intuitions about how the model works, Figure 3 presents the three most likely hypotheses an ideal learner trained on Informant One's data would consider for GRANDMA at three time points. Before observing data, an ideal learner should prefer the simplest hypotheses, which often generalize to many referents. In this example the three most likely hypotheses are defining hypotheses that select the speaker $X$, a male speaker and everybody but the speaker. After observing three data points, the hypotheses considered become much more plausible and shift to characteristic features. At this time, the three best hypotheses for grandma are that grandmas are either outgoing, nosy or small. In general the model is shifting from simple hypotheses that generalize broadly to hypotheses that narrow in a bit more, yet still over-extend. Immediately post-shift (i.e., 13 data points), we observe a mixture of characteristic and defining hypotheses. The best hypothesis is the speaker's parents' parents, which misses the female component of GRANDMA. The next best hypothesis is that grandmas are outgoing. The third best hypothesis is actually the definition of a GRANDMA-i.e., the female parents of the speaker's parents. This glimpse at the hypotheses just after the shift illustrates that without a sufficient amount of data, even the correct hypothesis is unlikely because it is more complex in the prior. As we observe more data, the imprecision of the two leading hypotheses decreases

[^135]their posterior probability relative to the correct hypothesis, which will make the correct hypothesis the maximum a posteriori (MAP).

The range of hypotheses are similar between the different trees. Across all trees, characteristic hypotheses have very low posterior weighted $F_{1}$ scores compared to the defining hypotheses. In other words, characteristic hypotheses mislabel referents more than defining hypotheses. Yet, the posterior probability of characteristic hypotheses suggests that characteristic hypotheses are clearly favored at low amounts of data. Given the perspective that the emergence of defining hypotheses is delayed due to the development of abstraction, it is particularly important to note that even in a model with abstraction available from the beginning, we observe a characteristic-to-defining shift. Further, compared to a neural network model where all features are initially considered (Shultz et al., 2008), a characteristic-to-defining shift is still observed in our model where it is initially more likely to only consider only a few features.

Taken together, this pattern of results demonstrates that the characteristic-to-defining shift could naturally fall out of a single statistical inference process with a single representational language ${ }^{3}$. It is not necessary to propose a discrete change in representation or processing. Characteristic hypotheses are favored early because with little data the prior dominates inference-they generalize well to small data amounts and are comparatively less complex in the prior than the best defining hypotheses. Only when there is enough data to warrant additional complexity will defining hypotheses come to dominate inference.

## Discussion

In this paper, we tested whether a characteristic-to-defining shift would emerge naturally in a statistically principled learning model without positing a discrete mechanistic or representational shift. In general, the model successfully learns kinship terms and demonstrates a characteristic-to-defining shift using a single representational language of thought and a single statistical inference mechanism. Therefore, while a discrete shift in mechanism or process is possible, it is not necessary to observe a characteristic-to-defining shift during concept learning.

In our model, kinship concepts are developed through statistical inference over word-referent data and observed kinship structures, which could plausibly be developed from statistical learning of structure (Katz, Goodman, Kersting, Kemp, \& Tenenbaum, 2008; Kemp \& Tenenbaum, 2008). When an ideal learner only observes data about a few referents, there are simple characteristic hypotheses based on perceptual observations that will explain the data; however, as more data is observed, these hypotheses fail to adequately fit the data and warrant a prior-likelihood trade-off, such that more complicated defining hypotheses (which are unlikely

[^136]Informant One
(109 features; 31 family members)

(29 features; 37 family members)

Figure 4: For each tree, the top panel displays the posterior probability of using a characteristic (solid line) or a defining (dashed line) hypothesis as a function of the amount of data observed. The bottom panel displays the posterior weighted $F_{1}$ score conditioned on hypothesis type (characteristic as solid line, defining as dashed line) as a function of data.
in the prior) are substantially more likely in explaining the data and thus come to dominate the posterior. Put simply, the characteristic-to-defining shift can be a by-product of datadriven learning.

There are two interesting implications/predictions of our model. First, our model predicts that the ideal learner will shift from characteristic to defining hypotheses even when she is capable of using abstraction from the outset of learning. This suggests that characteristic hypotheses may be useful, and that the observation that children accept and generate characteristic hypotheses at a young age does not preclude their ability to use abstraction or generate logical/defining hypotheses. Second, our model predicts that if there is a characteristic-to-defining shift, the relevant characteristic features should not capture a concept as well as defining features capture the concept; however, in order for a characteristic-to-defining shift to occur, the characteristic features must be informative to a certain degree. If characteristic features are completely uninformative, defining hypotheses should dominate across all amounts of data.

In our initial stab at the problem, we have made several simplifications. For one, the grammar generated hypotheses to be purely characteristic or purely defining. This simplification is reasonable given how adults would extend a kinship term. For example, if you meet a friend's family for the first time at a neighborhood BBQ, you would presumably extend the term uncle to their parent's male siblings and not the neighbors, who might share several characteristic features with your friend's uncles. This is not to say that competent adult speakers do not maintain characteristic information about kinship terms (e.g., grandmothers are typically nice, old ladies). In the same vein, our characteristic and defining features did not share the same formalism (i.e., feature matrices vs. graph-theoretical functions). A future version of the model should permit characteristic and defining primitives within the same hypothesis and possibly within the same formalism (e.g., a feature matrix containing both characteristic and defining features). This model should also be extended beyond the kinship domain. Lastly, the model is sensitive to the structure of the PCFG in determining the prior. Further research should characterise the robustness of the model to variation in the prior.

## Conclusion

In summary, the widely observed characteristic-to-defining shift falls out naturally from a rational data-driven process. Our simulations show that a data-driven inference mechanism (1) demonstrates a characteristic-to-defining shift in the task of concept learning without positing a change in cognitive representations or processes and (2) succeeds at learning most kinship words from a data distribution based on natural language statistics. We find that an ideal learner will demonstrate a shift even when more accurate abstract/logical representations are possible from the onset of learning provided that characteristic features are informative but imperfect in
their ability to capture the underlying concept. While we address the problem of concept learning within the kinship domain, the model framework can be extended to explain concept learning across multiple domains using different representational formalisms.

# An incremental information-theoretic buffer supports sentence processing 

Francis Mollica, Steven T. Piantadosi<br>\{mollicaf | spiantado\} @gmail.com<br>Department of Brain and Cognitive Sciences, University of Rochester, Rochester, NY 14627 USA

#### Abstract

People have the capability to process text three times faster than they would naturally read it, yet many current theories of sentence processing rely on natural reading times as a proxy for processing difficulty. How can people read material so quickly in spite of information processing limitations suggested by sentence processing theories? One possibility is that surprisal effects on reading time, the hallmark of processing difficulty under sentence processing theories, might arise from perceptual processing, implying no relation between surprisal and sentence processing difficulty. In this paper, we conducted a novel self-paced rapid serial visual presentation (RSVP) experiment, which controlled perceptual processes to probe for sentence processing related surprisal effects. We further tested how readers might compensate for information processing limits during RSVP. We find support for sentence processing related surprisal effects, the pattern of which is consistent with a First-In, First-Out (FIFO) buffer model.

Keywords: language processing; linguistic memory; RSVP

## Introduction

One of the remarkable feats of language processing is the quick pace at which various forms of information are seamlessly integrated (e.g., Tanenhaus, Spivey-Knowlton, Eberhard, \& Sedivy, 1995). Researchers have noticed that language can be processed much faster than how we naturally engage with it (e.g., Potter, 1984). For example, by presenting text faster than the human eye would naturally fixate, people are able to read a story $3-4$ times faster than natural. These observations have led to several apps training people how to read faster-although the efficacy of these apps has been contested (see Rayner, Schotter, Masson, Potter, \& Treiman, 2016). Even though researchers have noted that information processing in reading is faster than people's natural reading pace, psycholinguistics has relied upon the assumption that natural reading times are a reflection of processing difficulty. Using reading time as an index of processing difficulty has provided the data behind several theories in sentence processing (e.g., Grodner \& Gibson, 2005; Levy, 2008). Recently, this assumption has been formalized in terms of information theory: words that carry more information tend to increase reading times relative to words that contain less information, suggesting a fixed processing rate that is measured in bits of information per unit time (e.g., Hale, 2001; Levy, 2008). The amount of information conveyed by a word, colloquially referred to as surprisal, is equal to the negative $\log$ probability of the word given its context.

Given the importance of reading times as a measure of processing difficulty, it is surprising that people can read several times faster than they naturally would and it poses a very important question: Are the effects of surprisal observed in reading times reflective of linguistic information processing
limitations, or do they arise from some alternate perceptual process? We conducted a novel rapid serial visual presentation (RSVP) experiment in which we controlled perceptual processing to test if surprisal effects reflect language processing. Our experiment was also designed to probe how readers might be compensating for linguistic information processing limits when faced with rapidly presented text. Specifically, we consider two hypotheses that would reconcile information processing limits with rapid presentation of text. First, language users might suspend incremental information processing to store information in a buffer, until it can be processed. Given the quick response times in RSVP experiments, this would suggest fast rates of information processing, giving us real reason to check our assumption that reading time is a valid measure of sentence processing difficulty. Second, language users might compensate for RSVP by utilizing an incremental First-In, First-Out (FIFO) memory buffer, where information is immediately copied into a buffer and processed out of the buffer at a fixed rate. Many researchers using the RSVP paradigm have proposed the use of a buffer (e.g., Mitchell, 1984); however, buffer models have never been formalized in terms of information processing. In the remainder of the introduction, we motivate the perceptual and linguistic sources of surprisal effects and our buffer models.

## Perceptual Information Maintenance

When the reader manages visual presentation time, it is unclear if we see surprisal effects because readers maintain the visual input while they are syntactically processing the word or if we see surprisal effects for perceptual processing reasons. For example, both Bayesian models of word identification (Norris, 2006) and rational models of eye movements in reading (Bicknell \& Levy, 2012) posit that readers maintain information until they reach a level of confidence in a word's identity, resulting in log effects of word predictability-i.e., numerically the same value as surprisal. This hypothesis is corroborated by work on individual differences in eye-tracked reading that demonstrate a relationship between word-identification ability and reading speed (Kuperman \& Van Dyke, 2011). In our experiment, we control for a perceptual explanation of surprisal effects by using RSVP, which prohibits readers from influencing presentation time. Importantly, the same processes underlying natural reading are still thought to be at play in RSVP (Potter, 1984). Therefore, if surprisal effects were a result of readers maintaining the visual input until they were confident in the word's identity or had finished syntactically processing the word, we would expect that RSVP would eliminate all surprisal effects.

Figure 1: In 5-RSVP, each word is presented for 147 ms and immediately masked by the next word. The last word in each 5 word chunk is masked with random lowercase letters remaining until the participant presses a button to continue.

## Linguistic Information Processing Limits

One of the foundational questions in sentence processing research is how do people construct the correct syntactic parse for a sentence. As mentioned above, the primary method for teasing apart sentence processing theories is making predictions about processing difficulty for the constituent words of a sentence. Information theory has provided one way to formalize the amount of processing required for each word in a sentence. Hale (2001) first noticed that word reading times are proportional to the total probability of all syntactic structures that are no longer possible after observing a word, which happens to be the word's surprisal. Levy (2008) showed that surprisal can be given an alternative interpretation in terms of parallel-resource allocation. As each new word is processed, the syntactic parses under consideration are re-ranked and resources are allocated accordingly. The processing difficulty of that word is reflected in the amount of re-ranking required as measured by Kullback-Leibler divergence, which simplifies to the word's surprisal. Either way, a word's surprisal is a measure of the amount of processing, and surprisal effects in reading suggest processing difficulty caused by information processing limits. In our experiment, we have controlled for a perceptual origin of surprisal effects so that if we still see surprisal effects, we can be more confident in interpreting them as stemming from language processing.

If surprisal effects reflect information processing limits, the contradiction between readers being capable of reading rapidly presented text but possessing hard information processing limits still remains. Our novel five word self-paced RSVP task presents text in five word RSVP chunks for each button press (see Figure 1), allowing us to consider two hypotheses that would reconcile these observations. First, readers might focus on buffering linguistic information during rapid presentation and delay processing until the perceptual barrage has ended. Under this account, we would expect a small uniform profile of surprisal weights for each of the five words presented together (see middle panel of Figure 2). In RSVP tasks, readers only require a one second break between sentences to perform as well as control groups in recall tasks (Potter, 1984), which suggests an information processing rate roughly 100 bits/second ${ }^{1}$. This rate is too fast to predict sur-

[^137]

Figure 2: Predicted surprisal weights (beta values for surprisal) in the 5-RSVP task as a function of word position for our hypotheses.
prisal effects at naturalistic reading paces, which makes this an important hypothesis to rule out for expectation based sentence processing theories.

Second, readers might incrementally process linguistic information, but perception and language processing might not be as tightly coupled as previously thought. Perception might quickly place information into a buffer, where language processing then removes that information at a slower rate, but still very quickly. This allows perception to move ahead while language processing is ongoing. In this FIFO buffer model, the expected profile of surprisal weights depends on the rate of information processing. Roughly, the model yields three different profiles of surprisal weights (see Figure 3). At slow rates of information processing, multiple words will be seen before the processing of the initial word has ended. As a result, the majority of processing time for all of the words is reflected in reading time post visual presentation, which gives rise to a large uniform profile of surprisal weights. At rates of information processing closer to the average amount of information conveyed in a word, sometimes a word is completely processed before the next word appears and sometimes a word's processing briefly carries over to when the next word appears. As a result, early words contribute less to post-presentation reading time than later words, and the profile of surprisal weights increases with a word's presentation position. At fast rates of information processing, each word is completely processed before the next word appears. Therefore, there should be no influence of surprisal on postpresentation reading time, corresponding to a uniform zero profile of surprisal weights. Our a-priori prediction for the FIFO buffer assumed a rate of processing near the average amount of information (see right panel of Figure 2).

It is important to note that the FIFO buffer model shows the traditional surprisal effect with the rate of information processing parameter. The profile of surprisal weights in the FIFO buffer model do not necessarily reflect processing difficulty as in the typical surprisal effect; rather, the surprisal weights reflect each word's contribution to the information remaining in the buffer post-presentation.

## Experiment

Our plan of attack is to see if surprisal effects are present in a masked word-by-word self-paced reading (mSP) task and a novel 5-word chunk self-paced RSVP task (5-RSVP), which holds perceptual information constant but allows the reader unlimited time to process their input. As a result of the per-

[^138]

Figure 3: Predicted surprisal weights from an incremental FIFO buffer model for each word position (w1-w5) as a function of information processing rate. At slow rates, there is a large uniform surprisal effect. At very fast rates, there is no effect of surprisal. In the middle, surprisal weights increase as a function of their position in a chunk.
ceptual controls, we can interpret an effect of surprisal as reflecting linguistic information processing limits. Further, if there is an effect of surprisal, the profile of surprisal weights for each word in the 5-RSVP condition can distinguish between two hypotheses reconciling readers' ability to read rapidly presented text in spite of incremental processing limits (see Figure 2). Specifically, a uniform profile of surprisal weights would suggest a buffer model in which readers suspend incremental linguistic processing until after presentation ends. Whereas, a profile of surprisal weights that increases as a function of a word's position in the five word chunk would suggest a a FIFO buffer model (formalized below). In addition, participants completed a self-paced reading task (SP) to replicate the standard surprisal effect with our materials. Participants also read an additional story at their natural pace to provide a baseline accuracy and reading rate, which ensured our presentation rate was faster than our participants natural reading rate.

Participants. Sixty-four participants were recruited from the University of Rochester community. Participants were compensated for their participation, which lasted approximately 45 minutes. All participants were screened for normal or corrected-to-normal vision, and English as their native language.

Materials and Design ${ }^{2}$. Participants read four excerpts from articles published in 2008 issues of The New Yorker. To equate the length of the excerpts while preserving the naturalness of the reading material, articles were truncated to end with the paragraph containing the $1000^{\text {th }}$ word of the article. Word frequency and bigram probabilities with Laplace smoothing ( $\alpha=0.1$ ) were estimated using ZS (Smith, n.d.) to access Google N-grams (Michel et al., 2011). For each story, ten yes-no questions were constructed (5-yes, 5-no) to serve as a comprehension check. Four lists were constructed such that each list contained a story in every presentation con-

[^139]dition (Baseline, SP, mSP and 5-RSVP) and across lists each story occurred with every condition. To ensure precise presentation timing, stimuli were presented using a monitor with a 144 Hz refresh rate. Responses and reading times were collected using the keyboard. Stimulus presentation and timing and response collection was controlled by Psychopy (Peirce, 2007).

Procedure. Sixteen participants were randomly assigned to each list. Participants were told that they would be reading and answering questions about four short stories. All participants began the experiment with the baseline reading condition. In the baseline condition, the full body of text for one story was displayed on the screen in 17.5 point Free Sans Bold font. Participants could scroll through the text using the up and down arrow keys. Participants were instructed to press the space bar when they had finished reading the text, which started the comprehension check.

Following the baseline reading task, participants were introduced to the mSP condition with three practice trials. On the first trial, each word was presented in the center of the screen for 245 ms and then immediately masked with a random string of 14 lower-case letters. Participants were instructed to press the space-bar to reveal the next word. For the next two practice trials, the presentation duration of each word was decreased to 196 ms and 175 ms , respectively. Before each trial and story, a fixation cross appeared for 147 ms to orient the participant to the center of the screen. After the practice trials, the order of the remaining conditions was randomized for each participant.

In the SP condition, text was presented similar to the practice trials with one exception: each word was not masked and remained visible to the participant until they pressed the space-bar to advance. In the mSP condition, text was presented similar to the practice trials, except the duration for each word was set at 147 ms . In the 5-RSVP condition, each button press triggered the presentation of the next five words in the text. Each word was flashed on the screen for 147 ms . The first four words were masked by the next word's appearance. The fifth word was masked by a 14 character lowercase letter string.

After each story, the comprehension check for that story began immediately. For each of the ten questions, participants registered their answer by pressing the Y (yes) or N (no) key on the keyboard, which prompted the next question. The order of the questions was randomized for each participant. After the comprehension check, participants were instructed to find their experimenter to advance to the next story. Participants were strongly encouraged to take breaks in between stories and often did. In line with our experience and intuitions, our participants reported that reading in these presentation conditions is taxing ${ }^{3}$.

B

Figure 4: A. Average participant accuracy across presentation conditions. B. Surprisal weights from a linear mixed-effect regression of reading time in the SP, mSP and 5-RSVP conditions (as a function of each word's order in the 5-RSVP condition). Red diamonds represent the FIFO buffer model predictions with a best fit rate of $123 \mathrm{bits} / \mathrm{sec}$. All intervals reflect $95 \%$ bootstrapped confidence intervals.

## Results

To check that our presentation rate of $147 \mathrm{~ms} /$ word was less than participant's natural reading rate, we calculated each participant's average reading time per word in the baseline condition. The mean and median natural reading rate was 300 $\mathrm{ms} /$ word (SEM=11). Three participants had average natural reading rates faster than $147 \mathrm{~ms} /$ word, we retained their data in the remainder of the analysis ${ }^{4}$. Accuracy data was analysed using a mixed effect logistic regression with random intercepts for participants, item, story and list. Across all conditions, participant accuracy was on average greater than chance ${ }^{5}$ (see Figure 4A). The baseline accuracy was $74 \%$ suggesting there was no ceiling effect. In the mSP and 5RSVP conditions, accuracy was significantly lower than baseline; however, the effect size is small ( $\mathrm{mSP} O R=0.70$, 5 RSVP $O R=0.48$ ). To account for spurious button presses and abnormally long reading times, we removed the top and bottom $2.5 \%$ of the reading time data for each participant, resulting in a $5 \%$ data loss overall.

We analysed the reading times for each condition separately. With the SP condition, we aimed to replicate the effect of surprisal reported in the literature when presentation is central and perceptual information management is still in the reader's hands. Reading times were analysed using a mixed effect linear regression with surprisal, log frequency, zero-centered length, and position as fixed effects and random intercepts for participant and story. Replicating the prior literature, there was a significant increase in reading time as surprisal increased ( $\beta=0.54, t=4.60, p<0.05$ ).

With the mSP condition, we aimed to test if there would be an effect of surprisal when perceptual information management is no longer in control of the reader. Reading times were analysed using a mixed effect linear regression with the same effect structure as in the SP condition. Even though perceptual control was removed from the reader, there was a significant increase in reading time as surprisal increased ( $\beta=1.24, t=8.60, p<0.05$ ), suggesting that there are sentence processing related surprisal effects without perceptual

[^141]control.
Having observed a surprisal effect in mSP, we analyzed the 5-RSVP condition to tease apart whether readers compensate for information processing limits during rapid presentation by buffering information and suspending information processing entirely-resulting in a uniform non-zero profile of surprisal weights, or by incrementally buffering and processing linguistic information-resulting in an increasing profile of surprisal weights across subsequent words. To test these hypotheses, we fit two mixed effect linear models: one with a single beta weight for surprisal and one with a unique beta weight for each word's surprisal. Both models contained random intercepts for participant and story and fixed effects for zero-centered length, position and a frequency term for each of the five words presented in a chunk. We find a significant surprisal effect in both models (single beta model: $\beta=0.73, t=3.93, p<0.05$ ), which suggests that the observed surprisal effects are reflective of language processing. As can be seen in the profile of the individual beta weights for surprisal in Figure 4B, the profile is more consistent with a non-uniform profile of weights than the uniform profile $\left(\chi^{2}(4)=11.7, p<0.05\right)$.

## First-In, First-Out (FIFO) Buffer Model

To further explore the idea of an incremental linguistic information buffer, we formalize a FIFO buffer model with one free parameter, i.e., the rate of information processing, and fit the model to our data to provide us an estimate of the rate parameter. Our model operates in five 147 ms windows matching our presentation duration for each of the five words. In each window, the new word's information is added to the buffer, and the amount of information that could be processed in that window according to our rate parameter is removed from the buffer. As a result, if a word could not be completely processed in one window, its processing carries over to the next window. If all the information in the buffer is processed, the buffer is empty when the next word appears. The information left in the buffer after the fifth word's window is the information whose processing should contribute to our measured reading time. We use the rate of information processing to predict the expected reading time for that five word chunk. We repeat this process for every chunk in our stories. To arrive at predictions for the surprisal weights, we analyse
our expected reading times using linear regression with separate surprisal weights for each of the five words. We do not include an intercept value as we expect the entire reading time to be a function of each chunk's surprisal values. Predicted surprisal weights for a variety of processing rate parameters are shown in Figure 3. Our a-priori prediction was that surprisal weights should increase across word positions, as early words will tend to be fully processed so that later words have a larger effect on post-presentation reading time. As can be seen in Figure 3, our a-priori prediction holds true for a large range of plausible rate parameters.

We fit our buffer model to the observed pattern of surprisal weights using gradient descent to minimize squared error. We find that the best fit rate of information processing is 121 bits/second. The best model fit profile of surprisal weights is illustrated in Figure 4B as the red diamonds.

## Discussion

To address the apparent contradiction between the speed at which readers can comprehend text and the information processing limits proposed by sentence processing theories, we suggested that surprisal effects observed in reading tasks might actually be a result of perceptual processing (e.g., Norris, 2006) rather than linguistic information processing. If this were the case, we would expect to see no surprisal effects in the mSP and 5-RSVP conditions, where perceptual control was stripped from the reader. Instead, we found effects of surprisal, suggesting that surprisal effects in RSVP reading have a language processing origin.

Having established the existence of an information processing bottleneck in RSVP, we proposed two possible alternatives ${ }^{6}$ that reconcile information processing limits and rapid text comprehension. First, readers may compensate for RSVP by postponing information processing until presentation has ended to ensure all the input is copied into a buffer. Under this account, we would expect a small uniform profile of surprisal weights in our 5-RSVP condition. Second, readers may compensate for RSVP by incrementally buffering and processing linguistic information, allowing perceptual processing and information processing to occur on quick but separate timescales. Our a-priori prediction for the FIFO buffer, in line with the best fit prediction from our model, was that early words should contribute less to the postpresentation reading time than later words, resulting in an increasing profile of surprisal weights in our 5-RSVP condition. As can be seen in Figure 4B, the data are more consistent with the predictions of a FIFO incremental buffer model, suggesting that surprisal effects are present in RSVP and readers compensate for the rapid presentation of text by incrementally buffering and processing linguistic information.

While our experiment was designed to control for a perceptual origin of surprisal effects, it also rules out two deci-

[^142]sion/motor origins. First, surprisal effects would be expected under Hick (1952)'s law if for each word, readers were choosing the identity of the word from multiple alternatives. Presumably, such decision processes would be disrupted by our 5-SP-RSVP condition. Second, the programming of saccadic eye movements is related to the log predictability of the target (Carpenter \& Williams, 1995). RSVP and central presentation would not require eye movements nor provide sufficient time to plan them. It is unclear if our experiment rules out the optimal preparation model of Smith and Levy (2008), which predicts surprisal effects. To summarise their argument, people respond faster to expected events and slower to unexpected events, suggesting that they are preparing for future events according to their predictability. If this finding holds true for all levels of linguistic processing-i.e., under a scale free assumption, the effect of predictability must be on a $\log$ scale so as to satisfy the multiplicative nature of joint probabilities with the additive nature of reaction times. As a result, if a word is optimally prepared for, its processing time should be a multiple of its surprisal. Unfortunately, the model does not specify if there is a time cost to preparation or minimum required preparation time. If there is a cost to optimal preparation, our experiment might not have provided sufficient time to prepare. Similarly, the predictions of Smith and Levy (2013)'s highly incremental processing account of surprisal are unclear for our experiment.

Our results have several implications for sentence processing research. First, even with a linguistic information buffer the best fitting rate of information processing is large-i.e., $121 \mathrm{bits} / \mathrm{sec}$, which corresponds to a word processing rate of 12 words $/ \mathrm{sec}$. This rate is consistent with the upper limit on comprehension in RSVP tasks (Potter, 1984). Interestingly, even under the suspended processing buffer model the rate of information would be large ${ }^{7}$. So if readers are processing information at such a fast rate, why do surprisal effects show up at all in natural reading tasks? One possibility is that even though readers can process information at these rates, they might prefer to maintain the information they are processing before proceeding. Whether this processing is perceptuali.e., waiting for some level of certainty in the percept of the word, linguistic-e.g., parallel resource allocation in syntactic parsing, or optimal preparation is still an open question, with the important implication that surprisal effects in natural reading times might not be a measure of syntactic processing difficulty. Another important possibility is that rate of information processing is not consistent across different tasks. In our opinion, RSVP is a demanding task and as such the rate of information processing might differ from natural rates of processing. In this case, surprisal effects in natural reading could reflect a real processing bottleneck, inspiring the new question, why don't we adjust our processing rates to alleviate the bottleneck?

[^143]Second, our buffer model suggests that there is a decoupling of perceptual and linguistic information processing ${ }^{8}$, which is potentially relevant for two sentence processing phenomenon: spill-over effects and right context effects. In selfpaced reading and eye-tracking data (e.g., Smith \& Levy, 2013; Shvartsman, Lewis, \& Singh, 2014), researchers sometimes discover spill-over effects-i.e., properties of previously fixated/presented words are reflected in the reading time of the current fixated/presented word. Usually spillover effects are realized as increased reading times following a word thought to be difficult to process (or conveying a large amount of information). Spill-over effects could be explained as perceptual processes continuing to advance through the sensory input while being sensitive to the information processing slightly lagging behind in a buffer. For example, if a buffer had a fixed capacity, perceptual processing might stall on words further in the input than is currently being processed until the buffer has room for more information.

Right context effects occur when information further in the sensory input influences previously perceived information. This plays out differently depending on modality. Readers maintain perceptual uncertainty about word identities (Levy, Bicknell, Slattery, \& Rayner, 2009) and their regressive eye movements can be linked to future input increasing uncertainty about past input (Bicknell \& Levy, 2010). Eavesdroppers, on the other hand, do not have the luxury of playback. In speech processing, listeners maintain uncertainty about words (Bicknell, Tanenhaus, \& Jaeger, 2015) and have to hope that the future context will disambiguate the signal for them. The current proposal is that the processing of a segment of speech operates beyond the duration of the speech segment (Dahan, 2010). Arguably, the maintenance of unprocessed information implicates a linguistic buffer. Future research should look into using buffer models to account for these phenomenon.

Our results, in line with previous RSVP studies, show that readers can process text faster than they would process text naturally. Both the surprisal effect in our mSP condition and the information processing rate parameter in our model of the 5-RSVP condition are the first pieces of evidence for surprisal effects in RSVP. Our data are consistent with a FIFO buffer model suggesting that when readers are quickly bombarded with information, they store linguistic information in a buffer and immediately begin processing that information serially at a fixed rate. Our buffer model suggests a looser temporal coupling between perceptual processing and linguistic processing than had previously been theorized. Our initial analyses using a FIFO buffer model prompt further research on the nature of the buffer and how the buffer may be implicated in other sentence processing phenomena.

# Different processes for reading words learned before and after onset of literacy 

Padraic Monaghan (p.monaghan@lancaster.ac.uk) Ya-Ning Chang (y.chang5@lancaster.ac.uk)<br>Department of Psychology, Lancaster University, Lancaster, LA1 4YF, UK<br>Stephen Welbourne (stephen.welbourne@googlemail.com)<br>Neuroscience and Aphasia Research Unit (NARU), University of Manchester, Manchester, M13 9PL, UK

#### Abstract

Learning to read has a substantial effect on the representations of spoken and meaning forms of words. In this paper we assess literacy effects beyond representational changes, focusing on adaptations to the architecture of the reading system that maps between these representations. We present a connectionist model of reading that predicted distinct processing of pre- and post-literacy acquired words. For reading for meaning, words learned prior to literacy were processed more indirectly via phonological representations, whereas for post-literacy acquired words, processing was more direct along the orthography to semantics pathway. This more computationally intensive route was prioritised because indirect phonology to semantics mappings were unavailable. Such an effect was less apparent for naming, because learning direct orthography to phonology mappings is less computationally intensive. These results were confirmed in an analysis of naming and lexical decision behavioural data. The effect of literacy onset remains an observable artefact in adult reading.

Keywords: literacy; age of acquisition; language development; reading fluency; reading comprehension; computational modelling.

## Effects of literacy on reading

There are multiple influences on readers' speed and accuracy of reading, and these have been extensively documented in the literature over the last 50 years of reading research. For instance, higher-frequency words tend to be accessed more quickly and accurately than lower-frequency words, and early-acquired words tend to be responded to faster and more accurately than later-acquired words, referred to as an "age of acquisition" (AoA) effect (Brysbaert, \& Ghyselinck, 2006; Cortese \& Khanna, 2007; Juhasz, 2005; Monaghan \& Ellis, 2002).

Theories of the origin of the AoA effect on reading are two-fold. One view is that early acquired words result in prioritised lexical semantic representations, because they enter first of all into the lexical semantic associative network, and subsequently learned words are then connected to previously acquired words (Brysbaert \& Ghyselinck, 2006). Analyses of semantic associations by Steyvers and Tenenbaum (2005) confirmed that early acquired words do have more words associated with them than later acquired words, and they demonstrated that small-scale illustrative versions of this growing semantic associative network could prioritise early acquired words in semantic processing.

An alternative perspective is that AoA effects are instead found in the mappings between representations, rather than the representations themselves (Monaghan \& Ellis, 2010).

Early acquired words are learned when the neural network supporting the mappings among print, sound and meaning is plastic and able to acquire mappings effectively. Mappings for later acquired words are required to fit around the previously learned mappings, when the neural network has lower plasticity, resulting in prioritisation for early over later acquired words. Such AoA effects are predicted to be greater for arbitrary mappings, such as between meaning and sound, rather than for (quasi-)regular mappings such as between print and sound, because learning arbitrary mappings is more computationally intensive and therefore affected more by reduced plasticity (Lambon Ralph \& Ehsan, 2006). However, AoA effects ought still to be observed even for regular mappings because of the smaller, but still present, effect of reducing plasticity in learning the mappings.

These predictions have been supported by meta-analyses of behavioural studies (Brysbaert \& Ghyselinck, 2006) which have investigated AoA effects for naming and for lexical decision. It is generally assumed that for naming, semantic representations of words are minimally involved in producing the phonological form of a word from its orthographic form (Harm \& Seidenberg, 1999). However, lexical decision appears to implicate semantic representations to a greater degree (Chang et al., 2016; Plaut, 1997), in that semantic properties of words, such as imageability or concreteness, account for more variance in lexical decision or picture naming responses and little for written word naming (Balota et al., 2004; Catling \& Johnston, 2009). Brysbaert and Ghyselinck (2006) showed that AoA effects were much greater for tasks involving semantics, including lexical decision, than for tasks involving production of phonology (see also Cortese \& Khanna, 2007). However, the fact that AoA does still account for some variance in naming indicates the effects of plasticity in the quasi-regular print to sound mapping for English (see Lambon Ralph and Ellis, 2000, and Monaghan and Ellis, 2010, for computational illustrations of this).

Conversely, the size of the AoA effect can be used to indicate the extent to which the pathways to and from lexical semantics in the reading system are involved in reading. If the AoA effect is large, then semantics is likely to be involved, if the effect is small then semantics is less likely to be involved. Chang et al. (2016) implemented a triangle computational model of single word reading, and varied the point at which words were presented to the model, to simulate different AoA of words. For simulations of naming, AoA had a significant effect, but for simulations
of lexical decision, AoA accounted for a substantially larger proportion of variance.

One absence from these theoretical and implemented models of reading, however, is the role not only of AoA but also of different modes by which words are acquired. Literacy is known to have profound effects on language processing, resulting in changes to phonological awareness (Hulme, Bowyer-Crane, Carroll, Duff, \& Snowling, 2012; Morais, Cary, Alegria \& Bertelson, 1979), changes to phonological processing of words (Smith, Monaghan, \& Huettig, 2014), as well as semantic fluency (Kosmides, Tsapkini, Folia, Vlahou, \& Kiosseoglou, 2004), and even visual processing (Szwed, Ventura, Querido, Cohen, \& Dehaene, 2012).

However, less studied are the potential effects of literacy on the architecture of the reading system in terms of pathways employed between different representations of words. Prior to literacy, the learner acquires mappings between sound and meaning representations of words, through listening and comprehending words, and speaking words for others' comprehension. However, once the child begins to learn to read for these already known words, mappings will be generated from print to the stored sound and meaning representations. But for new words, the print form will be mapped onto newly acquired sound and meaning representations, where the mappings between sound and meaning are not available in advance.

In terms of the operation of the reading system, this difference between pre-literacy and post-literacy acquired words is likely to be profound. In the triangle model of reading (Seidenberg \& McClelland, 1989) there are two routes by which a printed word can be pronounced. This can occur directly, through learned mappings between print and sound, or indirectly from print via semantics to sound (see Figure 1). Similarly, for reading comprehension, the mapping from print can be directly to meaning, or indirectly, from print to sound to meaning. For pre-literacy acquired words, the indirect route is more likely to be available, because the sound to meaning routes are already acquired, whereas for post-literacy words, the indirect route requires two mappings to be acquired.

Furthermore, the properties of the mappings from print to sound and meaning will also contribute to the extent to which direct and indirect mappings are utilised. Regular mappings, such as between print and sound in English, are easier to acquire than arbitrary mappings, such as between print and meaning. Thus, the direct route is more likely to be prioritised for print to sound mappings than the indirect route, and the indirect route is more likely to be prioritised for print to meaning mappings than the direct route, because the indirect route is more easily acquired, at least for words acquired pre-literacy, where the sound to meaning mapping is already in place in the language processing system.

Based on this theory, we predict that there is likely to be a distinction between pre-literacy and post-literacy processing of words' print to meaning mappings, as in lexical decision. Pre-literacy, the indirect route is more likely to have a
greater influence on processing. Post-literacy, the direct route is likely to have a greater influence. Whereas for print to sound mappings, as in word naming, we predict no difference between pre- and post-literacy processing, because both will be mapped via fast-acquired direct print to sound mappings, which will have an equal influence on reading.

In this paper, we first provide a computational test of the extent to which the triangle model of reading predicts different processing routes for words pre- and post-literacy. We then test whether the predictions of the model are observed in behavioural data on word naming and lexical decision response times. For both the simulation and the behavioural data, we use the size of the AoA effect as an index of the extent to which direct mappings from orthography to semantics are implicated in the reading system. For naming, a larger AoA effect indicates greater use of indirect mappings via semantics for reading tasks, for lexical decision a larger AoA effect indicates greater use of direct mappings from orthography, where arbitrary mappings between orthography and semantics are implicated. A smaller AoA effect for lexical decision indicates that the indirect quasi-regular mapping from orthography to phonology is being prioritised. It is the case that mappings between phonology and semantics are also arbitrary, but these mappings would exert a smaller AoA effect than that observed for the newly acquired mappings because they are intensively trained, and acquired earlier in acquisition, thus reducing distinctions between words due to greater plasticity of resources for early-learned mappings (see e.g., Ellis \& Lambon Ralph, 2000; Monaghan, Chang, Welbourne, \& Brysbaert, 2017).

## Method

## Network Architecture

The model is based on the connectionist triangle model of reading (Harm \& Seidenberg, 2004; Seidenberg \& McClelland, 1989), as shown in Figure 1. The critical property of the model is that it incorporates three
representations of single words - print, sound, and meaning. Each of these representations is interconnected by sets of hidden units that permit the mappings between representations to be acquired as a consequence of exposure. The sound and meaning layers were also each connected to a set of attractor units that enable the model to develop highfidelity phonological and semantic representations of words.

Also included was a context layer to enable disambiguation of the meaning of homonyms (e.g., /beIs/ as the instrument bass and as the location base, see Chang et al., 2016, for more details).

## Representations

The representations of words were derived from Harm and Seidenberg's (2004) version of the triangle model. Printed words were represented across 14 letter slots, with each letter slot comprising 26 units relating to one letter of the alphabet. If a letter was present in a slot, then the unit corresponding to the letter had activity 1 , otherwise the units were inactive. Spoken words were represented in terms of segmental phonological features, across 8 phoneme slots of 25 binary phonological feature units, with distinct phonemes represented in terms of overlapping subsets of the units representing the features. Finally, lexical meaning representations were constructed from semantic features in WordNet (Miller, 1990). Each word activated a subset of the 2446 semantic features in the semantic layer of the model, with activity 1 if the semantic feature was associated with the word.

The model was eventually trained to read 6229 monosyllabic words, which were presented during reading training according to log-compressed frequency, where frequency was taken from the Wall Street Journal corpus (Marcus, Santorini, \& Marcinkiewicz, 1993), to be consistent with Harm and Seidenberg's (2004) implementation of the triangle model.

## Training Procedures

The training process had two phases: a pre-literacy and a post-literacy phase. In the pre-literacy training, the model learned to map between phonology and semantics on a subset of words from the entire training set, that children are more likely to have learned before beginning reading. In the post-literacy phase, the model was trained to learn to map all words from orthographic forms onto phonology and semantics.

In pre-literacy training, the model was trained on oral language tasks, including a speaking task (mapping from semantic to phonological representations), a hearing task (mapping from phonological to semantic representations), as well as tasks that assisted in developing stable attractors at phonology and semantics (mapping from phonological to phonological representations, and from semantic to semantic representations). For the speaking task, the semantic input pattern for a selected word was clamped for eight time steps, then in the last two time steps, the model was required to reproduce the phonological form for the word. The difference between the model's actual production and the target phonological production was backpropagated through
the network and connections were adjusted to reduce error. Similarly, for the hearing task, the phonological input and the context were clamped for 8 time steps, and the model was required to produce the target semantic form at the output. For the stable attractor tasks, the input was presented then activation cycled for 6 time steps, before the model was required to reproduce the originally inputted phonological or semantic representation. For pre-literacy training, the four tasks were interleaved, with $40 \%$ of trials each for the speaking and hearing tasks, and $10 \%$ each for the phonological and semantic attractor trials. There were 600,000 trials altogether.
For pre-literacy training, the model was exposed to 2,973 monosyllabic words, which were selected to be the most common words occurring in reading materials before age 18 , and therefore those words most likely that children come across prior to literacy onset. Words were presented randomly, but selected according to their frequency. The model was trained with a learning rate of 0.05 using backpropagation through time, and cross-entropy error was computed. No adjustments to weights were made if the model was within 0.1 of the target for each output unit.
In the post-literacy training, the model was given printed word forms, and required to learn to map onto phonological and semantic representations. Words were presented to the model incrementally, according to the reading-age at which words occurred. Similar to Monaghan and Ellis (2010), reading developed cumulatively, over 14 reading stages reflecting reading materials experienced from age 5 to 18 , determined from the educator's word frequency guide (Zeno et al., 1995), see Chang et al. (2016) for more details.

For each word, the model cycled for 12 time steps of activation after which the model had to generate the phonological and semantic representations of the word. These reading trials were interleaved with hearing and speaking trials, and phonological and semantic attractor trials, to ensure that the pre-literacy mappings were maintained during reading training. There were 1.74 million post-literacy training trials altogether.

Critically, by the end of training, the model had been exposed to all words, but some of these had been acquired prior to literacy onset, and others were acquired from print. We refer to these words as pre- and post-literacy words.

## Testing Procedures

To measure pre-literacy oral language skills, the model was tested on its productions for the speaking and hearing tasks. For semantics, if the model was closer to the target word than any other word, then it was judged to be accurate. For phonology, if the model was closer to the target phoneme at each phoneme slot then it was judged to be correct.
For the analysis of reading performance, we interpreted orthographic to phonological representations to be analogous to behavioural naming responses (Chang, Furber, \& Welbourne, 2012), and orthographic to semantic mappings to relate to lexical decision responses (see, e.g., polarity measure in Plaut, 1997, and Chang et al., 2016).

## Results

At the end of pre-literacy training, of the words to which the model had been exposed prior to onset of literacy, the model was able to speak $90.7 \%$, and comprehend $91.7 \%$ correctly. After reading training, the model was accurate for $99.4 \%$ of phonology and $93.3 \%$ of semantics for the reading task.

To assess whether literacy changed patterns of processing in the model, multiple regression analyses were conducted for the model's simulations of word naming and lexical decision tasks. The mean square error of the model's productions was taken as the dependent variable, and a set of psycholinguistic variables were included as predictors, to relate to previous regression analyses of behavioural data (e.g., Balota et al., 2004; Cortese \& Khanna, 2007). These variables were cumulative frequency (CF), orthographic neighbourhood size (OrthN) (Coltheart, 1977), word length (Len), consistency (Cons) (which was the proportion of words with the same pronunciation of the orthographic rime, e.g., "gave/save" versus "have"), and AoA, which was the reading stage during training for the model. Error scores were log transformed and all the predictor variables were centred.

To examine the effect of literacy onset on the model's performance, hierarchical regression analyses were conducted. At step 1, all psycholinguistic variables were entered, then at step 2 whether the word appeared pre- or post-literacy was entered as a variable interacting with AoA. If processing changes from pre- to post-literacy, then the effect of AoA at the point of literacy onset should change, as an index of the involvement of semantics - reflected in a significant interaction. It was not possible to include literacy onset as a separate variable because it is highly correlated with the interaction term. The results for naming and lexical decision are shown in Table 1.

Table 1. Results from the regression analysis for naming and for lexical decision in the computational model.

|  |  | Naming | Lexical Decision |
| :--- | :---: | :---: | :---: |
|  |  | $\beta$ | $\beta$ |
| Step 1 | CF | $-0.179^{* * *}$ | $-0.107^{* * *}$ |
|  | OrthN | $-0.256^{* *}$ | 0.012 |
|  | Cons | $-0.247^{* * *}$ | -0.016 |
|  | Len | $-0.071^{* * *}$ | $-0.127^{* * *}$ |
|  | AoA | $0.198^{* * *}$ | $0.452^{* * *}$ |
| Step 2 | AoA x | $0.219^{* * *}$ | $0.501^{* * *}$ |
|  | Literacy <br> onset | $\Delta R^{2}=0.37 \%$ | $\Delta R^{2}=1.96 \%$ |
| ${ }^{* * *} p<.001 ;{ }^{* *} p<.01 ; \beta$ is a standardized beta value. |  |  |  |

Literacy onset was a significant predictor of changes in the model's performance - at the point of literacy onset, the regression gradient for the AoA effect changed, such that words acquired pre-literacy demonstrated a smaller change in response times associated with increasing AoA compared to words acquired post-literacy. This effect was substantially larger for lexical decision than for naming responses, suggesting that processing for pre-literacy acquired words used the indirect route from orthography to semantics via phonology, whereas the post-literacy acquired words used the direct orthography to semantics route.

We next tested whether a similar change in processing was associated with literacy onset in naming and lexical decision behaviour.

## Testing the literacy effect in word processing

## Method

The data were a subset of responses from the English Lexicon Project (Balota et al., 2007), comprising naming and lexical decision response times from a set of 816 young adult participants from a range of universities. We acquired data for 2,536 monosyllabic words, for which all the psycholinguistic variables could be generated.

Word-form frequency, orthographic neighbourhood size, and word length were taken from the CELEX database (Baayen, Pipenbrock, \& Gulikers, 2005). These three measures were taken from the same dataset to ensure consistency across these measures. AoA was taken from Kuperman, Stadthagen-Gonzalez, and Brysbaert (2012). Consistency of words was determined in the same way as for the computational simulation.

## Results

We first aimed to replicate the results of Balota et al. (2004, 2007) in determining the role of frequency, word length, neighbourhood size, consistency, and AoA in a linear regression on naming response times and lexical decision response times.

Then, we measured whether there was an effect of onset of literacy in the behavioural data through adding an interaction between AoA and literacy onset. Age of literacy onset could not be included a priori as with the simulation, however, we assumed that if there is an effect of onset of literacy, then this should occur somewhere close to the age of 5 . Onset of literacy was thus determined iteratively between the age of $3,4,5,6$, and 7 years in order to assess whether there is a discontinuity in response times predicted by AoA that changes around the age children begin formal literacy. We took as an indicator of discontinuity a significant interaction between AoA and literacy onset, though see Baayen, Feldman, and Schreuder (2006) for an alternative means of measuring discontinuities (note they were unable to test AoA because of small sample size).

For naming and lexical decision response times, the results of the multiple regression are shown in Table 2. For naming, adding the interaction between onset of literacy and

AoA for any of the ages 3 to 7 did not significantly improve the model fit (Bonferroni corrected).

For lexical decision response times, there were significant effects of literacy onset found at ages 5, 6, and 7, with the largest effect for age 6. Figure 2 shows the effect of this discontinuity in predicting response times for lexical decision when the onset of literacy is implemented at age 6. The same Figure illustrates no statistically significant discontinuity effect for naming response times.

Table 2. Results from the regression analysis for naming and for lexical decision in the behavioural data.

|  |  | Naming <br> $\beta$ | Lexical Decision $\beta$ |
| :---: | :---: | :---: | :---: |
| Step 1 | Log-frequency | $-0.156^{* * *}$ | $-0.305^{* * *}$ |
|  | OrthN | $-0.255 * * *$ | -0.001 |
|  | Cons | $-0.115^{* * *}$ | -0.032* |
|  | Len | $0.165^{* * *}$ | $-0.062 * * *$ |
|  | AoA | 0.174*** | $0.440^{* * *}$ |
| Step 2 | AoA x Literacy onset age 3 | -3.220 | 1.572 |
|  | AoA x Literacy onset age 4 | -0.653 | 0.369 |
|  | AoA x Literacy onset age 5 | 0.150 | 0.387* |
|  | AoA x Literacy onset age 6 | 0.151 | $0.348^{* * *}$ |
|  | AoA x Literacy onset age 7 | 0.154 | $0.310^{* * *}$ |

## General Discussion

Onset of literacy has a profound effect on cognition, but generally these effects have been assessed on the representations involved in reading, rather than the pathways involved in mapping between these representations (Hulme et al., 2012; Morais et al., 1979; Smith et al., 2014). In this paper, we show that onset of literacy likely has a long-standing impact on the architecture of the reading system. For words that are in the learner's vocabulary prior to onset of literacy, reading can proceed via two routes - directly, by newly learned mappings from orthography to semantics, or orthography to phonology, or can instead exploit indirect pathways that incorporate learned mappings between phonology and semantics that the learner already has cemented in their language system.

Figure 2. Interaction between AoA and onset of literacy at age 6 in lexical decision but not in naming responses.

For naming tasks, the use of this prior semantics to phonology knowledge has a minimal effect, because the quasi-regularity of orthography to phonology mappings is relatively easy to acquire. The greater difficulty of learning an arbitrary mapping from orthography to semantics, then using this semantic representation to activate the previously acquired phonological representation for the known word, means that this indirect processing is unlikely to be involved differentially for words learned pre- versus post-literacy.
For lexical decision, or other tasks involving activation of semantic representations, the role of literacy onset appears to be quite different. The computational model predicted that when prior knowledge about phonological and semantic associations is available, as it is for pre-literacy acquired words, then an indirect route is likely to be involved in mapping from orthographic to semantic representations. For words learned post-literacy, this prior knowledge is not available, and so the reading system has to proceed via generating either a new mapping from orthography to semantics, or a new mapping from phonology to semantics. Thus, a distinct pattern of response is likely to be observed for lexical decision of pre- and post-literacy words.

The behavioural results provide support for the computational predictions of different pathways used in reading pre- versus post-literacy. Even though literacy onset was several years before the participants in the lexical decision study were tested, the vestiges of literacy onset appear to be still observable in reading behaviour. We acknowledge that literacy onset is not a sudden change, as some new words will still be acquired aurally even after reading training has commenced, and proficient reading is not immediate, but requires extensive, sometimes strenuous, training (e.g., Seidenberg, 2017). Nevertheless, we have shown that literacy onset changes the use that the reader makes of the language system, and this differential use of the system survives to be observed in behavioural responses
even after decades of reading practice

#### Abstract

Learning how words refer to aspects of the environment is a complex task, but one that is supported by numerous cues within the environment which constrain the possibilities for matching words to their intended referents. In this paper we tested the predictions of a computational model of multiple cue integration for word learning, that predicted variation in the presence of cues provides an optimal learning situation. In a cross-situational learning task with adult participants, we varied the reliability of presence of distributional, prosodic, and gestural cues. We found that the best learning occurred when cues were often present, but not always. The effect of variability increased the salience of individual cues for the learner, but resulted in robust learning that was not vulnerable to individual cues' presence or absence. Thus, variability of multiple cues in the language-learning environment provided the optimal circumstances for word learning.

Keywords: word learning; multiple cues; strategies; gesture; prosody; cross-situational learning.

## Cues for word learning

Learning how words relate to objects, actions, properties, or relations in the world is a complex task. One of the key difficulties is that word learning provides few explicit constraints on which words can relate to particular aspects of the environment (Quine, 1960). Thus, in acquiring vocabulary, children must resolve a many-to-many (possibly even an infinite-to-infinite) mapping between words in utterances and elements of the environment around them. So how do children solve this task?

There are two proposals for how learning word-referent mappings can be constrained. The first is that children have internal biases that apply to language learning situations that limit possible referents to words (Markman, 1994). For instance, mutual exclusivity refers to the assumption in word learning situations that each referent has only one name, leading children to pair an unnamed object with a novel word (Markman \& Wachtel, 1998). In terms of limiting referents, children seem to be biased to linking a word with a whole object rather than a part of an object (Macnamara, 1982), and may more readily form categories of objects with similar shape which are referred to by the same word (Baldwin, 1992).

The alternative proposal for resolving the many-to-many mapping problem in word learning is that the environment, rather than the learner, contains many properties that assist
in constraining possible mappings (MacWhinney, 1991). Though a single learning situation contains many possible words and many possible referents for those words, over multiple situations, children may observe that there are cooccurrences between particular words and particular elements of the environment. Yu and Smith (2007) showed that learners are able to exploit such cross-situational statistical relations between words and referents. However, the statistical associations are noisy in real-world childdirected speech settings (Yu \& Ballard, 2007), and so additional cues in the environment are likely to assist further in constraining learning.

One possibility is distributional information in terms of co-occurrences between words. In English child-directed speech, determiners reliably precede nouns in complex utterances (Monaghan \& Mattock, 2012), and these distributional cues can assist the child in knowing which potential words in an utterance are likely to refer to objects in their environment (Fitneva, Christiansen, \& Monaghan, 2009). Other distributional cues that are readily available to children can also provide information about verb categories, and function versus content word distinctions (Childers, 2011; Christiansen \& Monaghan, 2016).

Prosodic information is another cue to assist in reducing the many-to-many mapping problem, not only providing information about different grammatical categories (Christiansen \& Monaghan, 2016) but also indicating speaker focus in a learning situation: Messer (1981) found that approximately $50 \%$ of child-directed utterances with a learning goal had the referring word reaching the highest amplitude.

For further reducing the possibilities for the intended referent, gestural cues provide additional cues to constrain word learning, with $15 \%$ of child-directed speech utterances accompanied by gestures that guided the child to the object being referred to (Iverson, Capirci, Longobardi, \& Caselli, 1999).

## Combining cues for word learning

Individually, then, cues appear to be noisy but informative sources of information about intended referents. Thus, combining cues is likely to result in yet more robust and faster learning. There are several models for how multiple cues may interact for word learning.

First, cues may be additive, such that more information provides cumulative evidence about word-referent mappings. For instance, in a computational model, Yu and Ballard (2007) demonstrated that mapping accuracy improved with the addition of distributional cues.

However, an alternative model for how multiple cues may support learning is provided by Bahrick, Lickliter, and Flom's (2004) intersensory redundancy hypothesis. In this theoretical model, multiple cues that indicate the same structure in language (such as multiple cues indicating the word-referent mapping, for instance) enable the learner to realise that this relation is not random, but carries information about the stimuli. Consequently, cues that are correlated increase in saliency and are attended to more as learning proceeds.

However, this view of increased saliency from redundant cues only applies when there are overlapping cues to structure, and the distribution of cues in the learning environment may be very different. Monaghan et al. (2007) examined cues to grammatical categories of words across a range of languages. They found that distributional information provided, unsurprisingly, valuable information about the role of words in each language - for instance, in English words that belonged to the verb category tended to succeed "you" and precede "the", whereas words that belonged to the category of nouns tended to succeed "the", and precede "to". But, in addition, Monaghan et al. (2007) also found that phonological coherence also applied to these grammatical categories - though there is substantial variation, nouns tend to sound like other nouns and verbs tend to sound like other verbs, in terms of a range of phonological and prosodic properties.

Yet, it was the interplay of these cues that was striking: when distributional information was a weak indicator of grammatical category, Monaghan et al. (2007) found that phonological cues were more reliable, and vice versa. Thus, there was not so much a redundant overlap of cues, but rather a serendipitous arrangement of cues across situations to provide useful information (Christiansen \& Monaghan, 2016).

An alternative perspective, then, is that multiple cues for language structure enable robust learning, but not due to intersensory redundancy, but rather due to providing a safety net that is resistant to variation of their presence in the environment. In Monaghan (2017) this idea of degeneracy was implemented in a connectionist model that took as input multiple information sources to support learning of crosssituational statistical regularities between an object in vision and a word in auditory input, when both the object and the word occurred alongside others. The model was able to learn the cross-situational statistical regularities, but this learning was boosted when additional cues were added to the model's learning environment. One was distributional information (where the referring word was preceded by a marker word, such as "the" preceding a noun). Another was a prosodic cue, where the referring word in the utterance was emphasised in the auditory input. The final cue was a
gestural cue, where attention was drawn to the object that was being referred to in the utterance. In each case, adding the cue improved the model's learning. Furthermore, adding all the cues improved performance still further.

The second set of simulations in Monaghan (2017) tested what effect individually unreliable cues would have on learning. The presence of each of the three cues varied between $33 \%$ and $100 \%$ of the time, but note that in most learning situations, at least one of the cues was likely to be present. The reduction of reliability of multiple cues reduced the speed of learning, however, following training, the ability of the model to respond correctly to word-object mappings when they were presented with no additional cues in the environment was more robust when cues were individually unreliable. The presence of noise in the environment, when that environment provides an unreliable constellation of individual cues, meant that the model was better able to recognise words when the environment was momentarily impoverished. Consider a language instructor who always pointed to the object to which they were referring. That is likely to be helpful for constraining the potential referents for words that the learner hears. But what would happen when the instructor is distracted - or a new instructor with different habits arrives - and does not provide the gestural cue? If the cue was previously $100 \%$ reliable, then this would become a crutch that was relied upon for determining the speaker's intention, and the referent would not be identifiable if not gestured towards.

A computational approach with a similar outcome is Srivastava et al.'s (2014) dropout model, where hidden units in a model are stochastically deactivated to prevent the model overlearning one aspect of the input - to resist relying only on the most reliable information stream in the environment, and consequently preventing effective generalisation. This switching off meant that the model maximised use of information from the environment. However, critically for our purposes, the learning system does not selectively prevent attention to environmental information. The noise in the language environment provides this function. Far from being a problem for learning, environmental noise enabled effective, reliable, and robust learning to take place, providing a positive perspective on poverty of the stimulus (Chomsky, 2005). Indeed, stimulus poverty resulted in rich learning.

However, the benefit of multiple, noisy cues is a prediction of the degeneracy model (Monaghan, 2017) but has not yet been tested empirically. Here, we provide a behavioural test of whether the presence of multiple, variable cues promotes robust word-referent learning. We constructed a cross-situational learning task, with each situation presenting learners with two objects and a set of words (see Monaghan \& Mattock, 2012, for similar outline of the cross-situational word learning design). One of the words always referred to one of the objects, but the other object and the other words varied. Over multiple trials, participants may come to recognise that certain words and objects always co-occurred. We measured the extent to
which additional cues in the environment assisted in learning - implementing gestural, distributional, and prosodic cues to support learning, but we varied the extent to which these cues were present. The degeneracy model predicted that (very) noisy cues should slow learning, but that there may be an optimal level of variability at which learning is more accurate than perfect information conditions when all cues are present. We examined three levels of variability as well as no variability, where cues were present $25 \%, 50 \%, 75 \%$, or $100 \%$ of the time. We measured performance during training exposure, and we also measured whether learning was robust to omission of cues - by testing participants after learning on trials where no cues were present. Based on the predictions of the degeneracy model (Monaghan, 2017), we anticipated that learning would be resistant to omission of cues in all conditions, but that omission of cues may be least affected when those cues were variable during exposure.

## "tha FINTOOM noo chatten"

Figure 1. Example of a learning trial, containing distributional, prosodic (i.e., fintoom is emphasised in the speech), and gestural cues.

## Testing the effect of multiple, variable cues for word learning

## Method

## Participants

Participants were 72 native English speaking adults, mean age $=19.8$ years $(\mathrm{SD}=2.46)$, who were students at Lancaster University. Participants were paid $£ 3.50$ for participating, or received course credit. Participants were assigned to one of four conditions ( $\mathrm{N}=18$ per condition) which varied the extent to which cues were reliably present during training ( $25 \%, 50 \%, 75 \%$, or $100 \%$ of the time).

## Materials

The materials comprised a set of abstract objects and a set of novel words with which the objects were paired during learning. We took 10 arbitrary shape pictures from Fiser and Aslin (2002) (see Figure 1 for examples). For the speech, we generated 22 nonsense words. Ten of the words each referred to one of the object shapes. An additional 10 words did not refer to any shape. A final two words were also generated to act as distributional marker words. Words were read by a female native English speaker in monotone, and
were also read in emphasized form, with the speaker imagining they were speaking the word to a child. Emphasised words had higher mean pitch, greater pitch variation, longer duration, and greater intensity than monotone words (all $t(19)>8.98, p<.001$ ).

Each learning trial comprised an utterance containing a referring word and a non-referring word. When the distributional cue was present, the two words were preceded by marker words that distinguished the referring and nonreferring word. When the prosodic cue was present the referring word was emphasised, otherwise both words were monotonic. When the gestural cue was present, a finger pointed to the intended referent. In the example trial shown in Figure 1, "tha" indicates the following word is the referring word and "fintoom" refers to one of the pictures (in this case, the picture on the left). Cues were randomly selected individually according to the variability condition (e.g., for the $25 \%$ cue, there was a $1 / 4$ chance that each cue was present or absent, such that there were trials where 3,2 , 1, or no cues were present).

An additional training block was constructed from 6 novel shapes and 12 novel words, but these new training data are not reported further here.

## Procedure

Participants were instructed to try to learn which object was referred to by the speech. There were 6 blocks of training, each of which contained 30 trials, where for each trial an utterance was played through headphones and two objects were presented on a computer screen simultaneously. One of the objects was the target and always co-occurred with the referring word, the other object was selected from the remaining nine objects. Within each block of training, objects appeared an equal number of times as target and as foil, and were counterbalanced for appearing on the left or the right of the screen. Presence or absence of cues was manipulated between conditions by randomly selecting whether each cue was present or absent in $25 \%, 50 \%, 75 \%$, or $100 \%$ of trials.

Participants responded by pressing " 1 " or " 2 " for left object or right object, respectively, on a computer keyboard. No feedback was provided on accuracy of performance.

After training, participants were tested for their knowledge of word-referent mappings when all cues were absent, to determine whether learning was robust, or required presence of cues for accurate performance.

## Results

We conducted four separate analyses exploring how learning was affected by the variability of cues. In each analysis, a series of generalized linear mixed-effects models (GLMER) were performed, predicting the dependent variable of response accuracy (correct or incorrect). The models were built up incrementally, adding in fixed effects and performing likelihood ratio tests after the addition of each new fixed effect term (following Barr, Levy, Scheepers \& Tily, 2013). Random effects of participant and experiment version were included in all reported analyses.

First, we analysed learning during training. The effect of block (1-6) significantly improved model fit $\left(\chi^{2}(1)=314.1\right.$, $p<.001$ ), indicating that over the course of training, there was a significant increase in participant's response accuracy. Including variability condition ( $25 \%, 50 \%, 75 \%$ and $100 \%$ ) also significantly improved model fit $\left(\chi^{2}(3)=21.259, p<\right.$ .001). Crucially, there was a significant improvement to model fit when the interaction term of block x condition was added $\left(\chi^{2}(3)=71.113, p<.001\right)$, indicating that performance over the course of training varied by reliability condition. See Table 1 for the final model summary, which indicates that the $75 \%$ condition resulted in more rapid learning than the other conditions (see Figure 2).

Figure 2. Learning trajectories for the word-object mapping cross-situational learning task with multiple cues of different reliabilities.

Table 1. GLMER model summary predicting accuracy from training data.

| training data. |  |  |  |  |
| :--- | :---: | :---: | :---: | :---: |
| Fixed effects | est. | $S E$ | $z$ | $p$ |
| (Intercept) | $\mathbf{. 4 7}$ | $\mathbf{. 2 1}$ | $\mathbf{2 . 2 4}$ | $\mathbf{. 0 2 5}$ |
| Block | $\mathbf{. 3 0}$ | $\mathbf{. 0 3}$ | $\mathbf{1 0 . 9 6}$ | $<. \mathbf{0 0 1}$ |
| Condition $(25 \%-100 \%)$ | -.39 | .29 | -1.36 | .175 |
| Condition $(50 \%-100 \%)$ | -.17 | .29 | -0.58 | .559 |
| Condition $(75 \%-100 \%)$ | -.10 | .29 | -0.33 | .739 |
| Block*Condition(25\%-100\%) | $\mathbf{- . 1 7}$ | $\mathbf{. 0 4}$ | $\mathbf{- 4 . 8 1}$ | $<. \mathbf{0 0 1}$ |
| Block*Condition(50\%-100\%) | $\mathbf{- . 1 7}$ | $\mathbf{. 0 4}$ | $\mathbf{- 4 . 6 5}$ | $<. \mathbf{0 0 1}$ |
| Block*Condition(75\%-100\%) | $\mathbf{. 0 9}$ | $\mathbf{. 0 4}$ | $\mathbf{2 . 1 1}$ | $\mathbf{. 0 3 5}$ |

For the second analysis, we investigated the effect that variability of cues had on sensitivity to the individual cues during training, by measuring the effect of presence of individual cues on learning. In this analysis, only trials where at least one cue was present were included (see Figure 3).

The addition of variability condition significantly improved model fit $\left(\chi^{2}(3)=16.199, p=.001\right)$, indicating that there was a difference in overall accuracy across conditions, with performance in the $100 \%$ condition being significantly greater than the $25 \%$ and $50 \%$ conditions (both $p<.01$ ), but not the $75 \%$ condition ( $p>.05$ ). Next, the addition of cue type also significantly improved model fit $\left(\chi^{2}(2)=32.083, p<.001\right)$. This result indicates that there was a significant increase in accuracy when gesture cues were present, compared with when distributional and
prosodic cues were present, both $p<.001$. Importantly, there was a significant improvement to model fit when the interaction term of variability condition x cue type was added $\left(\chi^{2}(6)=23.665, p<.001\right)$. See Table 2 for the final model summary, which indicates that when variability is at $75 \%$, the salience of gesture cues was increased compared to the $100 \%$ condition, when cues were always present. Variability had the effect of emphasising the contribution of gesture. The benefit of gesture over the other cues was also present for $25 \%$ and $50 \%$ cues, but only when variability was at $75 \%$ was accuracy greater than the $100 \%$ condition.

Figure 3. Performance during training trials by variability condition and cue type.

Table 2. GLMER model summary predicting accuracy from trials when at least one cue was present.

| Fixed effects | est. | $S E$ | $z$ | $p$ |
| :--- | :---: | :---: | :---: | :---: |
| (Intercept) | $\mathbf{. 0 1}$ | $\mathbf{. 0 1}$ | $\mathbf{7 . 0 8}$ | $<.001$ |
| Condition (25\%-100\%) | $\mathbf{. 0 1}$ | $\mathbf{. 0 1}$ | $\mathbf{- 2 . 9 9}$ | $\mathbf{. 0 0 3}$ |
| Condition (50\%-100\%) | $\mathbf{. 0 1}$ | $\mathbf{. 0 1}$ | $\mathbf{- 2 . 5 2}$ | $\mathbf{. 0 1 2}$ |
| Condition (75\%-100\%) | .01 | .01 | 0.69 | .491 |
| Cue(dist-gesture) | .01 | .01 | 0.00 | .99 |
| Cue(dist-prosody) | .01 | .01 | 0.00 | .99 |
| Cue(dist-gesture)*Condition(25-100\%) | $\mathbf{. 0 1}$ | $\mathbf{. 0 1}$ | $\mathbf{3 . 5 3}$ | $<. \mathbf{0 0 1}$ |
| Cue(dist-gesture)*Condition(50-100\%) | $\mathbf{. 0 1}$ | $\mathbf{. 0 1}$ | $\mathbf{3 . 2 3}$ | $\mathbf{. 0 0 1}$ |
| Cue(dist-gesture)*Condition(75-100\%) | $\mathbf{. 0 1}$ | $\mathbf{. 0 1}$ | $\mathbf{2 . 9 8}$ | $\mathbf{. 0 0 3}$ |
| Cue(dist-prosody)*Condition(25\%-100\%) | .01 | .01 | 0.01 | .898 |
| Cue(dist-prosody)*Condition(50\%-100\%) | .01 | .01 | 0.62 | .535 |
| Cue(dist-prosody)*Condition(75\%-100\%) | .01 | .01 | 0.39 | .696 |

During the training trials, the number of cues available to the learner varied from 0 to 3 in the variability conditions. In order to determine the effect of number of cues present, we tested the number of cues present in terms of improvement to model fit. We found that they did $\left(\chi^{2}(1)=66.342, p<\right.$ .001 ), indicating that as the number of cues present increased, accuracy improved (see Figure 4). Further, the interaction of number of cues x variability condition also improved model fit ( $\chi^{2}(2)=14.309, p<.001$ ).

In order to determine how variability affected use of cues, we examined accuracy when all cues were present,
comparing across variability conditions. Importantly, when all three cues were present, accuracy in the $75 \%$ condition was significantly greater than the $100 \%$ condition (estimate $=.86, S E=.41, z=2.11, p=.035)$. Thus, $75 \%$ variability improved the accuracy of performance when all cues were present.

Finally, we determined whether learning was robust under conditions of cue variability, and how variability affected performance during the test trials when none of the cues were present. The addition of variability condition significantly improved model fit $\left(\chi^{2}(3)=11.357, p=.010\right)$, with significant differences between the $100 \%$ condition when compared to the $25 \%$ and $50 \%$ conditions (both $p<$ .05 ), but no significant difference between the $100 \%$ and $75 \%$ conditions $(p=.556)$. Importantly, this reflects the pattern of results found in the final block of training (see Figure 2), where performance improved as reliability of cues increased. See Figure 5 for results. Thus, in all conditions learning was robust to absence of cues.

Figure 4. Test of performance for different number of cues present during training.

Figure 5. Performance on all words after training for test trials, when no cue was present.

## Discussion

The main aim of this study was to test the effect of variation of multiple cues in the language environment for supporting word learning. We predicted, based on the degeneracy model of learning (Monaghan, 2017), that optimal performance would be a consequence of variable presence of multiple cues that aid learning. This was because the learner can exploit multiple information sources, without relying on any one cue, or coming to ignore the contribution of other highly correlated cues.

The results of the behavioural study of learning wordreferent mappings supported the degeneracy model, in that learning was faster and more accurate when distributional, prosodic, and gestural cues occurred in $75 \%$ of trials during training, than when cues were present $100 \%$ of the time.

However, greater variability - $25 \%$ and $50 \%$ occurrence of individual cues - reduced accuracy compared to the $75 \%$ condition, indicating that, for learning a small number of words, the optimal conditions were with cues present more than half the time, but not all the time. In natural language learning situations, reliability of individual cues to support word learning seems to be substantially lower. For instance, the prosodic cue of highest amplitude as an indicator of the referring word occurs in $50 \%$ of learning situations (Messer, 1981), and explicit gestural cues occur substantially less often - even as low as $15 \%$ of learning situations (Iverson et al, 1999). However, these are situations where the vocabulary is much greater than the 10 word-object mappings of the current learning situation, and additional cues to word-referent mappings when the possibilities for those mappings are exponentially higher may have a greater effect even when they occur more rarely. For instance, the model of Monaghan (2017) was trained on 100 words, and under those circumstances $50 \%$ variability was found to be optimal for learning. Scaling up the current language to larger vocabularies will be an important further test of the principles of variation in multiple environmental cues.

Analysis of the trials where individual cues were present or absent indicated that the benefit of variability in presence of cues was greatest for the gestural cue, with variability enhancing the use made of this cue when it occurred (Figure 3 ). Such a result is consistent not only with the degeneracy model of multiple cues, but also with the intersensory redundancy hypothesis (Bahrick et al, 2004), such that correlated cues increase in salience, but with the exception that the redundancy should not be absolute: if cues are perfectly correlated then their salience does not increase, as in the $100 \%$ condition.

The results from analyses of different numbers of cues present showed that combining cues boosted learning (Figure 4), indicating that the learner was exploiting information present from each of the individual cues. It was not the case, for instance, that participants learned to only attend to particular cues, as their confluence resulted in greater improvement. Indeed, when those cues were variable but all present, performance was best of all - again, the $75 \%$ variability condition outperformed the $100 \%$ condition when
all three cues were available in the trial.
In all variability conditions, learning was shown to be robust to absence of individual cues. This is an important result, because it demonstrates that though cues can support learning, they do not over-shadow the cross-situational statistical relations between particular words and objects cooccurring. This was the case even when cues were always present, thus, even if multiple cues are always present they do not result in brittle learning of statistical relations. It may be that individual cues, if occurring with high reliability could interfere with robust learning (e.g., Srivastava, 2014), and this is a topic for future investigation.

We know that the language environment is noisy, but replete with numerous multimodal cues that point in different ways to the same language structures (Whitacre, 2010; Winter, 2014; Yurovsky, Smith, \& Yu, 2013). We have shown that learners are able to exploit these multiple cues, and also their variability, to support word learning.

#### Abstract

In everyday life, before deciding what to do, one has to think about what could be done. We investigate option generation from a developmental perspective, testing the predictions of the Take-The-First-heuristic (TTF). Moreover, we examine the influence of time limitation on decision-making processes. Using soccer as a testbed, 6 - to 13 -year-old children $(N=97)$ were tested in a video-based option-generation paradigm. Children's performance was aligned with predictions of TTF: Children generated a mean of 2.21 options, did so in a meaningful way and selected the first as final option in $74 \%$. With shorter time, children generated fewer and higher quality options, selected better options and more often the first option as final decision. Further, with age, an increase of the number of options generated and an increase in quality of the final decisions emerged. This age effect was more pronounced with shorter time. Implications for real-life decision-making are discussed.

Keywords: option generation; decision making; heuristics; ecological rationality; development.

## Introduction

Imagine being a young, talented soccer player. You are running, alone, through the middle field towards the goal, dribbling one opponent after the other. You are now 20 meters from the goal, facing the opposing defense rapidly closing on you. What should you do? Maybe you should try to dribble the defense, get closer to the goal and shoot from a shorter distance? Should you try to shoot at goal from where you are now? Or should you pass to one of your team members - maybe Jack, approaching from the right? Or Mike, right behind you?

Most of the time, in everyday life, before deciding what to do, one has to think about what could be done. In this paper, we investigate option generation from a developmental perspective using sport as a testbed. Moreover, we examine the influence of time limitation on option-generation and decision-making processes.

## Option generation

A decision-making strategy usually consists of a search, a stopping, and a decision rule, all together defining how and how much information has to be collected before being able to make a decision (Gigerenzer \& Todd, 1999). However, most real-world situations require us to generate alternative options before making a decision, rather than selecting one from a set of options pre-defined and generated by an experimenter (Payne, Bettmann, \& Johnson, 1988).

Very little is known about how people generate options (for an exception see e.g., Johnson \& Raab, 2003), as most research on decision-making focuses on the other three building blocks of decision making. The Take-The-First heuristic (TTF) is a cognitive model that captures option generation and decision making in familiar, yet ill-defined tasks (Johnson \& Raab, 2003; Raab, 2012; Raab \& Johnson, 2007). In the TTF the building blocks are formally defined as follows: A search rule, suggesting that alternative options are generated in order of validity meaning that subjectively better options are generated earlier; A stopping rule, according to which the generation phase should stop after two to three options have been generated; A decision rule, assuming that people should choose one of the initial options generated (Johnson \& Raab, 2003). In this sense, people would generate a few options and select one of those, rather than exhaustively generating and processing all possible options. However, because those options were generated in order of validity, the decision, although fast and frugal, would tend to be accurate.

Studies with adults and adolescents testing the predictions of the TTF model have previously been conducted in sports (Belling, Suss, \& Ward, 2015; Raab, 2012; Ward, Ericsson, Williams, \& Williams, 2013). Indeed, because of its naturally occurring dynamics (e.g., decisions to be made under time pressure; many potential alternative actions to be considered), sport is the ideal domain to test whether people use fast-and-frugal decision-making heuristics, such as TTF. These studies show that the performance of experienced handball, basketball, and soccer players is pretty accurately predicted by the TTF model: Players tended to generate
alternative options (e.g., shoot at the goal or pass to their teammate) in order of validity and selected as their final decision the first option they had generated.

As for adults, most decision-making research with children focused on information search (see Davidson, 1991, 1996; Gregan-Paxton \& Roedder John, 1995, 1997; Howse, Best, \& Stone, 2003; Ruggeri \& Katsikopoulos, 2013; Ruggeri, Olsson, \& Katsikopoulos, 2015) or investigated cue-based decision strategies (Horn, Ruggeri, \& Pachur, 2016; Mata, von Helversen, \& Rieskamp, 2011). However, to our knowledge, option generation in children has never been studied before.

## Time-limitation effects on option generation and decision making

According to the ecological rationality framework (Todd, Gigerenzer, \& ABC Research Group, 2012), no strategy is always optimal, because the efficiency of a strategy depends on the environmental structure. In this sense, people should be adaptive and modify their strategies depending on how effective they are in a given environment (de Oliveira, Lobinger, \& Raab, 2014). In many real-life situations, as in sports, decisions have to be taken under limited time, and we know that adults adapt to time limitation by using faster and simpler strategies (Ben Zur \& Breznitz, 1981; Payne et al., 1988). In particular, previous studies examining the effects of time limitation on decision-making processes have found that, under pressure, adults tend to increase their information processing speed (e.g., Ben Zur \& Breznitz, 1981; Payne et al., 1988) and use more non-compensatory strategies (e.g., Payne et al., 1988). On the same line, in a study with adult soccer players, Belling and colleagues (2015) found that time limitation reduced the number of task-relevant options generated, although it did not impact the quality of players' decisions.

What about the effects of time limitation on children's decision-making? We know that children are ecological learners, able to adapt their learning strategies to the characteristics (e.g., the statistical structure) of the task at hand (Horn et al., 2016; Nelson, Divjak, Gudmundsdottir, Martignon, \& Meder, 2014; Ruggeri \& Lombrozo, 2015), and they do so already by age four (Ruggeri, Sim, \& Xu, 2017). However, Davidson (1996) investigated the influence of time limitation on children's (7- to 10-year-olds) information search behavior and found that time pressure promoted faster, but generally not more selective searching. In this sense, it is unclear whether children would adapt their option generation and subsequent decision-making strategies depending on the time available.

## The present study

In the present study we use soccer as a testbed for a dynamic, real-life decision-making situation children have experience with. In particular, we extend previous research in two ways. First, we investigate for the first time children's (6- to 13-year-olds) option generation process, testing the predictions of the TTF model. In general, children have been shown to
use simple, non-compensatory information-search strategies (Davidson, 1991; Ruggeri \& Katsikopoulos, 2013), and specifically adolescent handball players have been shown to act according to TTF (Johnson \& Raab, 2003), we expect children to make use of the TTF heuristic. Moreover, in line with studies that investigated decision-making from a developmental perspective and showed an increase of selective, non-compensatory strategy use with age (Davidson, 1991, 1996), we further expect older children to rely more on the TTF heuristic than younger children.

Second, we explore whether and how time limitation influences the option generation and decision making of children. In particular, based on prior research, it is unclear whether children would adapt their option generation and decision-making strategies under time limitation.

## Method

## Participants

Ninety-seven children, all male, participated in this study ( $M_{\text {age }}=10.49$ years, $S D=1.98$ years; ranging from 6.67 to 13.50 years). All participants were recruited from a professional soccer academy in Germany. Prior to beginning the study, written informed parental consent, and local ethical review board approval of the study protocol, were obtained.

## Materials

We used 21 video scenes of live soccer match footage (three for the practice trials, 18 for the test trials). After a short display of buildup play, the scenes suddenly stopped right before the player in possession of the ball had to make a decision. The duration of the video scenes ranged between seven and eleven seconds, and video duration was unrelated to the study variables (all $p>.05$ ). We adopted the same task and materials as in Belling et al. (2015) with one difference: Instead of using an occlusion image that displayed field lines and the location of the ball on a blank white screen, we used real play footage that ended in a frozen frame such that all players are visible and the player with the ball needs to decide (see Figure 1). We chose to end the video with a frozen frame to provide participants with a constant, non-memory based game situation allowing the same condition during the entire option-generation test. Materials were presented to children on a touchpad (size: 8.9'').

Figure 1: Decision-making test procedure. a) The video stopped right before the player in possession of the ball had to make a decision and ended with a frozen frame. b) The option generation phase in which children generated options. c) Option selection phase in which children saw their generated options and subsequently selected the option they thought was the best.

## Design and Procedure

The task was administered collectively in groups of five to nine same-aged children. Within one age group, children
were randomly assigned to the testing sessions. Children were asked to sit at individual desks where a tablet was positioned. They were then introduced to the task procedure via a standardized instructional video (duration: 2:51 min) showing a person conducting the decision-making test for one exemplary soccer scene. The instructional video showed exactly which steps children were required to do on their tablets throughout the testing procedure.

The test proceeded as follows: After viewing each of the 21 videos (see above), videos stopped and held on with a frozen-frame, which gave the children time to generate a maximum of six options directly marking them onto the field via touch-pad (see Figure $1 \mathrm{a}, \mathrm{b}$ ). The first three videos were practice trials, used to familiarize participants with the test. During this familiarization phase children could ask clarifying questions to the experimenter. The other 18 video scenes were used as test trials and were randomly assigned to either the short-time ( 9 videos) or the long-time ( 9 videos) condition. In the long-time trials, children were given 30sec to generate options, whereas in the short-time trials participants were given 7.5 sec to generate. The order of presentation of the test videos was randomized, irrespectively of to which condition they were assigned. Afterwards, participants were asked to select among the options they had generated the one they thought was the best (see Figure 1 c ).

## Results

Results were analyzed with respect to developmental differences on four outcomes: (1) the mean number of options generated across all 18 tests; (2) quality of the generated options; (3) quality of the selected options; (4) participants’ dynamic inconsistency, which is the rate at which children selected as the best option the one they had generated at first. Dynamic inconsistency rates were computed as the relative frequency that the first option was not selected by players to be their final decision: Number of videos minus the frequency of the first generated option being the final decision divided by the total number of videos. Finally, we tested the effect of the time limitation manipulation on above-mentioned outcome variables.
To assess the quality of (2) the options generated and (3) option selected, two experienced youth soccer coaches independently generated options for the 18 test videos presented and rated the quality of each option they had generated on a 10-point scale (from 0, 'not at all good', to 10 'very good'). Overall, coaches generated a total of 104 options for the 18 test videos. That is, a total of 52 options were generated by each coach ( $M=2.89$ options per coach per video). Of the 52 options generated independently, 42 identical options were generated by both coaches indicating an $81 \%$ overlap between coaches. The quality of the options generated only by one coach or not generated by the coaches at all was scored with 0 'not at all good'. Based on the moderate inter-rater agreement for the quality of all options generated (ICC $=.52, p=.01$ ), quality scores for each option were calculated by averaging coaches' quality ratings.

## Option Generation, Decision Making, and Developmental Effects

Children generated a mean of 2.21 options ( $S D=0.65$ ). Overall, the mean quality of the first option children generated was $4.72(S D=0.99)$. We conducted a repeated measures MANOVA with the within-subject factor serial position of option (1-6) and quality as a dependent variable. This analysis revealed that children generated options in a meaningful way indicated by a significant decline of option quality across the serial position, Greenhouse-Geisser corrected $F(2.70,259.43)=859.56, p<.001, \eta_{p}{ }^{2}=.90$.

The mean quality of the option selected as the best was 4.45 ( $S D=1.06$ ). Most importantly, children selected the first generated option as the best one in $74 \%$ of the cases ( $\mathrm{SD}=$ 18.59). Compared to options generated at later serial positions, the first option generated was selected to be the final decision more frequently, $\chi^{2}(5)=4411.70, p<.001$. This was reflected in a dynamic inconsistency rate (i.e., the mismatch between the first option generated and final decision) of $0.26(S D=.19)$. This is a relatively low value, considering that a random selection would have resulted in a dynamic inconsistency rate of 0.55 , resulting from: $1-(1 /$ 2.21). The more options children generated, the higher was the dynamic inconsistency of their decisions, $r=.555, p<$ . 001 .

Separate linear regression analyses revealed that children's age was a significant positive predictor of all optiongeneration and most decision-making variables, except for dynamic inconsistency ( $R^{2}=.02, p=.138$ ). The older the children, the more options they generated ( $R^{2}=.06, p=.019$, $\beta=.24$ ), and the higher was the quality of the first option generated $\left(R^{2}=.19, p<.001, \beta=.44\right)$ as well as that of the option selected as the best $\left(R^{2}=.10, p=.002, \beta=.31\right)$.

## Time Limitation Effects

To explore whether and how time limitation influenced the option generation and decision making of children, we performed a multivariate analysis of variance (MANOVA) with one within subject factor time limitation (short-time vs. long-time condition) and four dependent variables (number of options generated, quality of the first option, quality of selected option and dynamic inconsistency). The repeatedmeasures MANOVA showed a significant multivariate effect, Wilks's Lambda $\lambda=.20, F(5,92)=34.50, p<.001$, $\eta_{\mathrm{p}}{ }^{2}=.62$. Follow-up univariate effects were further inspected for each decision-making variable separately.

In the short-time condition, as compared to the long-time condition, children generated fewer options, $F(1,96)=$ 127.51, $p<.001, \eta_{\mathrm{p}}{ }^{2}=.57$, generated first options with higher quality, $F(1,96)=15.19, p<.001, \eta_{\mathrm{p}}^{2}=.14$, and selected options of higher quality as their final, best decisions, $F(1$, $96)=16.55, p<.001, \eta_{\mathrm{p}}^{2}=.15$. With shorter time, dynamic inconsistency was less apparent than in the long-time condition, $F(1,96)=14.39, p<.001, \eta_{\mathrm{p}}^{2}=.13$.

Table 1: Effect of time limitation on the considered option generation and decision making variables.

|  | Short-time |  |  | Long-time |  |
| :--- | :---: | :---: | :---: | :---: | :---: |
|  | condition |  |  | $\frac{\text { condition }}{M}$ |  |
|  | $M$ | $S D$ |  | $M$ | $S D$ |
| Total number of options | 1.84 | 0.56 | 2.59 | 0.86 |  |
| Quality of first option | 4.99 | 1.32 |  | 4.45 | 1.09 |
| Quality of final decision | 4.75 | 1.34 |  | 4.16 | 1.21 |
| Dynamic inconsistency | 0.22 | 0.20 | 0.29 | 0.21 |  |

Children generated their first option in a meaningful way: in the short-time condition, Greenhouse-Geisser corrected $F(2.35,225.77)=567.40, p<.001, \eta_{\mathrm{p}}^{2}=.86$, and in the longtime condition, $F(3.09,296.81)=489.89, p<.001, \eta_{p}^{2}=.84$, a significant decline of option quality across the serial position was apparent. Most importantly, children selected their first option to be the final decision in $71.1 \%(n=621)$ of the decisions in the long-time condition and significantly more often in $77.8 \%(n=679)$ of the decisions in the shorttime condition, $\chi^{2}(1, N=97)=11.60, p=.001, r=.16$.

In both conditions, the first option generated was selected to be the final decision more frequently, in the short-time, $\chi^{2}(5, N=97)=1982.61, p<.001, v=.67$, and in the longtime condition, $\chi^{2}(5, N=97)=2444.15, p<.001, v=.75$. For both time-limitation conditions, children's decision making was more dynamically inconsistent the more options they generated (short-time condition: $r=.448$, no time limitation: $r=.581$ ). Further, separate linear regression analyses were conducted for each time-limitation condition. Results revealed that the total number of options children generated predicted the degree of dynamic inconsistency in both conditions: The more options children generated in the shorttime, $\beta=.58, t(95)=6.95, p<.001, R^{2}=.33$, or in the longtime condition, $\beta=.45, t(95)=4.88, p<.001, R^{2}=.19$, the more dynamic inconsistent were their decisions.

We tested further whether age was differentially predictive when time is limited. In the short-time condition, children's age was a significant positive predictor of all optiongeneration and most decision-making variables, except for dynamic inconsistency ( $R^{2}=.01, p=.245, \beta=.12$ ). With time limitation, the older the children, the more options they generated $\left(R^{2}=.11, p=.001, \beta=.33\right)$ and the higher the quality of the first option generated ( $R^{2}=.13, p<.001, \beta=$ .36) as well as that of the option selected as best ( $R^{2}=.10, p$ $=.002, \beta=.31$ ). For the long-time condition, no age effect was found on the number of options generated ( $R^{2}=.02, p=$ $.153, \beta=.15$ ), the quality of the final option selected as best ( $R^{2}=.04, p=.057, \beta=.19$ ) and on dynamic inconsistency ( $R^{2}=.02, p=.130, \beta=.16$ ), but the older the children the higher the quality of the first option in the short-time condition ( $R^{2}=.13, p<.001, \beta=.36$ ).

## Discussion

Little, if anything, is known about how children generate options about which actions can be taken in real-life situations. To address this question, we tested the option
generation and decision making of children based on the predictions of the TTF heuristic. In addition, the influence of time limitation on option generation and decision making was explored. This allowed deepening our understanding of the adaptive relation between time limitation as one relevant environmental factor and the decision-making process predicted by TTF heuristic as argued from an ecological rationality perspective. In an experiment, children between the age of six and 13 years were tested in a video-based soccer decision-making task involving a within-subject timelimitation manipulation.

First, we investigated children's (6- to 13-year-olds) option generation process for the first time. Testing the TTF model revealed that predictions of the TTF heuristic also hold for children. In the option generation phase, as expected, children generated between two and three options, did so in a meaningful, non-random way and selected their first option as the final decision in more than $50 \%$ of the cases. Further, children's option generation influenced their decisions making: the more options children generated, the more dynamically inconsistent they decided. The pattern of results in children mainly matches option-generation and decisionmaking processes that have previously been demonstrated in adolescents and adults (Belling et al., 2015; Johnson \& Raab, 2003). The results are also consistent with findings showing that already schoolchildren use decision heuristics that match the task at hand (e.g., Horn et al., 2016).

Second, we explored whether and how time limitation influenced the option generation and decision making of children. Because of its naturally occurring dynamics, the sports domain is the ideal testbed to investigate situational, real life influence like time limitation. Our results revealed that time limitation affected all decision-making variables. In response to limited time, children generated fewer options, were less inconsistent in their decisions, generated higher quality first options and selected higher quality options as final decisions. This last result differs from what found with adult soccer players, whose quality of option generation and selection was not enhanced in response to time limitation (Belling et al., 2015). However, the positive effect of time limitation on children's option quality demonstrated in the present study theoretically matches predictions of the TTF heuristic and fits with the ecological rationality perspective (Johnson \& Raab, 2003; Todd et al., 2012). Compatible with the notion of "less-is-more", the time constraint prompted the generation of fewer but better options. Our results are also consistent with studies demonstrating that children are indeed ecological learners and speak for an adaptation of strategy use to the situation or task at hand (Horn et al., 2016; Ruggeri \& Lombrozo, 2015).
Finally, we found consistent developmental effects on both option generation and decision making: The number of options generated increased with age, but only in the shorttime condition. This short-time specific age effect hints at a developmental advantage for older children. With increasing age, children seem to adapt to time limitation by speeding up their generation to still produce a valid amount of options
they can choose from $\left(M(S D)_{\text {time }}\right.$ limitation $\left.=2.00(0.46)\right)$, whereas younger children do not $\left(M(S D)_{\text {time }}\right.$ limitation $=$ $1.67(0.60)$ ). In addition, older children seem to focus more on relevant, high-quality options early in the generation, irrespective of time limitation. This was indicated by the quality of the first option generated increasing with children's age irrespective of time limitation. In line with results showing that the information-search behavior of younger children (7- to 10-year-olds) was not more selective (Davidson, 1996), this study showed that selectivity for highquality information during generation seems to emerge later in childhood. For the quality of the final decision, as for the number of options, an increase with age was only apparent under limited time. This could be interpreted as a stronger adaption to time limitation by applying a strict, selective decision rule or applying it, according to the TTF heuristic, more accurately (Johnson \& Raab, 2003). Summing up, we showed that children adapted to the situational demands of time limitation by relying more on the simple TTF heuristic.

In conclusion, the present study shows that in familiar situations children tend to use simple, intuitive option generation and decision-making strategies. In particular, results support that TTF as a cognitive model can account for the option generation and decision making of children between the age of six and 13 years. Further, the study indicates that time limitation was an important situational factor impacting children's decision-making processes. Future studies should, therefore, explore other potentially relevant situational factors. Deepening our understanding of environmental or situational influences would also provide a concrete anchor for interventions targeting children's options and choices. Dynamic decision environments could, for example, be manipulated by the speed, distance or amount of stimuli provided. In particular, effects of situational factors on children's decision-making processes could be integrated into computer-based or real-life interventions and tested in a randomized control trial. Based on that, knowledge should be incorporated into prevention (e.g. traffic education) and training (e.g., sports, physical education) programs in a second step.

## Acknowledgments

We thank our colleagues in the Department of Performance Psychology for providing critical and constructive feedback on this project. We would also like to thank Sven Krüger, Silvana Höft, Elena Steen, Matthias Reubold, Lukas Hombach, Sinikka Heisler, Justin Klandermann, Taner Memis, Lukas Semmlinger, Estelle Schell, Matthias Rißmaier, and Benedikt Kosak for supporting data collection and coding.

#### Abstract

One of the most salient and well-recognized features of human goal-directed behavior is our limited ability to conduct multiple demanding tasks at once. Previous work has identified overlap between task processing pathways as a limiting factor for multitasking performance in neural architectures. This raises an important question: insofar as shared representation between tasks introduces the risk of cross-talk and thereby limitations in multitasking, why would the brain prefer shared task representations over separate representations across tasks? We seek to answer this question by introducing formal considerations and neural network simulations in which we contrast the multitasking limitations that shared task representations incur with their benefits for task learning. Our results suggest that neural network architectures face a fundamental tradeoff between learning efficiency and multitasking performance in environments with shared structure between tasks.

Keywords: multitasking; cognitive control; capacity constraint; learning; neural networks

## Introduction

Our limited capability to execute multiple tasks at the same time highlights one of the most fundamental puzzles concerning human processing, which must be addressed by any general theory of cognition (Shenhav, Botvinick, \& Cohen, 2013; Kurzban, Duckworth, Kable, \& Myers, 2013; Anderson, 2013): Why, for some tasks, is the human mind capable of a remarkable degree of parallelism (e.g., navigating a crowded sidewalk while talking to a friend), while for others its capacity for parallelism is radically limited (e.g., conduct mental arithmetic while constructing a grocery list)?

Early theories of cognition, that have continued to be highly influential, assert that the ability to multitask - that is, to carry out a set of tasks concurrently ${ }^{1}$ - can be understood in terms of a fundamental distinction between automatic and controlled processing, with the former relying on parallel processing mechanisms (that can support multitasking) and the latter assumed to rely on a serial processing mechanism with limited capacity (Posner \& Snyder, 1975; Shiffrin \& Schneider, 1977) that can only support processing of a single task at

[^145]a time. In this view, the constraints on the number of controldependent tasks that can be executed at one time reflect an intrinsic property of the control system itself. However, alternative ("multiple-resource") accounts (Allport, 1980; Meyer \& Kieras, 1997; Navon \& Gopher, 1979; Salvucci \& Taatgen, 2008) have suggested that multitasking limitations arise from local processing bottlenecks. That is, if two tasks share the same local resources (i.e. representations required to perform the tasks), then executing them simultaneously can lead to cross-talk and degraded performance. It has been argued that the very purpose of cognitive control is to prevent such cross-talk by limiting the number of active task processes engaged (Cohen, Dunbar, \& McClelland, 1990; Botvinick, Braver, Barch, Carter, \& Cohen, 2001). In this view, constraints in multitasking reflect the consequences of control doing its job, rather than limitations intrinsic to the mechanisms of control itself. This line of argument suggests that, to better understand the conditions under which multitasking is and is not possible, it is necessary to understand the extent to which the task processes involved share representations, and are thus subject to potential interference and the intervention of control to limit processing. This, in turn, raises the question of whether there are general principles of neural architectures that determine the use of shared representation, and how these interact with learning and processing.

One may argue that the constraints that shared representations impose on multitasking are negligibly small in a processing system as large as the human brain. However, simulation studies (Feng, Schwemmer, Gershman, \& Cohen, 2014), followed by analytic work (Musslick et al., 2016) have found that the multitasking capability of a network can drop precipitously as a function of overlap between task processes (i.e. number of shared representations), and that this effect is relatively insensitive to the size of the network.

The findings above suggest that maximal parallel processing performance is achieved through the segregation of task pathways, by separating the representations on which they rely. This raises an important question: insofar as shared representation introduces the risk of cross-talk and thereby limitations in parallel processing performance, why would the brain prefer shared task representations over separate ones? Insights gained from the study of learning and representation in neural networks provide a direct answer to this question:

Shared representations across tasks can support inference and generalization (Caruana, 1997). These benefits are strongly linked to the ability of neural networks to carry out "interactive parallelism", that is, the ability to learn and to process complex representations by simultaneously taking into account a large number of interrelated and interacting constraints (McClelland, Rumelhart, \& Hinton, 1986).

In this study, we examine the tension between interactive parallelism that promotes learning efficiency through use of shared representations, on the one hand, and "independent parallelism" (i.e. the ability to carry out multiple processes independently), on the other hand. That is, we are interested in studying biases that promote shared representations over multitasking performance. We first demonstrate that the wellrecognized (and valued) emergence of shared representations (Hinton, 1986) in response to extrinsic biases (i.e. shared structure in the task environment) leads to constraints in multitasking performance. In the second part, we introduce a formal characterization of a tradeoff between learning efficiency and multitasking performance and examine how intrinsic biases of the network toward the use of shared representations can expose this tradeoff in neural network simulations. The source code for all simulations is available at github.com/musslick/CogSci-2017.

## Neural Network Model

For the simulations described in the paper we focus on a network architecture that has been used to simulate a wide array of empirical findings concerning human performance (e.g. Cohen et al., 1990; Botvinick et al., 2001), including recent work on limitations in multitasking (Musslick et al., 2016). In this section we lay out the architecture of this network, its processing, as well as the task environments used to train it.

## Network Architecture and Processing

The network consists of two input layers, one of which represents the stimulus presented to the network and another that encodes the task that the network is instructed to perform on the stimulus. Stimulus input features can take any real value between 0 and 1 and can be grouped into stimulus dimensions that are relevant for a particular task. The network is instructed to perform a single task by clamping the corresponding task unit in the task layer to 1 while all other task units are set to 0 . These stimulus and task input values are multiplied by a matrix of connection weights from the respective input layer to a shared associative layer, and then passed through a logistic function to determine the pattern of activity over the units in the associative layer. This pattern is then used (together with a set of direct projections from the task layer) to determine the pattern of activity over the output layer. The latter provides a response pattern that is evaluated by computing its mean squared error (MSE) with respect to the correct (task-determined) output pattern. Similar to stimulus features, output units can be grouped into response dimensions that are relevant for a particular task. Note that the
weight projections from each task unit can act as control signals that bias processing towards task-relevant stimulus information represented at the associative and output layer.

In order to represent the task environment described below, the stimulus layer is compromised of 45 input units (features) and the task layer of nine task units. The output layer consists of 15 units and is organized into three response dimensions (with five units per response dimension.). The number of units in the associative layer is set to 100 .

Figure 1: Feedforward neural network used in simulations. The input layer is composed of stimulus vector $\overrightarrow{x_{s}}$ and task vector $\overrightarrow{x_{t}}$. The activity of each element in the associative layer $y_{h} \in \overrightarrow{y_{h}}$ is determined by all elements $x_{s}$ and $x_{t}$ and their respective weights $w_{h s}$ and $w_{h t}$ to $y_{h}$. Similarly, the activity of each output unit $y_{o} \in \overrightarrow{y_{o}}$ is determined by all elements $y_{h}$ and $x_{t}$ and their respective weights $w_{o h}$ and $w_{o t}$ to $y_{o}$. A bias of $\theta=-2$ is added to the net input of all units $y_{h}$ and $y_{o}$. Blue shades in the input and output units (circles) correspond to unit values of $>0$ and illustrate an example input pattern with its respective output pattern: The second task requires the network to map the vector of values in the first five stimulus input units to one out of five output units (yellow shade).

## Task Environment

Each task is defined as a mapping between a subspace of five stimulus features (referred to as a task-relevant stimulus dimension) onto five output units of a task-specific response dimension, so that only one of the five relevant output units is permitted to be active (see Fig. 1). The value of each stimulus feature is drawn from a uniform distribution $U[0,1]$. The rule by which 5 relevant stimulus features of any task-relevant stimulus dimension are mapped onto one of the 5 output units of the task-relevant response dimension corresponds to a nonlinear function that was randomly generated ${ }^{2}$ with a separate "teacher" network (cf. Seung, Sompolinsky, \& Tishby, 1992), and is the same across tasks. However, tasks are considered to be independent in that they differ which stimulus dimension is linked to which response dimension.

The task environment across all simulations encompasses nine tasks. As illustrated in Fig. 2 groups of three tasks map

[^146]onto the same response dimension. However, similarity between tasks could be varied by manipulating the overlap between their relevant stimulus dimensions. At the extremes, task environments can be generated such that tasks of different response dimensions relate to separate stimulus features (no feature overlap, Fig. 2a), or the same stimulus features (full feature overlap, e.g. tasks 1-3 in Fig. 2b).

Figure 2: Task environments. For each task, the network was trained to map a subset of 5 stimulus features onto a subset of 5 output units. At the extremes tasks that were mapped onto different response dimensions (e.g. tasks 1-3) could either (a) rely on separate stimulus features or (b) completely overlap in terms of their relevant stimulus features.

Networks are initialized with a set of small random weights and then trained on all tasks using the backpropagation algorithm ${ }^{3}$ (Rumelhart \& Geoffrey E. Hinton, 1986) to produce the task-specified response for each stimulus.

## Multitasking Limitations Due to Shared Structure in the Task Environment

A key feature of neural networks is their ability to discover latent structure in the task environment, exploiting similarity between stimulus features in the form of shared representations (Hinton, 1986; Saxe, McClelland, \& Ganguli, 2013). In this section we explore how the emergence of shared representations as a function of structural similarities between tasks can impact the multitasking performance of a network.

## Simulation Experiment 1: Shared Task Representations as a Function of Feature Overlap

In order to investigate the effect of structural similarities between tasks we generated task environments with varying overlap between task-relevant stimulus features. We define feature overlap as the number of relevant stimulus features that are shared between any pair of tasks linked to different response dimensions (see Fig. 3a). That is, two tasks involving two different response dimensions could either share

[^147]no relevant stimulus features (cf. Fig. 2a), all five stimulus features (cf. Fig. 2b) or any whole number of features in between, resulting in 6 different task environments. We trained 100 networks in each of the environments. The networks were trained on all nine tasks with the same set of 50 stimulus samples until the network achieved an MSE of 0.01.

Figure 3: Effects of task similarity. (a) Networks were trained in task environments with varying degrees of feature overlap. Yellow and red shades highlight task-relevant stimulus features for two tasks involving different response dimensions. (b) Final multitasking accuracy of the network as a function of the learned similarity between tasks involving different response dimensions. Colors indicate the degree of feature overlap present in the task environment as illustrated in (a).

In order to assess the similarity of learned task representations we focus our analysis on the weights from the task units to the associative layer, insofar as these reflect the computations carried out by the network required to perform each task. For a given pair of tasks we compute the learned representational similarity between them as the Pearson correlation of their weight vectors to the associative layer.

We measured multitasking performance for pairs of tasks (of different stimulus and response dimensions) by activating two task units at the same time and evaluating the concurrent processing performance in the response dimensions relevant to the two tasks. The accuracy of a single task $A_{\text {Single }}$ can be computed as

$$
\begin{equation*}
A_{\text {single }}=\frac{a_{c}}{\sum_{i=1}^{5} a_{i}} \tag{1}
\end{equation*}
$$

where $a_{i}$ is the activation of the $i$ th output unit of the taskrelevant response dimension and $a_{c}$ is the activation of the correct output unit. The multitasking accuracy is simply the mean accuracy of both engaged single tasks.

The simulation results confirm well-known explorations in neural networks (Hinton, 1986; McClelland \& Rogers, 2003; Saxe et al., 2013) that task similarities in the environment can translate into similarities between learned task representations. Critically, this extrinsic bias toward the learning of shared representations negatively affected multitasking performance (Fig. 3b). To illustrate this, consider the simultaneous execution of tasks 1 and 5 in an environment as depicted in Fig. 2b. If the network learns similar representations at the associative layer for tasks 1 and 2 (note that both tasks rely on the same stimulus features), then executing task 1 will implicitly engage the representation of task 2 which in turn causes interference via its link to the response dimension of task 5.

## Multitasking Limitations due to Intrinsic Learning Biases

In addition to environmental biases that shape the learning of shared task representations there may be factors intrinsic to the neural system that can regulate the degree to which such representations are exploited in learning. In this section we introduce a formal analysis of how such biases can affect the tradeoff between learning efficiency and multitasking performance. We then use weight initialization as a learning bias in simulations to establish a causal relationship between the use of shared representations on the one hand, and resulting effects on learning and multitasking, on the other hand.

## Formal Intuitions on the Tradeoff between Learning Efficiency and Multitasking Capability

To gain formal intuition into the tradeoff between multitasking ability and learning speed, we consider a stripped-down version of the introduced network model that is amenable to analysis. In the full model, nonlinear interactions between the task units and the stimulus units occur in the associative layer. Here we assume a gating model in which these nonlinear interactions are carried out through gating signals that can zero out parts of the activity in the associative and output layers, or pass it through unchanged. The choice of which parts of each layer are gated through on each input is left to the designer (not learned, as in the full model).

We study the scheme depicted in Fig. 4 consisting of $M$ input and response dimensions with full feature overlap (cf. Fig. 2b). For the output layer, we assume that the gating variables automatically zero all but the task-relevant response dimensions. For the associative layer, we separate the hidden units into dimensions, one for each input dimension, and make the gating variables zero all representations except the one coming from the task-relevant input dimension (Fig. 4a).

Crucially, when the gating structure is known on a specific example, the output of the network is a linear function of the neurons that are on. Given this setting, the learning dynamics can be solved exactly using methods developed by Saxe, McClelland, and Ganguli (2014). The key advantage afforded by the gating scheme is depicted in Fig. 4a: the input-to-hidden weights for one input dimension can be shared by all tasks that rely on that input dimension. This leads to a factor $\sqrt{M}$ speedup in learning relative to learning a single task by itself (proof omitted due to space constraints).

However, with this gating system, multitasking is not possible: gating another task through to the output will lead to interference. To counteract this, the gating scheme must be changed: response dimensions can be divided into $Q$ groups, each with a dedicated set of hidden units (Fig. 4b). This allows tasks that use response dimensions in different output groups to be performed simultaneously. Hence a maximum of $Q$ tasks can be performed simultaneously, but weight sharing is reduced across tasks by a factor $Q$, slowing learning.

This analysis provides, at least in a simplified system, a quantitative expression of the fundamental tradeoff between

Figure 4: Gating model used for formal analysis. (a) Task information directly switches on or off task-relevant dimensions in the output and associative layers. This allows input-to-hidden weights to be shared across the $M$ different tasks corresponding to different response dimensions, increasing learning speed by a factor $\sqrt{M}$. However, two tasks that rely on different input dimensions cannot be multitasked due to crosstalk at the output (convergent red and green arrows). (b) Multitasking ability can be improved by separating response dimensions into $Q$ groups, each with a dedicated set of units in the associative layer. Gating now permits one task from each group to operate concurrently (red and green arrows no longer converge). However, weight sharing is limited to the group, yielding a learning speed of $\sqrt{M / Q}$.
learning speed and multitasking ability. Let $t$ be the number of iterations required to learn all tasks, $Q$ the maximum number of concurrently executable tasks, and $M$ the number of input/response response dimensions. Then

$$
\begin{equation*}
t^{2} \propto Q / M \tag{2}
\end{equation*}
$$

where the proportionality constant is related to the statistical strength of the input-output association for one task, the learning rate, and the error cut-off used to decide when learning is complete (Saxe, Musslick, \& Cohen, 2017).

Due to the tradeoff in Eqn. (2), gating schemes that share more structure will learn more quickly. Hence generic, randomly initialized nonlinear networks will tend to favor shared representations, as shown in Simulation Experiment 1.

## Simulation Experiment 2: Effects of Learning Biases for Shared Representations

In Simulation 2 we focus on a bias intrinsic to the neural system, i.e. the initialization of the weights from the task layer. We use this factor to systematically examine how the use of shared representations facilitates the discovery of similarity structure while diminishing multitasking performance. To do so, we focus initially on a training environment in which tasks are maximally similar, as this is the condition in which there is most opportunity for exploiting shared representations. We then examine environments with $80 \%$ and $0 \%$ feature overlap between tasks, to test the generality of the observed effects.

To manipulate the bias towards shared task representations, we initialized the weights from the task units to the associative layer, varying the similarity among the weight vectors across tasks with the rationale that greater similarity should produce a greater bias toward the use of shared representations in the associative layer. Weight vectors for tasks relying on the same stimulus input dimensions were randomly initialized to yield a correlation coefficient of value $r$. The correlation value $r$ was varied from 0 to 0.975 in steps of 0.025 and was used to constrain initial weight similarities for 100 simulated networks per initial condition. The weight vectors for tasks of non-overlapping stimulus dimensions were uncorrelated. Finally, all task weights to the associative layer were scaled by a factor of 5 to enhance the effects of different initial task similarities. The networks were trained using the same parameters as reported for Simulation Experiment 1.

Simulation results indicate that networks with a higher similarity bias tend to develop more similar representations at the associative layer for those tasks (in terms of their final weight vector correlations), whereas a lower similarity bias leads to more distinct task representations at this layer. In environments with high feature overlap between tasks, stronger initial biases toward shared representations lead to increased learning speed (i.e. less iterations required to train the network), as similarities between tasks can be exploited (Fig. 5a). Critically, this comes at the cost of multitasking performance. Learning benefits gained from shared representations are less prevalent in environments with less feature overlap between tasks. However, effects of weight similarity biases on multitasking impairments remain (Fig. 5b).

Figure 5: Effects of weight similarity bias. Mean multitasking accuracy (for two tasks simultaneously) plotted against the mean number of iterations required to train the network. Data points represent the mean measures across networks initialized with the same task similarity (constrained by task weight vector correlation) for tasks relying on the same stimulus dimensions. Effects are shown for (a) environments with $100 \%$ feature overlap between tasks, as well as (b) across environments with different feature overlap. Different data point clusters correspond to different training environments.

## General Discussion and Conclusion

The limited ability to perform multiple control-dependent tasks at the same time is one of the most salient characteristics of human cognition, and is universally considered a defining feature of cognitive control. Despite these facts, the
sources of this capacity constraint associated with control remain largely unexplored. Here, we build upon the observation that multitasking limitations can arise from shared representations between tasks (Feng et al., 2014; Musslick et al., 2016), and use a combination of formal analysis and neural network simulations to examine biases towards shared representations that incur such costs in multitasking.

In the first part of this study, we build upon early insights of connectionism that shared representations emerge as a function of task similarities in the environment and demonstrate the deleterious consequences for multitasking performance. It has been shown that networks are capable of extracting similarities from a hierarchically structured input space (Hinton, 1986). Recent analytic and empirical work in the domain of semantic cognition paints a similar picture: neural systems may gradually discover shared structure in the task environment with a bias towards the initial formation of shared, lowdimensional representations (Saxe et al., 2013; McClelland \& Rogers, 2003). Our simulation results are in line with these observations showing that shared task representations emerge as a function of high stimulus feature overlap between tasks and furthered the insight that such similarities in the task environment lead to multitasking limitations.

In the second part, we examined how intrinsic learning biases towards shared or separate representations (by means of weight initialization) can be used to expose a tradeoff between learning efficiency and multitasking performance. Early work in machine learning suggests that learning biases towards a particular representation can be understood as biases of the learner's hypothesis space (Baxter, 1995), that is, the set of all hypotheses a learner may use to acquire new tasks. We formalized this hypothesis space in terms of the amount of shared representations between tasks and showed how this mediates an inverse relationship between learning efficiency and interference-free multitasking. Our neural network simulations confirmed these analytical predictions, showing that a weight initialization bias towards shared representations enables faster learning if shared structure in the environment can be exploited, but incurs a cost for multitasking. A promising direction for future research may be to explore another prediction: our formalism suggests a role for such biases in regularizing the representational complexity of the network, thereby promoting generalization performance.

Our analyses indicate that neural learning systems, whether natural or artificial, are subject to a tension between "interactive parallelism" on the one hand, which exploits the fine grained structure of representations and similarity in the service of learning, and "independent parallelism" that supports concurrent processing of distinct tasks, on the other hand. A similar tension can be found in the domain of learning and memory. The complementary learning systems hypothesis proposes two separate learning systems, one system that relies on shared representations to support inference, as well as another system that uses separate representations to support independent encoding and retrieval of information
(McClelland, McNaughton, \& O'Reilly, 1995). The latter system supports a form of independent parallelism for associational processes that is similar to the form of independent parallelism for executional processes described in this paper.

Altogether our results suggest that the brain may be confronted with balancing multitasking capability against extrinsic and intrinsic biases towards shared representations. A major goal for the development of artificial systems may be to systematically configure the balance between interactive and independent parallelism, as well as to exploit the relative advantages of each. Most efforts in complex neural architectures have focused predominantly on the discovery of shared representations for the purpose of inference and generalization (Bengio, Courville, \& Vincent, 2013). However, one of the future challenges will be to explore the tension between learning efficiency and multitasking in networks with higher complexity (i.e. deep networks), as well as in more naturalistic task environments. We hope that this work will help inspire a proliferation of efforts to further explore this area.

# Analogical Inferences in Causal Systems 

Matthew Myers (matthewmyers2020@u.northwestern.edu)<br>Department of Psychology, 2029 Sheridan Road<br>Evanston, IL 60208 USA

Dedre Gentner (gentner@northwestern.edu)<br>Department of Psychology, 2029 Sheridan Road<br>Evanston, IL 60208 USA

#### Abstract

Analogical and causal reasoning theories both seek to explain patterns of inductive inference. Researchers have claimed that reasoning scenarios incorporating aspects of both analogical comparison and causal thinking necessitate a new model of inductive inference (Holyoak, Lee, \& Lu, 2010; Lee \& Holyoak, 2008). This paper takes an opposing position, arguing that features of analogical models make correct claims about inference patterns found among causal analogies, including analogies with both generative and preventative relations. Experiment 1 demonstrates that analogical inferences for these kinds of causal systems can be explained by alignment of relational structure, including higher-order relations. Experiment 2 further demonstrates that inferences strengthened by matching higher-order relations are not guided by the transfer of probabilistic information about a cause from base to target. We conclude that causal analogies behave like analogies in gen-eral-analogical mapping provides candidate inferences which can then be reasoned about in the target.

Keywords: analogy; causality; structure mapping theory; inductive inferences

## Introduction

The current paper challenges recent claims that standard theories of analogy (such as structure-mapping theory; Gentner, 1983, 1989) cannot explain analogical inferences that incorporate causal relations. Holyoak and colleagues (Holyoak et al., 2010; Lee \& Holyoak, 2008) contend that causal analogies require a different kind of process from typical analogies. Specifically, they claim that structure-mapping theory (SMT) -and more broadly, all extant models of analogy—fail to predict people's inferences for causal analogies that involve both generative and preventative causal relations. In their view, causal analogies require models of analogy that incorporate the basic elements of causal models (Lee \& Holyoak, 2008).

We maintain that in causal analogies, the mapping between analogs is done by the same structure-mapping processes as in other domains. Assuming that the mapping yields candidate inferences in the target, normal causal reasoning processes then occur in the target to arrive at further conclusions. Specifically, we show that this division of labor holds for the kinds of materials used by Holyoak and colleagues (Holyoak et al., 2010; Lee \& Holyoak, 2008): analogical processes inform the construction of causal models in the target analog, after which causal reasoning processes are used to draw further inferences in the target. We believe our account provides a better explanation of people's reasoning at the level of representation and, more broadly, offers a more parsimonious
description of analogical reasoning.

## Inference and Similarity

Similarity plays an important role in SMT. While simple physical or property-based similarities can serve as cues to engage in analogical comparison, relational matches are more central to the content of analogical inferences (Gentner \& Markman, 1997). Relational similarity is assessed by a process of structural alignment in which components of the two analogs are placed in correspondence based on a maximal (or near-maximal) match in relational structure. Alignments with deeply embedded relational structures-in which higher-order constraining relations govern lower-order rela-tions-are perceived as more similar than those with shallow structures (Gentner, Rattermann, \& Forbus, 1993) and provide a better basis for candidate inferences to the target (Clement \& Gentner, 1991). Thus, the perceived structural similarity and inferential strength between two analogs typically exhibit a positive correlation.

Targets

Figure 1: The causal systems in Lee \& Holyoak (2008). G and $P$ represent generative and preventative causes. The effect is the outcome feature. Dotted elements in the targets represent information not given. In descending order, similarity ratings between base and target was $G_{1} G_{2} P_{1}, G_{1} G_{2}$, and $G_{1} P_{1}$. The order of inductive strength ratings was $G_{1} G_{2}$, $G_{1} G_{2} P_{1}$, and $G_{1} P_{1}$.

However, Lee and Holyoak (2008) found that these mea-
sures can be disassociated. In Experiment 1, they presented participants with a description of a fictional animal with four notable features. Three of the four features were described as causally related to the fourth: two were generative causes while the other was a preventative cause ( $G_{1}, G_{2}$, and $P_{1}$ ). This animal served as the base analog (see Figure 1). Participants were further given a description of a secondary target animal that possessed one of three combinations of the antecedent features described in the base (i.e., $G_{1} G_{2} P_{1}, G_{1} G_{2}$, and $G_{1} P_{1}$ ); however, they were given no information about how those features affected the outcome. The base animal (Animal A) and target animal (Animal B) were described in the following manner:

Animal A has dry flaky skin, muscular forearms, a weak immune system, and blocked oil glands.
For Animal A, dry flaky skin, tends to PRODUCE blocked oil glands; muscular forearms tend to PRODUCE blocked oil glands; a weak immune system tend to PREVENT blocked oil glands.

Animal B has dry flaky skin, muscular forearms, and a weak immune system.

Participants' task was to either rate the similarity of the base and target, or to estimate the likelihood that the effect would occur in the target. Lee and Holyoak reported that while participants' similarity ratings roughly corresponded with the number of structural relations shared by base and target ( $G_{1} G_{2} P_{1}$ was highest), their inferences did not. In descending order, the observed strength of the effect inference in the target was $G_{1} G_{2}, G_{1} G_{2} P_{1}$, and $G_{1} P_{1}$. The authors contend that these results are problematic for SMT and other models of analogy, for two reasons. First, SMT cannot account for the systematic non-correspondence observed between similarity and inference strength; and second, SMT cannot account for the transfer of probabilistic information from the base because it does not permit the transfer of nonrelational properties of the higher-order relations ${ }^{1}$.

In response to the first issue, Colhoun and Gentner (2009) note that the measure of inductive strength used in the previous experiment focused on a single variable: people's belief about the likelihood of the effect. This ignores a large number of other inferences that must be made between the analogs. Participants are told only that certain factors (e.g., $G_{1}$, dry flaky skin) exist in the target, but they are not told that these factors are causally connected to the effect $E$; these causal links must all be inferred from the base.

[^148]Arguing that the inductive strength of an analogy should be measured by all of its candidate inferences, and not solely a single effect inference, Colhoun and Gentner (2009) used Lee and Holyoak (2008) original stimuli and asked participants to rate their confidence in each of the required inferences in the target ( $G_{1}$ tends to produce $E$, etc.). The result was that the ordering of inductive strength ratings for inferences within the target closely matched the ordering of perceived similarity. In sum, this experiment showed that when the appropriate inferential questions are asked, there is no conflict between perceived similarity and perceived inferential strength.

## Inference and Structure

The second claim against SMT is that it would require the transfer of non-relational properties of higher-order relations, such as propensities for causal antecedents to produce or prevent an effect (as in $G_{1}$ tends to produce $E$ ). Lee and Holyoak (2008) claim that avoiding such a violation of systematicity would require a model to incorporate a kind of mapping process in which degrees of belief in the inferred property of a target are mutually informed by both analogical mapping procedures and causal strength assessments.

However, Colhoun and Gentner (2009) proposed an alternative solution. They suggest that the pattern of relations in the base allows people to infer that the pattern of $G_{1}, G_{2}$ and $P_{1}$ is sufficient to produce $E$. Specifically, participants are told that the base contains $G_{1}, G_{2}$, and $P_{1}$, that $G_{1}$ and $G_{2}$ both tend to produce $E$, that $P_{1}$ tends to prevent $E$, and that $E$ is present. Thus in encoding the base, the presence of the effect $E$ allows people to infer that the combined causal strength of $G_{1}$ and $G_{2}$ exceeds that of $P_{1}$. To test this, in Experiment 2, they presented participants with a base analog consisting of generative and preventive causes ( $G_{1}$ tends to produce $E$, etc.), but varied whether the effect $E$ was actually stated to be present in the base. Participants' task was to generate effect inferences for different targets. The result was that participants gave stronger effect inferences in the target when given a base analog in which the effect was clearly stated to be present than when given a base in which the effect might or might not be present.

Colhoun and Gentner (2009) argue that the presence of an effect in the base provides evidence of the relative strength of the antecedent causes. In other words, people are attending to and transferring a higher-order qualitative relation-that $G_{1}$ and $G_{2}$ are causally stronger than $P_{1}$. This suggests that, as in other areas of analogical reasoning, encoding processes occur in the base, followed by structure-mapping processes that align the base relational structure with that of the target and project candidate inferences to the target. Once these new inferences are projected, causal reasoning processes in the target can produce further inferences.

But there is an alternative account. Perhaps, consistent with the idea that causal propensities are intertwined with the analogical mapping process (Holyoak et al., 2010), the differences in observed inference ratings might simply have been the consequence of a probability calculation computed
in the base and subsequently mapped to a matching target. For example, people may have derived a series of probabilistic propensities for the causal antecedents to bring about the effect. Participants would then project those probabilistic properties of the higher-order predicate relations onto the target (e.g., predicates related by CAUSE- $10 \%$, CAUSE- $50 \%$, CAUSE- $93 \%$, etc.). We explore this possibility in the following two studies.

Figure 2: Base and target systems for Experiment 1 (Panel A) and Experiment 2 (Panel B). $G$ and $P$ represent generative and preventative causes. The experimental manipulations for Experiment 1 and 2 were the bases and targets, respectively.

## Experiment 1

Hypothetically, there are two ways people may calculate probabilistic likelihoods for an effect in a base analog: a global posterior calculation, in which all causal antecedents are factored into a probabilistic estimate; and a local posterior calculation, in which only those antecedent causes that occur in the target are analyzed in the base. Experiment 1 examines a scenario where predictions for global or local posterior calculations are pitted against predictions made by standard mapping theory. Figure 2 A illustrates the scenario used in this experiment. In this study, we varied the causal structure in the base, keeping the target $\left(G_{1} P_{1}\right)$ constant in both conditions. Further, in both conditions, participants are told that the effect $E$ occurs in the base. If participants generate a global posterior calculation for the effect in either the $G_{1} G_{2} P_{1}$ condition [i.e., $P\left(\right.$ Effect $\left.\mid G_{1} G_{2} P_{1}\right)$ ] or the $G_{1} P_{1} P_{2}$ condition $\left[P\left(\right.\right.$ Effect $\left.\left.\mid G_{1} P_{1} P_{2}\right)\right]$, then we should see no difference in inference ratings between conditions. Since people's probability estimates are calculated conditionally on the aggregate influence of all causal antecedents, there is no unitary piece of information that can inform them as to how likely the effect will be when transferred to a $G_{1} P_{1}$ target $^{2}$.

[^149]But suppose instead that participants use the base to generate a local posterior calculation (considering only the relations that match with those in the target)-e.g., $P$ (Effect $\left.G_{1} P_{1}\right)$. In this case, they have no basis for a difference in inference ratings between $G_{1} G_{2} P_{1}$ and $G_{1} P_{1} P_{2}$. Because the strength of the individual causal antecedents is unknown, they would have no information about the degree to which the unmapped cause in the base either prevents $\left(P_{2}\right)$ or contributes $\left(G_{2}\right)$ to the effect. Therefore there is no reason to expect that a systematic difference in effect strength estimates between the two conditions.

In contrast, suppose participants utilize the type of encoding and structure-mapping techniques as described above. In this case, when given the $G_{1} P_{1} P_{2} \rightarrow E$ base, participants should recognize that the effect of $G_{1}$ is stronger than that of both $P_{1} P_{2}$ and is therefore stronger than either of them alone. This relative strength relation is a higher-order relation which takes the causal relations as arguments. When this system is projected to the target $\left(G_{1} P_{1}\right)$, participants should assume that the effect $E$ will occur. In contrast, when given the other base, $G_{1} G_{2} P_{1} \rightarrow E$, participants have no reason to infer that either $G_{1}$ or $G_{2}$ is stronger than $P_{1}$ (since generative relations outnumber preventative relations). Thus the prediction is that the effect inference will be stronger for $G_{1} P_{1} P_{2}$ than for $G_{1} G_{2} P_{1}$ bases.

## Methods

Participants 40 undergraduate students from Northwestern University participated in the study for course credit. One student was excluded because of missing data points and seven were excluded for failing a comprehension check. In all, 32 participants were analyzed in this study.

Materials and Procedure The animal features and structures were those used in Experiment 1 by Lee and Holyoak (2008). Participants were given information about the two animals, a $G_{1} G_{2} P_{1}$ animal and a $G_{1} P_{1} P_{2}$ animal, which served as the different bases. They were also given a target, a $G_{1} P_{1}$ animal (Figure 2A). The bases were described using different sets of features, and therefore the target's features were unique to the given base. In both conditions, participants rated the likelihood of the effect in the target. Inferences were framed as suppositional queries asking participants to predict the number of animals that would exhibit the effect given 100 instances of the target. Furthermore, for the sake of completeness, similarity ratings between base and target were also obtained. These were assessed on a scale of zero to ten, with zero indicating "completely different" and ten indicating "identical". Similarity ratings always preceded inference ratings.

The experiment was conducted on a PC using the software program Qualtrics. Each participant received both $G_{1} G_{2} P_{1}$ and $G_{1} P_{1} P_{2}$ conditions. The order of the two base conditions were counterbalanced. Participants were first given the de-

[^150]scription of a single base and the target animal. Similarity and inference question were placed directly below the description on the same page. Once participants had recorded an answer, they were prompted to continue to the next page. After leaving the page, participants were unable to review the content and answers from the previous page.

Figure 3: Mean outcome (effect) inferences and similarity ratings between target and base. The base categories represent the type of causes each cause had. Error bars represent 1 standard error of the mean.

All participants in Experiment 1 also participated in Experiment 2, which directly proceeded Experiment 1. At the end of the Experiment 2, all participants were given a multiple choice comprehension test that consisted of two questions about the content of stories they were given. If either question was answered incorrectly, that participant's data was removed from analysis for both experiments.

## Results and Discussion

The mean results for both similarity and inference ratings can be seen in Figure 3. The analysis consisted of a paired-sample $t$-test for each rating type. There was a significant difference in mean inference ratings between the conditions: the target in the $G_{1} P_{1} P_{2}$ condition ( $M=62.28, S D=19.84$ ) was rated as significantly more likely to exhibit the effect $E$ compared to the target in the $G_{1} G_{2} P_{1}$ condition ( $M=47.28, S D=17.49$ ), $t(31)=3.44, p<.005$. This suggests that participants' inferences were informed by the higher-order relation observed in the $G_{1} P_{1} P_{2}$ base. There was no significant difference in similarity ratings between the $G_{1} P_{1} P_{2}(M=6.25, S D=1.59)$ and the $G_{1} G_{2} P_{1}(M=5.78, S D=1.75)$ condition $t(31)=1.54, p=.13$. However, the relative similarity ratings were in the same direction as ratings for inferential strength.

These results show that if we assume that people inferred a higher-order relation of relative strength among the causal relations while encoding the base analog, then this relation will be mapped to the target, where it can be used to make causal inferences about the effect $E$. As previously discussed, this pattern of results would be highly unlikely if participants were mapping either a global or local posterior calculation from the base to target. Thus, a higher-order relationship between the generative and preventative causes in the $G_{1} P_{1} P_{2}$
base gave information about the relative strength of $G_{1}$ in the $G_{1} P_{1}$ target. This was not the case for the $G_{1} G_{2} P_{1}$ base. In conjunction with the findings of Colhoun and Gentner (2009), our results suggest that mapping of relational structure, including higher-order relations computed in the base, can account for inferential strength ratings made among analog causal systems.

## Experiment 2

The previous study leaves open another possibility. Perhaps when given the base $G_{1} P_{1} P_{2} \rightarrow E$, participants recognized that $G_{1}$ was stronger than the combined $P_{1} P_{2}$, but simply inferred the absolute strength of $G_{1}$. That is, they inferred that $G_{1}$ was extremely likely to produce effect $E$. To test this, we use the same $G_{1} P_{1} P_{2} \rightarrow E$ base condition that had previously elicited increased inference ratings in Experiment 1. However, this time, the base is constant while the targets vary (see Figure 2B). In both conditions, participants receive the same generative cause (i.e., $G_{1}$ ) observed in the base analog, but also an additional preventative cause that differs by condition. In the Familiar $P$ condition $\left(G_{1} P_{1}\right)$, they receive the same $P_{1}$ feature found in the base. In contrast, in the Novel $P$ condition $\left(G_{1} P_{3}\right)$, they receive a novel preventative feature (i.e., $P_{3}$ ) that has no corresponding relation in the base. If participants simply infer extremely strong causal strength for $G_{1}$ (i.e., $G_{1}$ overpowers the preventative causes), then we should observe no difference between the two conditions. However, if participants are transferring a higher-order relational structure from the base to target, then we should find that people rate the effect to be more probable in the Familiar $P$ condition compared to the Novel $P$ condition.

## Method

Participants The same 40 Northwestern students who participated in Experiment 1 also participated in Experiment 2. Furthermore, the same eight participants whose data was removed from analysis were likewise removed for Experiment 2. A total of 32 participants were therefore analyzed.

Materials and Procedures The animal features for Experiment 2 were taken from Colhoun and Gentner (2009). All participants were run in both the Familiar $P$ and Novel $P$ conditions; order was counterbalanced between participants. They were given the same similarity and inference tasks as in Experiment 1. As before, similarity queries always preceded inference ratings. Participants began the experiment immediately after finishing Experiment 1.

## Results and Discussion

Figure 4 shows the mean inference and similarity ratings. As before, a paired-sample $t$-test was conducted for both measures. Consistent with the hypothesis, mean inference ratings for the likelihood of effect $E$ were significantly greater in the Familiar $P$ condition ( $M=62.31, S D=21.18$ ) than in the Novel $P$ condition $(M=48.59, S D=17.59), t(31)=3.71, p<.001$. Indeed, in the Novel $P$ target, the estimates of likelihood of $E$

Figure 4: Mean outcome (effect) and similarity ratings between target and base. The target categories represent the type of preventative cause present in the target. Error bars represent 1 standard error of the mean.
did not differ from chance (50\%). Similarity ratings were also significantly greater for the Familiar $P$ condition ( $M=6.44$, $S D=1.54$ ) than for the Novel $P$ condition ( $M=4.19, S D=1.67$ ), $t(31)=6.95, p<.001$. This is to be expected, because in the Familiar $P$ condition, there are two shared factors ( $G_{1}$ and $P_{1}$ ), while in the Novel $P$ condition only one factor is shared $\left(G_{1}\right)$.

These findings run contrary to the idea that participants are simply transferring absolute information about the strength of $G_{1}$ from the base to target. Had people simply transferred the strength of the generative relation, the effect inference would have been equally strong in both targets. Instead, participants only inferred that the effect occurs in the target when they could map higher-order relative strength relations from the base to the target. In sum, these findings suggest that participants' inferential strength ratings for the effect in a target can be accounted for by standard analogical mapping models.

## General Discussion

Holyoak and colleagues (Holyoak et al., 2010; Lee \& Holyoak, 2008) argue that causal analogies cannot be modeled in the same way as other analogies and instead require the creation of a specialized system. Specifically, they believe that most existing models, including SMT, cannot accommodate the probabilistic dynamics of causal systems. The evidence provided here suggests otherwise. Across two experiments, we demonstrate that the pattern of analogical inferences observed among various causal systems correspond with predictions made by SMT. Experiment 1 found that stronger effect inferences occurred when the causal relations in the base were united by a higher-order relation that took causes as arguments. In Experiment 2, we tested whether the results could be predicted by assuming the transfer of the individual causal strength of the generative relation from the base to target. On the contrary, the results suggest that a consistent relational structure is required in order for people to infer the effect in the target.

There has been immense progress in analogy research in the last few decades. The evidence suggests that analogy is
a domain-general process that applies across physical causality (Goldwater \& Gentner, 2015), mathematics (Mix, 2008; Rittle-Johnson \& Star, 2007), politics (Spellman \& Holyoak, 1992), spatial scenes (Doumas \& Hummel, 2013; Kurtz \& Gentner, 1993; Richland, Morrison, \& Holyoak, 2006; Richland et al., 2006; Markman \& Gentner, 1993; Sagi, Gentner, \& Lovett, 2012), and scientific reasoning (Gentner, 2002; Pearl, 1992). Our findings here support the idea that analogy is a domain-general process that supports alignment and inference both within and across domains.

# Individual Differences in Transfer Mediated by Conceptual Priming 

Jairo Navarrete (jnavarrete@ubiobio.cl)<br>Departamento de Ciencias Básicas, Universidad del Bío-Bío<br>Avda. Andrés Bello 720, Chillán, Chile

#### Abstract

Research in analogical transfer suggests a simple type of transfer that occurs due to the activation of key relational concepts. Analysis on mental structured representations indicates that this transfer may act differently depending upon structural and perceptual features of the priming task. Two hundred eight participants were assigned to three experimental groups where they received a structure-priming, tested once and afterwards they received a perceptual-priming and tested again. As predicted, the effect of structure-priming was found across conditions whereas the effect of perceptualpriming (a six-second animation) was detected only in subjects with high levels of cognitive reflectiveness. These individual differences are interpreted as evidence that only highly reflective subjects were able to process visuospatial cues in the animation and to extract their structural features, hence activating relational concepts that influenced their interpretations of subsequent tasks.

Keywords: Analogy, transfer, priming, cognitive reflection.

## Introduction

In the fields of problem solving and analogy research, certain transfer effects have been linked to the low level cognitive process of priming. In one study, subjects were confronted with a biochemistry problem and learned that an inhibitory enzyme decreased virus reproduction (Schunn \& Dunbar, 1996). The next day, the same subjects confronted a genetics problem involving the concept of an inhibitory gene. Although the two problems were not analogous, subjects exposed to the key concept of inhibition in the first session were more likely than control subjects to develop a solution based on the concept of inhibition for the transfer problem. Similarly, Day and Goldstone (2011) showed that subjects familiarized with a simulated physical system of motion were able to transfer the notion of "oscillatory motion" to interpret transfer tasks posed in a context of urban planning. This transfer arises not from a systematic mapping from source to target, but it is due to the activation of one or more key concepts (i.e. priming) and thus it has been called a "piecemeal transfer" (Holyoak, 2012, p. 246).

Similar effects were observed by Burns (1996) when researching transfer between episodes of analogical reasoning. The experimental tasks involved four-term letterstring analogies such as the one depicted in Figure 1. Burns had participants justify a given answer to a first analogy prior to having them propose solutions to a second (nonanalogous) one. Half of the subjects had the two analogical problems presented in the reversed order, and the differences between the two groups on the relative frequencies of all defensible solutions suggest order effects that are consistent with the hypothesis that concepts activated during the first episode effectively biased the solution strategies followed
by participants during the second episode. Burns explained these order effects as the formation of analogical mappings during the first analogical episode which afterwards are transferred to the second analogical episode.

> abc : abd :: xyz : ???

Figure 1: This analogical problem can be stated as "if you changed abc to abd, how would you change xyz in the same way?"
However, Burns' theoretical explanation cannot account for the "piecemeal transfer" observed in the aforementioned studies because the referred problems are not analogical episodes: Within the biochemistry problem, there are no analogical mappings that can be transferred to the genetics problem. Similarly, no analogical mappings in the physical system can be transferred to the domain of urban planning. Hence, this study adopts the view that the activation of key concepts (i.e. priming) helps subjects to spontaneously interpret subsequent tasks according to the primed concept. The research presented here contributes by identifying differences among two kinds of priming referred here as structural priming and perceptual priming. The former being akin to the effect documented by Burns whereas the latter more akin to the one observed by Day \& Goldstone.

A proper outline of the method and predictions for this study requires an analysis of the mental representations underlying tasks such as the one in Figure 1. The next section provides such analysis and proposes mechanisms by which priming may affect the interpretation of these tasks.

## Representations of Four-term Analogies

Four term analogy problems have the form A : B :: C : ? where A and B comprise the source of the analogy whilst C along with the unknown constitute the target of the analogy. To solve this problem, one must interpret the source domain and then look for a solution D such that the relations between A and B can be mapped to the relations between C and D . This kind of problems promote the identification of the source's structure (Indurkhya, 1989) and thus they will be used in the present study to induce structural priming.

Additionally, these tasks will be used here as a manner to measure the priming effect by assessing the interpretation given to the source domain when solving these problems. This is possible because four term analogies in letter-strings (see Figure 2) can be represented by propositions (Burns, 1996). For example, the "append" concept may be represented by the schema " + " in a way that " $+(\mathrm{ab}, \mathrm{cd})$ " represents "abcd". And certain notion of reflection can be represented by the schema "mirror" so that "mirror(xyzw)" becomes a representation of "wzyx".

Relational schemas (such as the ones mentioned above) play an important role in cognitive research because there is
evidence that they allow encoding structural knowledge as a combination of schemas and primitive elements (Halford, Bain, Maybery, \& Andrews, 1998). For example, the string "aab12aab" can be seen as emerging from two primitive elements, namely "aab" and " 12 ". And the source domain of the problem in Figure 2 (i.e. the first two terms) can be represented as it is depicted at the top of Figure 3. In such case, dominant theories of analogical mapping (Gentner, 1983; Holyoak \& Thagard, 1989) predict that "cde12ede" would be the response to this analogical problem.

> aab12aab : aab12baa :: cde12cde : ????????

Figure 2: An ambiguous four term analogy problem
However, the structure depicted in Figure 3 is not the only one that fits the problem, since the base analog could be alternatively conceptualized by a "shift" schema, namely an operation that takes the last letter and moves it to the first position (e.g. shift(xyzw) $=$ wxyz). Although shift and mirror schemas represent different concepts, they sometimes cannot be differentiated from their action on one particular instance. As an illustration, notice that

$$
\operatorname{mirror}(a a b)=\operatorname{shift}(a a b)=\text { baa } .
$$

This makes the analogy in Figure 2 an ambiguous problem: replacing all the "mirror" occurrences in Figure 3 by "shift" leads to another structured representation which predicts a different answer, namely "cde12ecd". This provides a basis to detect the priming effect by assessing the interpretation used by subjects in resolving the problem: if they conceptualized it through the mirror schema, they would prefer "cde12edc" as an answer, whereas if they used the shift schema, they would rather prefer "cde12ecd".

The present study tests the hypothesis that tasks requiring the generation of structured representations can prime a schema in a different manner than those tasks that do not require such structured representations. Several studies from analogical transfer research emphasize differences between abstract, structural aspects of an episode and its perceptual, concrete aspects. The evidence indicates that both aspects influence analogical transfer but that structural aspects have a greater impact than perceptual ones (Blanchette \& Dunbar, 2000; Holyoak \& Koh, 1987). Structural and perceptual features of a priming task may influence transfer as follows: a structure-based task (e.g. the one in Figure 2) might force subjects to create structured representations, thus activating the involved relational schemas. In contrast, a perceptionbased task (e.g. describing a dynamic visual stimulus) may evoke structured representations only in specific individuals, thus leaving open the possibility that schemas remain deactivated while performing the task. More precisely, these individuals may extract structural features from visuospatial cues in the perception-based tasks thus activating relational schemas that influence their interpretations of subsequent tasks. To address for this possibility, the cognitive reflection test (CRT, Frederick, 2005) was taken into account because research in decision making has shown that people who score highly on this test are more likely to engage in
rational, analytic thinking (Shah, Michal, Ibrahim, Rhodes, \& Rodriguez, 2017) whereas subjects with lower scores are less sensitive to notice abstract aspects of a task (Toplak, West, \& Stanovich, 2011).

Figure 3: (Top) The domain "aab12aab : aab12baa" is represented as a combination of schemas-"append" and "mirror"-and primitive elements-"aab" and " 12 ". (Bottom) The answer "cde12edc" for the problem in Figure 2 results from applying the same combination of schemas to the target domain by mapping primitive elements.

Summarizing, structural-tasks should force the generation of structured representations, meaning that the effect of this structural-priming on interpreting a subsequent episode is independent of participant's cognitive reflection. In contrast, perceptual-tasks may evoke structured representations only in subjects with high cognitive reflectiveness, meaning that the effect of perceptual-priming on interpreting subsequent episodes is expected to be effectively modulated by participant's cognitive reflection.

## Method

## Participants

An initial sample of 231 undergraduate students at a Chilean university (Age range $19-29$ years, $M=20.6 S D=2.1$ ) participated in the study for course credits. They were randomly assigned to one of three conditions: two priming conditions and one control condition.

## Procedure and Design

Subjects in the "first mirror then shift" condition (M-S) received a structure-priming favoring a "mirror" schema and were presented with a first test. Afterwards they received a perceptual-priming favoring the "shift" schema and were presented with a second test. Similarly, subjects in the "first shift then mirror" condition (S-M) received a structurepriming favoring the "shift" schema and were presented with the first test. Afterwards they received a perceptualpriming favoring the "mirror" schema and were presented with the second test. This design (detailed below) permits assessing the desired effect of priming on interpreting a transfer episode as follows: the effect of structure-priming can be assessed by comparing the experimental groups in terms of the scores collected in the first test. The effect of perceptual-priming will be assessed through comparing the change of scores (from the first test to the second test) experienced by each experimental group. The no-priming condition (NP) was taken as a control condition: subjects in this condition were primed to activate different schemas than the mirror and shift ones.

The experiment was administered in small groups at the computer laboratory of the university, with each participant working individually at her own pace. Participants took
between $15-20 \min (M=17.6 ; S D=4.6)$ to complete the experiment. The Qualtrics online platform was used to build a questionnaire comprising the following phases: (1) Introduction, (2) Structure priming, (3) Test 1, (4) Cognitive Reflection Test, (5) Perceptual priming, (6) Test 2 and (7) Test 3 (a hinted repetition of Test 2). As noted above, the between-subjects manipulation was restricted to phases 2 and 5; the other phases were identical across conditions. A detailed description of each phase is provided now.

Figure 4: Display for the acquisition of preference scores.

Introduction: In order to familiarize participants with 4-term analogies, the computer screen presented the analogy "Chile:Santiago::Argentina:???", along with its meaning i.e. "Chile is related to Santiago in the same way that Argentina is related to which city?". Three alternative answers were given (Buenos Aires, Mendoza and Paris) each one coupled with a sliding bar ranging from 1 to 100 (see Figure 4). A text below explained that the three scores must add up to 100 , and that they should reflect how good each answer seemed to be. The options were preset at scores of 90,9 and 1 , respectively, with an accompanying text stating that while Mendoza might be a plausible answer (score of 9) because the fact that it belongs to Argentina parallels the fact that Santiago belongs to Chile, a much better answer should be Buenos Aires (score of 90), because its being the capital of Argentina matches the "capital of" relation that holds between Santiago and Chile. Finally, the instructional text stated that Paris is not a good answer (score of 1) because it is hard to find a relation between Paris and Argentina that parallels some relation between Santiago and Chile.

Structure-priming: This phase was intended to activate particular schemas in participants' minds through a priming method similar to the one presented in Burns (1996). Participants in the M-S condition received the mno678 : onm876 :: def234 : ??? problem. According to my analysis, this problem allows only one acceptable solution that involves projecting onto the rightward term of the analogy the mirroring operations that transform the base structures "mno" and " 678 " into "onm" and " 876 ", respectively. The above transformations could only be
conceptualized in terms of mirroring operations, and thus it was expected participants to massively assign high scores to fed432 (derivable via mirroring) and low scores to both edf324 and 4def23 (not derivable via such operation). This should lead to an increased activation of the mirror-schema in relation to other possible transformations. Participants in the S-M condition received the mno678: omn867 :: def234 : ??? problem, an analogy whose only acceptable solution involved applying the "shift" operation that transform the base structures "mno" and " 678 " into "omn" and " 867 ", respectively. We expected participants in this group to assign high scores to fde423, and low scores to both edf324 and 4def23 alternatives. Participants in the NP condition received the human:lungs::fish:??? analogy, followed by the alternatives "gills", "spine" and "fins". Given that this analogy should be solved by evoking the relation "X breathes through $\mathrm{Y}^{\prime \prime}$, we expected this control condition to prime neither a mirroring nor a shifting operation. In these and all subsequent analogical problems, three competing solutions were presented in random order, with their corresponding sliding bars preset to one.

Test 1 To assess whether the structure-priming received in the previous phase can bias subsequent processing, participants of all conditions received the ambiguous problem aab12aab : baa12baa :: cde12cde : ???. This analogy is solvable by applying either mirroring or shifting operations (options edc12edc and ecd12ecd, respectively). The remaining option (dec 12dec) could not be derived from the leftward term of the analogy, and thus was expected to receive low scores regardless of condition.

Cognitive Reflection Test (CRT) This stage was presented to participants as a problem solving section. It comprised three algebra problems whose correct solution does not require complex calculations, but requires participants to suppress an "impulsive" solution that easily comes to mind ${ }^{1}$. As an example, the first item of the CRT consisted of the following problem: "A bat and a ball cost $\$ 1.10$. The bat costs $\$ 1.00$ more than the ball. How much does the ball cost?" Participants had no time limit to answer the problems. No particular criterion was taken into account in order to place the CRT here (between the two main measurement stages). After completing the third item, a yes/no question queried participants about whether they were familiar with any of the problems prior to the experimental session.

Perceptual priming: After being presented with a web video player, participants were asked to run a (six seconds)

[^151]video animation. They were told that they would be able to watch the animation just once, and that they should pay careful attention in order to answer one brief question about the animation (answer limited to 200 characters). This question was aimed to provide a control mechanism to assess whether participants attended to the animation. Depending on the condition, the animation displayed a geometrical array whose dynamic movement was either compatible with a mirroring operation (S-M), with a shift operation (M-S) or unrelated to both (NP).
For the S-M condition, the animation showed how a transparent panel containing three horizontally arranged card figures performed a $180^{\circ}$ turn along the middle vertical axis ${ }^{2}$. As the left-to-right order of the figures changed from "club, diamond, heart" to "heart, diamond, club", this animation was a visuospatial representation of the "mirror" operation. Participants were asked about how the spatial configuration of the club changed during the animation.

For the M-S condition, the animation showed a hammer imparting a rightward motion to the leftmost of three horizontally arranged geometrical figures; this rightward motion was transmitted to the middle figure and ultimately transmitted to the rightmost figure, making it slide-off through a circular circuit that ended up relocating it in the leftmost position ${ }^{3}$. As the left-to-right order of the figures changed from "circle, square, rhombus" to "rhombus, circle, square", this animation was intended to convey a visuospatial representation of the "shift" operation. Participants were asked about how the spatial configuration of the rhombus changed during the animation.

For the NP condition, the animation displayed a transparent rectangle containing three horizontally-arranged card figures (club, diamond and heart) which performed a $360^{\circ}$ turn along its middle horizontal axis, thus leaving the left-to-right ordering of the figures unchanged ${ }^{4}$. As this rotational movement was unrelated to either the mirror or shift operations, it was intended to avoid the activation of the mental representations associated to the two crucial operations. Subjects were asked how the spatial configuration of the club changed during the animation.

Test 2 To assess whether the visuospatial animations received during the previous phase altered subsequent processing, participants of all conditions received the ambiguous problem pq89pq : qp89qp :: xyz89xyz : ???. According to our analysis, this analogy is solvable by applying either mirroring or shifting operations (options zyx89zyx and zxy89zxy, respectively). As in Test 1, the remaining option (xyz89xyz) could not be derived from the leftward term of the analogy, and thus was expected to receive low scores regardless of condition. Upon assigning scores to each of the presented alternatives, subjects were asked to answer a yes/no question about whether the watched video had spontaneously popped up into their

[^152]minds while reading the analogy and/or evaluating the presented alternatives.

Test 3 This is a control measure aimed to assess the extent to which participants were potentially able to use the information contained in the animation for solving the problem presented in Test 2. Participants received the analogy and the same solution options as in Test 2, but it was preceded by an explicit hint, namely, to take into account the animation for assigning scores to the presented alternatives.

## Data Analysis

Participants were classified as having low cognitive reflection if their CRT score was equal to zero, and as having high cognitive reflection in the other cases. Since this study is based on priming effects, I discarded data from 23 participants (4 in the M-S condition and 19 in the S-M condition) who failed to assign high scores ( $>=80$ ) to the only defensible solution to the unambiguous problem of phase 2 , which was meant to operate as a structure-priming for the following phase. A preliminary analysis of the data revealed that a non-negligible proportion of participants in the control condition assigned high scores to the "incorrect" solution for the ambiguous problem presented during Test 1 , thus lessening preferences for the meaningful alternatives. To prevent this unanticipated behavior of the NP group from engendering spurious correlations, raw preference scores were converted to normalized scores which reflect the proportion of preference assigned to the mirror-alternative in relation to the total amount of preference assigned to the two competing and meaningful alternatives:

$$
N S P M=100 * \frac{P_{m}}{P_{m}+P_{s}}
$$

As an example, if a subject assigned a preference of 10 to the mirror-alternative, 40 to the shift-alternative and 50 to the incorrect alternative, its NSPM would be $20 \%$, reflecting that one fifth of the total amount of (the relevant) preference was assigned to the mirror-alternative whereas the remaining $80 \%$ was assigned to the shift-alternative. Due to the ratio form of NSPM scores ${ }^{5}$, I report geometric means (GM) obtained by computing arithmetic means on the logarithm of NSPM scores (see Table 1).

[^153]Table 1
NSPM scores at each stage of this study

Table 1: The rows of the table report the (within-subjects) change of NSPM scores across the three measurement phases. The effect of structural priming is reported in the columns associated to Test 1 . The column T2/T1 reports the ratio of geometric means associated to Test 1 and Test 2 and suggests a between-groups change of preferences detected only in subjects with higher levels of cognitive reflectiveness.

## Results

Structure-priming A two-way ANOVA was conducted to examine the effect of condition (S-M, M-S and NP) and CRT level (low vs. high) on the NSPM scores collected during Test 1 . Main effects emerged for condition $F(2,203)$ $=10.09, \eta_{\mathrm{p}}^{2}=.085, p<.0001$. Cognitive reflection does not affect the interpretation of the problem in Test 1 since the main effect of cognitive reflection, $F(1,203)=.0001, \eta_{\mathrm{p}}{ }^{2}=$ $0, \mathrm{p}=.99$ and the interaction condition x cognitive reflection, $F(2,203)=2.3, \eta_{\mathrm{p}}^{2}=.022, p=.10$ were not statistically significant. Planned comparisons confirmed differences on NSPM scores between the two competing conditions in each one of the two CRT levels. For high-CRT participants, the S-M condition produced significantly lower NSPM scores $(G M=13.85)$ than those of the M-S condition $(G M=52.41), t(47.16)=3.31, p=.0017, d=.58$. For lowCRT participants, the S-M condition produced significantly lower NSPM scores $(G M=24.18)$ than the $\mathrm{M}-\mathrm{S}$ condition $(G M=54.09), t(50.99)=2.32, p=.024, d=.19$. As a base line for comparison, NSPM scores of subjects in the control condition (NP) are reported in Table 1. These results are consistent with those obtained by Burns (1996), and extend those findings by confirming that the effect of structuralpriming on interpreting subsequent analogical tasks takes place regardless of whether participants exhibit (or not) a natural propensity to engage in rational, analytic thinking.

Perceptual-priming In order to detect possible small effects of perceptual priming, this experiment was designed to measure the extent to which a perceptual-priming can counteract the effect of a prior structure-priming. Therefore, participants whose structure-priming favored the mirror scheme later received a perceptual-priming favoring the shifting schema, and vice-versa. The eventual effect of perceptual-priming was assessed by analyzing the change of NSPM scores within subjects (from Test 1 to Test 2) i.e. the change of subject's appraisal for the mirror-compatible solution. To investigate this change of preferences at the level of individual participants, a $3 \times 2 \times 2$ ANOVA was conducted with condition (S-M, M-S and NP) and cognitive reflection (High vs. Low) as between-subjects factors and session (Test 1 vs. Test 2) as a within-subjects factor. Main
effects emerged for condition $F(2,197)=42.42, \eta_{\mathrm{p}}{ }^{2}=.069$, $p<.0001$, but neither for cognitive reflection $F(1,197)=$ $0.32, \eta_{\mathrm{p}}^{2}<.001, p=.57$ nor for session $F(1,197)=3.152$, $\eta_{\mathrm{p}}{ }^{2}=.0011, p=.077$. As expected, the three-way interaction was significant $F(2,197)=3.06, \eta_{\mathrm{p}}^{2}=.017, p=.045$. To further understand this interaction, planned comparisons in each CRT-level were conducted. In the high-CRT group, the change of mirror-preferences was in agreement with the perceptual-priming: changes in the $\mathrm{M}-\mathrm{S}$ condition ( $-7 \%$ ) were significantly different from the change experienced in the S-M condition $(23.2 \%), t(63.36)=-2.63, p=.011, d=$ 0.644. In contrast, the low-CRT group presented changes of mirror-preferences incompatible with the perceptualpriming: changes in the M-S condition (14.3\%) were not significantly different from the changes in the S-M condition $(-2.7 \%), t(48.31)=.75, p=.46, d=.177$. Data in Table 1 suggests that the control group increased its appraisal for the mirror-alternative from Test 1 to Test 2, which indicates an inherent bias in the experimental design. Still, the results are consistent with the expectations: within participants with high reflectiveness, those who watched the visuospatial representation of the shift-scheme tended to lower their appraisal for the mirror-alternative and those who watched the visuospatial representation of the mirrorscheme increased their appraisal for the mirror-alternative. This is in line with the idea that participants with high reflectiveness were able to process the visuospatial primingtask and extract its relational features thus activating a schema that lessened the effect of the one activated in the previous structure-priming phase. In contrast, participants with low reflectiveness completed the visuospatial primingtask without noticing its structural features, thus not activating any schema and leaving "untouched" the effect of the schema activated in the structure-priming phase.
The differential effect of visuospatial representations between the two experimental groups was not due to the relative proportions of subjects consciously recalling the animations: A chi-squared test showed that the low-CRT and high-CRT groups had similar proportions of participants stating to recall the video while solving the analogy presented during Test $2(21.5 \%$ vs. $28.3 \%$, respectively), $\chi^{2}(1, N=146)=0.58, p=.45$. Only a minor proportion of participants spontaneously recalled the animation while solving the analogy in Test 2. This evidences that such stimuli have primed-rather than consciously induced-participants' appraisal of the mirroralternative since a lack of conscious awareness represents a definitional feature of priming.
As cognitive reflection is correlated with general intellectual abilities (Frederick, 2005), an alternative interpretation for why participants with lower levels of cognitive reflection were not sensible to perceptual priming is that they are intrinsically less capable of translating the perceptual content of the animations to the more structured domain of letter-string problems. To assess this possibility, preferences on the two experimental groups was investigated when subjects were explicitly asked to recall
the videos and use them into solving the analogy problem presented in Test 3 (same problem presented in Test 2). A two-way ANOVA was conducted to examine the effect of condition (S-M, M-S and NP) and cognitive reflection (low vs. high) on NSPM scores collected during Test 3. Main effects emerged for condition $F(2,203)=17.88, \eta_{\mathrm{p}}^{2}=.147$, $p<.0001$; but neither for cognitive reflection $F(1,203)=$ $.08, \eta_{\mathrm{p}}^{2}=0, p=.77$, nor for the condition x cognitive reflection interaction, $F(2,203)=2.21, \eta_{\mathrm{p}}{ }^{2}=.021, p=.11$. This confirms that the uneven effect of perceptual animations as a function of cognitive reflection did not originate in a higher intrinsic ability of the higher cognitive reflection group to understand the correspondences between the visuospatial animation and the subsequent analogical activity.

## General Discussion

Theoretical analyses suggest a simple mechanism whereby transfer mediated by conceptual priming may occur, namely the activation of relational schemas-organized in structured representations-that influence the interpretation of subsequent tasks. The fact that analogical transfer is influenced both by structural and superficial features suggests that transfer mediated by priming should be also subjected to these two aspects: I expected differences of priming effects among tasks requiring structured representations and tasks requiring perceptual descriptions of visuospatial animations. The results confirm this hypothesis and link the disparity of effects to individual differences of subjects: structure-priming effects were found across conditions, whereas only those subjects with higher propensity to engage in analytical thinking were sensitive to perceptual-priming. These individual differences cannot be accounted for by group differences in neither the proportion of subjects consciously recalling the visual stimulus nor the ability to understand the correspondences between the visuospatial prime and the transfer task. Hence, the rationale is that highly reflective subjects unconsciously extract structural features from visuospatial cues thus activating relational schemas that influence their interpretations of subsequent tasks.

This seems to be consistent with certain evidence in literature. For example, students were asked to solve algebraic equations superimposed on a vertically oriented grating continuously moving either to the left or to the right (Goldstone, Landy, \& Son, 2010). This was meant to investigate the effect of these background motions on the "spatial transposition strategy" e.g. moving the number 8 from the left to the right of the equality in $4 * y+8=24$. The study found that the compatibility of the background motion and the motion of numbers implicated by the spatial transposition strategy affects accuracy. The analysis and results presented here indicate that participants with higher propensity to engage in analytical thinking should be more affected by this compatibility because they are more likely to activate a motion-schema from the background motion which, depending on the condition, either conflicts or agrees with the "spatial transposition strategy". Interestingly, the
aforementioned study reported that participants who have taken advanced courses of mathematics were indeed more affected by the compatibility between the two motions.

The results presented in this study are in line with claims in literature suggesting that deep structural aspects are more influential than perceptual-concrete aspects in achieving learning and transfer. But although these results must be viewed as preliminary given the specificity of this study's materials and scope, they open a question for further research: Can this general dichotomy between perceptual and structural aspects be linked to individual differences between subjects?

#### Abstract

How does the process of information transmission affect the cultural products that emerge from that process? This question is often studied experimentally and computationally via iterated learning, in which participants learn from previous participants in a chain. Much research in this area builds on mathematical analyses suggesting that iterated learning chains converge to people's priors. We present three simulation studies suggesting that when the population of learners is heterogeneous, the behavior of the chain is systematically distorted by the learners with the most extreme biases. We discuss implications for the use of iterated learning as a methodological tool and for the processes that might have shaped cultural products in the real world.

Keywords: Iterated learning; language evolution; cultural evolution; inductive biases; Bayesian cognition

Which aspects of our language or culture are shaped by the inductive biases possessed by people, and which aspects are shaped by the process of transmission from one learner to the next? A key framework for thinking about and disentangling these factors is known as iterated learning, shown schematically in Figure 1. Iterated learning is a particular kind of cultural transmission in which behavior arises in one individual (or generation) by learning from the observations of the previous person (generation), forming a chain of learners.

An appealing characteristic of iterated learning is that the behavior of iterated learning chains can be characterized mathematically: under certain assumptions, iterated learning chains with Bayesian learners will converge to a distribution that depends on the learners' priors and the size of the bottleneck (Griffiths \& Kalish, 2007; Rafferty, Griffiths, \& Klein, 2014). These results have allowed researchers to explore inductive biases in different tasks, including function learning (Kalish, Griffiths, \& Lewandowsky, 2007), visual working memory (Lew \& Vul, 2015), reasoning about everyday events (Lewandowsky, Griffiths, \& Kalish, 2009), and category learning (Canini, Griffiths, Vanpaemel, \& Kalish, 2014). They have been especially useful in studying language evolution (Kirby, Griffiths, \& Smith, 2014).

Figure 1: Schematic illustration of a typical iterated learning paradigm, which assumes that learner $n$ learns on the basis of the data provided by learner $n-1$.

Importantly, the theoretical proofs about how iterated learning chains converge depend critically on the assumptions made. For example, if learners select the hypothesis with the highest posterior probability rather than sample from their posterior, an iterated learning chain will tend to exaggerate the prior (Kirby, Dowman, \& Griffiths, 2007). Similarly, we use language to talk about things and events in the world. If one changes the mathematical assumptions to reflect this insight, then the stationary distribution of the chain more closely resembles the posterior distribution (Perfors \& Navarro, 2014). In this paper we consider the role played by individual differences. Such differences are robustly observed in many areas of cognition, yet theoretical results typically assume that all learners share the same biases.

When individual differences exist, what should we expect to observe? One possibility is that the chain converges to a distribution that reflects the "average prior belief" in some sense. For instance, if $10 \%$ strongly believe in hypothesis A and $90 \%$ of people strongly believe in hypothesis B, one might hope that an iterated learning chain reflects $10 \% \mathrm{~A}$ and $90 \%$ B hypotheses. Alternatively, perhaps the chain will produce some other reasonable compromise between A and B that weights each learner in equal proportion. Our findings indicate that neither of these situations necessarily occurs: if people do not share the same priors, iterated learning is not guaranteed to converge to the prior in any meaningful sense. Instead, the distribution to which it does converge is disproportionately influenced by the most biased learners. We illustrate this using three simulation studies.

## Case study 1: Language evolution

Do all learners have equal influence on the process of language evolution? Consider the pressures on a language to incorporate a particular grammatical rule or not. Some learners may have STRONG opinions about a particular rule or construction, whereas others might have WEAK opinions. Exactly who has which might might vary with the particular linguistic context and construction involved: for instance, children may to have a bias for regularization that adults do not share (Hudson Kam \& Newport, 2005), but adult secondlanguage learners may have biases based on transfer from their first language while children do not (Ellis, 2015). We are fairly agnostic at this point about what such biases might be; all that matters for the present purposes is that it is plausible that there are individual differences in at least some language learning biases. Our question is what effect this might have on the nature of the evolved language.

To study this, consider the following experimental design. Participants are presented with sentences in an artificial language that may incorporate a construction (e.g., pluralization rule, morphological marking, etc). After training, participants are asked to produce new sentences, which are presented as the input to the next learner in the chain. This is a relatively typical design, and a simple Bayesian model for this learning problem can be constructed as follows.

If $\theta$ denotes the probability that the grammatical rule should be followed, a Bayesian learner specifies a prior distribution $P(\theta)$. For simplicity we assume a $\operatorname{Beta}(a, b)$ distribution in which $P(\theta) \propto \theta^{a-1}(1-\theta)^{b-1}$. In our simulations we assume that some learners enter with a STRONG bias about the grammatical rule, formalized via a $\operatorname{Beta}(1,10)$ prior. In contrast, a WEAK learner might have the opposite bias, but not a strong one, which can be formalized with a $\operatorname{Beta}(2,1)$ prior. Regardless of the biases the learner possesses, it is assumed that belief updating follows Bayes' rule. After a training session in which $x$ of $n$ sentences follow the rule, the posterior distribution $P(\theta \mid x)$ is

$$
\begin{equation*}
P(\theta \mid x) \propto P(x \mid \theta) P(\theta) \tag{1}
\end{equation*}
$$

where $P(x \mid \theta) \propto \theta^{x}(1-\theta)^{n-x}$ is the probability of observing $x$ out of $n$ rule-consistent cases if the true probability is $\theta$. Under these assumptions, the posterior over $\theta$ is a $\operatorname{Beta}(a+x, b+n-x)$ distribution. When asked to generate a novel sentence, a Bayesian learner might sample a value of $\theta$ from their posterior, and their output satisfies the rule with probability $\theta$. The number of rule-consistent sentences $y$ generated by the learner is thus sampled from the posterior predictive distribution $P(y \mid x)$ :

$$
\begin{equation*}
P(y \mid x)=\int_{0}^{1} P(y \mid \theta) P(\theta \mid x) d \theta \tag{2}
\end{equation*}
$$

This kind of model is often used to study regularization in iterated learning designs (Ferdinand, Thompson, Kirby, \& Smith, 2013; Reali \& Griffiths, 2009).

Figure 2: Simulating an iterated learning investigation of language evolution. When the learners all share the same bias (left and middle columns) the average proportion of responses converges to the prior mean (top row), and the distribution of responses converges to the prior distribution (bottom row). When the chain is a mixture of STRONG and WEAK learners, the average proportion of responses does not correspond to the average prior expectation, nor does the distribution converge to the average prior in the population.

## Simulation

We simulate the results of three different kinds of iterated learning experiments. In all cases, the first person is taught ten sentences in an artificial language, five consistent with a grammatical rule; they then generate ten sentences used as input to the next learner. In the first experiment all learners have a STRONG bias about the rule, and in the second experiment all of them have a WEAK bias in the opposite direction. In the third experiment, half of the learners have STRONG biases and half have WEAK opposing ones. In each case results are aggregated across 100,000 simulated iterated learning chains.

The results are shown in Figure 2. As predicted by previous work, in both of the homogeneous cases iterated learning experiment transparently reveals the learner biases: the chain converges to the prior. However, when we consider the iterated learning experiment conducted with a mixed population (right panels of Figure 2) we observe a strikingly different result. In this situation - where half of the learners are STRONG and half are WEAK - the average bias in the population is to expect $38 \%$ of sentences to be rule-consistent. Yet, as the top right panel shows, the iterated learning chain converges to a smaller number, with only $27 \%$ of responses following the rule. More importantly, as the bottom right panel reveals, the distribution of responses bears very little resemblance to the underlying population biases. One might have hoped that, when learners bring different priors to an iterated learning experiment, the chain would converge to a weighted average of their priors. In this case, this weighted average would be a 50-50 mixture of the priors of STRONG learners and WEAK learners (plotted as a histogram). As the figure illustrates, the iterated learning chain (lines) does not converge to anything even remotely similar to this mixture distribution.

Figure 3: Distribution of responses in a mixed chain plotted as a function of the type of learner generating the response.

## Discussion

Why does the iterated learning procedure behave this way when the population is heterogeneous? The answer can be found by separating the responses on the last iteration by learner type, shown in Figure 3. As is clear from inspection, the WEAK bias learners (left) are greatly influenced by the STRONG bias learners: their responses are ruleconsistent $36 \%$ of the time, rather than $67 \%$ as one might expect given their $\operatorname{Beta}(2,1)$ prior, and the distribution of responses (lines) deviates markedly from their prior (histogram). The opposite effect occurs too (right panel), but it is much smaller: the STRONG bias learners increase the proportion of rule-consistent responses from the $9 \%$ rate implied by the $\operatorname{Beta}(1,10)$ prior to $17.5 \%$ in the iterated learning chain. Similarly, their distribution of responses is not markedly different from their prior.

As this example illustrates, when individual differences exist an iterated learning procedure is not guaranteed to reveal the inductive biases of the learner. The Strong learners apply a strong inductive bias, and these learners require a lot of evidence before they are willing (or able) to apply the grammatical rule in question. As a consequence, data generated by a WEAK learner will have minimal ability to sway such a person. The reverse does not hold: the WEAK learners in this scenario are very responsive to external input. As a result, a WEAK bias participant makes a much larger adjustment from the prior than does a STRONG bias one, with the consequence that the overall behavior of the mixed chain is much more heavily driven by the group with the strongest bias.

## Case study 2: Group decision making

Groups of people often arrive at beliefs that seem to lack any evidentiary basis, famously described by the "groupthink" phenomenon (Janis, 1982). How do these false beliefs arise? Do they necessarily reflect a bias shared by all reasoners, or can an entire community be misled by a small number of highly biased learners?

To examine this question, we consider a scenario in which a jury of 12 people begin their deliberations with a straw poll. A notepad is passed around the room, with each person writing down whether they would decide in favor of the plaintiff before removing their sheet of paper and passing the pad to the next juror. Unfortunately, each juror can read the inden-
tations left by the previous one, forming an iterated learning chain. A Bayesian juror might reason about this by considering two hypotheses, namely that the evidence favors the plaintiff $(e=1)$ or the defendant $(e=0)$. The trial evidence sets the juror's prior belief that $P(e=1)=\theta$, which is updated when the vote $v$ of the preceding juror is revealed. The juror unconsciously assigns a reliability value $r$ to this information, such that $P(v=1 \mid e=1)=P(v=0 \mid e=0)=r$. If the preceding juror voted for the plaintiff, the juror's posterior degree of belief that the verdict should favor the plaintiff becomes

$$
\begin{equation*}
P(e=1 \mid v=1)=\frac{r \theta}{r \theta+(1-r)(1-\theta)} \tag{3}
\end{equation*}
$$

and the posteriors are calculated similarly when the earlier vote favored the defendant. For simplicity, we assume that jurors generate their vote probabilistically by sampling from the posterior.

As these equations illustrate, when $r=0.5$ the current juror completely ignores the vote provided by the previous one and the posterior probability is identical to the prior. This arises naturally when the current juror is confident that their existing beliefs incorporate all relevant information about the case, and as such the opinions of other jurors can have no influence upon their own beliefs. We refer to such a juror as a GOAT someone who forms their own view and is not led to conclusions by the opinions of others. In contrast, suppose the juror is underconfident or unsure about their beliefs, perhaps suspecting that other jurors have access to different information. Such a juror will set $r>0.5$, because they attribute evidentiary value to the opinions of others. We refer to this kind of a juror as a SHEEP because they are more likely to adjust their vote to agree with the votes of others.

## Simulations with homogeneous chains

We consider three scenarios. In the first scenario all jurors are GOATS who set $r=0.5$ and have a modest opinion in favor of the defendant $(\theta=0.4)$. In the second scenario all jurors are SHEEP who set $r=0.95$ and have a modest opinion favoring the plaintiff $(\theta=0.6)$. Finally we consider a situation where half of the jurors are SHEEP and the other half are GOATS. To illustrate what happens in these situations we simulated each scenario 100,000 times. The results are plotted in Figure 4. Not surprisingly, because the GOAT jurors ignore the input and generate responses directly from their own prior beliefs, the "chain" starts at their prior (on average, $40 \%$ of jurors vote for the plaintiff) and the total number of votes in favor of the plaintiff follows a binomial distribution.

What should we expect to see if all jurors are SHEEP? One reading of the literature suggests that, since iterated learning chains of Bayesian learners converge to the prior, and since the first SHEEP samples from their own prior, we should see a result not dissimilar to the one we see for Goats. That is - while we might expect to see non-independence among successive jurors - we should find that on average a SHEEP juror should vote for the plaintiff $60 \%$ of the time, in accordance with their priors. However, as the middle column of

Figure 4: The jury straw poll. The top row plots the probability that each juror votes for the plaintiff, as a function of their position in the chain (the dashed line plots the population average prior), and the bottom row plots the distribution of votes for the plaintiff. The left and middle plots show juries composed entirely of GOATS and SHEEP respectively. The plots on the right depict a scenario when $50 \%$ of jurors are SHEEP and $50 \%$ are GOATS.

Figure 4 illustrates, this is not what happens. The first juror votes in accordance with their priors, but by the time the 12th juror is polled, the probability of voting for the plaintiff has risen to $67 \%$. Moreover, it is simple to prove that this reflects the true stationary distribution of the chain. To see this, let $p=P\left(v_{i}=1 \mid v_{i-1}=0\right)$ denote the probability that the $i^{\text {th }}$ juror in the chain votes for the plaintiff given that the previous juror voted for the defendant, and similarly let $d=P\left(v_{i}=0 \mid v_{i-1}=1\right)$ denote the probability that the $i^{\text {th }} \mathrm{ju}-$ ror switches the other direction. The transition matrix for the strawpoll is thus

$$
\boldsymbol{T}=\left[\begin{array}{cc}
1-p & p  \tag{4}\\
d & 1-d
\end{array}\right]
$$

A chain with this transition matrix converges to a stationary distribution $\boldsymbol{\pi}$ in which the (marginal) probability of voting for the defendant and plaintiff is proportional to $d$ and $p$ respectively. To verify this, note that

$$
\begin{align*}
\boldsymbol{\pi} \boldsymbol{T} & \propto[d, p]\left[\begin{array}{cc}
1-p & p \\
d & 1-d
\end{array}\right] \\
& =[d(1-p)+p d, d p+p(1-d)] \\
& =[d, p] \propto \pi \tag{5}
\end{align*}
$$

For a SHEEP juror, the probability of switching the vote from the plaintiff to the defendant is $d=(.1 \times .4) /(.1 \times .4+.9 \times$ $.6)=.069$, and similarly the probability of switching the vote towards the plaintiff is $p=(.1 \times .6) /(.1 \times .6+.9 \times .4)=.142$. In the long run, a chain of SHEEP converges to a $67 \%$ probability of voting for the plaintiff even though each individual SHEEP only assigns a $60 \%$ prior probability to the plaintiff.

On the surface, the SHEEP result seems at odds with the convergence proof in Kalish et al. (2007) - Bayesian learners sampling from their posterior do not (in this instance) converge to the prior. To that end, it is useful to note that the

SHEEP chain violates the assumptions of the original proof, because the SHEEP jurors use the wrong likelihood function for the learning problem. The SHEEP juror assigns evidentiary value to the opinions of other jurors when they should not, because all jurors have seen the same facts at trial. This miscalibration creates the "groupthink" behavior: the SHEEP jurors "double count" the evidence, and the iterated learning chain exaggerates their prior bias.

## Simulations with mixed chains

Now consider what happens when SHEEP and GOATS are mixed together in equal proportions (Figure 4, right). The SHEEP assign prior probability of 0.6 to the plaintiff, whereas the GOATS assign prior 0.4 , so the population average prior is 0.5 . Alternatively, if we consider the behavior of the two homogeneous iterated learning chains, the SHEEP on their own would be expected to converge to 0.67 and the GOATS would converge to 0.4 , so the average of these two long run probabilities is 0.54 . If one did not know the detail of the models, it would be reasonable to expect a mixed chain to produce an average probability of voting for the plaintiff somewhere between $50 \%$ and $54 \%$. Unsurprisingly, it does nothing of the sort. Because GOATS are insensitive to the opinions of others and SHEEP are highly sensitive, the GOATS dominate the mixed chain, and the long run behavior converges to a $43 \%$ probability of voting for the plaintiff. That is, the SHEEP "learn" to mimic GOATS but the GOATS make no such accommodation.

## Discussion

The implications of the jury scenario are twofold. First, the SHEEP-only chain illustrates that it is possible for an iterated learning chain to exaggerate biases even when Bayesian learners sample hypotheses from the posterior. The result complements an earlier result by Perfors and Navarro (2014), which showed that the convergence of iterated learning chains is affected when there is an additional input to the chain (i.e., the world passes new information to learners). In the SHEEP chain we find that convergence is even influenced when learners mistakenly believe there is additional information being passed into the chain. This miscalibration drives a kind of groupthink, in which a collection of individually underconfident learners becomes overconfident as a group.

Second, the behavior of a heterogenous chain is not easily predicted by considering the behavior of the corresponding homogeneous chains, or the priors of individual learners. The mixed chain of SHEEP and GOATS is mostly driven by the GOATS, even though a homogenous chain of GOATS produces a much less extreme outcome than the a chain of pure SHEEP. The reason for this is obvious when we consider the decision making strategies used by the two learner types, but we rarely have access to such information in real life.

## Case study 3: Categorization

Our third case study considers a categorization problem with non-Bayesian learners. We consider stimuli that vary along

Figure 5: Categorization with eight items that vary along one dimension (top panel). Items can be organized into categories that are coherent (left panel) or incoherent (right panel).
a single dimension, with 8 exemplars spaced evenly across the range (i.e., at $x=1, \ldots, 8$ ): an example is shown at the top of Figure 5. Each stimulus can be assigned to one of two categories (A or B), and we are interested in the inductive biases that people bring to this categorization problem.

An iterated learning design can be used to explore these biases. During category learning, each learner is shown training items that consist of four exemplars and their category labels, selected randomly subject to the constraint that there must be one exemplar of each category in the training set. During the test phase the learner must classify the remaining four exemplars. An iterated learning chain is constructed by using a random subset of responses from one learner as the training data for the next, again subject to the constraint that the learner must be shown at least one example of each category.

In our simulations we assume each participant applies the Generalized Context Model (GCM: Nosofsky, 1986). In the GCM, the probability of assigning a test item located at $y$ to category A, given training items $\boldsymbol{x}=\left(x_{1}, \ldots, x_{n}\right)$ with labels $\boldsymbol{l}=\left(l_{1}, \ldots, l_{n}\right)$ is proportional to the summed similarities between $y$ and the category A exemplars:

$$
\begin{equation*}
P(y \in A \mid x, \boldsymbol{l})=\frac{\sum_{i \mid l_{i}=A} S\left(x_{i}, y\right)}{\sum_{i \mid l_{i}=A} S\left(x_{i}, y\right)+\sum_{i \mid l_{i}=B} S\left(x_{i}, y\right)} \tag{6}
\end{equation*}
$$

where similarity decays exponentially with distance, $S(x, y)=$ $\exp (-\lambda|x-y|)$. This model has one free parameter: the specificity parameter $\lambda$ that describes how rapidly similarity decays. When $\lambda$ is large, similarity falls away very quickly with distance, and when $\lambda$ is small it diminishes more slowly.

## Category coherence bias

Although not framed as a Bayesian model, the GCM imposes biases on how learners categorize, and these biases depend on $\lambda$. For instance, the GCM prefers "coherent" categories that assign similar items to the same category. A simple measure of "coherence" counts the number of times that adjacent items are assigned to the same category: the categories on the left of Figure 5 have maximal coherence of six, whereas the incoherent categories on the right have coherence zero. To investigate GCM biases, we simulated the iterated learning experiment described above 100,000 times using different values of $\lambda$, assuming that all learners in a chain have the same $\lambda$. The results (Figure 6, left) show that the GCM bias for coherent categories is strongest for large values of $\lambda$.

Given that individual differences in categorization exist, we ran a second simulation study (Figure 6, right). This time

Category Coherence

Figure 6: Exploring the "category coherence" bias using iterated learning. The $y$ axis plots category coherence (defined in main text). Left panel: Category coherence assuming all participants share the same prior $(\lambda)$. Here there are three chains each reflecting one of the three $\lambda$ values. As $\lambda$ grows higher, iterated learning produces more coherent categories. The grey dashed line reflects the average of the three chains on iteration 15 . Right panel: When there are individual differences within participants, the learners all become somewhat more similar to one another but the effect is small.
we mixed learners that varied in their $\lambda$ values (sampling uniformly at random from $0.1,1$ and 10 ) into a single chain to investigate the effect heterogeneity has on each learner type. Unlike our previous simulations, the heterogeneity of the chain did not distort any of the three GCM learner types to a large extent: the right hand side of Figure 6 is not too dissimilar to the left. Based on this, one might conclude that the heterogeneity of the population has done very little to distort the categorization schemes produced by the various different learners. Unfortunately, this conclusion is unwarranted.

## Category size bias

Categorization is complex, and even this simple problem involves multiple biases. A preference for coherent categories is one kind of bias that a learner might express, but one might be just as interested in exploring the extent to which learners prefer categories to be of similar size. Does the GCM have a bias to split items evenly or unevenly? Does it depend on $\lambda$ ?

To that end, we counted the number of exemplars assigned to the smaller category in our previous simulations. Figure 7 plots this for the three homogeneous chains (left) and the single heterogeneous chain (right). The left panel shows that the GCM has a bias to prefer unevenly sized categories: this bias is weak when the learner generalizes narrowly $(\lambda=10)$, and strong when the learner generalizes widely $(\lambda=0.1)$. Unfortunately, almost none of this differentiation is evident when we look at the heterogeneous chains: the average response is substantially different from when the three learner types were taken separately, and there are almost no individual differences to be found, with all three learner types producing similar responses. With respect to the category size bias, mixing different learners into the iterated learning chain has almost completely erased their differences.

## Category Size

Figure 7: Exploring the "category size" bias using iterated learning. The $y$ axis plots the number of items assigned to the smaller category. Left panel: Homogenous iterated learning chains when all learners use the same value of $\lambda$. The three plots in the figure are quite dissimilar: when $\lambda$ is small the GCM strongly prefers an unequal allocation of items to categories, but when $\lambda$ is large the preference is weak. The grey dashed line reflects the average of the three chains on iteration 15. Right panel: When the same GCM learners are mixed into a heterogenous iterated learning chain, most of this variation is suppressed (the curves are close to each other), and the average size of the smaller category (grey dashed line) has substantially decreased.

## General discussion

The three case studies all display the same pattern. When all learners bring the same inductive bias to the problem, iterated learning behaves in the way that previous theoretical proofs suggest it should (Griffiths \& Kalish, 2007). In particular, when learners are Bayesians with identical priors and correctly specified likelihoods, iterated learning reveals those priors. For a non-Bayesian learner an analogous inductive bias is uncovered. However, when learners bring different biases to the problem there is no guarantee that the responses of any one participant genuinely reflects their prior biases, nor is there any guarantee that the average responses reflect the average bias in the population. To the contrary, our case studies suggest that those learners with the most extreme biases exert a disproportionate influence on the chain. We briefly consider the implications if this pattern holds more generally.

Iterated learning leads a double life within the psychological literature. As a theoretical tool, the underlying dynamics of the chain provide valuable insights into how cultural and linguistic evolution works. From that perspective, our results open up new questions: for instance, does language evolution reflect the cognitive biases of all speakers, or do some subpopulations (e.g., children) exert stronger influences on the process? Similarly, learners with the most confidence in their own beliefs will exert a disproportionate influence on others, providing a justification for expressing overconfidence: if the goal is to have cultural influence rather than be correct, strong biases are better than weak ones. Regardless, the effect of heterogeneity in this context need not be a reason for concern so much as a reason to ask new questions.

On the methodological side, iterated learning has often
been used as a tool for exploring the inductive biases of individuals. Based on formal results suggesting that the stationary distribution of an iterated learning chain is the prior, researchers in cognitive science have sometimes used these designs as a form of elicitation task, in which the (betweensubject) distribution of responses is taken to be reflective of some (within-subject) latent mental representation of the world. In this context, our results suggest that some care is required. When people bring different priors to a task, there is no inherent reason to think that the stationary distribution of an iterated learning chain reveals those priors. The distortions are both systematic and difficult to predict. The latter point is especially troublesome from a methodological perspective. In our third case study, it was not obvious to us that heterogeneity among category learners would produce a large distortion of "category size" biases, but almost no distortion to the bias for "coherent" categories. In this context, we suggest that the interpretation of iterated learning experiments is difficult when individual differences exist.

#### Abstract

Children can use the statistical regularities of their environment to learn word meanings, a mechanism known as crosssituational learning. We take a computational approach to investigate how the information present during each observation in a cross-situational framework can affect the overall acquisition of word meanings. We do so by formulating various in-the-moment learning mechanisms that are sensitive to different statistics of the environment, such as counts and conditional probabilities. Each mechanism introduces a unique source of competition or mutual exclusivity bias to the model; the mechanism that maximally uses the model's knowledge of word meanings performs the best. Moreover, the gap between this mechanism and others is amplified in more challenging learning scenarios, such as learning from few examples. Keywords: cross-situational word learning; computational modeling; word learning biases

## Introduction

How do people acquire the meanings of words as they begin to learn a language? A well-supported proposal is crosssituational learning (e.g., Pinker, 1989), which suggests that people are sensitive to the regularities that repeat in different situations, and use such evidence to identify the commonalities, from which they can infer word meanings. As an example, when a child hears what a cute kitty, be nice to the kitty, etc., she/he could infer that the word kitty refers to the common referent in all these situations, i.e., a cat. Recent word learning experiments confirm that both adults and infants keep track of cross-situational statistics across learning trials, and infer the correct word-meaning mappings even in highly ambiguous conditions (e.g., Yu \& Smith, 2007; Smith \& Yu, 2008; Yurovsky, Fricker, Yu, \& Smith, 2014).

Despite empirical evidence for statistical cross-situational learning, the exact mechanisms in play are still not fully understood. In this paper, we focus on the first step of a crosssituational framework - the learning that occurs on each observation of a word, which we call in-the-moment learning. Given the words in an utterance and their potential meanings in the accompanying situation, there are many possible ways to associate words and meanings, but only some of these associations are correct. We refer to these in-the-moment associations of words and meanings as alignments, and consider different strategies for assessing the strength of these alignments, drawing on the evolving knowledge of word meanings. We note that previous research has considered "hard" (or binary) in-the-moment learning strategies, where an alignment is either considered by the learner or not (e.g., Trueswell, Medina, Hafri, \& Gleitman, 2013); we instead examine "soft" strategies where alignments have strengths between zero and one.

We formulate various in-the-moment learning mechanisms that introduce different kinds of competition - i.e., the way in which the strength of a word-meaning alignment depends on and interacts with other possible alignments. Each mechanism corresponds to certain statistics of the word learning input, such as the weighted frequency of word-meaning pairs or their conditional probabilities. We show that the different types of competition lead to various kinds of mutual exclusivity behaviours. Mutual exclusivity has been proposed as an explicit bias, in which children assume each word has a single meaning (e.g., Markman, 1987; Markman \& Wachtel, 1988). Here, mutual exclusivity of words and/or meanings arises from competition in a way that focuses learning.

We take a computational modeling approach to investigate the effectiveness of these mechanisms in overall acquisition of word meanings in various long-term word learning scenarios. Using a computational model enables us to explore the impact of different learning mechanisms in a variety of conditions, and to examine the role of one factor (e.g., frequency) while controlling for another one (e.g., utterance length). We find that the mechanism that maximizes the use of the accumulated knowledge of learned meanings performs the best. Interestingly, the performance gap between this mechanism and others is most significant in more difficult learning conditions, such as learning of low frequency words given long utterances. This shows that using conditional probabilities (as opposed to counts) and introducing competition (leading to a mutual exclusivity bias) improves overall word learning and might be necessary to guide learning in the presence of ambiguity or little data.

## A Cross-situational Word Learning Framework

There has been an increased interest in the last decade in developing computational models as tools to study word learning in people. Of particular interest are cross-situational learners that are incremental (e.g., Siskind, 1996; Fazly, Alishahi, \& Stevenson, 2010; Kachergis, Yu, \& Shiffrin, 2012), which is necessary in studying developmental learning patterns. Notably, the model of Fazly et al. $(2008 ; 2010)$ (henceforth FAS) is the first probabilistic model that robustly predicts a range of observed behavior in child word learning. Moreover, this model has been adopted and extended by a series of successive work (e.g., Nematzadeh, Fazly, \& Stevenson, 2012a; Grant, Nematzadeh, \& Stevenson, 2016), demonstrating its robustness in accounting for empirical data. We adopt the FAS word learning framework to examine various in-the-moment learning mechanisms.

## The FAS Model

Word learning input and output. The model's input is a sequence of utterance-scene pairs simulating what the child hears and perceives, respectively. Each utterance is a set of words (ignoring their order), and the corresponding scene is a set of semantic features that represents possible meanings of words in the utterance (see Ex. 1). Word meanings are represented by multiple features, which exposes the model to naturalistic commonalities among the words.

> Utterance: $\{$ Joel, eats $\}$
> Scene: $\{$ PERSON, JOEL, ACT, CONSUME, $\ldots\}$

The output of the model, at each step in learning, is the current representation of the meaning of each word $w$ as a probability distribution, $p(\cdot \mid w)$, over all possible semantic features $f$ that the model has observed in the input scenes.
The word learning problem. Given a corpus of utterancescene pairs, the goal of the model is to learn the meaning probability distribution, $p(\cdot \mid w)$, for all words $w$. Prior to receiving any input, all features $f$ are equally likely for a word. As the model processes each input pair, the probability is adjusted to reflect the cross-situational evidence in the corpus, in two steps: (a) in-the-moment learning on this input pair and (b) update of the word meaning probabilities using the accumulated evidence over all inputs.
In-the-moment learning. Given an utterance and a scene, which features in the scene are part of a word's meaning? There are different possible ways to determine whether a semantic feature is associated with a word in the input pair, and the corresponding strength of that association. FAS assumes that each feature $f$ in scene $S_{t}$ at time $t$, independently of the other features, is aligned to all the words $w$ in the utterance $U_{t}$ with a particular strength (see Figure 1a):

$$
\begin{equation*}
a_{t}(w \mid f)=\frac{p_{t}(f \mid w)}{\sum_{w^{\prime} \in \mathrm{U}_{t}} p_{t}\left(f \mid w^{\prime}\right)} \tag{2}
\end{equation*}
$$

The alignment strength between a feature $f$ and word $w$ depends on the current probability that $f$ is part of the meaning of $w$-i.e., $p_{t}(f \mid w)-$ as well as the probabilities that $f$ is part of the meaning of other words in the utterance (the denominator above).

In this way, Eqn. (2) has words in the utterance "compete" to be associated with a given feature: a higher alignment strength of one word with a feature necessarily results in a lower alignment strength for other words with that feature. This can be interpreted as a directional mutual exclusivity bias: the alignment formulation limits the number of words a feature can be strongly associated with, but does not directly limit the number of features a word can be associated with.
Updating the word meanings. How is the information learned from an input pair incorporated into a learner's longterm knowledge of word meanings? The learner incrementally accumulates the alignment strengths between each $w$
and $f$ in an overall association score $\operatorname{assoc}(w, f)$, which is updated at each time $t$ that $w$ and $f$ co-occur in an input pair:

$$
\begin{equation*}
\operatorname{assoc}_{t}(w, f)=\operatorname{assoc}_{t-1}(w, f)+a_{t}(f \mid w) \tag{3}
\end{equation*}
$$

where $\operatorname{assoc}_{t-1}(w, f)=0$ if $w$ and $f$ have not co-occurred prior to $t$.

After updating the association scores, the meaning probability $p(\cdot \mid w)$ of each word $w$ in the current input is adjusted using a smoothed version of this formula:

$$
\begin{equation*}
p_{t+l}(f \mid w)=\frac{\operatorname{assoc}_{t}(f, w)}{\sum_{f_{j} \in \mathcal{M}} \operatorname{assoc}_{t}\left(f_{j}, w\right)} \tag{4}
\end{equation*}
$$

where $\mathcal{M}$ is the set of all features observed up to time $t$.
In Eqn. (4), the probability of a feature given a word is a normalization of their association score over all possible features, which introduces another source of competition, this time, among features for a given word. This competition can be thought of as a mutual exclusivity bias in the reversed direction of the alignment score in Eqn. (2); here a word can only be strongly associated to a limited number of features.

## Using Sets of Features as Referents

In FAS, an input scene is the set union of all meaning features for all words in the corresponding utterance. This representation lacks information that would be apparent to a child, namely that each set of meaning features belongs to a single entity or event - e.g., PERSON and JOEL, or ACT and CONSUME in Ex. 1. However, replacing such sets of features with a single symbol corresponding to the word meaning would prevent the model from learning semantic similarities among the words (e.g., Nematzadeh, Fazly, \& Stevenson, 2012b). Instead, following Alishahi, Fazly, Koehne, and Crocker (2012), we simply maintain each set of semantic features corresponding to the meaning of each word in the utterance, and we call these sets of features referents, as in Ex. 5: ${ }^{1}$

```
Utterance { Joel, eats, an, apple }
    Scene: {{PERSON, JOEL}, {ACT, CONSUME, ...},
    {SINGULAR, INDEFINITE, DETERMINER, ... },
    {APPLE, FRUIT, FOOD, ...} }
```

A scene is now a set of referents, each of which is a set of semantic features corresponding to the meaning of a word. In the FAS model, calculation of alignment strength between a word $w$ and feature $f$ at time $t$ uses the meaning probability $p_{t}(f \mid w)$. Now, aligning words with referents (as in 5) requires consideration of strength of alignment of a word with a set of features. In calculating alignment strength for a word $w$ and a referent $r$ at time $t$, we change the FAS model to consider $\operatorname{sim}\left(\mathrm{v}_{t}(w), \mathrm{v}(r)\right)$, the cosine similarity between the word's current meaning representation and the representation of the referent, where $\mathrm{v}(r)$ and $\mathrm{v}_{t}(w)$ are vectors in which the elements are meaning features. For $\mathrm{v}_{t}(w)$, the value for

[^154]each component feature $f$ is $p_{t}(f \mid w)$. (I.e, $\mathrm{v}_{t}(w)$ is a vector corresponding to $p_{t}(\cdot \mid w)$.) For $\mathrm{v}(r)$, the element values are 1 for features present in the definition of $r$ and 0 otherwise. In this way, alignment strength for word $w$ and referent $r$ is influenced by the strength of the meaning probabilities $p(f \mid w)$ for all features $f$ that are part of the representation of $r$. In the remainder of the paper, we explore variations in how the alignment process actually does this, in ways that implement different types of mutual exclusivity biases.

## In-the-Moment Learning Mechanisms

Competition in the model. We observed above that the alignment strength calculation in Eqn. (2) instantiates a form of mutual exclusivity bias, because words are competing to be strongly associated with a feature during this in-the-moment learning process. With the change of aligning words to referents instead of to features, we have the opportunity to explore various ways to formulate competition in determining the strength of alignments. The three alignment formulations explored here implement (1) no competition among words or referents, (2) competition of referents for a word (as in Alishahi et al., 2012), and (3) competition of words for a referent (analogous to the competition of words for a feature in FAS). Each of these ways of viewing competition implements a different approach to mutual exclusivity in the model, and we will explore the resulting impact on word learning in the results.
No competition. The no-competition mechanism (henceforth, no-comp) serves as a baseline for comparison to the other two. It assumes no mutual exclusivity bias - all the alignments between words and referents are calculated independently, and the value of one alignment does not effect any of the others (see Figure 1b). We formulate such an alignment between a word $w$ and a referent $r$ as simply the similarity between $\mathrm{v}_{t}(w)$ and $\mathrm{v}(r)$ as described above:

$$
\begin{equation*}
a_{t}(w, r)=\operatorname{sim}\left(\mathrm{v}_{t}(w), \mathrm{v}(r)\right) \tag{6}
\end{equation*}
$$

This formulation can be seen as a simple weighted count, where each feature relevant to $r$ (valued 1 in $\mathrm{v}(r)$ ) contributes to the overall alignment strength proportionally to the model's prior knowledge of its meaning probability with that word.
Referent competition. Here we adopt the alignment formulation of Alishahi et al. (2012), which we call "ref-comp" because referents compete for alignment with a word. This mechanism implements a directed mutual exclusivity bias in which each word has a preference to be strongly associated with one referent. In other words, referents in the scene compete for a given word, while the alignments of words are independent of each other (see Figure 1c). This preference can be implemented by normalizing the $\operatorname{sim}\left(\mathrm{v}_{t}(w), \mathrm{v}(r)\right)$ over all the referents in the scene:

$$
\begin{equation*}
a_{t}(r \mid w)=\frac{\operatorname{sim}\left(\mathrm{v}_{t}(w), \mathrm{v}(r)\right)}{\sum_{r^{\prime} \in \mathrm{S}_{t}} \operatorname{sim}\left(\mathrm{v}_{t}(w), \mathrm{v}\left(r^{\prime}\right)\right)} \tag{7}
\end{equation*}
$$

By normalizing the weighted count of $\operatorname{sim}\left(\mathrm{v}_{t}(w), \mathrm{v}(r)\right)$, this alignment formulation can be interpreted as the conditional probability of $r$ given $w$, rather than a simple count.
Word competition. Here, we consider a competition that is instead analogous to the competition of words for a feature in FAS; "word-comp" is the reverse of ref-comp, because here words compete for a referent. This leads to a directed mutual exclusivity bias, but in the opposite direction to ref-comp. The word-comp mechanism asserts a preference for each referent to be strongly associated with a single word, by having words compete for a referent, while the alignments of referents are independent of each other (see Figure 1d). This bias is formulated by normalizing the $\operatorname{sim}\left(\mathrm{v}_{t}(w), \mathrm{v}(r)\right)$ over the words in the utterance (as FAS did):

$$
\begin{equation*}
a_{t}(w \mid r)=\frac{\operatorname{sim}\left(\mathrm{v}_{t}(w), \mathrm{v}(r)\right)}{\sum_{w^{\prime} \in \mathrm{U}_{t}} \operatorname{sim}\left(\mathrm{v}_{t}\left(w^{\prime}\right), \mathrm{v}(r)\right)} \tag{8}
\end{equation*}
$$

This formulation also yields a conditional probability, but here of $w$ given $r$.
The association score. We note one final change to the FAS model to deal with referents: We must modify Eqn. (3) to keep track of associations between a word $w$ and all the features of a referent $r$. Since a feature $f$ can occur in more than one referent in scene $S$, which can have multiple alignment scores, we use the maximum alignment score of a referent that contains the feature in updating the feature's association score:

$$
\begin{equation*}
\operatorname{assoc}_{t}(w, f)=\operatorname{assoc}_{t-1}(w, f)+\max _{r^{\prime} \in S: f \in r^{\prime}} a_{t}\left(w, r^{\prime}\right) \tag{9}
\end{equation*}
$$

The meaning probabilities in the model continue to be calculated between individual features and a word. Recall that the meaning probability distribution $p(\cdot \mid w)$, as a conditional probability over semantic features, enforces a competition among them for the probability mass.

## Experiments

## Set-up

The utterances in the input are child-directed speech taken from the Manchester corpus (Theakston, Lieven, Pine, \& Rowland, 2001) in CHILDES (MacWhinney, 2000). To create the associated scene representations, each word in the corpus is entered into a gold-standard lexicon with a set of semantic features representing its gold-standard meaning, following the procedure of Fazly et al. (2008). The referents shown in Ex. 5 correspond to the gold-standard meanings of each of those words. (The word-mapping in the lexicon is only used to generate scenes, and is not seen by the model.) The model is trained on 20 K utterance-scene pairs, at which point behaviour is stable.

In the following experiments, we examine the quality of the individual learned word representations in two ways: the average acquisition score of all words observed by the model, and the proportion of observed words that is learned. The

Figure 1: Types of alignment mechanisms. Lines of the same color/style compete simultaneously. Thickness indicates varying strength of alignment during a competition.

Figure 2: Developmental plots
acquisition score of each word $w$ is obtained by comparing the word meaning representation $\mathrm{v}(w)$ with a gold standard representation of the word gold $(w)$ using cosine similarity:

$$
\begin{equation*}
\mathbf{a c q}(w)=\operatorname{sim}(\mathrm{v}(w), \operatorname{gold}(w)) \tag{10}
\end{equation*}
$$

where $\operatorname{gold}(w)$ is a vector over all semantic features, with value 1 for features part of the gold-standard meaning of $w$ and 0 otherwise. An observed word counts as "learned" if its acq score is higher than some threshold $\theta$, here set to 0.7 based on the experiments of Fazly et al. (2010).

## Results

## Overall Learning Patterns

Over time, all models converge to high average acq scores (Figure 2a) and proportions of words learned (Figure 2b), but with substantial differences between them. Notably, we find that on the average acq score, the word-comp formulation performs better than the original FAS (. 96 vs. .86), while the ref-comp and no-comp models do not learn the representations as well (both .83).

Two factors may underlie the varying performance of the models: the semantic grouping of features into referents (distinguishing our models from FAS), and the type of in-themoment competition (and resulting type of mutual exclusivity). For the first factor, the word-comp mechanism provides the most direct comparison to FAS: it uses the same direction of bias - in which words compete to align with the elements of the scene - but using referents instead of features. The grouping into referents appears to improve learning. When
aligning features individually as in FAS, the correct features for a word may be aligned more or less strongly (depending on competition for each from other words), so that the overall meaning probability vector may not converge as easily to the full set of correct features. By contrast, when a word has a strong alignment with the correct referent - which corresponds to the gold-standard meaning of the word - all features of the referent are boosted in the meaning probability of the word, yielding improved learning in word-comp over FAS.

Second, we find an interesting asymmetry between the two mechanisms involving competition between the words for a referent (word-comp) and between the referents for a word (ref-comp). Each imposes a conditional probability formulation of competition, but word-comp performs much better, with ref-comp behaving no better than the no-comp model. In fact, the advantage of using referents instead of individual features is completely eliminated in both the no-comp and the ref-comp mechanisms, as both perform worse than FAS.

The source of this asymmetry, we believe, is the deployment of learned knowledge by the model. In both the nocomp and the ref-comp model (Figure 1(b), (c)), a learned word meaning is compared to the referents in isolation from the learned meanings of the other words in the utterance. In this set-up, the knowledge of other word meanings cannot help to guide the model to determine how good a word's alignment to some referent is. By contrast, the word-comp model (Figure 1(d)) tunes the alignments by comparing how similar various learned word meanings are to a referent.

One might expect that mutual exclusivity in the reverse direction (as in the ref-comp model) would achieve the same effects: Tuning the similarity between a word meaning and a referent by the similarity between that word meaning and all other referents should guide the model to correct associations more quickly than not doing so. However, we do not find this effect. We will return to the reason for this lack of effect in the section on the role of frequency.

Competition is clearly important in focusing alignments and facilitating learning, but only in the context of appropriately constraining information: the most effective learning occurs when the competition draws on the maximal amount of learned knowledge in the model, in the form of the developing meaning probabilities. In what follows, we consider the impact of increased ambiguity in forming alignments, or decreased knowledge about words, to see how these factors

Figure 3: Average acquisition score after 20K input items.
impact these various mechanisms. Because the proportion of words learned shows similar relative behaviours to the acq score, in the remaining analysis we focus on comparing acq scores of each of the models after 20 K inputs.

## The Role of Frequency

Children are able to learn word meanings in various conditions, sometimes after only a few observations. Previous research suggests that children use biases such as mutual exclusivity to guide their learning. Learning low-frequency words is also a challenge for computational models, and understanding the mechanisms that improve learning from little evidence can shed light on how children address this issue. The type of competition in our various models plays an important role in their performance on low-frequency words. Figure 3a shows that for the two models with competition over words - the FAS and word-comp models - there is no decrease in performance for words of low frequency $(<5)$ compared to high frequency ( $>10$ ), while for the other two models, no-comp and ref-comp, there is a dramatic drop off in learning.

Specifically, the competition among words in the FAS and word-comp models - which maximizes the use of learned knowledge in focusing alignments - appears to play a crucial role in enabling these models to learn low-frequency words. Comparing the alignments in Figure 1c and Figure 1d in the face of a novel word and its novel referent (as an extreme case of low frequency) will clarify the utility of the learned meaning probabilities. In the word-comp model (Figure 1d), the meaning probabilities of previously-seen words competing for a new referent will not have a very good match to the feature vector for the new referent (since their probabilities will have been adjusted to better fit referents they have been seen with). The novel word will have uniform meaning probabilities that will enable it to better match the new referent, and thus will have a stronger alignment than previously-seen words. By contrast, in the ref-comp model (Figure 1c), the uniform probabilities of the new word will equally match all the referents competing for it, whether they have been seen before or not. There is no prior knowledge in the model in this competition that indicates the previously-seen referents have a better fit with other words. Thus a competition among words works well for novel or low-frequency words by drawing on the fact that previously-seen words will not compete as strongly for a new(er) referent. In short: a new word can
in principle go equally well with any referent in the situation, but a new referent not equally well with any word in the utterance.

## The Role of Utterance Length

Above, we found that the different types of competition gave more pronounced results for low-frequency words than for high-frequency ones. Similarly, we can explore whether there is a differential impact of utterance length on the different models. To simulate this, we manipulated the input generation procedure so that the model was trained only on utterances of length 5 or higher (long-corpus), or 3 and lower (short-corpus). Looking at Figure 3b, we observe that the acquisition scores are globally lower when the models are trained on long sentences only, likely due to the fact that there is more uncertainty about which words and which referents belong together.

Here we see that the word-comp model is the only one to not substantially decline in performance when comparing learning on the short-corpus and long-corpus. While the competition over words seems to help the FAS and wordcomp models equally in dealing with low-frequency words, here the bundling of features into referents as in word-comp is also necessary for performance to be robust to the added ambiguity of long utterances. The FAS model cannot "scale up" to deal with the very long unstructured lists of features in the long-corpus input. This also explains why the model of Alishahi et al. (2012) (the ref-comp approach) worked well in their experiments but not here: the utterances they used all had two words, unlike the naturalistic data we train on above, indicating that ref-comp also cannot scale effectively. Interestingly, as shown in Figure 3c, the word-comp model is particularly robust to the challenge of learning low-frequency words in the corpus of longer utterances, with a very small decrease in performance compared to the other models.

## The Role of Referential Uncertainty

To explore the impact of referential uncertainty - the occurrence of many more potential referents in a scene than there are words - we create a subcorpus that uses every $i^{t h}$ utterance from our full corpus, and uses the utterances in between those to generate "extra" referents in the scenes for utterances in the subcorpus. Here we report results on 20 K inputs with referents added to each scene $S_{i}$ from 0,1 , or 2 utterances in addition to referents taken from utterance $U_{i}$. Figure 4 presents

Figure 4: Average acquisition score after 20K input items, split over different amounts of referential uncertainty.
the results for no referential uncertainty, along with the two added levels of uncertainty. As we expect, the learning performance of all models degrades with higher referential uncertainty. However, in contrast to our previous results, here there is little benefit from either word-based competition or feature bundling. The high degree of ambiguity introduced by these levels of referential uncertainty may be better dealt with by attentional mechanisms that focus joint attention on a likely subset of relevant referents prior to alignment.

## Conclusions and Future Work

Previous research shows that children are sensitive to the cross-situational statistics of their environment: i.e., they can use the regularities across different situations to learn word meanings. However, the detailed mechanisms responsible for cross-situational word learning are still not fully understood, such as precisely what information is used from each observation in identifying the correct word meaning, and how this information is incorporated in the accumulated knowledge about a word. Moreover, children are good at learning word meanings in a variety of situations: they can learn a novel word from a few example and also acquire words from ambiguous/noisy conditions. Previous research has suggested that children are equipped with biases that guide them in word learning by reducing the difficulty/ambiguity of a learning situation. The necessity of these biases in children, and whether they are innate or learnable, are issues that have been debated among cognitive scientists.

Here, we show that one such bias - the mutual exclusivity bias that limits the number of meanings a word takes can be modeled as a competition mechanism during in-themoment learning. The competition exists when the model assesses possible word and referent associations with conditional probabilities as opposed to counts. In other words, the bias or competition is a learning mechanism that is able to condition in-the-moment learning to the learned knowledge of word meanings. We observe that the role of the bias is particularly significant when the learning is more challenging: for example, for learning low-frequency words or from longer utterances. Previous research has investigated how cognitive processes such as memory and attention interact with crosssituational word learning (e.g., Nematzadeh et al., 2012a). Future work should study how these cognitive processes affect the in-moment-learning.

# Evaluating Vector-Space Models of Word Representation, or, The Unreasonable Effectiveness of Counting Words Near Other Words 

Aida Nematzadeh, Stephan C. Meylan, and Thomas L. Griffiths<br>University of California, Berkeley<br>\{nematzadeh, smeylan, tom_griffiths $\}$ @ berkeley.edu

#### Abstract

Vector-space models of semantics represent words as continuously-valued vectors and measure similarity based on the distance or angle between those vectors. Such representations have become increasingly popular due to the recent development of methods that allow them to be efficiently estimated from very large amounts of data. However, the idea of relating similarity to distance in a spatial representation has been criticized by cognitive scientists, as human similarity judgments have many properties that are inconsistent with the geometric constraints that a distance metric must obey. We show that two popular vector-space models, Word2Vec and GloVe, are unable to capture certain critical aspects of human word association data as a consequence of these constraints. However, a probabilistic topic model estimated from a relatively small curated corpus qualitatively reproduces the asymmetric patterns seen in the human data. We also demonstrate that a simple co-occurrence frequency performs similarly to reduced-dimensionality vector-space models on medium-size corpora, at least for relatively frequent words.

Keywords: word representations; vector-space models; word associations

## Introduction

Finding good representations of the meaning of words is a fundamental problem in cognitive science and related disciplines. Vector-space models of semantics represent words as points in an $N$-dimensional Euclidean space where words with similar meanings are expected to be close together. These models have been successful in both modeling human semantic processing (e.g., Landauer and Dumais, 1997) and natural language processing applications (for a review, see Turney and Pantel, 2010). However, relating the similarity between words to their distance in a vector space means that these representations are subject to certain geometric constraints. Previous research has criticized this property of spatial representations because aspects of human semantic processing do not conform to these same constraints (e.g., Tversky, 1977). For example, people's interpretation of semantic similarity does not always obey the triangle inequality, i.e., the words $w_{1}$ and $w_{3}$ are not necessarily similar when both pairs of $\left(w_{1}, w_{2}\right)$ and $\left(w_{2}, w_{3}\right)$ are similar. While "asteroid" is very similar to "belt" and "belt" is very similar to "buckle", "asteroid" and "buckle" are not similar (Griffiths et al., 2007).

Recent work has resulted in significant advances in vectorspace models of semantics, making it possible to train models on extremely large datasets (Mikolov et al., 2013a; Pennington et al., 2014). The resulting vector-space modelsWord2Vec and GloVe-achieve state-of-the-art results for a wide range of tasks requiring machine representations of word meanings. However, the similarity between words in these models is typically measured using the cosine of the
angle between word vectors (e.g., Mikolov et al., 2013b; Pennington et al., 2014).

In this paper, we examine whether these constraints imply that Word2Vec and GloVe representations suffer from the same difficulty as previous vector-space models in capturing human similarity judgments. To this end, we evaluate these representations on a set of tasks adopted from Griffiths et al. (2007) in which the authors showed that the representations learned by another well-known vector-space model, Latent Semantic Analysis (Landauer and Dumais, 1997), were inconsistent with patterns of semantic similarity demonstrated in human word association data. We show that Word2Vec and GloVe suffer from similar problems. Recent probabilistic interpretations of Word2Vec (Levy and Goldberg, 2014; Arora et al., 2015) provide a way to construct a conditional probability from vector-space representations, although we show that this does not result in a significant improvement in performance over cosine similarity.

A probabilistic topic model performs less well than these vector-space models in predicting overall associations, but provides a better fit to human data on tasks where vectorspaced models are subject to geometric constraints. However, two advantages of the recent models are that they can produce word representations for very large vocabularies (millions of types) and can be trained on very large corpora (hundreds of billions of tokens). We investigate whether the performance of co-occurrence frequency-easily obtainable from large corpora-is comparable to the recent models. We find that vectors of simple co-occurrence frequency provide comparable performance to the above models, suggesting that dimensionality reduction may not be necessary feature for machine representations of words.

## Vector-Space Models

We first provide high-level descriptions of two recent vectorspace models that have received significant attention in the machine learning, natural language processing, information retrieval, and cognitive science communities.

## Word2Vec

Word2Vec (Mikolov et al., 2013b) is a shallow neural network model with a single hidden layer that learns similar vector representations for words with similar distributional properties. They present two variants: continuous bag of words or $C B O W$, in which a word token is predicted from its unordered context, and skipgram, in which a given word token is used to predict words in its context. Both variants perform well predicting associations, analogies, and can be used to
identify idiomatic multi-word phrases. We focus here on the skipgram formulation given its higher obtained performance in a variety of natural language processing tasks.

The objective of a Word2 Vec model is to maximize the average log probability of each word's context following

$$
\begin{equation*}
J=\frac{1}{T} \sum_{t=1}^{T} \sum_{-c \leq j \leq c, j \neq 0} \log p\left(w_{t+j} \mid w_{t}\right), \tag{1}
\end{equation*}
$$

where $T$ is the number of training words and $c$ is the number of context words. $p\left(w_{t+j} \mid w_{t}\right)$ is given by the softmax function,

$$
\begin{equation*}
p\left(w_{o} \mid w_{i}\right)=\frac{\exp \left(v_{w_{o}}^{\prime \top} v_{w_{i}}\right)}{\sum_{w=1}^{W} \exp \left(v_{w}^{\top} v_{w_{i}}\right)}, \tag{2}
\end{equation*}
$$

where $W$ is the number of unique words (type) in the corpus $w_{1} \ldots w_{T}$, and $v_{w}$ and $v_{w}^{\prime}$ are the input and output vector representations of word $w$.

Computing the normalizing term in the softmax is prohibitively expensive for large datasets in that the cost of the computation is proportional to $W$ (which may be in millions), thus an approximation is obtained through hierarchical softmax (Morin and Bengio, 2005), Noise Contrastive Estimation (Gutmann and Hyvärinen, 2012), or a related novel technique they introduce, negative sampling. In negative sampling, the model updates the representations of a small number of words such that the network predicts an observed "positive" word pair (e.g., chicken salad), and does not predict any of a number of "negative" pairs that are unlikely to be observed in the text (e.g. chicken battleship or chicken advantageously). The negative pairs are drawn from an explicitly specified noise distribution, typically a unigram model. Because a small number of negative samples are used-usually fewer than 20-a relatively small number of weights need to be adjusted each time the model updates the representation of a word. Mikolov et al. find additional performance gains by sampling less from high frequency words.

Performance of Word2Vec model thus depends on the number of hidden units (typically 50-600), the size of the context window, the degree to which frequent words are undersampled, and the choice of approximation to the full softmax; if negative sampling is used then the number of negative samples can have a significant effect on performance.

## GloVe

GloVe (Pennington et al., 2014) is a weighted bilinear regression model that uses global co-occurrence statistics to derive a real-valued vector representation of each word. Like Word2Vec, GloVe learns similar vector representations for words that appear in similar contexts, however the latter model differs significantly in that it fits co-occurrence frequencies from an entire corpus rather than iterating through local context windows. GloVe exhibits particularly strong performance in analogy tasks, but also performs well on similarity tasks and named entity recognition (NER).

In GloVe, the best word representations $W$ and $\widetilde{W}$ are found by minimizing a least squares objective:

$$
\begin{equation*}
J=\sum_{i, j=1}^{V} f\left(X_{i j}\right)\left(w_{i}^{T} \widetilde{w}_{j}+b_{i}+\widetilde{b}_{j}-\log X_{i j}\right)^{2} \tag{3}
\end{equation*}
$$

where $V$ is the vocabulary, $i$ and $j$ pick out words in the vocabulary, $\mathrm{f}\left(X_{i j}\right)$ is a weighting term (explicated below), $w_{i}$ is the representation of the $i$ th word, $\widetilde{w}$ is the representation of the $j$ th word, $b_{i}$ and $\widetilde{b}_{j}$ are bias terms, and $\log X_{i j}$ is the co-occurrence count of words $i$ and $j$. If $X$ is symmetric, $W$ and $\widetilde{W}$ are equivalent (differing only according to their random initialization). GloVe additionally introduces a weighting into the cost function of the model to avoid $\log 0$ errors and to dampen the effect of high frequency co-occurrences:

$$
f(x)=\left\{\begin{array}{l}
\left(x / x_{\max }\right)^{\alpha} \text { if } x<x_{\max }  \tag{4}\\
1 \text { otherwise }
\end{array}\right.
$$

where $x$ is the co-occurrence count, and $\alpha$ allows for an exponential weighting of for counts between 0 and the threshold $X_{\max }$. The performance of a GloVe model thus depends on the dimensionality of the word vector (typically 50-300), $X_{\text {max }}, \alpha$, and the size of the window used to compute cooccurrence statistics around each word.

## Co-occurrence Frequency

We also consider a baseline model that simply uses normalized co-occurrence frequencies of words to measure their similarity. In other words, given sufficient data, is a term-byterm matrix sufficient to predict human association norms? We note that this baseline is used by previous work to model human semantic and syntactic processing, as well as in infomration retrieval (e.g., Burgess and Lund, 1997; Azzopardi, 2005).

## Shortcomings of Spatial Models

Similarity between two words in a vector-space model is usually computed using the cosine of the angle or the Euclidean distance between the vectors representing the words. While intuitive, this approach has at least one significant shortcoming: cosine and Euclidean distance cannot capture the observed asymmetries in human similarity judgments because they are inherently symmetric measures. Tversky (1977) famously argued that spatial representations cannot capture human similarity judgments because the latter often violate the metric axioms. For example, elicited word (or phrase) similarity is asymmetric: when queried, most participants considered "North Korea" to be very similar to "China," while the reverse relationship was rated as significantly less strong ("China" is not very similar to "North Korea").

Griffiths et al. (2007) extended this argument to spatial representations of the semantic relationships between words, showing that similar violations of the metric axioms can be demonstrated for vector-space representations. We now revisit these analyses, examining the extent to which they are problematic for new vector-space models.

One of the properties of metric spaces is that the distance between each 3 -word tuple must satisfy the triangle inequality: given three points $x, y$, and $z, d(x, z) \leq d(x, y)+d(y, z)$, where $d()$ is a distance function. This inequality constrains the possible distance values among the vector representations for each of the three words: if distances between the words in two of the pairs are very small, the distance between the words in the third pair is also expected to be small.

After demonstrating that cosine-as a monotonic function of the angle between two vectors-satisfies an analogue of the triangle inequality Griffiths et al. (2007) studied to what extent this is true among the cue-target pairs in the Nelson norms. For the words $w_{1}, w_{2}$, and $w_{3}$, they plot the distribution of $p\left(w_{3} \mid w_{1}\right)$ when both $p\left(w_{2} \mid w_{1}\right)$ and $p\left(w_{3} \mid w_{2}\right)$ are greater than a given threshold $\tau$. They observe that even for large values of $\tau$, there are a lot of very small values of $p\left(w_{3} \mid w_{1}\right)$. Consistent with the intuition that human similarity judgments are not always transitive, they find many cases where two of the pairs $\left(w_{2}-w_{1}\right.$ and $\left.w_{3}-w_{2}\right)$ in a tuple ( $w_{1}$, $w_{2}$, and $w_{3}$ ) are highly similar, but the words in the third pair ( $w_{1}$ and $w_{3}$ ) are not.

As a result, by using cosine (or any distance measure more generally) on vector-space representations, we cannot replicate the asymmetric patterns of similarities observed in human judgments. To enable word representations derived with vector space models to account for a greater range of phenomena, we propose an elaborated, non-metric similarity measure for vector-space representations. Following recent work that provides a probabilistic interpretation of Word2Vec (Levy and Goldberg, 2014; Arora et al., 2015) we calculate the conditional probability for a given pair of words $w_{1}$ and $w_{2}$ using a softmax function:

$$
\begin{equation*}
p\left(w_{2} \mid w_{1}\right)=\frac{\exp \left(\mathbf{w}_{\mathbf{2}} \cdot \mathbf{w}_{\mathbf{1}}\right)}{\sum_{\mathbf{w}_{\mathbf{j}}} \exp \left(\mathbf{w}_{\mathbf{j}} \cdot \mathbf{w}_{\mathbf{1}}\right)} \tag{5}
\end{equation*}
$$

where $\mathbf{w}_{\mathbf{j}}$ is the vector representation of $w_{j}$ and $w_{2} . w_{1}$ is the dot product of the two vectors. Using this probabilistic measure, we can now examine how well Word2Vec and GloVe representations perform on tasks that do not satisfy the geometric constraints, i.e., triangle inequality and asymmetries in similarity judgments.

## Evaluating Vector-Space Representations

In this section, we describe the evaluation data and explain the tasks that we use to examine how well vector-space representations predict human word associations.

## Data: Nelson Association Norms

Following Griffiths et al. (2007), we use the association norms from Nelson et al. (1998) as our gold-standard evaluation data. Nelson et al. (1998) performed an extensive free association experiment where they asked 6000 participants to record the first word they can think of given a cue word. The experiment resulted in a set of 5018 cues, the target words produced in response of each cue (associates), and the probability of producing each target word for a given cue. Ap-
proximately $45 \%$ of the target words are present as cues in the dataset. The Nelson norms are well-suited for the evaluation of semantic similarity because unlike most gold-standard similarity lexicons (e.g., Hill et al., 2015), word associations obtained in this way potentially encode asymmetric relations: the Nelson association norms encode for many words both how likely people are to produce $w_{1}$ when cued with $w_{2}$, as well as $w_{2}$ when cued with $w_{1}$.

## Evaluation Tasks

We evaluate the word representations found by these models on four tasks to assess whether they capture empirical phenomena of interest in the Nelson norms. The first two, coefficient of correlation and median rank of associates, test whether these representations capture the strength of associations between each cue-target pair. The remaining two, the triangle inequality and ratio of asymmetries specifically test whether these representations can account for human behavior on tasks with asymmetric associations.
Coefficient of correlation. Computing the correlation between two list of scores is a standard way for measuring their similarity (Budanitsky and Hirst, 2006). We created a gold-standard list of similarity scores that, for each cuetarget pair in the norms, includes $p$ (target|cue). We then retrieved a list of similarities for the same cue-target pairs from the representations under study, measuring similarity as either cosine $\left(\mathbf{w}_{\text {target }}, \mathbf{w}_{\text {cue }}\right)$ or $p\left(\mathbf{w}_{\text {target }} \mid \mathbf{w}_{\text {cue }}\right)$, where $\mathbf{w}_{x}$ is the vector representation of $x$. To assess the extent to which these representations can predict human similarity judgments of semantic associations, we calculated the Spearman's rank correlation coefficient ( $\rho_{\text {assoc }}$ ) between these two lists.
Median rank of associates. We also assess the quality of the representations by checking whether they produce similar rankings of target words (associates) for each cue in the Nelson norms. For each cue, we rank all its associates based on their conditional probabilities (given the cue) from the Nelson norms, and also get a similar ranking for each cue in the model. For the first associate of each cue, i.e., the one with the highest probability per the Nelson norms ranking, we check its rank in the model list. We take the median rank of the first associate across all the cues from the Nelson norms, and repeat this process for second and third associates.
Triangle inequality. We extend the analysis in Griffiths et al. (2007) to the evaluate whether word representations satisfy the triangle inequality. For every $w_{1}, w_{2}$, and $w_{3}$ such that similarity of $w_{1}-w_{2}$ and $w_{2}-w_{3}$ are greater than a threshold $\tau$, we plot the distribution of similarity values of $w_{1}-w_{3}$. For the Nelson norms, similarity of words in a pair is their conditional probability; for other models similarity is given by the cosine or conditional probability. We select thresholds $(\tau)$ such that for each threshold, the number of pairs selected for each model is similar to that of the Nelson norms; The thresholds for the norms are taken from Griffiths et al. (2007).
Asymmetry ratio. Griffiths et al. (2007) show that the similarity of more than $85 \%$ of cue-target pairs in Nelson norms
are asymmetric by the criterion of at least an order of magnitude difference between $p(w 2 \mid w 1)$ and $p(w 1 \mid w 2)$. However, distance measures are inherently symmetric and for any distance function $d()$, we have $d\left(w_{1}, w_{2}\right)=d\left(w_{2}, w_{1}\right)$. To measure the performance of vector-space representations in predicting the asymmetries, for each cue-target pair in the Nelson norms, we calculate the ratio of asymmetry as follows:

$$
\begin{equation*}
\operatorname{asym}\left(w_{1}, w_{2}\right)=\frac{p\left(w_{2} \mid w_{1}\right)}{p\left(w_{1} \mid w_{2}\right)} \tag{6}
\end{equation*}
$$

We then calculate the Spearman's rank correlation coefficient between the asymmetry scores of these similarities and those from the Nelson norms.

## Corpora and Model Training

To support comparison with Griffiths et al. (2007) we trained GloVe, Word2Vec skipgram, and collected co-occurence frequencies on TASA, the Touchstone Applied Sciences Corpus (Landauer and Dumais, 1997). This corpus consists of approximated 8 M tokens taken from reading materials appropriate for a high school English students. In addition to TASA, we trained Word2Vec skipgram and GloVe, and collected cooccurrence frequencies on English Wikipedia (3.91B tokens). This corpus is too large for training a Latent Dirichlet Allocation (LDA) topic model using Gibbs Sampling. While we tried to replicate the LDA results for TASA with more scalable variational methods (Hoffman et al., 2010), the resulting topics produced associations that were significantly worse than those obtained through Gibbs sampling or either of the vector space models.

Preprocessing was matched to the extent possible across model inputs. All words were translated to their nearest lowercase ASCII equivalent. For both TASA and Wikipedia we discarded function words using the Python stopwords package. For TASA we removed the same set of lowinformation words and enforced the same frequency cutoff as Griffiths et al. (2007). For Wikipedia, we removed words that appeared on too many pages or too few, and retained only the top 100k most frequent remaining words.

To evaluate the performance of the Word2Vec skipgram model we trained 20 models across a range of hyperparameter settings, varying the size of the embedding vector (50, $100,200,300$ or 400 hidden units), the choice of optimization method (hierarchical softmax or negative sampling), and for models with negative sampling the number of negative examples $(5,10,15)$. Words with unigram probability higher than .001 are downsampled following Mikolov et al. (2013b).

Because of an implementation error, we were unable to explore a large parameter space with GloVe, and report only the results with the default parameters $\left(X_{\max }=10, \alpha=.75\right.$, 50-dimensional vectors, and a 7 -word symmetric window on either side of the target word). This leaves open the possibility that GloVe may exhibit even higher performance on TASA and Wikipedia with appropriate parameter settings.

We also compute association using the LDA results (sampled document-topic and topic-word assignments) from Griffiths et al. (2007).

Finally, we used large-scale pre-trained models distributed by the authors of Word2Vec and GloVe. These largestavailable models often exhibit best-in-class performance because they reflect extensive parameter search, proprietary corpora, and distributed implementations that can handle more training data than publicly-distributed single-machine implementations. For Word2Vec we used a pre-trained 300dimensional model obtained by using the continuous bag of words architecture (CBOW) on a corpus of 100 billion words from Google News. For GloVe we used a 300-dimensional model trained by Pennington et al. (2014) using a 2014 export of Wikipedia and the Gigaword 5 corpus, consisting of approximately 6 billion tokens in total. ${ }^{1}$

## Results

Overall associations. We first look at the coefficient of correlation that shows how the various models perform in predicting the overall associations. We find that using conditional probability in place of cosine results in slightly better performance in predicting the semantic associations when the models are trained on medium or large corpora (see cosine ("cos.") and conditional probability ("cond. pr.") columns in Table 1). We also observe that given small and medium corpora (first and second row of Table 1), the Word2Vec skip-gram has the highest correlation with human word associations; but, given the largest corpora, GloVe performs slightly better than the Word2Vec model. Interestingly, given the small and medium corpora, simple co-occurrence frequencies perform similarly to or better than the Word2Vec CBOW and GloVe representations. Looking at the second measure of associations, the median rank of the associates (Table 2), we observe that the LDAmodel and co-occurrence frequencies perform similar to Word2Vec on TASA and Wikipedia; both models exhibit better performance than GloVe. The representations of the pretrained GLoVe model (on the largest corpus) have the lowest (best) median ranks.
Geometric constraints. The results for the triangle inequality analysis using the conditional probability measure are shown in Figure 1 (cosine results are omitted as they cannot produce the pattern). We observe the expected pattern for the Nelson norms, the LDA model, and co-occurrence frequency (see Figure $1 \mathrm{a}-\mathrm{c}$ ): even for large values of $\tau$, there are a lot of pairs that have probabilities close to zero. However, as shown in Figure 1 d-f, we do not see pairs with very small values of similarity when examining large thresholds for any of the recent vector-space representations. Our results reveal that even with a probabilistic measure, Word2Vec representations cannot predict the triangle inequality: for very high thresholds on the similarity of $w_{1}-w_{2}$ and $w_{2}-w_{3}$, there are

no $w_{1}-w_{3}$ pairs with low similarity. These results suggest that using a probabilistic measure do not address the limitations of the vector-space models with respect to the triangle inequality.

Finally, we examine whether the representations capture the observed asymmetry in human similarity judgements as calculated in Eqn. (6). Note that we can only use conditional probabilities in this analysis because the cosine measure is symmetric. This probabilistic measure of similarities in both Word2Vec and GloVe to some extent predicts the asymmetric patterns of similarity observed in the Nelson norms (Table 3). We observe that the performance of the LDA model is comparable to the GloVe representations trained the largest corpora. The GloVe models performs significantly better than the Word2Vec models, which we believe is a result of its objective function-it uses the ratio of conditional probabilities of word pairs in training.

Table 3: The Spearman's rank correlation coefficient ( $\rho_{\text {asym }}$ ) between asymmetry scores of Nelson norms and representations from the models. In our data, there are 7096 cue-target pairs for which target-cue also exits. [*] Data unavailable or infeasible to compute given current resources.

## Discussion

The selection of models, corpora, and tasks presented above suggests that LDA and co-occurrence frequencies have certain advantages when compared with the vector-space representations produced by Word2Vec and GloVe. We expound on a few key points below to contextualize our results and set the stage for future research.

Most of the targets and queues analyzed here are of rel-
atively high frequency rank. In future work we would like to investigate exactly how robust each of these models are to sparsity to test the hypothesis that reduced-dimensionality models are better at generalizing, such that they better predict associations for low frequency words.

The two vector-space models investigated here were both developed with the explicit objective of capturing meaningful linguistic difference in the linear substructure of the model (e.g., the vector produced by king - man + woman is closest to queen). As such, these models show strong performance on analogy tasks, while LDA typically fairs poorly. One question is thus whether a single representation could predict word associations, while preserving linear substructure.

## Conclusion

We show that representations from two new vector-space models, Word2Vec and GloVe, suffer from the same geometric constraints as predecessors, and are consequently unable to predict some of the characteristics of human similarity judgments, such as asymmetric similarity relations between two words or triangle inequality. Besides performing well in the above task, word representations derived from LDA topic modeling show remarkable predictive power with respect to human judgments given that they are learned from a dataset two orders of magnitude smaller than comparably performing vector-space models.

#### Abstract

Human communication has a remarkable capacity to describe events that occurred elsewhere and at other times. In particular, when describing complex narratives, speakers must communicate temporal structure using a mixture of words (e.g., "after"), gestures (e.g., pointing rightward for a later event), and discourse structure (e.g., mentioning earlier events first). How do listeners integrate these sources of temporal information to make sense of complex narratives? In two experiments, we systematically manipulated gesture, speech, and order-of-mention to investigate their respective impacts on comprehension of temporal structure. Gesture had a significant effect on interpretations of temporal order. This influence of gesture, however, was weaker than the influence of both speech and order-of-mention. Indeed, in some cases, order-of-mention trumped explicit descriptions in speech; for instance, if 'earlier' events were mentioned second, they were sometimes thought to have occurred second. Listeners integrate multiple sources of information to interpret what happened when.

Keywords: time; gesture; iconicity; multimodal communication; memory.

## Introduction

Human communication stands out among naturally occurring communication systems in its ability to convey information about events occurring in other places and at other times, a feature known as displacement (Hockett, 1960). This includes the concrete details of displaced events-who did what to whombut also when things occurred. If you observed a woman receiving the winning lottery ticket and also getting her purse stolen, then you would want to be clear about which event occurred first. While temporal order is an abstract feature of a complex event, it is often critical for communicative success.

To communicate about temporal order (and to communicate in general), speakers have several
strategies to deploy. The first and most obvious is in their choice of words, like "before" or "after," "earlier" or "later." Second, speakers also communicate about temporal order using visible and systematic motion of their bodies (Cooperrider \& Nunez, 2009; Casasanto \& Jasmin, 2012). Spontaneous co-speech gestures produced by North-American native English speakers often indicate relative temporal order by locating events along an imagined spatial timeline, with earlier events placed to the left and later events placed to the right. Finally, speakers encode temporal order in the structure of their larger discourse. Earlier events are typically expressed earlier in an utterance, while later events are expressed later ("order-of-mention," a.k.a. temporal iconicity, Jakobson, 1971). For instance, if somebody first went to the gym and then stopped for coffee, it would be most natural for them to say, "I went to the gym and stopped for coffee," rather than the reverse; the order in which the events are mentioned can stand in for the order in which they occurred.

During real-world communication, all three of these strategies can be deployed at the same time, complementing each other. For instance, if a speaker were to describe a series of events that occurred on a recent vacation, they might use expressions like "first," "and then," and "finally" to express explicitly, using lexical resources, the temporal order of events. In coordination with these expressions, they might point along the left-to-right spatial axis to convey the temporal order of the events. And, at the same time, they might choose to describe the events in the same order in which they actually occurred.

While we know that speakers do this, less is known about whether listeners actually care. Temporal terms are notoriously hard for children to acquire (Tilman et al., 2017; Shatz et al., 2010); the words "before" and "after," for instance, continue to be confused by most children until they are five years old (Clark, 1971). Listeners are also known to rely on order-of-mention to infer the order in which events occurred (Jakobson, 1971), although past work has focused primarily on contexts where temporal order is ambiguous in speech and gesture.

It's also currently unknown whether listeners rely on temporal gestures to make inferences about the abstract concept of temporal order. By contrast, listeners are demonstrably sensitive to concrete information expressed in gesture. For example, concrete, iconic gestures boost comprehension (Thompson, Driscoll \& Markson 1998) and can even add information not otherwise present in speech (Church et al. 2007; Singer \& Goldin-Meadow 2005). Less is known, however, about the communicative impact of gesture on the interpretation of temporal structure. Speakers use gesture to express a range of information about time, including duration and sequential order (Cooperrider \& Núñez, 2009). There is mixed evidence that, when speech is ambiguous (e.g., 'the meeting was moved forward,' which can mean earlier or later), observers use gesture to determine how the speaker's metaphorical conceptualization of time (Jamalian \& Tversky, 2012), although perhaps only when communication is copresent and not computer-mediated (Lewis \& Stickles, 2016). As far as we know, no previous research has investigated whether gestures about temporal order are actually communicative.

What about when these sources of information are not aligned but contradictory? Sometimes, we mention a later event first, perhaps because of the event's salience. When this occurs, the conflict is reflected in the listener's neural response to the sentence as they resolve the conflict (Münte et al, 1998). Previous research has assumed that, in cases of conflict, speakers will default to the information expressed lexically, overriding the temporal order suggested by order-of-mention. However, discourse comprehension involves probabilistic judgments about how best to integrate potentially contradictory information (e.g., Gibson et al, 2014). Under some circumstances, therefore, speakers are likely to rely on order-of-mention, overriding or ignoring the temporal order conveyed explicitly in speech.

To investigate the communication of complex temporal structure during multimodal discourse, we conducted two studies in which we systematically manipulated how information about temporal order was expressed in speech, gesture, and order-of-mention. Participants viewed brief videos in which a speaker described a complex series of events. Descriptions varied in the use of explicit temporal terms (e.g. "earlier" or "later") and temporal gesture (e.g., a leftward pointing gesture to indicate an earlier event) to order the events in the sequence. Within these descriptions, moreover, pairs of events were sometimes mentioned in the same order as they occurred, so that order-of-mention was a helpful guide to temporal order, but other times the order-ofmention did not align with their actual temporal order. All three sources of information-temporal terms,
temporal gesture, and order-of-mention-were thus fully crossed within subjects.

We foresaw a number of possible outcomes. On the one hand, temporal terms are so explicit and unambiguous that they may overwhelm information from any other source, including gesture and order-ofmention. On the other hand, a complex situation can involve multiple interrelated events, outstripping the relatively simple binary distinctions that are most common in speech (before/after, earlier/later). Under these circumstances, temporal gestures may be especially beneficial, as they allow a listener to track the relative ordering of multiple events. A series of three gestures, for instance, can use relative spatial location to order events without any of the ambiguity that can plague speech. Lastly, order-of-mention may sometimes trump both speech and gesture. First, it uses time (of mention) to represent time (of occurrence)-a direct mapping that may be difficult for a listener to ignore when constructing their discourse model. Second, we know that memory for specific words isn't great as a delay period increases (Sachs, 1967)—when listeners are trying to reconstruct the order of events after the fact, the may be more likely to recall the order in which they were mentioned than the specific words used to describe their order. Thus, there are good reasons to predict that all three sources of information may dominate listener's interpretations of multimodal communication about temporal order.

## Experiment 1

The main purpose of Experiment 1 was to investigate how participants use the temporal information available in multiple communicative resources to construct a temporal narrative of events. We were especially interested in how individuals reconcile situations in which different sources provide conflicting temporal information. And finally, because of past work suggesting that gesture effects on comprehension are amplified over a delay (Church et al. 2007), we added a Memory Condition (Immediate or Delayed) to investigate whether the temporal resources participants use to order a sequence of events changes over a delay.

## Methods

Participants: Forty undergraduate students $(\mathrm{N}=31$ female) participated in this study in exchange for course credit. Sample size was determined in advance on the basis of similar studies of gesture (e.g., $N=45$ in Church et al. 2007).

Materials: We filmed 16 vignettes in which a woman narrated a brief story consisting of four events. The events in a given sequence had all already occurred or all were going to occur. That is, half of the vignettes discussed future events (i.e. planning a hiking trip,
preparing to go camping) while the other half of the videos discussed a sequence of events that had already occurred (i.e. recalling a vacation, recapping a day at work).

Videos were filmed from the neck downwards, ending at the top of the narrator's legs, with the arms clearly visible. Because we manipulated whether or not temporal information is delivered through explicit temporal terms in speech, we cut the narrator's head and neck out of the frame to avoid giving participants visual clues (i.e. voice box movements) from which to draw temporal information. All of the video stimuli were generated originally and contained arbitrarily related events to ensure that participants could not determine the temporal order of events by relying on causal or canonical relationships (i.e. hiking up a cliff generally precedes jumping down a waterfall).

Procedure: Participants watched short video clips that described a four-event vignette. For example, a participant could hear, about an upcoming climb up Mount Everest, that "I should probably replace my old hiking boots and then pick up some snow gear for encountering snowy conditions. I also cannot forget to first get a hiking permit and then purchase an airline ticket to Nepal." In this case, most of the clauses contain explicit temporal terms that disambiguate the actual temporal order. Within each sentence, order of mention also indicates the correct temporal order (e.g., the narrator intends to get a hiking permit before purchasing an airline ticket to Nepal); by contrast, the two sentences' order of mention conflict with the order in which the events occurred. There were sixteen different vignettes in total. The videos of each vignette were randomly presented, and participants saw each of the unique vignettes one time. The video of each vignette, however, was played twice, back to back, to the participant.

Participants also completed a set of seven comprehension questions after viewing a video stimulus. For half of the vignettes, participants received the comprehension task immediately following the presentation of that particular vignette video (our Immediate memory condition). For the other half of the vignettes, participants received the corresponding set of comprehension questions following a 10 minute delay (our Delayed memory condition). During this 10 minute delay, participants completed multiplication and long division problems.

Each comprehension question was presented in 2AFC format (i.e. "Do I need to buy more winter gear before or after getting an airline ticket?") with a 10 second response window. Four of these seven questions tested the temporal relationship of events in the story (target questions). The remaining three questions in the comprehension set were unrelated to temporal content and probed the basic content of each video (filler questions). Question order was randomized for each
video and for each participant. At the end of the experiment, participants filled out a debrief questionnaire.

## Analysis

Before analyzing the data, we removed filler questions, trials with a response time faster than 200 ms , and trials that were two and a half standard deviations faster or slower than each participant's mean response time on each vignette. We excluded participants whose accuracy on the comprehension task was below $50 \%$ (chance) when considering trials where temporal term, gesture information, or both were present, as these individuals were below chance performance even when explicit ordering information was available to them. We also excluded responses for participants who failed our debrief point-of-view item. In this question participants were asked, "Which of the following gestures would the narrator use to accompany the word 'earlier'?" They were given two short video clips, one with the narrator making a rightward (from her point of view) gesture stroke, and one with her making a leftward gesture stroke from which to respond. Participants who chose the rightward gesture stroke-which appears as a leftward stroke from their mirrored perspective-as accompanying the word "earlier," were considered to have failed the debrief and were excluded from this analysis since we wanted to ensure they were interpreting the gestures in the videos the way we intended.

Our primary dependent measure was participants' response (before vs. after), as a function of the information expressed in order-of-mention, speech, or gesture (before, nothing, or after). When neither speech nor gesture include explicit temporal information, there is no 'ground truth' about the order of events. Each resource was dummy coded for its temporal information ("before" $=-1$, no info $=0$, "after" $=1$ ). All analyses used generalized mixed-effects models with a logistic link function, with centered predictors and the maximal converging effects structure justified by the design (Barr et al, 2013).

## Results

## Effects of language, gesture, and order-of-mention

We first examined how comprehension of temporal sequences is affected by temporal terms in speech, temporal gesture, and order-of-mention. All three sources of information had a significant effect. Temporal terms reliably influenced participants' interpretation of temporal order $(b=0.95 \pm 0.17 \mathrm{SEM}, z=5.45, p<$ 0.001 ), with more before interpretations after the use of the word "before" ( $M=77 \%$ ) but more after interpretations after the use of the word "after" ( $M=$ $72 \%$ ). Similarly, order-of-mention had a significant, if smaller, impact $(b=0.72 \pm 0.15$ SEM, $\mathrm{z}=4.94, \mathrm{p}<$
0.001 ), with more before interpretations when the event was mentioned first, but more after interpretation when the event was mentioned second. And temporal gestures, too, had a significant impact ( $\mathrm{b}=0.48 \pm 0.12$ SEM, $\mathrm{z}=$ $3.94, \mathrm{p}<0.001$ ), with more before responses after leftward "past" gestures ( $M=63 \%$ ), and more after responses are rightward "after" gestures ( $M=67 \%$ ). Participants thus were sensitive to all three of the semiotic resources available during multimodal comprehension, with larger influences of temporal terms and order-of-mention, and a smaller but significant influence of gesture.

The only other significant effect we observed was an interaction between temporal terms and temporal gesture ( $b=-0.38 \pm 0.16$ SEM, $z=-2.21, p=0.0271$ ). This was driven by a large effect of gesture when temporal terms were absent entirely from speech ( $b=0.54 \pm 0.17$ SEM, $z=3.19, p=0.0014)$, but a much smaller effect of gesture when accompanied by explicit temporal terms ( $b=0.72$ $\pm 0.21$ SEM, $\mathrm{z}=3.47, \mathrm{p}=0.00541$ ).

## Effects of recall

We were also interested in the effect a delay period would have on participants' comprehension of temporal events. Specifically, we wondered whether we would see the effects of particular resources (i.e. temporal gesture) strengthen over time, as previous research with iconic gesture has found (Church et al., 2007). Our results indicated that participants actually performed the same on the comprehension task regardless of whether it was completed immediately following the video vignette or after a 10 minute delay period. We did not find evidence of interactions between any of the resources and our memory condition factor.

## Discussion

Our study aimed to investigate how people draw on and integrate multiple sources of temporal information during comprehension of complex temporal sequences. We found that participants are independently influenced by the information available through temporal terms, gesture, and order-of-mention.

The presence of temporal terms and temporal gesture each influences participants to respond according to the order presented through these resources perhaps in explicitly conveying temporal order. Order-of-mention is also largely influential as a listener builds a temporal narrative, perhaps because of the salience of the iconicity (i.e. letting the order events are uttered in speech stand in for the order events occur in time).

Interestingly, we found an interaction between temporal terms and gesture, mediated by whether or not information from temporal speech is present-when ordering information from temporal terms is already
present, we see less of an impact of temporal gesture than when it is absent.

We were additionally surprised to not detect an effect of memory condition given our predictions that the effects of gesture are strengthened over time. Perhaps our delay was not long enough to elicit a difficult recall situation, in which temporal ordering information would decay over time. Creating that kind of recall situation is important to reveal any effects that our temporal resources may selectively provide over time.

## Experiment 2

Experiment 2 was designed to replicate and extend slightly the results of Experiment 1. The slight extension was to address our unexpected finding that the relative impact of gesture did not differ after a delay. This appeared to contradict previous evidence that the impact of gesture increases with the passage of time (Church et al, 2007). Based on this, we predicted that, as more time passed after observing an utterance, the relative contributions of explicit terms, gesture, and order-ofmention should change-with, in particular, an increased reliance on gesture.

However, participants' recall was not severely impacted after the delay, suggesting that this delay may not have been sufficiently long enough to observe a shift in importance between temporal terms, temporal gesture, and order-of-mention. We thus increased this delay from 10 minutes to 30 minutes.

## Methods

Participants: Adults ( $N=50,33$ women) participated in exchange for partial course credit.
Materials: The same as in Experiment 1.
Procedure: The same as in Experiment 1, except that we extended the delay period from 10 to 30 minutes.

## Analysis

All exclusionary criteria and data cleaning procedures used in Experiment 1 were also applied for Experiment 2. Analyses again used logistic mixed-effects models, with centered predictors and the maximal converging effects structure justified by the design (Barr et al, 2013).

## Results

Effects of language, gesture, and order-of-mention Experiment 2 replicated the main findings of Experiment 1. Participants reliably drew on information presented through temporal terms $(b=0.86 \pm 015$ SEM, $z=5.68$, $\mathrm{p}<0.001$ ), with more before interpretations after the use of the word "before" ( $M=72 \%$ ) but more after interpretations after the use of the word "after" ( $M=$ $71 \%$ ). They also use the information available via order-of-mention ( $b=0.62 \pm 0.12$ SEM, $z=5.00, p<0.001$ ), with more before interpretations when the event was
mentioned first, but more after interpretation when the event was mentioned second. And similarly, participants also rely on the information present in temporal gesture ( $\mathrm{b}=0.28 \pm 0.14, \mathrm{z}=2.00, \mathrm{p}<0.05$ ), with more before responses after leftward "past" gestures ( $M=62 \%$ ) but more after responses are rightward "after" gestures ( $M=$ $59 \%$ ). These findings replicate the results of our previous experiment: participants are sensitive to the information from temporal terms and order-of-mention in particular, and less reliably applying the information gleaned from gesture (Fig. 1).

We did not, however, replicate the interaction of temporal terms and temporal gesture ( $b=-0.10 \pm 0.14, \mathrm{z}$ $=-0.77, p=0.44)$.

## Effects of recall

We next turned our attention to the effect of the delay period, and how the available temporal resources would be deployed over time. Our results did not reveal an effect in line with our prediction that the impact of gesture would increase over time (Gesture x Memory Condition, $b=0.27 \pm 0.17 \mathrm{SEM}, \mathrm{z}=1.47, \mathrm{p}=0.14$ ), even with a longer delay period.

Figure 1. Impact of each resource on participants' response. Color indicates the log-odds of interpreting an event to have occurred after (vs. before). All three resources had an impact. As gesture went from expressing 'before' to 'after' (i.e., moving rightward), 'after' responses increased (i.e., shift from red to blue). Similarly, as speech went from 'before' to 'after' (ie., bottom to the top), 'after' responses increased. And when order-of-mention suggested that the event occurred after (i.e., right panel), there was a higher proportion of 'after' responses (i.e., shift toward blue).

## Discussion

Experiment 2 replicated the main findings of Experiment 1. We found that in multimodal communication, participants reliably glean information from explicit temporal terms in the utterance, order-of-mention, and to a lesser extent temporal gesture. The only effect that did not replicate was the interaction between gesture and temporal terms, which suggests that this effect is either small and fickle or potentially a false-positive from Experiment 1.

Even with a 30 -minute delay, the benefits of these metaphorical temporal gestures did not increase with the passage of time, unlike past findings for concrete representational gestures (Church et al., 2007). One explanation is that 30 minutes is insufficient to elicit the selective benefits of gesture.

## General Discussion

We set out to investigate how we communicate about the temporal structure of complex events. Multimodal communication offers a range of resources for expressing temporal order: words, gestures, discourse structure. Across both studies, we found that listeners made use of all three of these sources of information, integrating them to make sense of the temporal structure of complex narratives.

## The ephemeral and spatial nature of gesture

A central finding of these studies is that gestures that encode temporal order are genuinely communicative. Gestures are ephemeral, disappearing as soon as they are produced, and are only intermittently interjected into the the speech stream. Despite this, listeners made reliable use of gesture to interpret complex narratives.

Perhaps temporal gesture is especially useful in that it can help create a schematic "bird's eye" view of a complex event by laying out all of the events in their temporal order. A single temporal gesture can depict a pairwise relation between two events by placing them in space - but a sequence of gestures can construct a schematic representation of an entire narrative, including multiple subevents. By enacting a spatial timeline, temporal gestures supply an object for joint attention, available to both speaker and listener.

The utility of gesture may depend on the listener's perspective on the speaker. Because time recruits lateral space, assigning meaning to the right (future) and left (past) sides of space, interlocutors who face each other are confronted with an added challenge: adopting the perspective of their partner. The fact that participants in our study were able to interpret the speaker's lateral temporal gestures - despite the fact that the speaker was both head-on and video recorded - is a testament to the centrality of gesture to human communication.

## Integrating the complementary and contradictory

While we began by considering reasons that one source of information might dominate listeners' comprehension of temporal order, both studies found that all three sources of information make independent and reliable contributions. While the impact of gesture was less pronounced than that of speech or discourse structure, it was nonetheless robust across both studies. All three sources of information appear to make independent contributions to the interpretation of temporal structure.

One avenue for future research is whether there are individual differences in the reliance on these sources of information. Are some listeners especially sensitive to when an event is mentioned in the discourse, while others are more sensitive to how that event is gestured relative to others? If such individual differences exist, and we suspect they do, then these may lead to radically different interpretations when different sources of temporal information come into conflict - when the first event mentioned actually occurred last, or when the speaker gestures left but accidently says 'and then afterward....' Understanding these dynamics will help us understand how miscommunications occur - and are repaired.

Similarly, these three sources of information may have differential impacts in different communicative settings or under different task demands. For instance, Lewis and Stickles (2016) reported that gestures expressing metaphors for time were communicative-but only when the speaker was co-present with the listener, rather than appearing on video. Gestures expressing temporal order may also decrease in importance during videomediated communication, with speech and order-ofmention weighted more heavily. This may account for gesture's relatively smaller effect size in the current studies.

## Conclusion

We began by asking how listeners understand the temporal structure of complex narratives by integrating information from various sources: words, gesture, order-of-mention. We found that each of these resources made independent contributions to the comprehension of temporal order. In particular, these results demonstrate that metaphorical gestures can communicate complex temporal relations. The power of human communication may lie in its use of multiple strategies to communicate abstract information.

#### Abstract

The actualization of affordances can often be accomplished in numerous, equifinal ways. For instance, an individual could discard an item in a rubbish bin by walking over and dropping it, or by throwing it from a distance. The aim of the current study was to investigate the behavioral dynamics associated with such metastability using a ball-to-bin transportation task. Using time-interval between sequential ball-presentation as a control parameter, participants transported balls from a pickup location to a drop-off bin 9 m away. A high degree of variability in task-actualization was expected and found, and the Cusp Catatrophe model was used to understand how this behavioral variability emerged as a function of hard (time interval) and soft (e.g. motivation) task dynamic constraints. Simulations demonstrated that this two parameter state manifold could capture the wide range of participant behaviors, and explain how these behaviors naturally emerge in an under-constrained task context.

Keywords: affordances; dynamic systems; cusp catastrophe; dynamic modeling; simulations; constraints;

## Introduction

Reorganizing one's activity in relation to changing task demands is a ubiquitous aspect of everyday life and is often required to ensure task success. In order to solve everyday perception-action tasks, human (and animal) behavior is functionally (re)organized in relation to the affordances that define a given task context. Here, the term affordance simply refers to the action possibilities that characterize a given agent-environment system (Gibson, 1979).

Starting with Warren's (1984) seminal work on the perception of climb-ability, affordance perception research has demonstrated that affordances are defined by dimensionless ratios (termed pi-numbers) that capture the intrinsic, or body-scaled "fit" between the relevant aspects
of an environmental surface or object and an intentional agent's perception-action capabilities (i.e. effectivities). For instance, a stair riser is perceived to afford (comfortable) climbing if the ratio of the perceivers leg-length with respect to the height of the riser is less than approximately $\pi=.85$.

Similar body-scaled ratios are known to define a wide range of action possibilities, from the stand-ability and sitability of surfaces (e.g., Fitzpatrick, Carello, Schmidt \& Corey, 1994; Mark, 1987), to the pass-through-ability of apertures (Warren \& Whang, 1987), and the reach-ability and grasp-ability of objects (e.g., Carello, Grosofsky, Reichel \& Solomon, 1989; Cesari \& Newell, 1999; Richardson, Marsh \& Baron, 2007). In each case, this research has demonstrated how individuals correctly detect affordance boundaries (i.e., the boundary between when an action is or is not possible) by means of intrinsic bodyscaled information (e.g., eye-height information) and organize or reorganize their behavioral activity accordingly (Carello et al., 1989). For instance, individuals are able to correctly perceive when an object is reach-able or not by extending their arm when seated, or by bending their torso and extending their arm, or by standing up and walking over to the object and organize their behavior accordingly.

It is important to appreciate, however, that in most task contexts the different ways in which an affordance can be actualized are not organizationally discrete, but overlap. For instance, an object that is reachable by extending the arm, is also often reachable by bending the torso and extending the arm. Similarly, an object that is graspable with one hand, is also likely graspable with two hands. Furthermore, a small, light ball could be gripped with the fingers or grasped with the whole hand, and then carried or thrown to its final destination. In this sense, afforded task goals often entail a nested structure of multiply realizable action possibilities.

In dynamical systems terms, a nested affordance structure corresponds to a multi-stable system, whereby two or more states or modes of behavioral order are simultaneously stable (and could be actualized). Regarding the perception and actualization of nested affordances, a sign of multistability is hysteresis (Kelso, 1995; Turvey, 1990). This occurs when an individual transitions between two different behavioral modes or states at different body-scaled ratios depending on its history of previous performance. For example, an individual will typically transition from onehand to two-hand grasping at a larger arm-span/object-size ratio (i.e., $\pi=.8$ ) as object size is increased, compared to when transitioning from two-hand to one-hand grasping (i.e., $\pi=.65$ ) as object size is decreased (e.g., Frank, Richardson, Lopresti-Goodman \& Turvey, 2009; van der Kamp, Savelsbergh \& Davis, 1998). Although hysteresis has been observed in numerous affordance studies, other dynamic patterns of behavior have also been observed. For instance, in many task contexts individuals exhibit a fixed or critical point transition between different affordances or modes of affordance actualization. That is, individuals exhibit a nonlinear phase transition between different affordances or behavioral modes at the same body-scaled ratio irrespective of whether it is scaled up or down (Richardson et al., 2007; van der Kamp, et al., 1998). Enhanced contrast or negative hysteresis has also been observed and is defined by individuals transitioning between different behavioral modes in a prospective or anticipatory manner (Richardson et al., 2007; LoprestiGoodman et al. 2013). While these transitions show distinct changes in the actualization of an affordance over time, they are still stable solutions in terms of the task goal, or metastable. For example, in order to successfully grasp planks as plank size is increased, a transition (that varies inter-individually) between one-handed and two-handed grasping is necessary to maintain the task goal. Of course, fixed state behavior has also been observed, whereby an individual will enact the same affordance even if other behavioral modes are more effective or stable. For example, in an object grasping task a pair of individuals may choose to pick up objects together, even when it is more efficient and stable to pick up smaller objects separately (Richardson et al., 2007).

Of particular relevance here, is that the varied manner in which individuals are known to actualize a given affordance or transition between different affordances implies that affordance actualization is not determined by body-scaled ratios alone, but rather is determined by a more complex set of behavioral and contextual constraints. For example, the amount of time an individual has to perform a given task, an individual's motivation, and an individual's perceived ability for achieving task success are known to play a determining role in how a particular affordance is actualized (e.g., Lopresti-Goodman, Richardson, Marsh, Carello, \& Baron, 2007; Wilson, Weightman, Bingham, \& Zhu, 2016).

In an attempt to better understand how differing task constraints influence affordance actualization, Fajen (2007)
has proposed a distinction between hard versus soft constraints. Briefly stated, hard constraints are constraints that define a clear line between task success and failure. For example, when driving there is a minimum distance in which a driver would need to start braking in order to avoid colliding into a car stopped in front of them. The boundary between stopping and colliding thus corresponds to a hard task constraint, and if crossed will result in rather dramatic and potentially deadly task failure. However, even in this situation, successfully stopping could entail breaking close to this hard constraint or well before it. Of course, what determines which successful type of breaking behavior a driver chooses to actualize will depend on many different factors, such as the time of day, mood, or the degree to which a given driver prefers a large or small margin of safety. It is these kinds of latter constraints that correspond to soft constraints (Fajen, 2007; also see Harrison, Turvey \& Frank, 2016).

## Current study

The aim of the current study was to examine and model the effects of hard and soft constraints on affordance actualization, for a ball-to-bin transportation task. Of particular interest was the role that temporal constraints play on shaping the behavioral dynamics of an under- or softlyconstrained affordance actualization task. To achieve this, individuals were instructed to transport balls from a starting location to a target bin located 9 meters away. The interval between sequentially presented balls was manipulated by increasing or decreasing number of seconds between 2 and 14 (or vice versa) in 1 second steps every fourth ball. Importantly, individuals could complete the ball-to-bin transportation task in any way they wished; by walking/running and dropping the balls into the target bin or by throwing the balls into the bin from whatever distance they liked. Of interest was the distance that individuals chose to move prior to releasing the ball and the degree to which time-interval, as a control parameter, operated as a constraint on the observed behavioral dynamics.

Given the under-constrained nature of the task and the fact that it was impossible for individuals to achieve complete task success, the expectation was to observe a variety of behavioral dynamics. More specifically, using distance moved prior to attempting to throw the ball into the bin as the dependent variable, the expectation was that participants would exhibit one of four general classes of behavior as time-interval was increased or decreased across a continuous sequence of 52 balls: (I) fixed large distance moved (essentially always walking or running nearly the complete distance to the target bin); (II) fixed small distance moved (essentially always throwing from the ball pickup location); (II) gradual transition from large to small distance moved (or vice versa); and (IV) a non-linear transition between large and small distance moved.

It was also expected that the variation in the behavioral dynamics observed could be modeled using a two parameter, bifurcation or catastrophe model (namely, the
cusp catastrophe, in which the first parameter was represented by time interval and the second represented the collective approximation of the unknown soft constraints that influenced a given individual's behavioral dynamics. Before explicating this modeling endeavor however, the method and data analysis employed for the experimental study is detailed.

## Method

## Participants

Sixty-nine undergraduates from the University of Cincinnati participated in the experiment for partial course credit.

## Materials

At the starting area, seven-inch plastic playpen balls were put through an angled PVC pipe (marked '4' in Figure 1) that protruded into the pick-up area located on a wooden table (marked ' 3 ', dimensions: 40 cm wide, and 26.5 cm deep). The mouth of the PVC pipe extended back through an opaque curtain (marked ' 2 ') and a large wooden bin (marked ' 1 ', dimensions: 110 cm wide, 55 cm deep, and 120 cm high) was positioned at nine meters from the back edge of the ball pickup area. A computer program was used to visually signal an experimenter ('E') positioned behind the pickup location curtain (2) when to release the balls (one by one). A video-camera was used to record participants' (' P ') movements and actions throughout the experiment.

Figure 1: General experimental setup.

## Task and Procedure

Participants were told that the task involved transporting plastic playpen balls from a pickup area to a wooden bin located on the other side of the laboratory room. They were instructed they could only use one ball at a time and that the task was to get the balls into the bin, while at the same time not letting multiple balls stack up at the pickup location. They were told that the time between ball presentations would change from fast to slow or slow to fast (depending on sequence condition). They were also told that if they drop a ball accidentally then it could be picked up, however, if there was an attempt to get the ball into the bin but they missed, then they should ignore it and move on to the next one. Finally, they were instructed to solve the task in any way they liked as long as they followed the rules. (There were no consequences if rules were broken, and no incentive was given for performance).

Participants completed two trial series, with each series including the sequential presentation of fifty-two balls. Thirty-five participants started their first series at an increasing rate: beginning with a 14 second interval of ball presentation, this interval was decreased by 1 second after four balls down to 2 seconds (i.e., four balls were presented sequentially at each time interval). A small break was provided and then the second series began with the control parameter scaled in the reverse direction (i.e., from 2 to 14 seconds). The other thirty-four participants completed these same two trial sequences in the reverse order (i.e., 2 to 14 second sequence, followed by the 14 to 2 second sequence).

## Data Analysis and Behavioral Classification

The distance that participants moved prior to releasing (throwing or dropping) the ball was determined from the video recordings, along with task success (i.e., whether participants successfully got the ball into the bin or not). Although not reported here, the number of balls left within the pickup area at the time that the participant was attempting to get their current ball in was also recorded.

The movement distances were analyzed using Matlab 2016a (MathWorks, MA), with the behavior exhibited by participants in each temporal series (i.e., 2 to 14 second and 14 to 2 second series) graphically classified into one of four different types of dynamics (see below for more details). Prior to classification, the movement distances were averaged over each change in time interval, i.e. the average distance moved prior to releasing the ball was calculated over the four balls that had a fourteen second interval, then the average distance moved prior to releasing the ball was calculated over the four balls within thirteen second intervals, etc. This resulted in thirteen averaged movement distances for each 52-ball sequence. From these behavioral time-series, two descriptive statistics, namely mean distance moved ( $D_{m}$ ) and largest change in distance moved across a change in time interval ( $\Delta D$; i.e. the maximum of the differentiated 13-point behavioral time-series) were used to classify each behavioral time series as follows:

- Stable (fixed) small distance ( $\boldsymbol{s t} \boldsymbol{D}_{\text {small }}$ ) moved, whereby participants essentially always throw the ball from the pickup location or near the pickup location. More specifically, $D_{m}<4.8$ meters and $\Delta D<1.58$ meters.
- Stable (fixed) large distance ( $s t \boldsymbol{D}_{\text {large }}$ ) moved, whereby participants essentially always moved across nearly the complete distance to the target bin prior to releasing the ball. More specifically, $D_{m}>4.8$ meters and $\Delta D<1.58$ meters.
- Gradual change (phase transition) in distance ( $\boldsymbol{p t} \boldsymbol{D}_{\text {gradual }}$ ) moved, whereby participants gradually increased or decreased the distance as time interval decreased or increased, respectively (i.e., an inverse relationship between distance moved and time interval). More specifically, $1.58<\Delta D<3.8$ meters.
- Nonlinear change (phase transition) in distance ( $\boldsymbol{p} \boldsymbol{t} \boldsymbol{D}_{\text {nonlinear }}$ ) moved whereby participants exhibited a large
or nonlinear change in distance moved across a small change in interval. More specifically, $\Delta D>3.8$ meters.

Example time-series of each behavioral type are provided in Figure 2 for both increasing and decreasing interval sequences.

Figure 2: Two examples each of participant (full line, square markers) and simulated (dotted line, triangle markers) trajectories: $s t D_{\text {small }}$ trajectories (top), $s t D_{\text {large }}$ (second), $\boldsymbol{p t} \boldsymbol{D}_{\text {gradual }}$ (third) and $\boldsymbol{p t} \boldsymbol{D}_{\text {nonlinear }}$ (bottom).

## Modeling and Simulation

The possible emergence of the above four types of behavioral dynamics was modeled using a two-parameter task manifold defined by the Cusp Catastrophe (Thom, 1975) equation

$$
\begin{equation*}
\dot{x}=a+b x-x^{3} \tag{1}
\end{equation*}
$$

where $x$ represented that state or dependent variable, i.e., the distance (rescaled) moved prior to releasing or throwing the ball, the parameter $a$ represented (normalized) time interval from $(-2.5=2$ seconds to $+2.5=14$ seconds), and the parameter $b$ represented the collective state of (unknown) soft constraints that might be influencing a participant's behavior at any point during the task (i.e., motivation, intention, perceived ability, learned helplessness, etc.). The manifold in Figure 3 represents the fixed points of $x$, for different parameter settings of $a$ and $b$. That is, each point on the manifold can be understood as representing the distance moved prior to releasing the ball for each $(a, b)$
setting, where $x$ is rescaled (normalized) as a function of $b$ (e.g., from $-2=0$ meters moved to $+2=9$ meters walked when $b=2.8$ and from $-1=0$ meters moved to $+1=9$ meters walked when $b=-1.8$ ).

As can be seen in Figure 3, this manifold includes both mono-stable and bi-stable (multi-stable) regions and predicts the same four patterns of behavioral dynamics defined above depending on the values of $a$ and $b$. More specifically, as $a$ is scaled up or down, larger values of $b$ can result in behavioral trajectories qualitatively consistent with $\boldsymbol{s t} \boldsymbol{D}_{\text {large }}$ and $\boldsymbol{s} \boldsymbol{t} \boldsymbol{D}_{\text {small, }}$, depending on the initial condition of $x$. For $-.5<b<3$, however, the manifold predicts varying degrees of $\boldsymbol{p t} \boldsymbol{D}_{\text {nonlinear }}$ type behavior as $a$ (time interval) is scaled up or down. Finally, when $b<-.5$ the manifold predicts $\boldsymbol{p} t \boldsymbol{D}_{\text {gradual }}$ as $a$ (time interval) is scaled up or down.

It is worth noting at this point that Eq. (1) or the Cusp Catastrophe model has been employed to abstractly capture a wide range of natural bifurcation phenomena, including human anxiety and performance, organizational order, decision-making and dating behavior (e.g., Guastello, 1995; Hardy, 1996; Hardy \& Fazey, 1987; Richardson, Dale \& Marsh, 2014; Tesser, 1980). Typically, the $b$ parameter is fixed and the different behaviors that Eq. (1) can produce are explored by scaling $a$. In fact, this is how the exemplar trajectories plotted on the manifold in Figure 3 were generated (i.e., by fixing the value of $b$ and then scaling $a$ for a given initial condition $x_{0}$ ). In the current task context, this would be equivalent to assuming that although the soft constraints that influence a participant's behavior might change across trial sequences, they remain fixed over a ball sequence. However, there is no reason to assume that this is the case for the current task, rather it seems more likely that the various soft constraints that influence participant behavior change both during and across sequences. For instance, an individual's motivation or goal intention may have been continuously modulated during the task. Thus, at each interval change (or individual ball), the resulting distance moved may reflect a continuous (or discrete) change in both $a$ and $b$.

With the latter point in mind, a range of behavioral trajectories were simulated along the cusp catastrophe manifold by scaling $a$ in interval steps consistent with the time interval steps employed in the experimental study (i.e., from 2.5 to -2.5 in 13 steps), as well as scaling $b$ recursively by adding a number from a unimodal random distribution, with a mean of -.6 (when increasing interval, +. 6 when decreasing) and a standard deviation of 1.65 . The mean of $\pm .6$ was employed as the experimental data revealed that participants had a preference for higher movement (see results section for details). Two sets of 70 trajectories were simulated, with the initial condition $x_{0}$ set at +2 for simulation set one and a normal distribution with $50 \%$ chance of being above 0 for simulation set two (again inspired by participant behavior). The simulated data that resulted was rescaled to the distances of the real (human) experimental data ( $\sim .75$ meters to $\sim 8.75$ meters).

Figure 3: Cusp Catastrophe Model manifold. Blue points represent an exemplar $\boldsymbol{p t} \boldsymbol{D}_{\text {gradual }}$ behavioral trajectory. Red points represent two exemplar $\boldsymbol{p t} \boldsymbol{D}_{\text {nonlinear }}$ behavioral trajectories. The black and green points represent exemplar $\boldsymbol{s t} \boldsymbol{D}_{\text {large }}$ and $\boldsymbol{s t} \boldsymbol{D}_{\text {small }}$ behavioral trajectories, respectively.

## Results

As can be seen from an inspection of Figures 2 and 4, and Table 1, participants produced all four of the behavioral dynamics expected. The variability within and across participants and ball sequences is most easily discerned from an inspection of Figure 4, in which the behavioral dynamics classification is plotted as a function of mean distance moved ( $D_{m}$ ) and maximum change in distance moved across a change in time-interval ( $(\Delta D)$.

Table 1: Distribution of trajectories per type of data.

| Trajectory | Simulated | Actual |
| :--- | :---: | ---: |
| $\boldsymbol{s t} \boldsymbol{D _ { \text { small } }}$ | $8.57 \%$ | $9.42 \%$ |
| $\boldsymbol{s} \boldsymbol{t} \boldsymbol{D}_{\text {large }}$ | $33.57 \%$ | $35.51 \%$ |
| $\boldsymbol{p} \boldsymbol{D _ { \text { gradual } }}$ | $22.14 \%$ | $23.91 \%$ |
| $\boldsymbol{p t D _ { \text { nonlinear } }}$ | $35.71 \%$ | $31.16 \%$ |

The simulated trajectories also produced a comparable set of behavioral trajectories and classifications. Again, this can be seen from an inspection of Figures 2 and 4 and Table 1. The classification system was verified using a K-means Nearest Neighbor (KNN) classifier (in Matlab, with ten number of neighbors, Euclidian distance and squared inverse distance weights) finding $99.28 \%$ correspondence between initial classification and KNN classification of real data.

A curve estimation analysis was conducted on the total frequencies of each distance across all data-points, revealing a linear increase in frequency as distance increased ( $\beta=.85$, $t(34)=9.43, p<.01$, where $x=$ distance moved). A twotailed, bivariate correlation analysis was run to investigate the relationship between distance moved and success (hit) versus failure (miss), revealing a positive association ( $r=$ $.64, p<.01$ ) in that, as distance moved increased so did the probability of success.

Figure 4: Participant (top) and simulated data (bottom) behavioral classification as a function of mean distance moved $\left(D_{m}\right)$ and maximum change in distance $(\Delta D)$.

## Discussion

The current study was designed to explore the effects of hard and soft constraints on the manner in which a task goal was actualized. As expected, a variable range of behavioral dynamics was observed, reflecting the under-constrained nature of the task goal. Furthermore, simulations using a two-parameter Cusp Catastrophe manifold illustrated how the wide range of participant behaviors observed naturally emerged due to an under- or softly-constrained task context. That is, by the continuous modulation of soft constraints during ongoing task performance.

The significance of the current findings with regard to understanding human, affordance-based behavior is twofold. First, the current results highlight how both steady state linear and nonlinear behavioral patterns, as well as metastable and transient behavioral patterns, can all result from the same task dynamic, further emphasizing how complex and context sensitive determinism underlies the emergent (re)organization of ongoing human behavior.

Second, the current results illustrate the need for appropriately identifying what and how soft constraints modulate the actualization of nested affordances or multistable behavioral modes. While there was no attempt to specifically identify what soft constraints guided task performance in the current study, the experimental and modeling methodology developed here could be employed
to identify these constraints in future research. Different hard constraints could be imposed or manipulated, or the saliency of soft constraints within the task context could be explicitly defined. For example, one could introduce the hard (goal) constraint that a participant would fail completely (and need to redo the task) if there is ever more than one ball in the pickup area. This would likely see the elimination of $s t \boldsymbol{D}_{\text {large }}$ behavior. Furthermore, if the salience of a soft constraint were also increased, say by adding motivation in terms of a points or monetary reward system that empathized getting balls in the bin, then one would also predict the (near) elimination of $\boldsymbol{s t} \boldsymbol{D}_{\text {small }}$, with participants predominately producing $\boldsymbol{p t} \boldsymbol{D}_{\text {gradual }}$ or $\boldsymbol{p t} \boldsymbol{D}_{\text {nonlinear }}$ behavior.

It is also possible that task success or failure on each ball throw could have modulated the collective motivational state of participants. The general relationship between longer distance and higher success rate speaks to this point, although it does not apply as motivation to all participants equally. (If this were applicable on an individual basis, there would likely be no $\boldsymbol{s t} \boldsymbol{D}_{\text {small }}$ trajectories.) However, a confounding variable here is the general preference across the entire dataset for longer distances. The interaction of this preference with the individually different effect of timeinterval on distance moved, needs to be examined further in future research.

# Broadening the Scope of Recognition Memory 

Justin M. Olds (justin.olds@unil.ch) \& Julian N. Marewski (julian.marewski@unil.ch)<br>Department of Organizational Behavior, University of Lausanne<br>1015 Lausanne, Switzerland

#### Abstract

Within the literature of psychological and decision sciences, there is a critical difference in the way recognition is defined and studied experimentally. To address this difference, the current experiment examines and attempts to disentangle the influence of two recognition judgment sources (from within an experiment and from an individual's prior life experiences) upon two different recognition judgments. By presenting participants with a set of related stimuli that vary naturally in environmental occurrence and by manipulating exposure within an experimental context, this experiment allows for a broader and more ecologically valid assessment of recognition memory. Contrasting with the typical wordfrequency effect, the results reveal an overall bias to judge high-frequency items as studied on an episodic recognition test. Additionally, the results underscore the role of context by showing that a single study exposure increases the probability that individuals will judge stimuli as presented outside the laboratory.

Keywords: Recognition memory; decision-making; ecological validity

## Recognizing the Difference between Recognition and Recognition

In general, recognition refers to the experience wherein upon encountering a stimulus an individual has a sense that she has encountered that stimulus before. A recognition judgement, in turn, is when an individual explicitly claims that a stimulus was previously encountered. Within the literatures of psychological and decision sciences, there is a critical difference in the way recognition is studied experimentally. While one set of research focuses on an individual's capacity to recognize stimuli presented previously within an experimental episode (episodic recognition memory), the other set focuses on an individual's capacity to recognize stimuli as previously encountered during the individual's prior life experiences before beginning an experiment (pre-experimental recognition memory). Although these types of recognition are typically studied independently, the sources of experience related to both are inherently interconnected. Indeed, the experience of recognition is influenced by an individual's prior life experiences as well as by the experiences she has during an experiment. The current work provides a framework for studying recognition memory in a way that more readily relates to these two intertwined factors.

In what follows, we first broadly describe the lines of research related to both types of recognition judgements,
including prior work that has examined their interconnected nature. Within this review, we note criticisms of each line of research. Following this, we (1) describe a research methodology that draws upon both lines of work to address these concerns, (2) present the results of an experiment adopting this approach, and (3) discuss implications of these results and considerations for future work.

## Episodic Recognition in Memory Research

Recognition memory has been studied extensively with listlearning experiments. Here, stimuli, such as words or pictures, are presented individually in the form of a study list. After a delay ranging from a few seconds to multiple days, participants are presented with a recognition memory test list, and are asked to discriminate targets (stimuli from the study list) from foils (new items). Episodic recognition memory has been the focus of decades of extensive research and has been noted as an increasingly prevalent research paradigm (e.g., Hintzman, 2011).
A major strength of the episodic recognition memory line of research is experimental control. This is, in part, achieved by minimizing the role of individual stimuli, such as by presenting mixed lists of unrelated and uncommon concrete nouns. This approach follows in the footsteps of pioneering memory researcher Ebbinghaus (1885), who used nonsense stimuli to avoid the influence of everyday exposure.
The advantage of striving for experimental control in this way is also a disadvantage when it comes to understanding how memory judgments operate within everyday decisionmaking. For example, Neisser (1976) argued that memory research should strive toward ecological validity. Drawing upon work in perception by Brunswik (1957) and Gibson (1979), ecological validity refers to applicability outside the laboratory. The importance of ecological validity is underscored by research on eyewitness testimony. For instance, when participants study mixed lists of unrelated words, a positive relationship between accuracy and confidence is typically found (e.g., Dallenbach, 1913; Dunlosky \& Metcalfe, 2009). This intuitive finding dovetails with the 1972 and 1976 U.S. Supreme Court rulings suggesting that highly confident eyewitness identification is likely accurate. This pattern, however, does not hold for lists of similar material (i.e., categorized lists, see e.g., DeSoto \& Roediger, 2014), such as description details of suspects presented to an eyewitness (e.g., Smith, Kassin, \& Ellsworth, 1989). It is disconcerting to consider how other memory research findings might also be misleading due to a similar lack of ecological validity.

Departing from the convention of presenting participants with mixed lists of uncommon, unrelated stimuli would inherently introduce an additional factor, which might interact with or overshadow other experimental manipulations. Specifically, a by-product of presenting participants with a more ecologically valid set of related stimuli is that the individual items will vary based on how often each occurs outside the laboratory. The influence of environmental frequency upon episodic recognition judgements has been the focus of extensive research (e.g., Dennis \& Humphreys, 2001; Estes, 1994; Glanzer \& Adams, 1985; Lohnas \& Kahana, 2013; McClelland \& Chappell, 1998; Shiffrin \& Steyvers, 1997). In these experiments, study and test lists are composed of unrelated words that are sampled randomly from a range of low linguistic frequency words and high linguistic frequency words. The typical word-frequency finding on an episodic recognition memory test is that low-frequency target words are more accurately judged to be "old" than high-frequency target words and low-frequency foil words are more accurately judged to be "new" than high-frequency foils. Although this line of research does begin to reintroduce the influence of pre-experimental exposure into a laboratory setting, these experiments still tend to favor experimental control over ecological validity in numerous ways. First, the study lists in these experiments are typically composed of stimuli that are sampled from opposite poles along a continuum of environmental frequency-either extremely low-frequency or extremely high-frequency (but see Lohnas \& Kahana, 2013, for an exception), essentially transforming the naturally continuous variable of environmental frequency into a dichotomized factor. Second, the study and test lists used in these experiments are often composed of unrelated words. That is, the stimuli belong to many disparate categories and, thus, do not related to one another regarding any real-world inferences, such as person details in relation to culpability.

It may be the case that, similar to experiments investigating the word-frequency effect (e.g., Glanzer \& Adams, 1985), a mnemonic advantage for low-frequency items emerges if participants are tested with a related set of stimuli sampled with varying degrees of environmental frequency. There is some evidence, however, suggesting that this pattern of superior recognition accuracy for lowfrequency items might not persist. Specifically, in an experiment by Jacoby, Woloshyn, and Kelley (1989), which investigated the influence of environmental frequency by composing study and test lists of famous and nonfamous names, the results of an episodic recognition test revealed that famous names (i.e., high-frequency items) were more likely to be judged as presented on the study list than nonfamous ones (i.e., low-frequency items), regardless of whether or not they were actually studied. Thus, it may turn out that the low-frequency item advantage, borne out of memory research favoring experimental control over ecological validity, may not hold when participants are tested with sets of related stimuli.

## Pre-Experimental Recognition in Decision-Making Research

Numerous researchers have investigated how individuals use pre-experimental recognition, a sense of prior exposure to a stimulus outside the laboratory, during decision-making (e.g., Dougherty, Gettys, \& Ogden, 1999; Erdfelder, Küpper-Tetzel, \& Mattern, 2011; Goldstein \& Gigerenzer, 2002; Hertwig, Herzog, Schooler, \& Reimer, 2008; Marewski \& Schooler, 2011). A sense of pre-experimental recognition has been shown to influence a wide array of judgments, including about population size (e.g., Marewski \& Schooler, 2011), fame (Jacoby, Woloshyn, \& Kelley, 1989), and company revenue (Hertwig, et al., 2008), to name but a few. This work has shown that the frequency of occurrence for a given stimulus in the environment (which can be estimated by counting how often a stimulus, say a city name, occurs on the Internet or in the print media), allows for modeling how likely and how quickly the stimulus is to be recognized (e.g., Hertwig et al., 2008). Overall, this body of research underscores the intuitive notion that a sense of recognition is paramount for making many everyday decisions.

The influence of pre-experimental recognition upon decision-making is typically studied within probabilistic inference experiments, in which individuals are assumed to use known attributes of a stimulus as cues to make inferences about an unknown or future criterion. These experiments typically include a recognition task and a paired-comparison inference task. In the recognition task, participants are shown a list of related stimuli, such as city names, and asked to judge if they recognize each item from their prior life experience. Additionally, some experiments ask individuals to report if they have additional knowledge beyond a sense of pre-experimental recognition for each object. Reponses from this task and their respective response times are later used, to predict judgments on the paired-comparison inference task. In the paired-comparison inference task, individuals are shown two items at a time from a related set of stimuli and asked to infer which alternative is higher or lower on some judgement criterion, such as which of two cities has a larger population size.

In part because of its rigid simplicity, one decision strategy in particular, the recognition heuristic (Goldstein \& Gigerenzer, 2002), has been the focus of much research and debate. This strategy assumes that, stemming from an existing relationship in the world between environmental occurrence and a given criterion (e.g., population size), a sense of pre-experimental recognition can readily guide decisions in a straightforward way. Specifically, the recognition heuristic assumes that on a paired-comparison inference task, if one decision alternative is recognized and the other is not, individuals will judge the recognized alternative to have a higher value on the criterion.

In general, this line of research is aptly commended for showcasing and exploring how memory is employed for everyday decisions. One major criticism of this research, however, is that the assumptions about recognition memory
fail to appropriately draw upon theory from the abundance of related recognition memory research (e.g., Dougherty, Franco-Watkins, \& Thomas, 2008; Newell \& Fernandez, 2006). It appears that much of the work on recognitionbased decision-making assumes that pre-experimental recognition is a fixed commodity, whereas research concerning episodic recognition memory has revealed many ways in which a sense of recognition is influenced by contextual conditions. For example, Jacoby et al. (1989) found that presenting nonfamous names within an experiment study phase increased the likelihood that these nonfamous names would be incorrectly judged as famous later (see also Hertwig et al., 2008). Related to this, Pohl and colleagues (Pohl, Erdfelder, Michalkiewicz, Castela, \& Hilbig, 2016), point out two typical experimental procedure choices that fail to consider how a sense of pre-experimental recognition might be influenced by experimental conditions. Both entail how participants, during an earlier part of the experiments, are often exposed to the stimuli that they are later asked to consider during a paired-comparison inference task. First, to obtain a large number of paired-comparison inference trials, items are often paired repeatedly with different items, such that each item appears numerous times during the task. Additionally, the order of the two tasks is often counterbalanced across participants, such that some participants have the recognition task first and others have the paired-comparison inference task first. These two typical methodology choices may influence the sense of preexperimental recognition and respective recognition speed that individuals might use during decision-making. Although Pohl and colleagues (2016) focused on recognition speed specifically in relation to these methodology concerns, context conditions such as exposure within an experiment might also influence the probability that participants will judge stimuli as recognized from outside the laboratory. This is one of the concerns the current approach addresses.

## Experiment

The purpose of the current experiment is to investigate the influence of two fundamental sources of experience, one stemming a person's prior life experiences before entering the laboratory and another stemming from the experiences within an experimental context, upon recognition judgements. Specifically, the memory source related to the experimental context here is a single study exposure and the memory source related to prior life experiences is preexperimental exposure (estimated with web frequencies). The influence of both sources is examined for both episodic recognition (e.g., "Was this city name presented earlier during the experiment?") and pre-experimental recognition (e.g., "Have you ever heard of this city name before beginning the experiment?"). In line with ecological validity, instead of informing participants that stimuli presented during the study phase would be presented during a later memory test, incidental study exposure was adapted from Hertwig et al. (2008).

In relation to previous work, the current experiment also addresses the following two questions. First, does the typical low-frequency item advantage for episodic recognition memory (e.g., Glanzer \& Adams, 1985) occur when individuals are tested with a more ecologically valid set of stimuli (i.e., stimuli from a related set that vary based on their natural occurrence outside the laboratory)? Second, to what extend does a single incidental study exposure influence judgements of pre-experimental recognition, and, if so, does this influence depend on the environmental frequency of stimuli?

## Method

Participants A total of 63 individuals (mean age $=21.5$ years, $56 \%$ female) recruited from the University of Lausanne were paid roughly 26 Swiss francs each (depending on performance) for participating in the experiment. They were tested individually.
Design The study was conducted as a within-subjects design with one independent variable, study status, one pseudoindependent variable, environmental frequency, and two dependent variables (measured using within-subjects blocks), episodic recognition judgements and preexperimental recognition judgements. Study status was manipulated within-subjects by presenting half of the to-betested stimuli within a preceding study phase. Preexperimental frequency was estimated for each stimulus using Wikipedia page occurrences as a proxy for environmental occurrence.
Stimuli The stimuli presented during the experiment were from a set of 200 city names from North American and Western European countries (Canada, England, France, Germany, Italy, Spain, and USA). Additionally, eight extra city names were used at the beginning and end of the study task to minimize primacy and recency study effects. The city names used in the experiment were sampled such that the entire set would include cities from each country that varied in both population size (population statistics obtained from www.citypopulation.de) and environmental occurrence (as approximated by Wikipedia page occurrences) and excluded capital cities. All stimuli were counterbalanced such that each occurred roughly equally often in all study and test conditions.
Procedure The experiment was conducted on a computer using E-Prime experimental software (Psychology Software Tools). Participants were informed that there would be three separate tasks and payment would depend of their performance in each task. First, all participants had an incidental study task, in which half of the city names (100) were presented. Specifically, participants were shown each city name individually and asked to count the number of vowels in each city name. At the beginning of each trial a fixation cross (+) appeared on the screen for 2 s along with a reminder of the task. Participants were informed that the fixation cross would occur immediately before each city name was presented to help them prepare to respond. Afterwards, a city name replaced the fixation cross and
participants were prompted to press the appropriate number key on the keyboard corresponding to the number of vowels in the city name. Participants were given up to 4 s to make their response and a blank screen was presented for 2 s between trials.

The following test phase consisted of two separate tasks, an episodic recognition task ("Was this city name presented during the vowel counting task") and a pre-experimental recognition task ("Have you ever heard of this city name before beginning the experiment?"). Participants were asked to respond with one of two keyboard keys to respond "yes" or "no" for each test trial. Participants were given as long as needed to make their response in both tasks. Each task block consisted of 100 trials, which included half studied and half unstudied city names. Importantly, city names were not repeated across test tasks, but were counterbalanced between-subjects such that each city name would occur roughly equally often in each test phase. The order of test tasks was counterbalanced between-subjects. Similar to the study phase, each trial began with a 2 s fixation cross and was followed by a 2 s intertrial interval during both recognition tasks.

## Results

The data from all 63 participants was analyzed, excluding trials for one city name due to a clerical error. Wikipedia page occurrence values were log transformed to approximate a linear relationship across city names (e.g., Marewski \& Schooler, 2011). Given the two binary dependent variables, separate logistic regressions were planned for both episodic recognition and pre-experimental recognition judgments.

Episodic Recognition Results from the episodic recognition task are presented in Figure 1. From visual inspection of Figure 1, two patterns are apparent. First, the probability that participants judged city names as presented during the study phase was higher for studied city names than for unstudied city names. Second, the probability of judging city names as studied increased as a function of environmental frequency. Moreover, the difference in recognition probabilities between studied and unstudied city names did not seem to vary as a function of environmental frequency. To test the influence of both factors (study status and environmental frequency), a multilevel logistic regression analysis was conducted to fit the episodic recognition data. A test of the model against a constant only model indicated that the predictors as a set provided an improved fit $\chi^{2}=980, d f=2, p<.001$, Nagelkerke's $R^{2}=$ .20). The Wald criterion demonstrated both factors, study status ( $z=5.38$ ) and environmental frequency $(z=6.82)$, contributed to the model fit $(p<.001$ for both). Additionally, by comparing the model to another which included an additional interaction term of the two factors, evidence of an interaction between study status and environmental frequency was not found ( $\chi^{2}=.27, d f=1, p=$ .61). To control for the variance associated with the random factor of repeated measurements from individual
participants, follow-up generalized linear mixed models were conducted. The same pattern emerged: both factors of study status $(z=5.22, p<.001)$ and environmental frequency ( $z=6.77, p<.001$ ) contributed to the model fit, and there was no evidence of an interaction between the two found ( $\chi^{2}=.78, d f=1, p=.38$ ).

Figure 1: Mean episodic recognition rates. The left side depicts the mean influence of study exposure for all city names with standard error bars. The right side depicts the influence of both study exposure and environmental frequency for each city name with a moving average for both studied and unstudied city names across environmental frequency.
Comparison to previous results The results from the episodic recognition task contrast with the typical wordfrequency effect (e.g., Glanzer \& Adams, 1985), which reveal an interaction between study and environmental frequency, such that low-frequency targets are recognized more accurately (i.e., higher hit rate and lower false alarm rate) than high-frequency targets and low-frequency lures are correctly rejected more accurately than high-frequency lures (e.g., Lohnas \& Kahana, 2013). Instead, the current results show that when participants are tested with a set of related stimuli, high-frequency items are more likely to be judged as studied regardless of if they were studied or unstudied (i.e., higher hit and false alarm rates for highfrequency items). Why did this pattern of results differ from the typical word-frequency effect? Although further work is required to better address this question, we can provide some speculation. The potentially stronger association with the experiment context for low-frequency items, perhaps due to item distinctiveness, may have been relatively diluted in the current experiment for a number of reasons. First, one important difference to remark upon is the overall low episodic recognition accuracy from the current experiment compared to previous word-frequency experiments (e.g., Lohnas \& Kahana, 2013). We suspect this difference can be attributed to the difficulty inherent in testing sets of related stimuli and stemming from incidental study (e.g., Criss \& Shiffrin, 2004). This increased task difficulty may have led participants be more influenced by the pre-existing associations for high-frequency items, since these
associations are less contingent upon the study conditions than the associations between the context and studied items.

Pre-Experimental Recognition Results from the preexperimental recognition task are presented in Figure 2. From visual inspection of Figure 2, two patterns are apparent. First, the probability of judging city names as recognized from outside the laboratory increased as a function of environmental frequency. Second, the probability that participants judged city names as recognized from outside the laboratory was slightly higher for studied city names than for unstudied city names. Additionally, it appears that the influence of a study exposure was relatively consistent across varying degrees of environmental frequency. To test the influence of both factors (study status and environmental frequency), a multilevel logistic regression analysis was conducted to fit pre-experimental recognition judgements using study status and environmental frequency as predictors. A test of the model against a constant only model indicated that both predictors as a set provided an improved fit $\left(\chi^{2}=1739, d f=\right.$ 2, $p<.001$, Nagelkerke's $R^{2}=.323$ ). The Wald criterion demonstrated both factors, study status $(z=4)$ and environmental frequency $(z=32)$, contributed to the model fit ( $p<.001$ for both). Additionally, by comparing the model to another which included an additional interaction term for the two factors, evidence of an interaction between study status and environmental frequency was not found ( $\chi^{2}$ $=.621, d f=1, p=.431)$. Evidence for the same pattern was suggested by a generalized linear mixed model with the categorical variable of participant included as a random factor.
Comparison to previous results Similar to previous work (e.g., Marewski \& Schooler, 2011), the current results support the use of web frequencies as a reasonable predictor of pre-experimental recognition. The results from the preexperimental recognition task also converge with previous work showing that an experimental exposure increases the probability of inferring an item to be higher on a criterion related to pre-experimental exposure, such as the fame of individuals (Jacoby et al., 1989) or population size of cities (Hertwig et al., 2008). Unlike previous work, however, the current experiment examines the relationship of a single incidental study exposure across items varying in environmental frequency continuously from extremely infrequent to extremely frequent. Importantly, the current work examines pre-experimental recognition instead of inference judgments, which are assumed to be influenced by a sense of pre-experimental recognition. By focusing on this more basic memory judgment, the current approach and respective data reveal that the presentation of stimuli within an experimental context influences a sense of preexperimental recognition that is core to much research on memory-based decision research (e.g., Goldstein \& Gigerenzer, 2002). One novel finding is that, because of the lack of an interaction between study and environmental frequency, it appears a single study exposure results in a
relatively constant increase in the probability of preexperimental recognition across all items, regardless of environmental frequency.

Figure 2: Mean pre-experimental recognition rates. The left side bar graph depicts the mean influence of study exposure for all city names with standard error bars. The right side depicts the influence of both study exposure and environmental frequency for each city name with a moving average for both studied and unstudied city names across environmental frequency.

## Discussion

The main purpose of the current work is to showcase a broad approach to studying recognition memory-one that considers how different types of recognition emerge as a function of the interconnected factors of (1) an individual's prior life experiences and (2) an individuals' recent and current experiences within an experimental context. This approach was designed to better translate results from memory experiments into real-world situations. This was achieved by testing recognition judgements for related stimuli, which, in turn, we assume more readily relate to everyday recognition judgments and memory-based inferences. For instance, one might be asked to identify or corroborate which colleagues were present at a company meeting or holiday party. This would entail gauging exposure within a context for a related set of stimuli (e.g., co-workers) that vary based on their environmental frequency (i.e., some are more well-known than others). This kind of everyday memory task contrasts sharply with the typical kind of recognition memory task used in psychology experiments, in which stimuli are unrelated and environmental occurrence is either constrained or dichotomized into highly disparate factor levels (extremely low and high-frequency bins).

The importance of adopting a broader and more ecologically valid approach to understanding recognition memory is underscored by the current experiment results. In contrast to the typical word frequency effect (increased episodic recognition accuracy for low-frequency items) found in many previous experiments, (e.g., Glanzer \& Adams, 1985; Lohnas \& Kahana, 2013), the current
experiment results showed an increased tendency to judge high-frequency items from a set of related stimuli as studied.

The current experiment results also provide evidence suggesting that context conditions, such as a single incidental study exposure, influence pre-experimental recognition judgements. This finding suggests that researchers examining memory-based inferences should strongly consider how often and in what manner stimuli are presented within an experiment. Related to this concern, although separate sets of stimuli were presented during both recognition test phases (episodic and pre-experimental) of the current experiment, we reanalyzed both sets of data with the inclusion of test task order as a factor to help rule out the influence of task demands upon the results. For both recognition tasks, the same main effects (study exposure and environmental frequency) and lack of interaction were supported. Importantly, these results did not interact with task order and a main effect of task order was not found.

There are numerous possible extensions of the current work. One is to incorporate the influence of context factors into models of memory-based decision-making. Additionally, the influence of list composition (e.g., Malmberg \& Murnane, 2002) upon both episodic and preexperimental recognition can be explored with sets of related stimuli, such as city names. Although the current experiment included related stimuli that varied widely on environmental frequency and the stimulus set was somewhat balanced, in that half of the city names were typically recognized, it remains largely unexplored to what degree a sense of recognition is influenced by the composition of study and test lists of related sets of stimuli. Similar to list composition effects, testing other stimulus materials, such as eyewitness-related description details, may help reveal the influence of varying environmental occurrence patterns.

# A Computational Logic Approach to Human Syllogistic Reasoning 

Ana Oliveira da Costa* and Emmanuelle-Anna Dietz Saldanha* and Steffen Hölldobler* and Marco Ragni**1<br>* International Center for Computational Logic, TU Dresden, Germany, ana.oli.costa@gmail.com, $\{$ dietz,sh $\} @ i c c l . t u-d r e s d e n . d e$<br>${ }^{* *}$ Cognitive Computation lab, University of Freiburg, Germany, ragni@cs.uni-freiburg.de

#### Abstract

A recent meta-analysis (Khemlani \& Johnson-Laird, 2012) about psychological experiments of syllogistic reasoning demonstrates that the conclusions drawn by human reasoners strongly deviate from conclusions of classical logic. Moreover, none of the current cognitive theories predictions fit reliably the empirical data. In this paper, we show how human syllogistic reasoning can be modeled under a new cognitive theory, the Weak Completion Semantics. Our analysis based on computational logics identifies seven principles necessary to draw the inferences. Hence, this work contributes to a computational foundation of cognitive reasoning processes.

Keywords: Human Reasoning; Syllogistic Reasoning; Logic Programming; Three-valued Łukasiewicz Logic; Abduction

## Introduction

The way of how humans ought to reason correctly about syllogisms has already been investigated by Aristotle (Smith, 1989). A syllogism consists of two premises and a conclusion. Each of them is a quantified statement using one of the four quantifiers all (A), no (E), some (I), and some are not $(\mathrm{O})^{2}$ about sets of entities which we denote in the following by $a, b$, and $c$. An example of a syllogism is:

Some $b$ are a
No bare $c$
In experiments, participants are normally expected to complete the syllogism by drawing a logical consequence from the first two premises, e.g. in this example 'some a are not $c^{\prime}$. The response of the participant - the conclusion - is evaluated as true if it can be derived in classical first-order logic (FOL), otherwise as false. The four quantifiers and their formalization in FOL are given in Table 1. The entities can appear in four different orders called figures as shown in Table 2. Hence, a problem can be completely specified by the quantifiers of the first and second premise and the figure. The example discussed above is denoted by IE4.

Altogether, there are 64 syllogisms and, if formalized in FOL, we can compute their logical consequence in classical logic. However, a meta-analysis by Khemlani and Johnson-Laird (2012) based on six experiments has shown that humans do not only systematically deviate from the predictions of FOL but from any other of 12 cognitive theories. In the case of IE4, besides the above mentioned logical consequence, a significant number of humans answered 'no valid conclusion', which does not follow from IE4 in FOL, as 'some a are not c' follows from IE4 as can be seen in the Venn diagram in Figure 1: $X$ has the property $a$ but not the property $c$.

[^156]Table 1: The four moods and their logical formalization.

| Mood | Natural language | First-order logic | Short |
| :--- | :--- | :--- | :---: |
| affirmative universal all $a$ are $b$ | $\forall X(a(X) \rightarrow b(X))$ | Aab |  |
| affirmative existential some $a$ are $b$ | $\exists X(a(X) \wedge b(X))$ | lab |  |
| negative universal | no $a$ are $b$ | $\forall X(a(X) \rightarrow \neg b(X))$ | Eab |
| negative existential | some $a$ are not $b \exists X(a(X) \wedge \neg b(X))$ | Oab |  |

Table 2: The four figures used in syllogistic reasoning.

|  | Figure 1 | Figure 2 | Figure 3 | Figure 4 |
| :---: | :---: | :---: | :---: | :---: |
| First Premise | a-b | b-a | a-b | b-a |
| Second Premise | $\mathrm{b}-\mathrm{c}$ | $\mathrm{c}-\mathrm{b}$ | $\mathrm{c}-\mathrm{b}$ | $\mathrm{b}-\mathrm{c}$ |

Figure 1: 'some a are not $c$ ' follows from IE4.

Recently, a new cognitive theory based on the Weak Completion Semantics (WCS) has been developed (Hölldobler, 2015). It has its roots in the ideas first expressed by Stenning and van Lambalgen (2008), which unfortunately had some technical mistakes. These were corrected by Hölldobler and Kencana Ramli (2009a), by using the three-valued Łukasiewicz (1920) logic. WCS has been successfully applied - among others - to the suppression task (Dietz, Hölldobler, \& Ragni, 2012), the selection task (Dietz, Hölldobler, \& Ragni, 2013), the belief-bias effect (Pereira, Dietz, \& Hölldobler, 2014a, 2014b; Dietz, 2017), to reasoning about conditionals (Dietz \& Hölldobler, 2015; Dietz, Hölldobler, \& Pereira, 2015) and to spatial reasoning (Dietz, Hölldobler, \& Höps, 2015). Hence, it was natural to ask whether WCS can also model syllogistic reasoning.

We introduce seven principles motivated by findings made in Cognitive Science and Computational Logic, and show how syllogisms together with these principles can be encoded in logic programs. After that we compare the predictions under WCS with the results of FOL, the syntactic rule based theory PSYCOP (Rips, 1994), the Verbal Model Theory (Polk \& Newell, 1995) and the Mental Model Theory (Johnson-Laird, 1983). ${ }^{3}$ The two model-based theories performed best in the meta-analysis (Khemlani \& Johnson-Laird, 2012).

The predictions of the theories FOL, PSYCOP, Verbal, and Mental Models for the syllogisms OA4, IE4, and IA2 and those of a significant percentage of the participants are depicted in Table 3, where the participants were 156

[^157]Table 3: Conclusions drawn by a significant percentage of participants are highlighted in gray and compared to the predictions of FOL, PSYCOP, Verbal, and Mental Models theory for OA4, IE4 and IA2. NVC denotes no valid conclusion.

| Participtants |  | FOL | PSYCOP | Verbal Models | Mental Models |
| :---: | :---: | :---: | :---: | :---: | :---: |
| OA4 | Oca | Oca | Oca, | Oca, | Oca, |
|  |  |  | Ica, lac | NVC | Oac, NVC |
| IE4 | Oac, | Oac | Oac, | NVC, | Oac, NVC |
|  | NVC |  | lac, Ica | Oac | Eac, Eca, Oca |
| IA2 | lac, Ica | NVC | NVC | NVC, Ica | lac, Ica, NVC |

high school or university students. A conclusion is drawn by a significant number of participants, if the number of participants chosing this particular conclusion is statistically too high for the conclusion to be chosen at random. The interested reader is referred to Khemlani and Johnson-Laird (2012) for more details.

FOL and the other three cognitive theories make different predictions. Each theory provides at least one prediction which is correct with respect to FOL and provides an additional prediction which is false with respect to FOL. Currently, the best results are achieved by the Verbal Models Theory which predicts $84 \%$ of the participants responses, closely followed by the Mental Model Theory with $83 \%$, whereas PSYCOP predicts $77 \%$ of the participants responses.

## Weak Completion Semantics

## Logic Programs

A (logic) program $P$ is a finite set of clauses of the form $A \leftarrow \top, A \leftarrow \perp$ or $A \leftarrow B_{1} \wedge \ldots \wedge B_{n}, n>0$, where $A$ is an atom, $B_{i}, 1 \leq i \leq n$, are literals, and $\top$ and $\perp$ denote truth and falsehood, respectively. Clauses are assumed to be universally closed. $A$ is called head and $\top, \perp$ as well as $B_{1} \wedge \ldots \wedge B_{n}$ are called body of the corresponding clause. Clauses of the form $A \leftarrow \top$ and $A \leftarrow \perp$ are called facts and assumptions, respectively. ${ }^{4} \neg A$ is assumed in $\mathcal{P}$ iff $\mathcal{P}$ contains an assumption with head $A$ and no other clause with head $A$ occurs in $\mathcal{P}$. We restrict terms to be constants and variables. We assume for each program $\mathcal{P}$ that the underlying alphabet consists precisely of the symbols occurring in $\mathcal{P}$ and that non-propositional programs contain at least one constant.
$\mathrm{g} \mathcal{P}$ denotes the set of all ground instances of clauses occurring in $\mathcal{P}$, where a ground instance of clause $C$ is obtained from $C$ by replacing each variable occurring in $C$ by a constant. A ground atom $A$ is defined in $g \mathcal{P}$ iff $g \mathcal{P}$ contains a clause whose head is $A$; otherwise $A$ is said to be undefined. $\operatorname{def}(A, \mathcal{P})=\{A \leftarrow \operatorname{Body} \mid A \leftarrow \operatorname{Body} \in \mathrm{~g} P\}$ is called definition of $A$ in $\mathcal{P}$. To clarify the definitions, consider $\mathcal{P}_{\text {ex }}$ :
$p(X) \leftarrow q(X) \wedge \neg r(X) \wedge s(X) . \quad q(a) \leftarrow \top . \quad r(a) \leftarrow \perp$.

[^158]Table 4: The truth tables for the connectives under three-valued Łukasiewicz logic. Note that for the unknown holds: $(\mathrm{U} \leftarrow \mathrm{U})=T$.

The second and the third clause is a fact and an assumption, respectively. $\mathrm{g} \mathcal{P}_{\text {ex }}$ is as follows:

$$
p(a) \leftarrow q(a) \wedge \neg r(a) \wedge s(a) . \quad q(a) \leftarrow \top . \quad r(a) \leftarrow \perp
$$

$p(a), q(a), r(a)$ are defined and $s(a)$ is undefined in $g \mathcal{P}_{\mathrm{ex}}$. Classical logic and logic programs are discussed in detail in e.g. (Hölldober, 2009; Lloyd, 1984).

## Three-Valued Lukasiewicz Logic

We consider the three-valued Łukasiewicz (1920) logic for which the corresponding truth values are true $(\top)$, false $(\perp)$ and unknown $(\mathrm{U})$. A three-valued interpretation $I$ is a mapping from the set of formulas to the set $\{\top, \perp, \mathrm{U}\}$. The truth value of a given formula under $I$ is determined according to the truth tables in Table 4. We represent an interpretation as a pair $I=\left\langle I^{\top}, I^{\perp}\right\rangle$ of disjoint sets of ground atoms, where $I^{\top}$ is the set of all atoms that are mapped to $\top$ by $I$, and $I^{\perp}$ is the set of all atoms that are mapped to $\perp$ by $I$. Atoms which do not occur in $I^{\top} \cup I^{\perp}$ are mapped to $U$. Let $I=\left\langle I^{\top}, I^{\perp}\right\rangle$ and $J=\left\langle J^{\top}, J^{\perp}\right\rangle$ be two interpretations: $I \subseteq J$ iff $I^{\top} \subseteq J^{\top}$ and $I^{\perp} \subseteq J^{\perp} . I(F)=\top$ means that formula $F$ is mapped to true under $I . \mathcal{M}$ is a model of $\mathcal{P}$ if it is an interpretation, which maps each clause occurring in $\mathrm{g} \mathcal{P}$ to $\top . I$ is the least model of $\mathcal{P}$ iff for any other model $J$ of $\mathcal{P}$ it holds that $I \subseteq J$.

## Least Models under the Weak Completion

For a given program $\mathcal{P}$, consider the following transformation: (1) For each ground atom $A$ which is defined in $g \mathcal{P}$, replace all clauses of the form $A \leftarrow \operatorname{Bod}_{1}, \ldots, A \leftarrow$ Body $_{m}$ occurring in $g \mathcal{P}$ by $A \leftarrow \operatorname{Bod}_{1} \vee \ldots \vee \operatorname{Body} y_{m}$. (2) Replace all occurrences of $\leftarrow$ by $\leftrightarrow$. The obtained set of formulas is called weak completion of $\mathcal{P}$ or $w c \mathcal{P} .{ }^{5}$

It has been shown by Hölldobler and Kencana Ramli (2009b) that programs as well as their weak completions admit a least model under three-valued Łukasiewicz logic. Moreover, the least model of $w c \mathcal{P}$ can be obtained as the least fixed point of the semantic operator $\Phi$, which is due to Stenning and van Lambalgen (2008). Let $I=\left\langle I^{\top}, I^{\perp}\right\rangle$ be an interpretation, then $\Phi_{\mathcal{P}}(I)=\left\langle J^{\top}, J^{\perp}\right\rangle$, is defined by:

$$
\begin{aligned}
J^{\top}= & \{A \mid A \leftarrow \operatorname{Bod} y \in \operatorname{def}(A, \mathcal{P}) \text { and } I(\operatorname{Bod} y)=\top\}, \\
J^{\perp}= & \{A \mid \operatorname{def}(A, \mathcal{P}) \neq \emptyset \text { and } \\
& I(\operatorname{Body})=\perp \text { for all } A \leftarrow \operatorname{Bod} y \in \operatorname{def}(A, \mathcal{P})\} .
\end{aligned}
$$

Weak Completion Semantics (WCS) is the approach to consider weakly completed programs, to compute their least

[^159]models, and to reason with respect to these models.
We write $\mathcal{P} \models_{w c s} F$ iff formula $F$ holds in the least model of $w c \mathcal{P}$. Consider again $\mathcal{P}_{\text {ex }}$. Starting with $\langle\emptyset, \emptyset\rangle$, we obtain:
$$
\Phi_{\mathcal{P}_{\mathrm{ex}}}(\langle\emptyset, \emptyset\rangle)=\langle\{q(a)\},\{r(a)\}\rangle=I_{1}=\Phi_{\mathcal{P}_{\mathrm{ex}}}\left(I_{1}\right) .
$$
$I_{1}$ is the least model of $w c \mathcal{P}_{\text {ex }}$.

## Integrity Constraints

An integrity constraint is an expression of the form $\mathrm{U} \leftarrow$ Body, where Body is a conjunction of literals and $U$ denotes the unknown. An interpretation $I$ maps an integrity constraint $\mathrm{U} \leftarrow$ Body to $\top$ iff $I(\operatorname{Body}) \subseteq\{\perp, \mathrm{U}\}$. Given an interpretation $I$ and a finite set IC of integrity constraints, $I$ satisfies IC iff all clauses occurring in IC are true under $I$.

## Abductive Logic Programming

In Logic Programming, abduction is the reasoning process of searching for explanations given a program and some observations, which do not follow from the program (Peirce, Hartshorne, \& Weiss, 1974). Explanations are usually restricted to certain formulas called abducibles. Let $\mathcal{P}$ be a ground program. The set of abducibles of $\mathcal{P}$ is
$\begin{aligned} \mathcal{A}_{\mathcal{P}} & =\{A \leftarrow \top \mid A \text { is undefined or } \neg A \text { is assumed in } \mathcal{P}\} \\ & \cup\{A \leftarrow \perp \mid A \text { is undefined in } \mathscr{P}\} .\end{aligned}$
An abductive framework consists of a program $\mathcal{P}$, a finite set $\mathcal{A}$ of abducibles, a finite set IC of integrity constraints, and an entailment relation. Let $\left\langle\mathcal{P}, \mathcal{A}\right.$, IC,$\left.\models_{w c s}\right\rangle$ be an abductive framework, $\mathcal{E} \subseteq \mathcal{A}$, and $O$ a non-empty set of literals called observation. An observation $O=\left\{o_{1}, \ldots, o_{n}\right\}$ is explained by $\mathcal{E}$ given $\mathcal{P}$ and $I C$ iff $\mathcal{P} \cup \mathcal{E} \models_{w c s} o_{1} \wedge \ldots \wedge o_{n}$ and $\mathcal{P} \cup \mathcal{E} \neq_{\text {wcs }}$ IC. $O$ is explained given $\mathcal{P}$ and $I C$ iff there exists an $\mathcal{E}$ such that $O$ is explained by $\mathcal{E}$ given $\mathscr{P}$ and IC. We prefer subset-minimal explanations. An explanation $\mathcal{E}$ is minimal iff there is no explanation $\mathcal{E}^{\prime}$ such that $\mathcal{E}^{\prime} \subset \mathcal{E}$.

Consider the program $\mathcal{P}=\{w \leftarrow g, w \leftarrow s, g \leftarrow r\} .{ }^{6}$ Suppose we observe $O=\{w\}$. Because the least model of wc $\mathcal{P}$ is $\langle\emptyset, \emptyset\rangle$ the observation does not follow. However, $O$ can be explained by $\mathcal{E}=\{s \leftarrow \top\}$. Starting with the empty interpretation we obtain:

$$
\begin{aligned}
& \Phi_{\mathcal{P} \cup \mathcal{E}}(\langle\emptyset, \emptyset\rangle)=\langle\{s\}, \emptyset\rangle \\
& \Phi_{\mathcal{P} \cup \mathcal{E}}(\langle\{s\}, \emptyset\rangle)=\langle\{s, w\}, \emptyset\rangle=\Phi_{\mathcal{P} \cup \mathcal{E}}(\langle\{s, w\}, \emptyset\rangle) . \\
& \langle\{s, w\}, \emptyset\rangle \text { is the least model of } w c(\mathcal{P} \cup \mathcal{E}) \text {. It entails } O \text {. } \mathcal{E} \text { is } \\
& \text { minimal, whereas } \mathcal{E}^{\prime}=\{s \leftarrow \top, r \leftarrow \top\} \text { is not. }
\end{aligned}
$$

## Seven Principles in Reasoning with Quantifiers

We will apply seven principles in developing a logical form for the representation of syllogisms.

## Licenses for Inferences (licenses)

Stenning and van Lambalgen (2008) propose to formalize conditionals by licenses for inferences. For example, the conditional for all $X$, if $p(X)$ then $q(X)$ is represented by the program $\{q(X) \leftarrow p(X) \wedge \neg a b(X), a b(X) \leftarrow \perp\}$. Its first

[^160]clause states that for all $X, q(X)$ holds if $p(X)$ and $\neg a b(X)$ holds, i.e. nothing abnormal for $X$ is known. This in turn is stated by the second clause. Clauses are assumed to be universally closed and, hence, the universal quantifier can be omitted.

## Existential Import and Gricean Implicature (import)

Humans seem to understand quantifiers differently due to a pragmatic understanding of language. For instance, in natural language we normally do not quantify over things that do not exist. Consequently, for all implies there exists. This appears to be in line with human reasoning and has been called the Gricean Implicature (Grice, 1975). Several theories like the theory of mental models (Johnson-Laird, 1983) or mental logic (Rips, 1994) assume that the sets we quantify over are not empty. Likewise, Stenning and van Lambalgen (2008) have shown that humans require existential import for a conditional to be true. Furthermore, as mentioned in Khemlani and Johnson-Laird (2012), the quantifier 'some a are b' often implies that 'some a are not $b$ ', which again can be explained by assuming the Gricean Implicature: Someone would not state 'some a are $b$ ' if that person knew that 'all a are $b$ '. As the person does not say 'all $a$ are $b$ ' but instead 'some a are $b$ ', we have to assume that 'not all a are $b$ ', which in turn implies 'some a are not $b$ '.

## Unknown Generalization (unknownGen)

Humans seem to distinguish between 'some $y$ are $z$ ' and 'all $y$ are $z$ ', as we have already explained in the previous paragraph. Accordingly, if we observe that an object $o$ belongs to $y$ and $z$ then we do not want to conclude both, 'some $y$ are $z$ ' and 'all $y$ are $z$ '. In order to prevent such unwanted conclusions we introduce the following principle: if we know that 'some $y$ are $z$ ' then there must not only be an object $o_{1}$ which belongs to $y$ and $z$ (by Gricean implicature) but there must be another object $o_{2}$ which belongs to $y$ and for which it is unknown whether it belongs to $z$.

## Converse Interpretation (converse)

Although there appears to be some evidence that humans seem to distinguish between 'some y are $z$ ' and 'some $z$ are $y$ ' (see the results reported in Khemlani \& Johnson-Laird, 2012) we propose that premises of the form lab imply lba and vice versa. If there is an object which belongs to $y$ and $z$, then there is also an object which belongs to z and y .

## Block Conclusions by Double Negation (doubleNeg)

Consider the following two negative sentences (i.e. including negation) and the positive one: ' If not $a$, then $b$. If not $b$ then $c . a$ is true.' The program representing these sentences is $\mathcal{P}=\{b \leftarrow \neg a, c \leftarrow \neg b, a \leftarrow \top\}$. The weak completion of $\mathscr{P}$ is wc $\mathcal{P}=\{b \leftrightarrow \neg a, c \leftrightarrow \neg b, a \leftrightarrow T\}$. Its least model is $\langle\{a, c\},\{b\}\rangle$, and thus $a$ and $c$ are true: $a$ is true because it is a fact and $c$ is true by the negation of $b . \quad b$ is derived to be false because the negation of $a$ is false. This example shows that under WCS, a
positive conclusion ( $c$ being true) can be derived from two clauses, which include negation. Considering the results of the participants' responses in (Khemlani \& Johnson-Laird, 2012), they seem not to draw conclusions through double negation. Accordingly, we block them through abnormalities.

## Search Alternative Conclusions to NVC (abduction)

Our hypothesis is that when participants are faced with a NVC conclusion ('no valid conclusion'), they might not want to accept this conclusion and proceed to check whether there exists unknown information that is relevant. This information may be explanations to facts in our program, and we model such repair mechanism using abduction. Facts in our programs come either from an existential import or from unknown generalization. We use only the first as source for observations, since they are used directly to infer new information.

## Negation by Transformation (transformation)

A negative literal cannot be the head of a clause in a program. In order to represent a negative conclusion $\neg p(X)$ an auxiliary atom $p^{\prime}(X)$ is introduced together with a clause $p(X) \leftarrow \neg p^{\prime}(X)$ and the integrity constraint $\mathrm{U} \leftarrow p(X) \wedge p^{\prime}(X)$. This is a widely used technique in logic programming. Together with the principle licences for inferences, the additional clause is $p(X) \leftarrow \neg p^{\prime}(X) \wedge \neg a b(X)$.

## Representation of Quantified Statements

Based on the principles presented in the previous section, we discuss the representation of three examples.

OA4 The two syllogistic premises of OA4 are as follows:
Some $b$ are not $a$. (Oba)
all $b$ are $c .(A b c)$
The program $\mathcal{P}_{\mathrm{OA} 4}$ representing OA4 consists of:

$$
\begin{array}{lr}
a^{\prime}(X) \leftarrow b(X) \wedge \neg a b_{\text {bna }}(X) . & \text { (transformation \& licenses) } \\
a b_{b n a}\left(o_{1}\right) \leftarrow \perp . 亡 . \\
a(X) \leftarrow \neg a^{\prime}(X) \wedge \neg a b_{\text {naa }}(X) . & \text { (transformation \& licenses) } \\
(\text { trenses) } \\
b\left(o_{1}\right) \leftarrow T . & \text { (import) } \\
\left.a o_{2}\right) \leftarrow T . & \text { (unknownGen) } \\
a b_{\text {naa }}\left(o_{1}\right) \leftarrow \perp . & \text { (doubleNeg \& licenses) } \\
a b_{\text {naa }}\left(o_{2}\right) \leftarrow \perp . & \text { (doubleNeg \& licenses) } \\
c(X) \leftarrow b(X) \wedge \neg a b_{b c}(X) . & \text { (licenses) } \\
a b_{b c}(X) \leftarrow \perp . & \text { (licenses) } \\
b\left(o_{3}\right) \leftarrow T . & \text { (import) }
\end{array}
$$

In addition, we have the following integrity constraint:

$$
\mathrm{U} \leftarrow a(X) \wedge a^{\prime}(X) .
$$

(transformation)

IE4 The two syllogistic premises of IE4 are as follows:
Some bare a. (lba) no bare c. (Ebc)
The program $\mathcal{P}_{\text {IE4 }}$ representing IE4 consists of:

$$
\begin{aligned}
& a(X) \leftarrow b(X) \wedge \neg a b_{b a}(X) . \\
& a b_{b a}\left(o_{1}\right) \leftarrow \perp . \\
& b\left(o_{1}\right) \leftarrow \mathrm{T} . \\
& b\left(o_{2}\right) \leftarrow T .
\end{aligned}
$$

(licenses)
(licenses\&unknownGen)
(import)
(unknownGen)

$$
\begin{array}{lr}
b(X) \leftarrow a(X) \wedge \neg a b_{a b}(X) . & \text { (converse\&licenses) } \\
a b_{a b}\left(o_{3}\right) \leftarrow \perp . & \text { (converse\&licenses\&unknownGen) } \\
a\left(o_{3}\right) \leftarrow T . & \text { (converse\&import) } \\
a\left(o_{4}\right) \leftarrow T . & \text { (converse\&unknownGen) } \\
c^{\prime}(X) \leftarrow b(X) \wedge \neg a b_{b n c}(X) . & \text { (transformation \&licenses) } \\
a b_{b n c}(X) \leftarrow \perp . & \text { (licenses) } \\
c(X) \leftarrow \neg c^{\prime}(X) \wedge \neg a b_{n c c}(X) . & \text { (transformation \&licenses) } \\
b\left(o_{5}\right) \leftarrow T . & \text { (import) } \\
a b_{n c c}\left(o_{5}\right) \leftarrow \perp . & \text { (licenses\&doubleNeg) }
\end{array}
$$

In addition, we have the following integrity constraint:

$$
\mathrm{U} \leftarrow c(X) \wedge c^{\prime}(X) . \quad \text { (transformation) }
$$

IA2 The two syllogistic premises of IA2 are as follows:

## Some $b$ are $a$. (lba)

all $c$ are $b$. (Acb)
Program $\mathcal{P}_{\mathrm{A} 22}$ consists of the following clauses:

| $a(X) \leftarrow b(X) \wedge \neg a b_{b a}(X)$. | (licenses) |
| :--- | ---: |
| $a b_{b a}\left(o_{1}\right) \leftarrow \perp$. | (licenses\&unknownGen) |
| $b\left(o_{1}\right) \leftarrow T$. | (import) |
| $b\left(o_{2}\right) \leftarrow \mathrm{T}$. | (unknownGen) |
| $b(X) \leftarrow a(X) \wedge \neg a b_{a b}(X)$. | (converse\&licenses) |
| $a b_{a b}\left(o_{3}\right) \leftarrow \perp$. | (converse\&licenses\&unknownGen) |
| $a\left(o_{3}\right) \leftarrow T$. | (converse\&import) |
| $a\left(o_{4}\right) \leftarrow \mathrm{T}$. | (converse\&unknownGen) |
| $b(X) \leftarrow c(X) \wedge \neg a b_{c b}(X)$. | (licenses) |
| $a b_{c b}(X) \leftarrow$. | (licenses\&unknownGen) |
| $c\left(o_{5}\right) \leftarrow \mathrm{T}$. | (import) |

## Entailment of Syllogisms

Khemlani and Johnson-Laird (2012) do not report a formal definition for the entailment of syllogisms. They use FOL as a normative theory and test if the conclusions drawn by the participants are correct with respect to a first-order representation of a syllogism. In FOL, a set of formulas $\mathcal{K}$ entails a formula $F(\mathcal{K} \models F)$ if all interpretations which map $\mathcal{K}$ to true map $F$ to true as well. We believe that the entailment relation should reflect the principles on which the representation is based. In the following, an entailment relation regarding WCS is presented, where $y z$ is to be replaced by $a c$ or $c a$.

- $\mathcal{P} \models A y z$ iff there exists an object $o$ such that $\mathcal{P} \models \models_{w c s} y(o)$ and for all $o$ we find that if $\mathcal{P} \models_{w c s} y(o)$ then $\mathcal{P} \models_{w c s} z(o)$.
- $\mathcal{P} \models E y z$ iff there exists an object $o$ such that $\mathcal{P} \models_{w c s} z(o)$ and for all $o$ we find that if $\mathcal{P} \models_{w c s} z(o)$ then $\mathcal{P} \models_{w c s} \neg y(o)$.
- $\mathcal{P} \models I y z$ iff there exists an object $o_{1}$ such that $\mathcal{P} \models_{w c s} y\left(o_{1}\right) \wedge z\left(o_{1}\right)$ and there exists an object $o_{2}$ such that $\mathcal{P} \models_{w c s} y\left(o_{2}\right)$ and $\mathcal{P} \not \models_{w c s} z\left(o_{2}\right)$ and there exists an object $o_{3}$ such that $\mathcal{P} \models_{w c s} z\left(o_{3}\right)$ and $\mathcal{P} \not \models_{w c s} y\left(o_{3}\right)$.
- $\mathcal{P} \models O y z$ iff there exists an object $o_{1}$ such that $\mathcal{P} \models_{w c s} y\left(o_{1}\right) \wedge \neg z\left(o_{1}\right)$ and there exists an object $o_{2}$ such that $\mathcal{P} \models_{w c s} y\left(o_{2}\right)$ and $\mathcal{P} \not \models_{w c s} \neg z\left(o_{2}\right)$.

In case we can not conclude any of these moods, then no valid conclusion is entailed, denoted as $\mathcal{P} \models$ NVC.

## Accuracy of Predictions

We evaluate our approach the same way as the other theories have been evaluated (Khemlani \& Johnson-Laird, 2012): There are nine different answers for each of the 64 syllogisms that can be ordered in a list: Aac, Eac, lac, Oac, Aca, Eca, Ica, Oca, and NVC. We consider two lists: a list for WCS predictions and a list for participants' answers. In the WCS list, we assign 1 to an answer if it is predicted under WCS; else we assign 0 . In the list with the participants' answers we use a threshold function and assign 1 to answers that were drawn by more than $16 \%$ of the participants; else we assign 0 . Both lists can then be compared for their congruence as follows, where $i$ is the $i$ th element of both lists:

$$
\operatorname{Comp}(i)= \begin{cases}1 & \text { if both have the same value for } i \text { th element } \\ 0 & \text { otherwise }\end{cases}
$$

The matching percentage of this syllogism is then computed by $\sum_{i=1}^{9} \operatorname{COMP}(i) / 9$. Note that the percentage of the match does not only take into account when WCS correctly predicts a conclusion, but also whenever it correctly rejected a conclusion. The average percentage of accuracy is then the average of the matching percentage of all 64 syllogisms.

## OA4 - Perfect Match ( $\mathbf{1 0 0 \%}$ )

Consider $\mathcal{P}_{\mathrm{OA} 4}$. The least model of wc $\mathcal{P}_{\mathrm{OA} 4}, I=\left\langle I^{\top}, I^{\perp}\right\rangle$, is:
$I^{\top}=\left\{b\left(o_{1}\right), b\left(o_{2}\right), b\left(o_{3}\right), a b_{c a}\left(o_{1}\right), a^{\prime}\left(o_{1}\right), c\left(o_{1}\right), c\left(o_{2}\right), c\left(o_{3}\right)\right\}$, $I^{\perp}=\left\{a b_{b n a}\left(o_{1}\right), a b_{\text {naa }}\left(o_{1}\right), a b_{b c}\left(o_{1}\right), a b_{b c}\left(o_{2}\right), a b_{b c}\left(o_{3}\right), a\left(o_{1}\right)\right\}$. This model entails only the conclusion 'some $c$ are not $a^{\prime}$ (Oca): There exists an object, viz. $o_{1}$, such that $\mathcal{P}_{\mathrm{OA} 4}==_{w c s} c\left(o_{1}\right) \wedge \neg a\left(o_{1}\right)$ and there exists another object, viz. $o_{2}$, such that $\mathcal{P}_{\mathrm{OA} 4} \models_{w c s} c\left(o_{2}\right)$ and $\mathcal{P}_{\mathrm{OA} 4} \not \vDash_{w c s} \neg a\left(o_{2}\right)$.

## IE4 - Partial Match (89\%)

Consider $\mathcal{P}_{\text {IE } 4}$. The least model of wc $\mathcal{P}_{\text {IE } 4}, I=\left\langle I^{\top}, I^{\perp}\right\rangle$, is

$$
\begin{aligned}
I^{\top} & =\left\{a\left(o_{i}\right) \mid i \in\{1,3,4\}\right\} \cup\left\{b\left(o_{i}\right) \mid i \in\{1,2,3,5\}\right\} \\
& \cup\left\{c^{\prime}\left(o_{i}\right) \mid i \in\{1,2,3,5\}\right\} \\
I^{\perp} & =\left\{a b_{b a}\left(o_{1}\right), a b_{a b}\left(o_{3}\right), a b_{n c c}\left(o_{5}\right), a b_{b n c}\left(o_{5}\right)\right\} \\
& \cup\left\{a b_{b n c}\left(o_{i}\right) \mid i \in\{1,2,3,4,5\}\right\} \cup\left\{c\left(o_{i}\right) \mid i \in\{1,2,3,5\}\right\} .
\end{aligned}
$$

This model entails only 'Some a are not $c$ ' ( Oac ).

## IA2 - Explain NVC: Perfect Match (100\%)

Consider $\mathcal{P}_{\mathrm{AA} 2}$. The least model of wc $\mathcal{P}_{\mathrm{A} 2}, I=\left\langle I^{\top}, I^{\perp}\right\rangle$, is

$$
\begin{aligned}
& I^{\top}=\left\{a\left(o_{1}\right), a\left(o_{3}\right), a\left(o_{4}\right), b\left(o_{1}\right), b\left(o_{2}\right), b\left(o_{3}\right), b\left(o_{5}\right), c\left(o_{5}\right)\right\}, \\
& I^{\perp}=\left\{a b_{b a}\left(o_{1}\right), a b_{a b}\left(o_{3}\right)\right\} \cup\left\{a b_{c b}\left(o_{i}\right) \mid i \in\{1,2,3,4,5\}\right\} .
\end{aligned}
$$

This model entails 'no valid conclusion' (NVC). However, a significant percentage of participants answered lac and Ica, despite IA2 being an invalid syllogism in classical FOL. According to the sixth principle, abduction, we believe that these participants might have searched for alternatives to NVC. We model this by applying skeptical abductive reasoning.

Each head of an existential import generates a single observation. We apply abduction sequentially to each of them. To prevent empty explanations we remove from the current program the fact that generated the observation.

For each observation and each of its minimal explanations we compute the least model of the weak completion of the program extended with the explanation and collect all entailed syllogistic conclusions. Observations that cannot be explained are filtered out. The set Answers consists of all entailed conclusions for the observations left. For the final conclusions, we apply skeptical reasoning, i.e., the final answer to the current syllogism is given by FinalAnswer $=\bigcap_{A \in \text { Answers }} A$. In the case that FinalAnswer is empty, we entail the NVC conclusion.

Reconsider IA2, where the observations are $O_{1}=\left\{b\left(o_{1}\right)\right\}$, $O_{2}=\left\{a\left(o_{3}\right)\right\}$ and $O_{3}=\left\{c\left(o_{5}\right)\right\}$. If we examine $O_{i}=\{o\}$ with $i \in\{1,2,3\}$, then we will try to find an explanation for $O_{i}$ with respect to $\mathcal{P}_{\mathrm{A} 2} \backslash\{o \leftarrow T\} .^{7}$ The set of abducibles is:

$$
\begin{aligned}
& \cup\left\{c\left(o_{i}\right) \leftarrow \top, \quad c\left(o_{i}\right) \leftarrow \perp \quad \mid i \in\{1,2,3,4\}\right\} \\
& \cup\left\{a b_{c b}\left(o_{5}\right) \leftarrow \top \quad \mid i \in\{1,2,3,4,5\}\right\} \\
& \cup\left\{a b_{b a}\left(o_{1}\right) \leftarrow \top, a b_{a b}\left(o_{3}\right) \leftarrow \top\right\} .
\end{aligned}
$$

$\mathcal{E}_{1}=\left\{c\left(o_{1}\right) \leftarrow \top\right\} \quad$ and $\quad \mathcal{E}_{2}=\left\{c\left(o_{3}\right) \leftarrow \top, a b_{b a}\left(o_{3}\right) \leftarrow \perp\right\}$ are the minimal explanations for $O_{1}$ and $O_{2}$, respectively. Note that for $O_{3}$ there is no explanation.

Consider the observation $O_{1}=\left\{b\left(o_{1}\right)\right\}$ and the program $\mathcal{P}_{\mathrm{IA} 2}^{1}=\left(\mathcal{P}_{\mathrm{AA} 2} \backslash\left\{b\left(o_{1}\right) \leftarrow \top\right\}\right) \cup \mathcal{E}_{1}$. The least model of wc $\mathcal{P}_{\mathrm{IA} 2}^{1}$ is $\left\langle I^{\top} \cup\left\{c\left(o_{1}\right)\right\}, I^{\perp}\right\rangle$ where $\left\langle I^{\top}, I^{\perp}\right\rangle$ is the least model of wc $\mathcal{P}_{\mathrm{A} 2}$, as defined before. Thus, $c\left(o_{1}\right)$ is newly entailed to be true after applying abduction. This model entails what participants concluded, namely lac and lca. lac is entailed as there exists an object, viz. $o_{1}$, such that $\mathcal{P}_{\mathrm{IA} 2}^{1} \models_{w c s} a\left(o_{1}\right) \wedge c\left(o_{1}\right)$ and there exists another object, viz. $o_{4}$, such that $\mathcal{P}_{\mathrm{AA} 2}^{1}=_{w c s} a\left(o_{4}\right)$ and $\mathcal{P}_{\mathrm{AA} 2}^{1} \not \models_{w c s} c\left(o_{4}\right)$, and there exists another object , viz. $o_{5}$, such that $\mathcal{P}_{1 \mathrm{~A} 2}^{1} \models_{w c s} c\left(o_{5}\right)$ and $\mathcal{P}_{\mathrm{IA} 2}^{1} \not \vDash_{w c s} a\left(o_{5}\right)$. Analogously, 'some c are a' (Ica) holds.

For the observation $O_{2}=\left\{a\left(o_{3}\right)\right\}$ we consider the program $\mathcal{P}_{\text {IA } 2}^{2}=\left(\mathcal{P}_{\text {IA } 2} \backslash\left\{a\left(o_{3}\right) \leftarrow \top\right\}\right) \cup \mathcal{E}_{2}$. The least model of $\mathcal{P}_{\text {IA } 2}^{2}$ also entails the conclusions lac and Ica.

Answers $\left(\mathcal{P}_{\mathrm{IA}_{2}}\right)=\{\{|a c| c a\},,\{|a c| c a\}$,$\} is the collection$ of all conclusions. FinalAnswer $\left(\mathcal{P}_{\mathrm{A} 2}\right)=\{|a c| c a$,$\} consists of$ the skeptically entailed conclusions, i.e. it is the intersection of all conclusions, which in this case are 'some a are c' (lac) and 'some c are $a$ ' (Ica).

## Overall Accuracy of $89 \%$

The results of the three examples formalized under WCS are summarized and compared to FOL, PSYCOP, the Verbal, and the Mental Model Theory in Table 5. For some syllogisms the conclusions drawn by the participants and WCS are identical and for some syllogisms the conclusions drawn by the participants and WCS overlap. Combining the syllogistic premises representation and entailment rules for all 64 syllogistic premises and applying abduction when NVC was entailed (which happened in 43 cases), we accomplished an average of $89 \%$ accuracy in our predictions. In 18 cases we have a perfect match, in 30 cases the match is $89 \%$, in 13

[^161]Table 5: The conclusions drawn by a significant percentage of participants are highlighted in gray and compared to the predictions of the theories FOL, PSYCOP, Verbal, and Mental Models as well as WCS for the syllogisms OA4, IE4, and IA2.

cases the match is $78 \%$, and in the remaining three cases the match is $67 \%$. We achieve the best performance compared to the other state-of-the-art cognitive theories with the current best performance of $84 \%$ (Verbal Model Theory).

## Conclusions

We developed seven principles for modeling a logical form for the representation of quantified statements in human reasoning, mostly motivated from findings in Cognitive Science. We show how these principles can be encoded within a computational logic approach, the Weak Completion Semantics. After that we discuss the predictions of three examples under WCS and compare them to the conclusions humans draw from in (Khemlani \& Johnson-Laird, 2012). The result with respect to all 64 syllogistic premises under WCS shows that we achieve the best results with a prediction of $89 \%$, compared to the results of other cognitive theories.

# Speakers' gestures predict the meaning and perception of iconicity in signs 

Gerardo Ortega ${ }^{1,2}$ (gerardo.ortega@mpi.nl), Annika Schiefner ${ }^{1}$ (a.schiefner@student.ru.nl), \& Aslı Özyürek ${ }^{1,2,3}$ (asli.ozyurek@mpi.nl)<br>${ }^{1}$ Centre for Language Studies, Radboud University,<br>${ }^{2}$ Max Planck Institute for Psycholinguistics, and ${ }^{3}$ Donders Centre for Cognition<br>Wundtlaan 1, 6525XD Nijmegen, The Netherlands

#### Abstract

Sign languages stand out in that there is high prevalence of conventionalised linguistic forms that map directly to their referent (i.e., iconic). Hearing adults show low performance when asked to guess the meaning of iconic signs suggesting that their iconic features are largely inaccessible to them. However, it has not been investigated whether speakers' gestures, which also share the property of iconicity, may assist non-signers in guessing the meaning of signs. Results from a pantomime generation task (Study 1) show that speakers' gestures exhibit a high degree of systematicity, and share different degrees of form overlap with signs (full, partial, and no overlap). Study 2 shows that signs with full and partial overlap are more accurately guessed and are assigned higher iconicity ratings than signs with no overlap. Deaf and hearing adults converge in their iconic depictions for some concepts due to the shared conceptual knowledge and manual-visual modality.

Keywords: iconicity; gesture; sign language; embodied cognition

## Introduction

A question that has puzzled psychologists and linguists for decades is to what extent sign iconicity is accessible to individuals with no knowledge of a sign language. Iconicity, defined as the direct relationship between a linguistic form and its referent, is a ubiquitous property of sign languages observable at many of their linguistic levels of organisation (Cuxac, 1999; Perniss, Thompson, \& Vigliocco, 2010; Pietrandrea, 2002). Sign-naïve adults can accurately guess the meaning of only a small proportion of signs (Griffith, Robinson, \& Panagos, 1981; Grosso, 1993; Klima \& Bellugi, 1979; Pizzuto \& Volterra, 2000), but it has been hard to establish what factors allow them to map certain features of a sign to its correct referent. In an attempt to shed light on this question, we look at the iconic gestures produced by hearing non-signers. Given that iconic gestures are expressed through the same (manual-visual) modality, and importantly, they also share the property of iconicity (Kendon, 2004; McNeill, 1992), we entertain the hypothesis that non-signers may rely on their own gestural repertoire to make form-meaning judgements about signs.

## Iconicity in gesture and sign

Gestures are a fundamental aspect of human communication and are present in all ages and cultures (Kendon, 2004; McNeill, 1992). Gestures are holistic units highly integrated with speech that together convey unified semantic information of a multimodal utterance (Kelly, Creigh, \&

Bartolotti, 2010; McNeill, 1992). Sign languages, in contrast, occur independently from speech, and critically, they have the same levels of linguistic organisation as those reported in spoken languages (Sandler \& Lillo-Martin, 2006).

One point of intersection between sign and gesture is iconicity. Speakers can depict through iconic gestures the visual form of a concept and integrate them with speech as part of a multimodal message. For instance, when a speaker says 'I'll be outside' while producing the gesture of smoking it is clear to the interlocutor that she is going for a cigarette. On the other hand, a large proportion of a signed lexicon has iconic motivation (Pietrandrea, 2002), and crucially, signs may have overlapping structures as gestures (e.g., the sign TO-SMOKE depicts a person smoking a cigarette).

The similarities between sign and gesture were overlooked for many decades, but in recent years scholars have begun systematically comparing both modes of manual communication to shed light on their differences and similarities (e.g., Cormier, Schembri, \& Woll, 2013; Goldin-Meadow \& Brentari, 2015; Perniss, Özyürek, \& Morgan, 2015; Quinto-Pozos \& Parrill, 2015). Given the growing body of evidence showing that gestures and signs share more forms and functions than previously assumed (arguably due to the shared manual-visual modality) (Perniss et al., 2015), we investigate whether non-signing adults fall back on their own gestural repertoire to make judgements about conventionalised signs. The aim of the present study is therefore to investigate whether the overlap in form between signs (i.e., linguistic structure) and gestures (i.e., iconic depictions) predicts non-signers' ability to guess the meaning of signs and assign iconicity ratings.

## Perception of sign iconicity

Iconicity and the extent to which sign-naïve adults can understand the meaning of iconic signs has been a central focus of attention in sign research. The first investigations on the topic demonstrated that iconicity is not easily accessible to non-signers and that the meaning of signs is very difficult to access. In their seminal study, Klima and Bellugi (1979) asked hearing adults without any knowledge of a sign language to guess the meaning of a set of signs. When signs were presented in isolation and when they had to select the correct meaning out of five plausible candidates, participants showed a very low success rate (less than $10 \%$ ). They showed significant improvement, however, when they were presented the sign along with its English translation, and were asked to explain the iconic relationship
between the sign and its meaning. Participants showed overall agreement in that they were able to accurately describe the iconic motivation of more than $50 \%$ of the signs (e.g., most participants agreed that the sign VOTE depicted a person putting a ballot in a box). This study set a benchmark in sign language research and convincingly argued that iconicity is difficult to access by hearing nonsigners and that the notion of iconicity is better understood as a property that lies in a continuum with the meaning of some signs being more transparent than others.
Another study highlights the possibility that similarities between signs and the gestures used by the hearing community may assist sign-naïve participants in guessing the meaning of signs. Grosso (1993) showed a set of iconic and arbitrary signs in Italian Sign Language (LIS) to hearing non-signing adults and asked them to guess their meaning. Participants could not provide a correct response for a large proportion of signs ( $76 \%$ ) but they were very accurate for a considerable number of items on the list (24\%). A detailed analysis of the correctly guessed items revealed that these signs resemble the emblems commonly used by Italian speakers (e.g., the sign GOOD has the same form and meaning as the emblem used by hearing Italians). Emblems have a conventionalised, culture-specific form and meaning (Kendon, 1995, 2004) so when non-signing adults are confronted by signs that overlap in structures, they rightly assume that they also share the same meaning. This study is one of the first to suggest that non-signers' ability to guess the meaning of signs is based on the structural similarities between conventionalised (linguistic) signs and the gestures produced by the surrounding speaking community.
A limitation of this study is that it presupposes that only emblems facilitate the accurate guessing of the meaning of signs but does not say how other types of gestures may also be recruited. Emblems have highly conventionalised hand configurations, are used for specific pragmatic purposes (Kendon, 1995, 2004), and have mental representations akin to those of abstract words (Gunter \& Bach, 2004), so they are retrievable gestural entities that can be compared with convetionsalised signs. However, other types of iconic gestures may also be used as a basis to make judgments about the meaning of signs. In this study, we turn to the systematic iconic gestures shared in a community of speakers to investigate how overlap in form with conventionalised signs influences meaning-based judgements about signs.

## Systematicity in iconic gestures

The form of iconic gestures has been assumed to be variable, with their structure depending on the context in which they are used, the interlocutor, and the communicative intent of the speaker. It has been assumed that individuals tailor their gestures to the main focus of a conversation and as a result they vary in form and meaning from one conversation to the next (Müller, 2013). However, recent studies have found that contrary to this received knowledge, the iconic gestures produced by hearing adults exhibit a high degree of systematicity, and tend to represent very similar forms across individuals.

For instance, it has been found that the iconic co-speech gestures used in object descriptions are highly systematic and their form depends on the physical properties of the referent (Masson-Carro, Goudbeek, \& Krahmer, 2015). Objects that can be manipulated with the hands (e.g., a pen) are represented with gestures mimicking how the object is held; while objects with low manipulability affordances (e.g., a sink) are represented through gestures outlining their shape. A striking degree of systematicity has also been reported in elicited silent gestures (i.e., pantomimes). When asked to express concepts in pantomime, participants tend to systematically differentiate actions from tools through distinct gestural forms (i.e., re-enactment of bodily movements for verbs and handshapes representing the form of objects for nouns) (Padden et al., 2013; Padden, Hwang, Lepic, \& Seegers, 2015). More recently, high degree of systematicity in the structure of pantomimes has also been found across different semantic domains and for geographically unrelated cultures. Ortega and Özyürek (2016) elicited pantomimes from Dutch and Mexican adults and found that both groups employ remarkably similar strategies to depict referents. Through the implementation of specific types of iconic representations and their combinations, participants systematically represent concepts across different semantic domains. These pantomimes bare strong resemblance with the structures of recently discovered sign languages (Safar \& Petatillo, in preparation), so it has been argued that pantomimes reveal some of the cognitive dispositions that give rise to a signed lexicon in emerging sign languages.

The relevance of these studies is two-fold: first, they demonstrate that iconic gestural depictions are not as variable as previously assumed, but rather are deployed systematically to represent concrete concepts within specific semantic domains. Second, such systematicity results in shared knowledge about some manual forms across a community of speakers. As a consequence, individuals are likely to have expectations of how a concept should be represented in the manual-visual modality - at least for a set of referents. This has important implications for the perception of sign iconicity by non-signers. Non-signing adults confronted by conventionalised signs for the first time will not make judgements about their meaning in a vacuum. Rather, they are likely to fall back on their gestural knowledge to make judgments about the meaning of iconic signs.

## The Present Study

Based on evidence that many iconic gestures are highly systematic across individuals (Masson-Carro et al., 2015; Ortega \& Özyürek, 2016; Padden et al., 2013, 2015; van Nispen, van de Sandt-Koenderman, Mol, \& Krahmer, 2014) it is possible to assume that non-signing adults have at their disposal a cohort of shared gestures with specific forms and meanings on which they may base their judgment about signs. In order to test this hypothesis, we carried out two studies. In Study 1 we elicited pantomimes from nonsigning adults to determine which gestures were the most systematic across participants. Once these pantomimes were
selected, we compared them to signs from Sign Language of the Netherlands (NGT) and looked for signs that overlapped in form to different degrees (full, partial, or no overlap). These signs served as stimulus materials for Study 2. In this study, a different group of participants were presented with the signs and were asked, first, to guess their meaning. After they gave their response, they were given the correct translation, and then were asked to give iconicity ratings. The prediction is that when signs map directly to their gesture non-signing adults will be more accurate at guessing their meaning and will assign higher iconicity ratings (e.g., the gesture and the NGT sign TO-SMOKE represent a person smoking a cigarette so participants are likely to be very accurate and give high iconicity ratings). The expected results will lend credence to the hypothesis that sign-naïve adults base their responses not only on their emblems (Grosso, 1993), but also on other types of (iconic) gestures that are systematic within a community.

## Methodology

## Study 1: Pantomime generation task Participants

Twenty native speakers of Dutch ( 10 females, age range: 21-46, mean: 27 years) living in the area of Nijmegen, the Netherlands, took part in the study.

## Procedure

Participants were seated in front of a computer and were asked to produce a gesture that conveyed exactly the same meaning as the word on the screen. They were explicitly told that it was not allowed to speak or to point to any object in the room and that they could say 'pass' if they were unable to generate a pantomime. Two cameras were positioned on each side of the participant to record their gestural productions. Trials started with a fixation cross $(500 \mathrm{~ms})$ followed by the target word ( 4000 ms ) time during which they had to produce their gesture. After the 4000 ms ended, the next trial began. The motivation behind this strict timing was to elicit participants' most intuitive response. Participants were presented a total of 273 words.
Pantomimes were coded according to the description parameters proposed by Bressem (2013), which are based on the phonological parameters handshape, location, and movement of sign languages. Based on these features, we looked at the gestures that exhibited the same structure across a large number of participants. If the same gesture was produced by at least 12 out of 20 participants, it was considered the default gesture for that concept. These resulted in a total of 119 pantomimes that were consistent across a large proportion of the pool of participants (mean number of participants producing the same pantomime: 15.14).

These default gestures were compared to their NGT translation on each phonological parameter (i.e., handshape, location and movement) to select items with different degrees of form overlap. This comparison resulted in three categories of signs. 1) Full overlap ( $\mathrm{N}=36$ ): gesture-sign pairs did not differ in any parameter (Figure 1A). 2) Partial overlap ( $\mathrm{N}=56$ ): this category includes signs in which only
one parameter differed from the gesture (Figure 1B). 3) No overlap ( $\mathrm{N}=54$ ): signs in which two or more parameters differed. This category consisted of 27 signs that did not overlap at all with the elicited gesture, plus an additional 27 signs for which no default gesture could be established (Figure 1C). These three groups of NGT signs ( $\mathrm{N}=146$ ) were the stimuli for Study 2.

## Study 2: Open-cloze and iconicity rating Participants

The participants of this study were a different group of 20 hearing native speakers of Dutch ( 14 female, mean age $=$ 21.8 years) with no knowledge of NGT or any other sign language. None of them took part in the pantomime generation task.

## Stimuli

The stimuli consisted of videos of the 146 NGT selected from Study 1 (i.e., signs with full, partial, and no overlap with gesture). Videos were produced by a deaf signer with neutral face and without mouthings to avoid giving away cues about the meanings of the signs.

$$
\text { GESTURE } \quad \text { SIGN }
$$

Figure 1: Examples of sign-gesture pairs with different degrees of overlap. A) TO-CUT shares all the components (handshape, location, movement) between sign and gesture. B) TO-SAW differs in only one parameter (handshape). C) In LAPTOP, sign and gesture have no overlap.

## Procedure

At the beginning of each trial, an NGT sign in citation form was presented. After the video had played in full and disappeared from the screen, a new screen was presented instructing participants to guess the meaning of the sign and write its meaning in one word (typed). Participants were required to type in an answer for every item but they were also allowed to skip items if they could not come up with a
meaning. After participants had entered an answer, a new screen of instructions came up. Here participants were given the actual meaning of the sign and were asked to judge how well the sign represented its meaning. The sentence read: 'The meaning of the sign is [translation equivalent]. How much does the sign look like its meaning?' The screen displayed a 7-point Likert and participants were required to type in their rating ( 1 representing the lowest similarity and 7 the highest).

## Analysis

Participants gave a response for a large proportion of the signs with passes representing only $6.5 \%$ of responses. Despite being instructed to write only one word, many responses were phrases, but they were still included in the analysis. Based on the Dutch version of the Boston Naming Task (Roomer, Hoogerwerf, \& Linn, 2011), answers were coded as correct and incorrect. Answers were coded as correct if they matched exactly the expected answer (e.g., sign: TO-PULL; response: to pull) or if they were synonyms of each other (e.g., sign: TO-PHONE; response: to ring). This category also included answers that were not the same part of speech as the target sign, but where the answer was specific to the target concept (e.g., sign: TO-PHONE; response: telephone) ${ }^{1}$. We also included phrases containing a verb and the correct argument depicted in the sign (e.g., sign: BANANA; response: to peel a banana). Responses that did not fit into any of these categories were classed as incorrect answers.

Incorrect answers were subdivided into responses that were semantically related and unrelated to the sign. Semantically related answers included responses that belonged to the same semantic domain (e.g., sign: DUCK; response: penguin); as well as answers that were lacking the appropriate abstraction to the target concept (e.g., the sign MONKEY, which re-enacts how a primate scratches the sides of its torso, was often labelled as scratching).
The semantically unrelated category included responses that were plainly wrong, or answers derived from visual information of the sign, but that had no relationship with the concept (e.g., the sign MOUNTAIN describes the outline of two horizontal bumps, but it was often interpreted as a camel).

For the open cloze, the proportions of correct, semantically related, and semantically unrelated answers were calculated for every item, thereby collapsing across participants' answers. Missing answers were discarded for this analysis and did not contribute to the proportions. For the iconicity ratings, all values were averaged across participants to obtain the mean ratings for each of the 146 signs.

[^162]
## Results

Performance on the open cloze was highly variable across participants and items. While only nine items ( $6.2 \%$ ) were correctly identified by all participants, half of the signs (73 signs) were correctly identified by at least $25 \%$ of participants. For 26 items (17.8\%), all answers were semantically related to the target meaning, suggesting that participants were able to correctly identify some aspect of the sign but did not make the full abstraction to the target meaning (e.g., sign: TO-FLY; response: bird). Regarding the iconicity ratings, participants were able to give a response for all items. In order to establish to what extent sign-gesture overlap contributes to guessing the meaning of a sign and assign iconicity ratings, we considered the following variables in the statistical analysis.
Independent variable: Degree of overlap (full, partial, and no overlap)

## Dependent variables:

i. Proportion of correct answers (open cloze)
ii. Proportion of semantically related answers (open cloze)
iii. Proportion of semantically unrelated answers (open cloze)
iv. Mean iconicity rating

A multivariate ANOVA was run to determine the relationship between type of gestural overlap (full, partial and, no overlap) and the dependent variables of the open cloze and the iconicity ratings. Using Pillai's Trace we found a significant overall effect of the degree of overlap, $V$ $=0.541, F(6,230)=14.205, \eta^{2}=.27, p<.001$. The following sections will describe the between-subjects effects for each dependent variable.
i) Turning to the proportion of correct answers in the open cloze, tests of between-subjects revealed a significant effect of degree of overlap, $F(2,116)=24.168, \eta^{2}=.194, p<$ .001. Planned contrasts revealed an increase of correct answers from no overlap items ( $M=0.12, S E=.03$ ) to partial overlap $\left(M=0.46, S E=.05, \Delta=-0.31, S E_{\Delta}=.06, p\right.$ $<.001, \mathrm{BCa} 95 \%$ CI $[-0.45,-0.18]$ ), but no significant difference between partial and full overlap ( $M=0.61, S E=$ $.06, p=.209$ ). The proportion of correctly identified items was thus higher for items with full and partial overlap than for those with no overlap (Figure 2).
ii) Regarding the proportion of incorrect answers that were semantically related to the sign, a test of betweensubjects effects revealed no significant effect of the degree of overlap between gestures and signs, $p=.305$. That is, wrong answers in the open cloze were equally distributed across the three types of signs (full, partial, and no overlap).
iii) Turning to the proportion of incorrect answers that were semantically unrelated to the target concept, tests of between-subjects effects revealed a significant effect of the degree of overlap, $F(2,116)=26.909, \eta^{2}=.317, p<.001$. Signs with no overlap were significantly less likely to be guessed correctly ( $M=0.75, S E=.05$ ) than those with partial overlap $(M=0.41, S E=.05, \Delta=0.34$, BCa $95 \%$ CI [0.21, 0.47], $p<.001$ ). Signs with full overlap were
significantly more likely to be guessed accurately than signs with partial overlap ( $M=0.21, S E=.04, \Delta=0.192, \mathrm{BCa}$ $95 \%$ CI $[0.05,0.33], p=.009$ ). In other words, the less similar a sign is from a gesture, the more likely it is to be guessed inaccurately.
iv) When we look at iconicity ratings, we found an association with the degree of overlap between sign and gesture $F(2,111.836)=54.13, \eta^{2}=.483, p<.001$. Planned contrasts revealed a significant increase of mean iconicity ratings from no overlap ( $M=3.18, S E=0.22$ ) to partial overlap $(M=5.34, S E=.17, \Delta=-2.13$, BCa $95 \%$ CI [2.617, -1.642$], p<.001$ ) but not from partial to full overlap ( $M=5.92, S E=.15, p=.07$ ). These results suggest that when signs have greater overlap in form with their gestures they perceive signs as more iconic (see Figure 3).

## Discussion

These data expands on previous research by showing that the gestural repertoire of non-signing adults is recruited to make judgments about the meaning of lexical signs. We showed that signs that overlap in form with their gestures are guessed more accurately and are judged as more iconic. The proportion of correct answers and iconicity ratings were higher for signs that overlapped in form with gestures, but there was no additional improvement between full and
partial overlap. This suggests that despite their slight structural differences, these two types of signs bear enough resemblance to participants' gestures to make an association between them.

Signs and gestures share the same physical constraints to express a concept in the manual modality, with the referent shaping to some extent the features than can be expressed with the hands (Masson-Carro et al., 2015). It is therefore not surprising that signs and gestures converge in the strategies to depict the visual characteristics of many concepts. If signs and gestures have similar structures for some concepts, it means that deaf and hearing adults share conceptual knowledge about these concepts (i.e., visual, semantic, perceptual, sensorimotor representations). When there is sufficient overlap between signs and gesture, nonsigning adults may tap into these schemas to make judgements about the meaning of signs. These findings also relate to research showing that humans - as well as other primates - understand and evaluate the correctness of others' actions through the activation of brain regions engaged when they perform the same actions themselves (Koelewijn, van Schie, Bekkering, Oostenveld, \& Jensen, 2008; Rizzolatti, Fadiga, Gallese, \& Fogassi, 1996).

The errors produced by participants, however, clearly show that if gesture and sign mismatch, or if the meaning of signs departs slightly from the features they depict, participants are unable to estimate accurately the meaning of a sign. As a result, they will also rate the sign as less iconic. Non-signers have a very limited scope to assign meanings to signs and seem to be inclined to describe only what is directly encoded in them. While they are capable of extracting some visual information from the signs they often fail to respond with the correct metonymic associate (e.g., they respond scratch instead of monkey). This goes to show that despite their similarities, sign languages have established linguistic conventions not shared with gestures and thus are inaccessible to non-signing adults.

This study adds to the body of research investigating how modality shapes linguistic/communicative structures (Perniss et al., 2015).

## Acknowledgments

This work was supported by a Veni grant by the Netherlands Organisation for Scientific Research (NWO) awarded to the first author. We would like to thank the members of the Multimodal Language and Cognition lab at Radboud University for their helpful comments, in particular to Swen Schreiter, Linda Drijvers, and James Trujillo for their support.

#### Abstract

This paper introduces a formal method to model the level of demand on control when executing cognitive processes. The cost of cognitive control is parsed into an intensity cost which encapsulates how much additional input information is required so as to get the specified response, and an interaction cost which encapsulates the level of interference between individual processes in a network. We develop a formal relationship between the probability of successful execution of desired processes and the control signals (additive control biases). This relationship is also used to specify optimal control policies to achieve a desired probability of activation for processes. We observe that there are boundary cases when finding such control policies which leads us to introduce the interaction cost. We show that the interaction cost is influenced by the relative strengths of individual processes, as well as the directionality of the underlying competition between processes.

Keywords: cognitive control; multi-tasking; intensity; identity

## Introduction

A long standing focus in cognitive research has been towards understanding the ability to execute tasks/processes ${ }^{1}$ that demand cognitive control. In this context, cognitive control is defined as the set of mechanisms required to pursue a goal, especially when distraction or strong competing responses (interferences) must be overcome (Posner \& Snyder, 1975; Shiffrin \& Schneider, 1977; Cohen, Dunbar, \& McClelland, 1990). Earlier work (Posner \& Snyder, 1975; Shiffrin \& Schneider, 1977; Cohen et al., 1990; Botvinick \& Cohen, 2014) has argued that the processes demanding control can be distinguished from automatic processes in terms of the strength of the associations in the pathways underlying processing: automatic processes are characterized by pathways with associations strong enough to resist interference from competing processes, whereas controlled processes are weaker, and therefore rely on input from control mechanisms to support their execution against interference.

Another longstanding observation is that the allocation of cognitive control is costly (often discussed in terms of "mental effort" (Posner \& Snyder, 1975; Botvinick \& Braver, 2015; Shenhav et al., 2017)). This cost has been interpreted in physical terms (such as metabolic demands (Muraven, Tice,

[^163]\& Baumeister, 1998)) or in terms of an opportunity cost reflecting the allocation of a limited resource (Kurzban, Duckworth, Kable, \& Myers, 2013). Elsewhere (Feng, Schwemmer, Gershman, \& Cohen, 2014; Musslick et al., 2016), we have proposed that limitations in the capacity for controldependent processing reflect the purpose of control to diminish interference rather than any intrinsic limitation in the mechanism responsible for control. This view suggests that the architecture of the processing system as a whole constrains the opportunities for control-dependent processing, resulting in opportunity costs associated with allocating control to any particular task(s).

Here, we build on a closely related proposal, by Koechlin and Summerfield (2007), to define the cost of control in terms of internal representational requirements to insure that a given stimulus (or a set of stimuli) produces the desired response (or a set of responses), given the intrinsic architecture of the system. Their work focused on a single task. Here, we extend this to consider an arbitrary number of tasks and thus accommodate their possibility for, and costs of, multitasking (i.e.parallel processing of task pathways). To do so, we follow the framework proposed by Shenhav, Botvinick, and Cohen (2013) that distinguishes two components of control signals: intensity and identity. Specifically, Shenhav et al. (2013) defined the intensity of a control signal as the strength of the signal needed to insure performance of a particular task, and the identity as which control signal should be selected to achieve a desired objective given environmental conditions. Here we build on that distinction to define two corresponding components of the cognitive control costs - a cost associated with intensity, and a cost associated with interaction. Furthermore, we define the interaction cost to capture the level of interference between the processes in a network.

In this paper, we begin by introducing formal constructs for intensity and interaction costs by using the graph theoretic representation of a neural network and terms/notions adopted from probability theory. We describe an intensity cost that represents the control signals (as biases infused into a neural network), above and beyond the specified strength of the signal (stimulus) itself. This is achieved by developing a formal relationship between the probability of successful execution of desired processes and the control signals. In turn, this defines an optimization problem, which can then be solved to find optimal control signals that achieve a specified activation for desired processes. However, we observe that there

Figure 1: Illustration of a single-layered, feed-forward network with 3-input and 3-output layer components, wherein the individual features are scalar in nature.
are boundary cases in which this optimization problem can not be solved. These cases reflect situations in which the simultaneous execution of the processes is not feasible due to interference. Hence, interaction cost analysis motivates an additional investigation towards finding a proper metric that continuously measures the level of interference between processes. To achieve this we introduce the definition of interaction cost associated with process mappings in a network configuration. Specifically, it measures the level of interference introduced by competing processes that interfere with the tasks of interest. In their study, Koechlin and Summerfield (2007) have already used information theoretic terms to measure cognitive control. However, in order to apply these metrics to neural networks while considering parallelism, we augment some of these measures, and through simulations we will demonstrate how interaction cost can be used to predict interference in neural network architectures. Finally, we will discuss general research directions revealed by the analysis presented here.

## Intensity: the cost of control

Cognitive control is defined as the underlying mechanism that biases the processing of a task in order to maximize the reward (Botvinick, Braver, Barch, Carter, \& Cohen, 2001; Botvinick, Cohen, \& Carter, 2004; Bogacz, Brown, Moehlis, Holmes, \& Cohen, 2006; Botvinick, 2007). Here, we adapt the notion of intensity cost from Shenhav et al. (2013) as a function of the amount of control bias that cognitive control applies to the system. However, Shenhav et al. (2013) described this function in qualitative rather than quantitative terms. In this work we provide an explicit characterization of the cost of cognitive effort in terms of a set of physically meaningful parameters, which allow the manipulation of the response of a cognitive architecture.

Following earlier works (Feng et al., 2014; Musslick et al.,
2016), we consider a single-layered, feed-forward network with $N$ input and $M$ output layer components to formalize the notion of intensity cost in a cognitive control context (Fig. 1 shows a simple example of such a network). In this framework, each component represents an input/stimulus or output/response dimension (vector subspace), and the connection from an input to an output component constitutes the processing pathway for a given task. This allows us to define an abstraction of the network as a directed bipartite graph $\mathcal{G}_{B}=(\mathcal{V}, \mathcal{E})$, wherein the set of vertices $\mathcal{V}$ can be partitioned into two disjoint sets $\mathcal{V}_{\text {in }}$ and $\mathcal{V}_{\text {out }}$, representing the input and output layer components respectively. Moreover, a directed edge $(i, j) \in \mathcal{E} \subseteq \mathcal{V}_{\text {in }} \times \mathcal{V}_{\text {out }}$ represents a connection from the vertex $i$ in the input layer to vertex $j$ in the output layer (i.e., a task). In this setting, we represent the processing pathway by introducing a weight matrix $W$ with elements $w_{i j}$. As we will see later, this abstraction plays an important role in formalizing the interaction cost of cognitive control.

In this setting, we assume that control signals bias the processing of a stimulus towards a specified response at two different levels, i.e. $g_{i}$ and $b_{j}$, which we refer to as preinteraction and post-interaction control biases, respectively. This complies with early computational models of cognitive control in which control signals act as an increase in gain of non-linear processing units (Cohen et al., 1990; Botvinick et al., 2001) and allows us to treat such control biases as key contributing factors towards the intensity cost for cognitive control. It is worth noting here that for simplicity the only sources of nonlinearity in this setting are the logistic ${ }^{2}$ activation functions which act upon the linearized output vector $\tilde{\mathbf{y}}=\left[\tilde{Y}_{1}, \tilde{Y}_{2}, \ldots, \tilde{Y}_{M}\right]$. Without loss of generality, in what follows we consider the individual features to be scalar, and carry out a formal investigation on how these control biases $\mathbf{g}=\left[g_{1}, \ldots, g_{N}\right]$ and $\mathbf{b}=\left[b_{1}, \ldots, b_{M}\right]$ influence the response from this cognitive architecture. In our formulation, the corresponding magnitude, i.e. $\|\mathbf{g}\|^{2}+\|\mathbf{b}\|^{2}$, can be treated as a measure of control intensity applied to the system, and therefore the cost for cognitive control.

We begin our analysis by assuming the vector of features $\mathbf{s}=\left[S_{1}, S_{2}, \ldots, S_{N}\right]$ to be an $N$-dimensional multivariate Gaussian random variable with mean $\mu^{S}$ and covariance $\Sigma^{S}$. (The assumption of Gaussianity is motivated by the technical tractability). With this assumption, the vector $\left[X_{1}, X_{2}, \ldots, X_{N}\right]$ becomes an N -dimensional multivariate Gaussian random variable with a shifted mean and same covariance. Furthermore, as all the transformations (before the nonlinear logistic activation function) are linear in nature, $\left[Y_{1}, Y_{2}, \ldots, Y_{N}\right]$ also remains a multivariate Gaussian random variable whose mean and covariance are given by $\mu^{Y}=W\left(\mu^{S}+\mathbf{g}\right)$ and $\Sigma^{Y}=$ $W \Sigma^{S} W^{T}$, respectively. Similarly, the vector of linearized outputs $\left[\tilde{Y}_{1}, \tilde{Y}_{2}, \ldots, \tilde{Y}_{N}\right]$ is also a multivariate Gaussian, with a shifted mean and the same covariance.

[^164]Hence, each individual linearized output $\tilde{Y}_{i}$ is itself a Gaussian random variable with

$$
\begin{aligned}
\text { mean: } & \mu_{i}^{\tilde{Y}}=\sum_{j=1}^{N} w_{j i}\left(\mu_{j}+g_{j}\right)+b_{i} \\
\text { and variance: } & \sigma_{i i}^{\tilde{Y}}=\sum_{j=1}^{N} \sum_{k=1}^{N} w_{j i} w_{k i} \sigma_{k j},
\end{aligned}
$$

where $\mu_{j}$ is the mean of stimulus $S_{k}$ and $\sigma_{k j}$ is the covariance between stimuli $S_{k}$ and $S_{j}$. As a consequence, the corresponding output (response) will have a logit-normal distribution, and this leads us to our key result in this section.

As outlined by Shenhav et al. (2013), the response $O_{i}$ should overcome a specified threshold in order to execute the corresponding process (task). Then, by letting $\alpha_{i} \in(0,1)$ represent this activation threshold associated with output $O_{i}$, the corresponding probability of task execution (probability of the output $O_{i}$ surpassing the threshold $\alpha_{i}$ ) is expressed as

$$
P\left[O_{i} \geq \alpha_{i}\right]=\frac{1}{2}-\frac{1}{2} \operatorname{erf} \underbrace{\left(\frac{\log \left(\frac{\alpha_{i}}{1-\alpha_{i}}\right)-b_{i}-\sum_{j=1}^{N} w_{j i}\left(\mu_{j}+g_{j}\right)}{\sqrt{2 \sum_{j=1}^{N} \sum_{k=1}^{N} w_{j i} w_{k i} \sigma_{k j}}}\right)}_{f\left(\alpha_{i}, b_{i}, w, \mu, \mathbf{g}, \Sigma^{S}\right)} .
$$

Here we have exploited the monotonicity of the logistic function to compute its inverse. Then the result follows from the cumulative distribution function of $\tilde{Y}_{i}$.

We characterized the activation probability of a given network in terms of the pre-interaction and post-interaction control biases. This is crucial because it provides new directions to incorporate the cost of control into the design of a cognitive network architecture. For example, the problem of allocating a limited amount of cognitive control into different components of the network to maximize the associated probability of activation can be formulated as an optimization problem in which the goal becomes minimizing $f\left(\alpha_{i}, b_{i}, w, \mu, \mathbf{g}, \Sigma^{S}\right)$ over $\mathbf{g}$ and $\mathbf{b}$ subject to the constraints $\sum_{i=1}^{N} g_{i}^{2} \leq C_{g}$ and $\sum_{i=1}^{M} b_{i}^{2} \leq C_{b}$, where $C_{g}$ and $C_{b}$ define the maximum amount of control that can be applied. Alternatively, in this setting, we can also approach the problem of minimizing the cost of control, while still maintaining a desired value of probability of activation.

One can consider the joint distribution of the processes of interest to incorporate the effects of interaction between tasks. To be consistent with (Feng et al., 2014; Musslick et al., 2016), it is reasonable to begin with a focus narrowed to the situation where the choice of interaction weights and the prior distribution of the stimuli render the interactions undesirable. Then the effect of multitasking can measured by introducing a suitable distance metric (for example, the Kullback-Leibler divergence (Ortega \& Braun, 2013)) between the joint distributions of relevant processes and the product of corresponding marginals, and one can attempt to minimize this distance
at the expense of a limited amount of cognitive control. However, as one might expect, this optimization problem can have an empty solution set under certain values of the interaction weights and activation thresholds, meaning that certain network configurations strictly prohibit successful multitasking performance (Musslick et al., 2016). Before approaching this computation in detail, it would be beneficial to investigate how the interaction structure influences the solution space, and that leads us to our next section wherein we introduce the notion of interaction cost.

## Interaction: the cost of mapping

In this section, we will introduce a detailed formalism of the interaction cost associated with process mappings in a network configuration to accommodate the possibility for multitasking. In our earlier work (Musslick et al., 2016), we have formalized three distinct types of interference (Fig. 2).

Convergent interference (Fig. 2a) occurs when two inputs/stimuli (e.g. $S_{1}$ and $S_{2}$ ) compete to determine a common output (e.g. $O_{1}$ ). We also consider divergent interference in our analysis (Fig. 2b). Although this does not pose an impediment to performance, i.e. it is possible to generate two distinct outputs (e.g. $O_{1}$ and $O_{2}$ ) to the same input (e.g. $S_{1}$ ), it represents a restriction on the number of independent stimuli (and therefore the number of tasks) that the system can process at once, and thus was treated formally as a type of interference due to this dependency in our analysis of parallel processing capability. Finally, we consider a third, indirect interference that supervenes on the first two (shown in Fig. 2c and Fig. 2d). In this case, the two tasks with strengths $w_{11}$ and $w_{22}$ in question do not directly interfere with one another. However, their simultaneous execution would necessarily engage a third task with strength $w_{21}$ (also possibly a fourth task with strength $w_{12}$ ) that would produce interference in output $O_{1}$ (and $O_{2}$ ). While Musslick et al. (2016) treated these three types of interference identically in terms of their effect on the overall parallel processing capability of a network, the proposed interaction cost will also distinguish between these three types of interference.

In interaction cost analysis, we will assume that a stimulus is of value 1 when it is active, and 0 otherwise. Moreover, to increase tractability, we will consider linear activation at the output level, which also implies that without loss of generality the pre- and post-interaction biases can be assumed to be zero. A more detailed version of the interaction cost analysis, involving the strength of stimuli, as well as the nonlinear activation function, will be discussed in subsequent publications.

To introduce the interaction cost, we take an approach similar to the one adopted by Koechlin and Summerfield (2007). In their work, Koechlin and Summerfield (2007) proposed a metric for selecting a single action among multiple alternatives. Here, we will refine this metric to introduce the interaction cost for neural network architectures. Towards this objective, we first leverage the assumptions discussed earlier in

Figure 2: The illustration of convergent, divergent, asymmetric, and symmetric interference.
the section, and abstract out the network configurations presented in Fig. 2 from the network shown in Fig. 1. We also assume that the strength of a task $i j$ from stimulus $S_{i}$ to output $O_{j}$ is represented by its non-negative weight $w_{i j} \geq 0$.

Let us first consider the case shown in Fig. 2a. It is obvious that the response in the output component $O_{j}$ is completely determined by the stimulus if either $S_{1}$ or $S_{2}$ is activated in the network (executing a single process). However, activating both stimuli $S_{1}$ and $S_{2}$ simultaneously creates a conflict, since the output can not respond to two distinct stimuli simultaneously (as the activations are linear, the network will always have a response in the output level). In order to measure the level of this competition between stimuli, we define a random variable $a_{1}$ associated with the output $O_{1}$ such that $a_{1} \in\{1,2\}$ (Fig. 2a). This implies that $a_{1}=1$ or $a_{1}=2$ when the output $O_{1}$ is driven completely by $S_{1}$ or $S_{2}$, respectively. Since a stronger task will have a higher probability of being selected to generate the response, we consider the relative strengths of the task pathways (with associated strengths $w_{11}$ and $w_{21}$ ) in order to define the probability of the possible outcomes, i.e. the probability of $a_{1}=1$ and $a_{1}=2$ when both $S_{1}$ and $S_{2}$ activated. Hence, we compute the probability as

$$
P\left[a_{1}=1\right]=\frac{w_{11}}{w_{11}+w_{21}}, \quad \text { and, } \quad P\left[a_{1}=2\right]=\frac{w_{21}}{w_{11}+w_{21}} .
$$

Next, we extend this framework to consider networks with $N$ stimuli and $M$ outputs, wherein an output $O_{j}, j \in$ $\{1, \ldots, M\}$ responds to a set of stimuli. Let us assume that there are $n \leq N$ incoming edges to a particular output $O_{j}$, and each edge is originated from a distinct stimulus $S_{i}, i=$ $i_{1}, \ldots, i_{n}$, where $i_{k} \in\{1, \ldots, N\}$. Then the probability of the event that output $O_{j}$ is responding to stimulus $S_{i}$ is given by,

$$
\begin{equation*}
P\left[a_{j}=i\right]=\frac{w_{i j} \mathbb{1}\left(S_{i}\right)}{\sum_{k=1}^{n} w_{i_{k} j} \mathbb{1}\left(S_{i_{k}}\right)}, \tag{1}
\end{equation*}
$$

where $\mathbb{1}\left(S_{i}\right)$ is the indicator function that represents the activation of stimulus $S_{i}$ such that $\mathbb{1}\left(S_{i}\right)=1$ if stimulus $S_{i}$ is active and $\mathbb{1}\left(S_{i}\right)=0$, otherwise. Then, by building upon the ideas proposed by (Koechlin \& Summerfield, 2007), we define the interaction cost as

$$
\begin{equation*}
\Psi\left(a_{j}=i\right)=-\log \left(P\left[a_{j}=i\right]\right) \tag{2}
\end{equation*}
$$

where the logarithm is with respect to base 2.

Equation 1 implies the $P\left[a_{j}=i\right]=1$ when only the relevant stimulus $S_{i}$ associated with task $i j$ is activated in the network. Hence the interaction cost is computed as $\Psi\left(a_{j}=\right.$ $i)=0$ which implies that there is no interaction cost. Moreover, when multiple processes are competing due to the activation of multiple stimuli, $P\left[a_{j}=i\right] \rightarrow 0$ as the competition increases, and as a consequence the interaction cost $\Psi\left(a_{j}=i\right) \rightarrow \infty$.

We further extend equation 1, to encapsulate the probability associated with parallel processing of task pathways in the network. Thus, we introduce the joint probability of distinct output components responding to a set of stimuli. For instance, let us consider the parallel processing of tasks with strength $w_{11}$ and $w_{21}$ in Fig. 2a, and calculate $P\left[a_{1}=1, a_{1}=2\right]$. This is the probability of output component $O_{1}$ responding to both $S_{1}$ and $S_{2}$, and by definition we know that this probability is zero. For the case illustrated in Fig. 2b, the joint probability $P\left[a_{1}=1, a_{2}=1\right]=1$ since activation of $S_{1}$ will activate both processes with strengths $w_{11}$ and $w_{12}$, and there is no competition in outputs $O_{1}$ and $O_{2}$. This result is parallel to the observation made by (Musslick et al., 2016), who stated that divergent interference is not actually an interference but a dependency on the stimuli.

Now let us consider the case introduced in Fig. 2c which can be thought of as the composition of the two cases presented in Fig. 2a-b. We compute the interaction cost of parallel processing the tasks with strengths $w_{11}$ and $w_{22}$. This requires simultaneous activation of $S_{1}$ and $S_{2}$, which indirectly engages the task with strength $w_{21}$, and initiates a competition in the output $O_{1}$. Thus, the interaction cost of parallelism between tasks represented by $w_{11}$ and $w_{22}$ is given by

$$
\begin{aligned}
\Psi_{1}\left(a_{1}=1, a_{2}=2\right) & =-\log \left(P\left[a_{2}=2\right] \cdot P\left[a_{1}=1 \mid a_{2}=2\right]\right) \\
& =-\log \left(1 \cdot \frac{w_{11}}{w_{11}+w_{21}}\right)
\end{aligned}
$$

Here $P\left[a_{2}=2\right]=1$ since task with weight $w_{22}$ is not competing with any other process in the output $O_{2}$. The competition, however, takes place in $O_{1}$, and the interaction cost associated with $w_{11}$ for this case has already been computed when we discussed the case in Fig. 2a.

In a similar way, we can compute the interaction cost of parallelism between tasks represented by $w_{11}$ and $w_{22}$ in Fig. 2d, and we have

$$
\begin{aligned}
\Psi_{2}\left(a_{1}=1, a_{2}=2\right) & =-\log \left(P\left[a_{2}=2\right] \cdot P\left[a_{1}=1 \mid a_{2}=2\right]\right) \\
& =-\log \left(\frac{w_{11}}{w_{11}+w_{21}} \cdot \frac{w_{22}}{w_{22}+w_{12}}\right)
\end{aligned}
$$

In this case, simultaneous activation of $S_{1}$ and $S_{2}$ causes competition in both outputs $O_{1}$ and $O_{2}$. Thus, by revealing further insight about the strength and directionality of interference, the interaction cost serves as an extension of the interference definition presented by (Musslick et al., 2016). For instance, for the same values of $w_{11}, w_{21}, w_{22} \geq 0$ in both configurations in Fig. 2c-d, and given $w_{12} \geq 0$ for the configuration in

Fig. 2d, it is obvious that

$$
\Psi_{1}\left(a_{1}=1, a_{2}=2\right) \leq \Psi_{2}\left(a_{1}=1, a_{2}=2\right)
$$

## Neural Network Simulation

In order to investigate the effect of directionality for the third indirect interference during parallel processing, we implemented a synthetic neural network simulation ${ }^{3}$ identical to our earlier work (Musslick et al., 2016). The neural network used for this simulation maps stimulus input encoded at a stimulus layer via a non-linear associative layer to nonlinear response layer. A separate task input layer encodes the current task to be performed with respect to that stimulus and projects to both the associative layer and response layer. Units in the stimulus layer were grouped into six stimulus dimensions with three units per dimension. Similarly, units in the response layer was grouped into six response dimensions with three units per dimension. The network was trained on 12 tasks, where each task corresponds to a one-to-one mapping between a subset of three input features in a stimulus layer to a subset of three response units in an output layer.

We then used the methods described in Musslick et al. (2016) to extract a bipartite task graph from single representations encoded at the associative layer. The representations associated with each task can be characterized by calculating, for each unit in the associative and output layers, the mean of its activity over all of the stimuli for a given task; this mean pattern of activity can then be used as a representation of the task. Correlating these patterns of activity across tasks yields a task similarity matrix that can be examined separately for the associative and output layers of the network. This can then be used to assess the extent to which different tasks rely on similar or different representation within each layer of the network. Tasks that have similar representations over the associative layer can be inferred to rely on the same input dimension that is, they share an input component in the bipartite graph representation of the network and tasks that are similar at the output layer can be inferred to share an output component. Accordingly, a bipartite graph can be constructed by measuring the patterns of activity observed in the network while it performs each individual task.

The extracted bipartite graph can be used to extract interference patterns between pairs of tasks (cf. Fig. 2). We use this to extract all possible learned task-pairs involving no interference case (Fig. 3a), and two distinct cases of interference as shown in Fig. 3b and Fig. 3c from single-task representations. Fig. 3 shows the activation patterns of the output units for the simultaneous execution of two tasks, averaged across the patterns of all task pairs for a given interference structure. That is, no interference (Fig. 3a) leads to very accurate response patterns (i.e. the current activation shown in orange) is very close to the desired activation pattern shown in grey). For the case in Fig. 3b, the response pattern of task $\left(S_{1}: O_{1}\right)$ is primarily impaired due to the interference aris-

[^165]ing from task $\left(S_{2}: O_{1}\right)$. However, for the case of interference illustrated in Fig. 3c, the response patterns for both tasks $\left(S_{1}: O_{1}\right)$ and ( $S_{2}: O_{2}$ ) are impaired as observed by the activation patterns. These simulation results reflect the influence of the directionality of interference between tasks as predicted by the proposed interaction cost.

Figure 3: This figure illustrates the performance of a task-pair for a given interference pattern. Each tasks maps a subset of three stimulus input units onto three response units (see text). The orange color in the bar plots indicates unit activation of response units relevant to the depicted tasks, while gray indicates desired response pattern of those units.

## General Discussion and Conclusion

In this study, we have introduced two new measures to determine costs associated with intensity and interaction for the demand on control. First, we quantify the intensity cost as a function of the amount of control bias that is supplementary to stimulus-specific processing in order to achieve a desired response from the network. Doing so, we formalize the probability of achieving a desired task given the stimulus, weights and biases infused to the network. Since the stimuli and weights are considered as network properties, the intensity cost to achieve desired response is defined as the amount (value) of control biases required to be injected to the input and output components of the network. The detailed analysis of intensity cost revealed an interesting optimization problem to maximize the probability of surpassing a specified activation for a given budget of resources (i.e. an upper bound on the control biases). The existence of a solution of this optimization problem implicitly reveals whether the desired objective is feasible. However, as it can be foreseen that under certain circumstances the solution does not exist due to interference between the involved processes. Such boundary conditions motivated the second metric introduced in our paper in which we formalize the interaction cost to measure the level of interactions/interference between processes by means of their type of connections and weights.

With the introduced characterization of intensity and interaction costs, it is possible to formally define whether a process is considered a reflex, automatic or controlled. Concretely, a process is considered a reflex if the underlying weight guarantees a successful execution. In other words, a reflex can be successfully executed without any intensity or interaction costs. We assume that the execution of both controlled and automatic processes carries with it an intensity cost as some amount of control bias is needed to elicit a response. However, unlike the former, controlled processes are
subject to interference and thus yield interaction costs large than zero.

The metrics proposed here can also be used towards further understanding cognitive effort as well as synthetic neural networks designed to achieve goal-driven tasks. By using the intensity cost, which reveals the interrelationship between control bias and probability of achieving a desired objective, we will investigate the limitations of any given neural network architecture by allocating a budget of control bias. The intensity cost can also be used to investigate the feasibility of achieving a desired objective defined by the set of processes of interest in a network.

In the interaction cost analysis, we have assumed that there exist a response in the output for any stimulus activation and this may not be the case for a nonlinear activation in the output components. Hence, one major research direction is the detailed analysis for the classification of processes with nonlinear activation in output. Another possible direction for future work is to further analyze the interaction cost in order to capture the properties of the overall network (not only a subset of tasks of interest). This will allow one to use the interaction cost as an objective function for network training. Another possible direction is to explore the interrelationship between intensity and interaction cost. In our work (Musslick et al., 2016), we noticed a fundamental trade-off between shared representations in a network and its parallel processing capability (separated representations). Intuitively, we envision this separation will decrease interaction cost while increasing the likelihood of successful execution for a given budget of control bias.

## Acknowledgements

We would like to thank Zahra Aminzare, Adam Charles, Jonathan Pillow and Vaibhav Srivastava for their help in the formalism of the problem.

# Optimization of American English, Spanish, and Mandarin Chinese over time for efficient communication 

John K Pate (johnpate@buffalo.edu)<br>Department of Linguistics, 609 Baldy Hall<br>Buffalo, NY 14260 USA

#### Abstract

Frequent words tend to be short, and many researchers have proposed that this relationship reflects a tendency towards efficient communication. Recent work has sought to formalize this observation in the context of information theory, which establishes a limit on communicative efficiency called the channel capacity. In this paper, I first show that the compositional structure of natural language prevents natural language communication from getting close to the channel capacity, but that a different limit, which incorporates probability in context, may be achievable. Next, I present two corpus studies in three typologically-diverse languages that provide evidence that languages change over time towards the achievable limit. These results suggest that natural language optimizes for efficiency over time, and does so in a way that is appopriate for compositional codes.

Keywords: Communicative efficiency; Uniform Information Density; Smooth Signal Hypothesis; Noisy channel

## Introduction

Natural language researchers have long been interested in the prospect that natural language is organized for efficient communication: frequent words tend to be shorter than rare words, allowing talkers to produce shorter word-forms on average. More recent work (Plotkin \& Nowak, 2000; Genzel \& Charniak, 2002; Aylett \& Turk, 2004; Levy \& Jaeger, 2007; Jaeger, 2010; Piantadosi, Tily, \& Gibson, 2011; Seyfarth, 2014) has sought to formalize this work in the context of information theory by proposing that natural language communicates information close to a limit called the channel capacity, although it has left open the question of how closely the limit is approached.

In this paper, I first show that it is not possible for a compositional code like natural language to transmit information close to the channel capacity. Specifically, average signal lengths must exceed the entropy of the distribution over messages by at least the Kullback-Leibler divergence of the true probability distribution over messages from a fully-factorized probability distribution in which every component of the message is statistically independent. Natural language communication must then underperform the channel capacity by at least this Kulback-Leibler divergence.

However, in light of recent work (Piantadosi et al., 2011) that showed a stronger relationship between a word's length and its average probability in context than its unigram probability, I investigate the possibility that language changes over time so that the optimal length of a word, as computed from its average probability in context, better matches its actual length. I present two corpus studies over 350 years in American English, Spanish, and Mandarin Chinese that compare
actual word lengths to optimal word lengths in context and in isolation. The first 'backward-looking' study computes optimal word lengths using modern-day language data, and finds that the mismatch between optimal and actual word lengths is smaller for older words. Moreover, the mismatch drops more rapidly, as a function of word age, when the optimal word length is computed relative to a context-sensitive trigram model than when it is relative to a unigram model.

The second 'forward-looking' study divides the 350-year period into 25-year partitions, uses language data from each partition to compute optimal word lengths for each partition, and trains a regression model to predict whether the wordform appears in the next 25-year partition as a function of the mismatch between the word's actual length and its optimal length. This study finds that words with larger mismatches are less likely to 'survive' to the next partition, and moreover finds a stronger effect of mismatch relative to the contextsensitive trigram model than relative to the unigram model. Together, these two studies provide evidence that natural language lexicons change over time in a way that reflects communicative efficiency pressures on a compositional code.

I start by presenting previous work on informationtheoretic approaches to language production, along with the minimal technical background necessary for this paper. I then show why natural language does not approach informationtheoretic bounds, and use this result to suggest a new bound for compositional codes that may be achievable by considering probability in context. Finally, I present two corpus studies that find evidence that three typologically-diverse languages have changed to approach this new bound.

## Background

Linguists have proposed that language is adapted for communication in a general sense for decades. Zipf (1949) proposed the 'Principle of Least Effort' to explain the observation that frequent words tend to be short: frequent words tend to be short so that talkers usually only have to say short words. Lindblom (1990) proposed Hyper- \& Hypo-articulation theory to explain the observation that vowels in careful speech tend to be less centralized in formant space: talkers provide more distinct vowels when they believe errors are more likely.

Plotkin and Nowak (2000) proposed an explicit model of word formation over the course of language change in an information-theoretic framework, and showed, analytically and via simulation, that it approached information-theoretic bounds as the vocabulary size increases. However, their model considered words in isolation, but natural language ut-
terances consist of sequences of words. This paper will show that codes with the compositional structure that characterizes natural language cannot approach these information-theoretic bounds, and focus on optimizing sentence lengths.

Subsequent work has mainly consisted of corpus studies that show that synchronic samples of natural language exhibit the correlations on would expect, under an informationtheoretic account, between different measures of word length or distinctiveness and word probability, both overall and in context (Aylett \& Turk, 2004; Frank \& Jaeger, 2008; Bell, Brenier, Gregory, Girand, \& Jurafsky, 2009). Piantadosi et al. (2011) revisited Zipfian distributions, and compared both log word probability and average $\log$ word probability in context, operationalized as a trigram model, with word lengths, operationalized as the length of the word's spelling in letters. They found that, of the two probability measures, average log probability in context exhibited a stronger correlation with word lengths. At first glance, this result would seem to contradict an information-theoretic approach: the optimal length of a word in isolation simply is its negative log probability, with an appropriate choice of base for the logarithm. However, I soon show that average probability in context is a more appropriate measure for optimizing sentence lengths.

In this paper, I return to Plotkin and Nowak's (2000) proposal that language adapts towards these bounds over time, using a corpus-based methodology and an emphasis on the relationship between words and their sentential contexts.

## Information theory

In the information-theoretic framing of language, a talker has a message $m$ that is a sequence of message characters $m_{i}$ from some alphabet of message characters $\mathcal{M}$. For example, $\mathcal{M}$ may be the set of lexical entries or, as in CCG, a set of (syntactic category, semantic category) pairs. The message cannot be transmitted directly, so the talker encodes it into a signal $s$ that is a sequence of signal characters $s_{i}$ from some alphabet of signal characters $\mathcal{S} .{ }^{1}$ For example, $\mathcal{S}$ may be the inventory of syllables or phonemes of the language.

An efficient code has two properties. First, it is short: the number of signal characters per message character, on average, is low. Second, it is robust: the probability that the listener fails to identify the correct message is low. The length of the shortest possible code depends only on the probability distribution over messages $P(\boldsymbol{m})$, and is given by the entropy of that distribution:

$$
\begin{equation*}
H(\boldsymbol{m})=\sum_{m \in \boldsymbol{m}} P(m) \log _{b}\left(\frac{1}{P(m)}\right) \tag{1}
\end{equation*}
$$

where $\boldsymbol{m}=\mathscr{M}^{+}$is the set of all messages (i.e. all sequences of message characters). The log term is called the Shannon information of $m$, and the entropy is just the expected Shannon information under the probability distribution $P(m)$. If we set

[^166]$b$ to be the size of the signal alphabet $|S|$, then the Shannon information of $m$ is the optimal signal length in signal characters for message $m$. Adjusting signal lengths to match the Shannon entropy, called source coding eliminates redundancy in the code, and achieves property 1 : short codes.

Listeners may encounter noise in real-world situations, due to slips of the tongue on the part of the talker, distraction or cognitive overload on the part of the listener, dialect differences, environmental noise, or other sources of noise. Noise can be countered by adding redundancy to the signal. For example, a word may differ from all other words by several phonemes, allowing the listener to recover the intended word even if some phonemes are mis-perceived or masked by environmental noise. While the resulting code is more robust, it is also longer, and we might worry that signals will have to become arbitrarily long to drive the error rate toward zero.

The Noisy Channel theorem shows that an arbitrarily low error rate can be achieved with signals that are not arbitrarily long, as long as they do not exceed the channel capacity (Shannon, 1948). The channel capacity depends on both $H(\boldsymbol{m})$ and the uncertainty about the intended signal, given the received signal. Adding redundancy, such as pronouncing words more slowly, that anticipates likely noise is called channel coding, and makes signals robust but still short.

For our purposes, the crucial observation is that it is not possible to get arbitrarily close to the channel capacity if it is not possible to obtain a source code that is arbitrarily close to the entropy of the distribution over messages. The next section shows that, for compositional codes like natural language, optimal source coding is not possible. ${ }^{2}$

## Compositional codes and optimality

This section shows that optimal source coding is not possible for a compositional code like natural language. If a code is optimal and compositional, then it follows that the components of every message are statistically independent. However, this is not true for natural language, since, e.g., transitive verbs tend to appear with at least two noun phrases.

By 'compositional,' I mean only that natural language messages consist of components that are realized the same way across different messages, and that the length of the signal for a message is the total length of the signal for each component of that message. Setting $l_{m}$ to be the length of the signal for message $m$ and $l_{m_{i}}$ to be the length of the signal for component $m_{i}$, compositionality provides:

$$
\begin{equation*}
l_{m}=\sum_{i=1}^{|m|} l_{m_{i}} \tag{2}
\end{equation*}
$$

For example, if a message is a sequence of lexical entries, and a signal is a sequence of phones, then Equation 2 says that the length of a sentence in phones is the sum of the lengths

[^167]of the phonological forms of the lexical entries in that sentence. ${ }^{3}$ Equation 2 is not trivial. Arithmetic codes, for example, encode each message as a number between 0 and 1 that is determined by the conditional probability of each message character given the previous message characters; an individual message character is not directly expressed in any part of the signal, and $l_{m_{i}}$ is not even defined.

Now assume that the length of the sentence $l_{m}$ for each message $m$ is optimal. Because the optimal signal length for a message $m$ is $-\log _{b}(P(m))$, the probability distribution over messages $P_{\boldsymbol{m}}$ can be recovered from $l_{m}$ by exponentiating:

$$
\begin{equation*}
P_{\boldsymbol{m}}(m)=b^{-l_{m}} \tag{3}
\end{equation*}
$$

Since only sentence lengths are assumed to be optimal, component signal lengths $l_{m_{i}}$ may not be negative $\log$ probabilities. They do, however, assume an implicit distribution for which they are least sub-optimal (MacKay, 2003, Ch. 5):

$$
\begin{equation*}
Q_{m}\left(m_{i}\right)=\frac{b^{-l_{m_{i}}}}{z} ; z=\sum_{m_{i} \in \mathcal{M}} b^{-l_{m_{i}}} \tag{4}
\end{equation*}
$$

Equations 2, 3, and 4 imply that each message component is statistically independent:

$$
\begin{align*}
P_{\boldsymbol{m}}(m) & =b^{-l_{m}}=b^{\Sigma_{i=1}^{|m|}-l_{m_{i}}}=b^{\Sigma_{i=1}^{|m|} \log _{b}\left(z Q_{m}\left(m_{i}\right)\right)}  \tag{5}\\
& =z^{|m|} \prod_{i=1}^{|m|} Q_{m}\left(m_{i}\right) \stackrel{\text { def }}{=} Q_{\boldsymbol{m}}(m) \tag{6}
\end{align*}
$$

There does not seem to be any notion of message in natural language that allows for statistically independent message components. For example, messages may be high-level event representations, but such messages that include transfer tend to include at least three entities (a giver, a receiver, and a thing being transferred), and such messages that include edible entities tend to include entities that can eat. Alternatively, messages may be syntactic analyses, but such messages with a determiner tend to have at least one noun, and such messages with a complementizer tend to have at least two main verbs. While other framings are possible, they do not appear to satisfy the independence assumption above. Thus, natural language is not information-theoretically optimal.

More specifically, the average signal length of the best compositional source code must exceed the entropy of the true distribution over messages $P_{\boldsymbol{m}}$ by at least the KullbackLeibler divergence of the fully factorized distribution $Q_{m}$ from the true distribution:

$$
\begin{equation*}
H\left(P_{\boldsymbol{m}}\right)+\mathrm{KL}\left(P_{\boldsymbol{m}} \| Q_{\boldsymbol{m}}\right) \tag{7}
\end{equation*}
$$

Intuitively, language uses at least an extra $\operatorname{KL}\left(P_{\boldsymbol{m}} \| Q_{\boldsymbol{m}}\right)$ signal characters per message character because it incorrectly assumes the message characters are statistically independent.

[^168]
## Optimizing towards the new bound

While the bound in Equation 7 shows that natural language does not approach the channel capacity, natural languages may still adapt over time for communicative efficiency towards the less efficient bound. In fact, the findings of Piantadosi et al. (2011) suggest that languages adapt to minimize $\mathrm{KL}\left(P_{\boldsymbol{m}} \| Q_{\boldsymbol{m}}\right)$. Piantadosi et al. examined how a word's length (in orthographic letters) relates to its unigram probability and its probability in context (operationalized as a smoothed trigram model). Across all eleven languages they examined, word lengths had a stronger relationship with average probability in context than unigram probability.

I propose the following interpretation of their result. Message characters are lexical entries, signal characters are orthographic letters, and probability in context is $P_{m}$. While $Q_{m}$ is determined by word lengths, $P_{m}$ is determined by a stochastic grammar and lexicon together with typical real-world situations. Their results suggest that, as a speech community gains experience with the use of lexical entries in real-world situations, the grammar, including the lexicon, adapts so that $P_{m}$ is better approximated by $Q_{m}$. This adaptation could be achieved by adjusting the grammar, narrowing or broadening word meanings, or deleting lexical entries whose length often differs substantially from their optimal in-context length.

The next two sections present corpus studies that look at adaptation of this sort over centuries in three languages.

## Corpus studies

I now present two corpus studies that find evidence of optimization relative to probability in context over time for English, Spanish, and Mandarin Chinese. The first 'backwardslooking' study relates a word's mismatch with its optimal length to its age. If the lexicon evolves over time for efficient communication, the lengths of oldest words should most closely match their optimal lengths. Moreover, to the extent that efficiency pressures respect sentence length, there should be a stronger relationship between a word's age and its mismatch with optimal lengths under a trigram model than between a word's age and its mismatch under a unigram model.

The 'forwards-looking' study uses a sequence of language models, estimated in 25-year partitions, to predict whether a word appears in the next partition based on how well its length matches its optimal length under each language model. If language change reflects efficiency pressures, words with many extra characters should be less likely to remain in use; and if efficiency pressures respect sentence lengths, the effect of mismatches under trigram models should be stronger.

## Corpus study 1 - Looking backwards

In this study, I used a large dataset containing texts from about 1990 to about 2010 for each of the three languages to compute synchronic unigram and trigram language models for each language. The language models are used to compute optimal lengths for each word in and out of context by subtracting the optimal lengths from the actual lengths to quantify extra characters. I used Google books, a dataset of scanned books, to

Table 1: Study 1 dataset sizes

|  | Language Model | Regression |  |
| :--- | :--- | :--- | :--- |
| Dataset | Tokens | Unigrams | Trigrams |
| English | $71,531,906$ | 81,742 | $24,965,851$ |
| Spanish | $279,744,284$ | 545,708 | $74,144,973$ |
| Chinese | $26,800,660$ | 3,182 | $13,642,166$ |

Figure 1: Heatmaps of actual length minus optimal word length for trigram (left) and unigram (right) models, as a function of the word's earliest appearance in Google books. The blue line is a GAM fit.
estimate when each word of the synchronic time slice first appeared, and perform a regression of the extra character measure against year of first appearance, probability model type, and their interaction, to identify how word length inefficiency varies as a function of word recency and probability model type. A positive coefficient for year of appearance will indicate that more recent words are longer than they should be, and a negative coefficient for the interaction will indicate a stronger relationship between year of appearance and inefficiency relative to a trigram model than between year of appearance and inefficiency in isolation.
Data I approximated a word's year of first appearance as the first year that it appeared in the Google Books unigram records in each language (Michel et al., 2010).

To estimate the American English language models, I used the spoken portion of the Corpus of Contemporary American English (CoCA) (Davies, 2008), which contains news broadcasts from 1990 to 2012. To estimate the Spanish and

Chinese language models, I used 'story' documents from the $3^{\text {rd }}$ edition of the Spanish Gigaword dataset of newswire text from 1993 to 2010 (Ângelo Mendonça, Jaquette, Graff, \& DiPersio, 2011) and the Tagged Chinese Gigaword version 2.0 dataset of newswire text from 1991 to 2004 (Ren Huang, 2009), respectively. While written Chinese does not separate words with whitespace, this dataset is segmented into words.

For each language, I discarded punctuation and words that contained a symbol that was not part of the usual character set for that language, estimated unsmoothed trigram and unigram probabilities. The datasets for regression were obtained by discarding words that did not appear in Google Books after 1650, producing datasets with sizes as reported in Table 1.

These particular languages were chosen because they appeared in Google Books, allowing us to obtain an estimate of word age, and because they use words in very different ways. Spanish has relatively rich derivational and inflectional morphology, with agreement for person and number for verbs and number and gender for adjectives. While English also has relatively rich derivational morphology, it has little inflectional morphology with few agreement constraints. Mandarin Chinese occupies a morphological extreme, with no inflectional morphology or agreement.

Method For each word token in CoCA and Gigaword datasets, I computed the optimal length of the word under its unigram probability and probability in context, operationalized as its trigram probability. The numbers of 'extra' letters relative to each model $e_{\text {uni }}$ and $e_{\text {tri }}$ are then the actual length minus the optimal length:

$$
\begin{aligned}
e_{\mathrm{uni}}(w) & =l(w)-\left(-\log _{b}(P(w))\right) \\
e_{\mathrm{tri}}\left(w_{i} \mid w_{i-2}, w_{i-1}\right) & =l\left(w_{i}\right)-\left(-\log _{b}\left(P\left(w_{i} \mid w_{i-2}, w_{i-1}\right)\right)\right)
\end{aligned}
$$

where $b$ is the size of the signal alphabet. English and Spanish both have a mostly alphabetic orthography, with roughly one letter per sound, so I simply set $b$ to the number of distinct letters in these datasets. For English $b=27$ (a-z plus hyphen), and for Spanish, $b=33$ (with some additional accented letters). Chinese orthography has one character per syllable, and so similarly provides a good indication of word length, but the alphabet size is more complicated. The strict phonotactics of spoken Chinese lead to a syllabic inventory of about 1,500 syllables, but our Chinese dataset contained 6,780 distinct characters (many characters are homophonous). I set $b=1,518$, the number of distinct syllables in the CEDict pronouncing dictionary, to reflect the size of the 'syllable alphabet' for spoken Chinese (CC-CEDICT, 2016). ${ }^{4}$

I performed linear regressions of extra letters against the word's year of first appearance, probability model type, and an interaction between the word's first appearance and probability model type. To make the regressions easier to interpret, I subtracted 1650 from the year of first appearance, so that the oldest words had a year of first appearance of zero.

[^169]Table 2: Coefficients of one linear regression each for American English, Mandarin, and Spanish, of extra letters (English, Spanish) or extra characters (Mandarin) against first appearance, a main effect of probability model type (with unigram coded as 1), and an interaction between first appearance and probability model. All coefficients are significant ( $p<0.01$ ).

|  | Am. English | Spanish | Mandarin |
| :--- | :--- | :--- | :--- |
| Intercept | 3.289 | 4.408 | 1.067 |
| Year of first appearance (since 1650) | 0.006481 | 0.007399 | 0.00214 |
| Which language model | -0.491 | -2.506 | -1.288 |
| Years of first appearance (since 1650) $\times$ Which language model | -0.001465 | -0.001438 | -0.000349 |

Results Figure 1 presents hexagram-binned heatmaps with a Generalized Additive Model fit for each language of extra letters against year of first appearance, separated by language model. All cases show a broad trend where older words have fewer extra letters. The trend is roughly linear except for the latest decades; information-theoretic pressures may be different for recently-coined words.

Table 2 presents coefficients from the three regressions of extra characters against a word's year of first appearance, the probability model used, and their interaction. Each intercept expresses the number of predicted extra letters or characters under the trigram model for words that first appeared in 1650. Adding the 'Which Language Model' coefficient to the intercept obtains the predicted extra letters or characters under the unigram model for words that first appeared in 1650.

The 'Year of first appearance' coefficient expresses how many extra characters we expect a word to have for each year that it is younger than the oldest words. For all three languages, this coefficient is positive, indicating that younger words tend to be longer, than older words, relative to their ideal length under the trigram model. Dividing this coefficient into 1 obtains how old we expect a word to be before an additional letter or character has been 'optimized' away. American English optimizes one letter every 154 years, Spanish optimizes one letter every 135 years, and Mandarin Chinese optimizes one character every 467 years. ${ }^{5}$

Finally, the interaction between year of first appearance and model type expresses the effect of a word's year of appearance under the unigram model minus the effect of a word's year of appearance under the trigram model. The coefficients are negative but smaller in absolute magnitude than 'Year of first appearance,' which indicates that first appearance still has a lengthening effect relative to the unigram model, but a weaker one. American English optimizes an extra letter relative to the unigram model only every 199 years, Spanish optimizes an extra letter only every 168 years, and Mandarin optimizes an extra character only every 558 years.

These results show that words that first appeared in books recently tend to be further from their informationtheoretically optimal lengths than words that first appeared in books several decades ago, and so provide evidence of optimization of the lexicon towards efficiency bounds.

[^170]Moreover, the extra characters relative to the trigram model decreased faster than the extra characters relative to the unigram model. This is a remarkable finding, since it is much harder to optimize for the trigram model - there are many trigram contexts but only one unigram 'context,' and, under this operationalization of 'word,' a word has only one length. However, as previously discussed, there are good reasons to optimize towards a context-sensitive probability model. Communicative efficiency ultimately depends on sentence lengths, not word lengths directly, so considering context can make sentences shorter even if it does not minimize the typical length of individual words.

## Corpus study 2 - Looking forwards

This corpus study looks for evidence that a word is less likely to remain in use if it has more extra characters. For each language, I divided the 350 years of Google Books data described above into 14 partitions of 25 years each, and estimated a unigram and a trigram language model for each of the first 13 partitions to compute extra characters for each word and trigram in each partition under each probability model. To guard against OCR errors in Google Books, I computed extra characters only for words that also appeared in the language model datasets from Study 1. I then performed a logistic regression that predicted whether each word that appeared in partition $n$ also appeared in partition $n+1$ using the extra characters measure, probability model type, and an interaction between extra characters and the probability model type.

Results Table 3 presents strikingly consistent regression results across the three languages. The large intercepts indicate that most words carry over from one partition to the next. As the unigram model is again coded as 1 , the negative main effect of extra characters indicates that words with more extra letters relative to a given partition's trigram model are less likely to persist in the next 25-year partition. Moreover, the positive coefficient of the interaction indicates that the effect of extra letters relative to the unigram model is weaker: the coefficients suggest the effect of unigram mismatch is about half the effect of trigram mismatch in English, two-thirds in Spanish, and about one-third in Mandarin.

## Conclusion

This paper has answered an important question about natural language communication, whether talkers approach information-theoretic limits on efficiency, in the negative. Be-

Table 3: Coefficients of a logistic regression each for American English, Mandarin, and Spanish, of appearance in the next 25year partition against extra letters or characters, a main effect of probability model type (unigram coded as 1), and an interaction between extra characters and probability model. All coefficients are significant ( $p<0.01$ ).

|  | Am. English | Spanish | Mandarin |
| :--- | :--- | :--- | :--- |
| Intercept | 11.772 | 7.477 | 10.415 |
| Extra letters or characters | -0.316 | -0.320 | -2.360 |
| Which language model | -1.015 | -0.852 | -2.415 |
| Extra characters $\times$ Which language model | 0.165 | 0.101 | 1.713 |

cause language is compositional and natural language messages are highly interdependent, natural language cannot approach information-theoretic limits on efficiency. I have used this result to propose a new bound that appreciates probability in context, and interpreted a previous result as evidence that languages optimize for this more appropriate bound.

I then performed two corpus studies that examined how the mismatch between a word's actual length and its optimal length relates to its preservation over the course of language change. The first 'backwards-looking' study found, using optimal lengths computed using fairly homogenous modern-day corpus data, that present-day words more closely match their optimal lengths if the word has been in use for a long time. Moreover, this first study found that the mismatch according to probability in context decreased more rapidly as words age. The second 'forwards-looking' study found that if a word's length more closely matches its optimal length under a language model computed in one 25 -year partition, it is more likely to be retained in the next 25 -year partition. Moreover, extra letters relative to probability in context was a stronger predictor than extra letters relative to a unigram model. Together, these results indicate that natural language lexicons develop over time towards an information-theoretic efficiency bound that is appropriate for compositional codes.

## Acknowledgements

I thank Rui Chaves for feedback on a very early draft, and anonymous reviewers for helpful comments.

# Relational Concept Learning via Guided Interactive Discovery 

John D. Patterson ${ }^{1}$ (jpatter4@binghamton.edu)<br>David Landy ${ }^{2}$ (dlandy@indiana.edu) Kenneth J. Kurtz ${ }^{1}$ (kkurtz@binghamton.edu)<br>${ }^{1}$ Department of Psychology, Binghamton University, 4400 Vestal Parkway East, Binghamton, NY 13905 USA<br>${ }^{2}$ Department of Psychological and Brain Sciences, Indiana University, 1101 East 10th Street Bloomington, IN 47405 USA

#### Abstract

A key goal in both education and higher-order cognition research is to understand how relational concepts are best learned. In the current work, we present a novel approach for learning complex relational categories - a low-support, interactive discovery interface. The platform, which allows learners to make modifications to exemplars and see the corresponding effects on membership, holds the potential to augment relational learning by facilitating self-directed, alignably-different comparisons that explore what the learner does not yet understand. We compared interactive learning to an identification learning task. Participants were assessed on their ability to generalize category knowledge to novel exemplars from the same domain. Although identification learners were provided with seven times as many positive examples of the category during training, interactive learners demonstrated enhanced generalization accuracy and knowledge of specific membership constraints. Moreover, the data suggest that identification learners tended to overgeneralize category knowledge to non-members - a problem that interactive learners exhibited to a significantly lesser degree. Overall, the results show interactive training to be a powerful tool for supplementing relational category learning, with particular utility for refining category knowledge. We conclude with implications of these findings and promising future directions.

Keywords: relational categories; structural alignment; discovery learning; category learning; generalization

## Introduction

A key aim of higher-order cognition research is to understand the mechanisms that undergird the ability for humans to acquire and use abstract, complex categories. The literature in concepts and categories research has primarily been devoted to the study of attribute categories categories whose members possess a set of independent features by which they can be classified. Research on attribute category learning has unequivocally advanced our understanding of human concept acquisition and its many facets.

However, much of the category knowledge we possess is not reducible to knowledge of specific attributes - myriad concepts such as positive feedback loop are abstract, attribute-agnostic, and dependent on relationships rather than features. Fittingly, an increasing amount of empirical attention has been granted to the study of relational categories (Gentner \& Kurtz, 2005; Markman \& Stilwell, 2001). Relational categories are rule-like categories whose members share a common relational structure characterized by extrinsic relationships between objects and/or attributes (e.g., protection, sibling, reciprocity). Because relational
categories need only share a relational structure to belong, members of a category can be quite featurally disparate (e.g., your sibling and your dog's sibling hopefully don't look alike). In this way, relational category members share analogical similarity. It should be noted that relational categories are not an idiosyncratic facet of category learning - roughly half of the 100 highest frequency nouns are relational (Asmuth \& Gentner, in press). Thus, to understand human category learning generally, it is critical to understand relational category learning.

A question that bears both theoretical and applied import is: how do we come to acquire relational category knowledge? Previous research has explored the potential for comparison to promote relational discovery and transfer. This work follows from a large body of research showing the benefits of comparison to analogical transfer (Gick \& Holyoak, 1983; Loewenstein, Thompson, \& Gentner, 1999; see also Alfieri, Nokes-Malach, \& Schunn, 2013 for a metaanalysis and review). Studies of comparison with relational categories have largely corroborated findings from the analogical transfer literature; presenting same-category pairs (Patterson \& Kurtz, 2015) or a mixture of same- and different-category pairs (Kurtz, Boukrina, \& Gentner, 2013) during training leads to enhanced learning and transfer over sequential item presentations. The power of comparison can be understood through a process of structural alignment (Markman \& Gentner, 1993). Comparing instances facilitates the alignment of their parallel relational predicates. This serves to highlight common relational structure that is not salient when either instance is considered in isolation. Additionally, comparison facilitates abstraction, which promotes later analogical retrieval and transfer.

As many of the core concepts taught in educational settings are relational in nature (e.g., evolution by natural selection, Newton's laws), relational categories represent a key bridge between cognitive and educational research (Goldwater \& Schalk, 2016). Thus, investigating how relational categories are best learned can both palpably advance educational techniques and further basic, theoretical understandings. In the present work, we draw on an innovative area of education research that serves as a promising avenue for enhancing relational category learning: discovery learning. Discovery learning generally refers to unsupported learning where the learner actively constructs their understanding of some target information using only a set of materials or a task environment. Though many flavors of discovery have been the subject of study, a
common theme in the literature is that completely unassisted discovery approaches are not effective for learning (Mayer, 2004; for a meta-analysis see Alfieri, Brooks, Aldrich, \& Tenenbaum, 2011). Among other reasons, the large cognitive load incurred by needing to generate and explore hypotheses (Sweller, 1988) while metacognitively maintaining an idea of what is known and what needs to be known (Kirschner, Sweller, \& Clark, 2006) can present challenges for the approach. However, when some guidance is introduced (such as direct instruction - e.g., Chen \& Klahr, 1999), discovery learning can be a highly effective tool (Alfieri et al., 2011).

Discovery learning has the clear potential to augment the learning of complex relational concepts in educational settings - particularly when the target category is abstract or when classroom instruction is subpar. With a basic understanding of the target category, an interactive environment that enables learners to freely create or modify category exemplars and receive dynamic category membership feedback ought to enhance category knowledge, notably through three mechanisms. First, it would allow learners to engage in self-directed exploration that is specifically catered to what they do not understand or need further clarification on. The opportunity to select exemplars for study has been shown to confer benefits on rule-based category learning (e.g., Markant \& Gureckis, 2014). Second, the dynamic membership feedback provided by the task interface would implicitly encourage explanations about the causes underlying the effects of learners' modifications. Such self-explanation has been demonstrated to be a powerful facilitator of concept acquisition (e.g., Chi, de Leeuw, Chiu, \& LaVancher, 1994). Third, critically, a learning environment such as this should strongly engage analogical processing faculties. In modifying an exemplar and receiving membership feedback, the learner effectively creates a temporally juxtaposed comparison between the item's new state ( $s$ ) and $s-1$. Modifications that do not break membership create alignably-different, same-category comparisons. These comparisons should promote highlighting of common relational structure and facilitate abstraction. Conversely, modifications that do break membership create alignablydifferent different-category comparisons, which critically should serve to highlight membership-relevant relations.

In the present work, we explore the efficacy of a lowsupport, interactive discovery learning tool to promote the learning of complex relational categories. To avoid effects of domain knowledge, we created an artificial, multiconstraint category that served as the target of learning. Advised by the discovery learning literature and pilot data, we gave participants some support to reduce cognitive load. This support was a clear, but quite abstract, definition of the category that was given to all learners immediately prior to the learning phase. In the interactive condition, participants were given a computerized interface where they could engage in self-directed exploration of three examples of the category. We contrasted interactive training with an
identification learning control in which learners were exposed to a larger number of exemplars in the context of a member identification task. To evaluate the effectiveness of the interactive learning mode, we compared the two learning conditions on their ability to generalize category knowledge to novel exemplars. We predicted interactive learning would lead to enhanced generalization performance.

## Method

## Participants

Seventy undergraduates from Binghamton University participated to partially fulfill a course requirement.

## Materials

The training and generalization stimuli consisted of arrangements of blocks that varied in their size (small, medium, or large), color (white, gray, or dark brown), border color (black or distinctive blue), and spatial location (see Figure 1 for examples). The 'matched containment' concept instantiated by these blocks was quite complex. Category members were characterized by the presence of three or more blocks that obeyed all of the following constraints: (1) the blocks were aligned vertically or horizontally, (2) two of the involved blocks were special by sharing a distinctive blue border color, (3) the special blocks were exactly matched in their attributes, (4) the special blocks contained/flanked at least one additional 'normalbordered' block in the lineup, and (5) all of the contained, normal blocks matched the special blocks on at least one attribute (i.e., color, size, or both).

Twenty-one category members and 21 non-members were used as the stimuli for the identification condition. All members contained the category-defining core - constituted by either three (Length 3 [Len3]; two flanking, one flanked) or four (Length 4 [Len4]; two flanking, two flanked) objects - and one additional distracter block, such that all examples had length +1 blocks. The category core and distracter block were varied in their attributes (i.e., orientation of core [vertical, horizontal], spatial location, color, size) across examples to ensure an attribute-based solution was not available.

The members were comprised of six item types, each which instantiated the special-normal match constraint in a unique way. For both Len3 and Len4 stimuli, there were items whose flanked object(s) matched based on (1) color, (2) size, (3) or both color and size. For Len4 stimuli there were also items whose flanked objects consisted of (4) one color and one size match, (5) one both and one color match, or (6) one both and one size match. The item breakdown can be seen in Table 1. Since the Len4 stimuli included matching types that were distinct from those present in the Len3 stimuli, the Len4 examples were weighted on types 46 to ensure comprehensive coverage of the category for identification learners. The non-member set used was programmatically generated by randomly sampling and arranging blocks, with the constraint that two of the blocks
had to possess the distinctive border. Number of blocks was matched between the members and non-members. The interactive condition was given considerably fewer examples: one Len 3 color match and two Len 4 examples, each which had one color match and one size match.

To evaluate participants' ability to generalize their knowledge, a distinct set of 30 members and 30 nonmembers was created. The members were sampled from several match types. Critically, non-members consisted of items that violated the constraints of membership in several focal ways (see Table 2 for generalization item breakdown). As knowledge of the specific constraint that was violated was necessary to get each of these items correct, they served as a stringent test of category knowledge.

Figure 1: Eight example stimuli from the training (identification) and generalization phases.

## Design and Procedure

Participants were randomly assigned to either identification ( $\mathrm{n}=39$ ) or interactive $(\mathrm{n}=31)$ learning conditions in a between-subjects design. Due to a spreadsheet error, condition assignments were slightly imbalanced.

In the pre-training instructions, all subjects were first informed they would be learning about something called a 'Togging situation' - the arbitrary category label - before being provided with an abstract definition of the category: "A Togging situation occurs when (1) there are two matching special objects with other objects in the space between them; and (2) all the objects in the space between have at least one thing in common with the special objects." Subjects were then told they were to gain a full and clear understanding of Togging situations by engaging in the upcoming learning experience.

Table 1: Number of category members by length and type for identification training.

| Special-Normal Match <br> Type | Length 3 Items | Length 4 Items |
| :--- | :---: | :---: |
| Color | 3 | 1 |
| Size | 3 | 1 |
| Both Size and Color | 3 | 3 |
| One Both, One Color | -- | 2 |
| One Both, One Size | -- | 2 |
| One Size, One Color |  | 3 |
| Total | 9 | 12 |

Condition-specific instructions for the interactive group informed learners they would receive (1) an 'exploration zone' that would tell them if the objects inside were currently in a Togging situation and (2) a set of 'exploration tools' that could be used to modify the objects/attributes in informative ways. They were then told they could gain an understanding by paying attention to modifications that break the Togging situation and by trying to create novel Togging situations. To combat confirmation bias - as piloting revealed this to be a considerable impediment to learning - subjects were also told to try to prove their ideas about Togging wrong by fully testing them. Lastly, subjects were informed they would be tested later and that they would have seven minutes with the learning task. Following these general task instructions, interactive learners then read a brief tutorial that described the ways they could modify the examples with the exploration tools.

Table 2: Number of exemplars by length, type, and membership in the generalization assessment.

| Members: | Length 3 Items | Length 4 Items |
| :--- | :---: | :---: |
| Special-Normal Match Type | 8 | 1 |
| Color | 7 | 2 |
| Size | 4 | 0 |
| Both Size and Color | - | 1 |
| One Both, One Color | - | 7 |
| One Size, One Color | 19 | 11 |
| Total | 8 |  |
| Non-member Type | 4 | 3 |
| No Special-Normal Match | 3 | 3 |
| No Special-Special Match | 2 | 0 |
| Only One Special Block | - | 0 |
| Special Objects not Aligned |  | 7 |
| Only One Special-Normal Match | 17 | 13 |
| Total |  |  |

Instructions in the identification condition informed learners they would receive a series of frames with objects inside, some of which would have a Togging situation. They were told they could gain an understanding by paying attention to the frames and feedback they received and by learning to identify which frames contained a Togging situation. The identification learners also received an analogous instruction to try to prove their ideas about Togging wrong by fully considering the frames and feedback on each trial. Finally, identification learners were informed of the upcoming test.

To remind participants, and guide learning, both conditions were again given the abstract category definition immediately prior to the learning task.

Training - Interactive Condition The training interface can be seen in Figure 2. In the center of the interface was an 'exploration zone' that dynamically checked whether the constraints of category membership were met by the objects inside. The zone's border color turned green if the constraints were met, and red if not. A textual notification above the zone regarding membership mirrored the color feedback. The exploration zone started with a positive example of the category, randomly selected from the three
positive examples that were provided to the interactive group.

Participants could freely engage the training interface in five distinct ways. First, clicking the 'new' button cycled through the three positive examples. The button allowed learners to reset the exploration zone to a positive example if they became lost with their current discovery path and also get experience with the three different instantiations of the category. Second, double clicking a block would change its color - cycling in order through the three colors with each double click. Third, clicking and dragging the bottom right corner of a block diagonally allowed participants to stretch or shrink it to one of the three discrete sizes. Fourth, clicking and dragging elsewhere on a block allowed participants to change its spatial location. Lastly, participants could add or remove objects from the exploration zone. To the left of the zone was a space containing additional normal blocks that varied in their size and color. Participants could bring additional blocks into the exploration zone or remove any of the blocks from the zone to this space. This allowed participants to: (1) swap blocks to change attributes, (2) simplify the example in the exploration zone, and (3) create more elaborate examples of the category that involved more objects.

Figure 2: Visual of the interactive workspace.
Since there were many ways participants could interact with the interface, they were provided with a 'how to' cheatsheet to the right of the exploration zone. During the task, participants had seven minutes for self-directed investigation of the category. A timer in the upper left corner of the interface showed how much time remained. To encourage participants to stay on task, a query was presented below the text notification of membership. The query corresponded to the current state of the objects in the exploration zone. When category constraints were met, the query asked participants if they could, "find a way to break the Togging situation." When the constraints were not met, it asked if they could "find a way to make a Togging situation again." Besides this general query, no additional direction was given during the task.

Training - Identification Condition Learners in the identification group were directly provided with 21
examples of the category - seven times as many as were provided to interactive learners. These 21 positive cases were combined with the 21 negative cases in a random order for each participant. Participants made one pass through the set. On each trial, the participant was presented with an item and two response buttons ("Togging situation", "Not a Togging situation"). The amount of time to study the example and make a response was unconstrained. Participants selected their response using the mouse and were given feedback indicating if they were (in)correct and whether the item was (not) an example of a Togging situation. Feedback was presented for 2.5 s before moving on to the next trial.

Generalization Assessment Following the learning phase, all participants were given a generalization assessment to assay their ability to both identify category members and correctly reject near-miss non-members. The 60 generalization items were presented in a randomized order for each participant. The trial structure of the generalization phase was identical to that of identification training, except no feedback was given.

## Results

## Training

All except three learners in the identification condition ( $M=$ $.83, S E=.02$ ) performed reliably above chance. Data from these non-learners were retained in the subsequent analyses for two reasons: (1) the general pattern of results did not change when their data were excluded, and (2) there was not a comparable basis for excluding interactive learners. Identification training took 3-8 minutes ( $M=3.89$ minutes, $S E=.14$ ). Though there was a wide range, time spent during training did not predict generalization accuracy in a trialwise logistic regression $(\beta=-0.005, S E=0.01, Z=-.44, p=$ .66).

Interactive learners made between 151 and 321 manipulations $(M=227.21, S E=6.60)$. Number of manipulations, however, did not predict generalization accuracy $(\beta=-0.0001, S E=0.001, Z=-.12, p=.91)$, suggesting that the quantity of manipulations was not critical. However, higher rates of crossover - the proportion of the manipulations that switched the state from member to non-member (or vice versa) - were associated with higher generalization accuracy ( $\beta=3.05, S E=0.86, Z=3.54, p<$ .001), suggesting that generating alignably-different different-category comparisons is key for getting the most out of the platform.

## Generalization Accuracy

Trial-wise accuracy data were modeled with logistic regressions. Using condition as the lone predictor, the main analysis yielded the key finding that interactive learning ( $M$ $=.73, S E=.01$ ) significantly augmented generalizable category knowledge over identification learning ( $M=.67$, $S E=.01) ; \beta=0.29, S E=0.07, Z=4.27, p<.001$.

To further probe the effect of condition, we conducted a follow-up analysis to see how each condition performed on members and non-members. To this end, we used condition, item membership ( 1,0 ), and their interaction as predictors. Interestingly, the regression revealed a highly reliable crossover interaction between condition and item membership (see Figure $3 ; \beta=1.35, S E=0.18, Z=7.70, p<.001$ ). The interaction was marked by a reliable enhancement for the identification group on category members (identification: $M$ $=.93, S E=.01$; interactive: $M=.87, S E=.01 ; \beta=-0.63, S E$ $=0.15, Z=-4.20, p<.001$ ), but a reliable enhancement for the interactive group on non-members (identification: $M=$ $.41, S E=.01$; interactive: $M=.59, S E=.02 ; \beta=0.72, S E=$ $0.09, Z=8.01, p<.001)$. It should be noted that average accuracy on non-members was generally low. This is directly attributable to their more challenging nature. Contrasted with the member set, on which it was possible to successfully identify all items using knowledge of any single relational constraint, the non-member set consisted of items that each focally violated a constraint of membership. To perform successfully on these, participants required knowledge of the specific constraint that was violated in each instance. Thus, performance on the non-members serves as a proxy for learners' understanding of the category's composite constraints. While learners still had much to learn about the category, low means should not be interpreted to mean that performance was at chance or random in nature. Rather, the high accuracy observed for members suggests that learners took a limited understanding of the constraints of membership and overgeneralized it to non-members.

Given the curious reversal in the effect of condition between levels of item membership, we were prompted to explore the possibility that identification learners were more likely to overgeneralize category knowledge, which ostensibly would explain this pattern of results. We used two signal detection theory measures to this end: $d^{\prime}$ and $\beta$. $d^{\prime}$ is a measure of sensitivity to the signal when present that reflects hit rate on signal trials while adjusting for false alarm rate on noise trials. A higher $d^{\prime}$ indicates a greater sensitivity to the underlying signal (category members). $\beta$ is a likelihood ratio that reflects response bias. A $\beta$ of 1 indicates learners were neither biased towards nor against extending the category label, whereas $\beta$ below or above 1 indicates a bias towards extending or not extending the label, respectively. $d^{\prime}$ and $\beta$ were computed for each subject and the values for each were then predicted by condition in separate linear regressions. Despite showing increased accuracy for members, identification learners were not more sensitive, owing to a significantly increased false alarm rate (identification: $M=0.58, S E=.04$; interactive: $M=0.41$, $S E=.04 ; \beta=-0.17, S E=0.05, t(68)=-3.19, p<.01)$. In fact, a numerical advantage in $d^{\prime}$ favored interactive learners but did not reach significance (identification: $M=1.46, S E$ $=.09$; interactive: $M=1.71, S E=.21 ; \beta=0.24, S E=0.21$, $t(68)=1.16, p=.25)$. Additionally, identification learners were found to be significantly more biased towards
endorsing items as members - showing lower $\beta$ than their interactive counterparts (identification: $M=0.34, S E=.06$; interactive: $M=0.61, S E=.09 ; \beta=0.27, S E=0.11, t(68)=$ $2.50, p<.05)$. Collectively, these measures indicate that the identification group's enhanced accuracy for members was not the result of greater sensitivity. Instead, it appears to be a byproduct of a liberal extension of a limited understanding of the category, relative to interactive learners.

## Discussion

The primary goal of this study was to evaluate the potential for a novel, interactive discovery platform to facilitate the acquisition of a complex relational concept. Consistent with our hypothesis, our findings resolutely show that interactive training is an effective way to affect relational category knowledge. Compared to identification training - a learning mode organic to both category learning experiments as well as common educational practices - interactive learners exhibited an enhanced ability to generalize and enriched knowledge of specific membership constraints.

The results of this study inform both basic and applied interests. Our data suggest that our interactive platform can aptly supplement learning when complex, abstract relational categories are the target of learning. On an intriguing note, this paradigm appears to possess a distinct utility for combating overgeneralization by helping learners to explore and refine the boundaries of membership. It should be noted these advantages accrued despite the minimalistic support that was given (compared to other guided discovery approaches; e.g., Chen \& Klahr, 1999), the short amount of time allotted for learning, and the transfer appropriate processing advantage granted to identification learners in the shared task between training and test.

A limitation of this study is the use of randomly generated non-members in the identification training condition. As a function of the random generation, they tended to be slightly more entropic than the positive examples. This exposes a possible deflationary account of these findings - that identification learners may have simply learned to differentiate more and less entropic examples from each
other, which might explain poorer generalization performance. However, this account is unlikely for two main reasons. First, learners were provided a definition of the relational concept not once, but twice, prior to training. A basic understanding of the category should have guided learners to seek information that extended that understanding, not part with it altogether. Second, if learners acquired and used an entropy strategy during training, the effects of this should have been notable in the generalization data. Unlike the training set, non-members in the generalization phase were orderly. If learners adopted an entropy strategy, they would likely use it before realizing, later in the generalization phase, that there were not any entropic cases - at which point they might shift to the principle-relevant knowledge they acquired through the definition and learning experience. If this occurred, we should expect better performance later in the generalization phase. To investigate this possibility, we compared performance on the first 30 trials to the second 30 trials of generalization for identification learners. The difference was non-significant ( $p=.81$ ), suggesting identification learners engaged the task the way we intended. Nevertheless, planned research using yoked controls will provide more definitive evidence.

Further work will be necessary to specify the cognitive processes behind the benefits of interaction in relational category learning. Consistent with Markant \& Gureckis (2014), the effect of actively selecting modifications that supplement one's current understanding is likely to be critical. However, our next main pursuit in developing this platform is to more deeply explore the potential for analogy and comparison to serve as the engine for interactive relational category learning. Much of the power of this learning paradigm likely follows from its facilitation of informative, user-created comparisons with alignable differences - a possibility echoed by the higher generalization accuracy associated with higher rates of category crossover. To the extent that this underlies its utility, providing learners with co-presented exemplars that are dynamically linked in their manipulations should promote enhanced generalization and transfer, and possibly serve to shorten acquisition time. Contrasting this interactive approach with static comparisons and other educational tools, such as the explicit elicitation of selfexplanations, will be integral to the evaluation of this tool's potency in upcoming research.

## Acknowledgments

We greatly thank David Brokaw for his help with programming and the Learning and Representation in Cognition (LaRC) lab for their valuable input.

#### Abstract

This paper examines the use of iconic words in early conversations between children and caregivers. The longitudinal data include a span of six observations of 35 children-parent dyads in the same semi-structured activity. Our findings show that children's speech initially has a high proportion of iconic words, and over time, these words become diluted by an increase of arbitrary words. Parents' speech is also initially high in iconic words, with a decrease in the proportion of iconic words over time - in this case driven by the use of fewer iconic words. The level and development of iconicity are related to individual differences in the children's cognitive skills. Our findings fit with the hypothesis that iconicity facilitates early word learning and may play an important role in learning to produce new words.

Keywords: iconicity; vocabulary development; child-directed speech; sound symbolism

## Introduction

How do young children learn to understand and use their first words? Philosophers have pointed out the inductive challenge of learning to associate the sound of a word with its meaning (Quine, 1960), and developmental psychologists observe that this challenge is compounded for an infant (Imai \& Kita, 2014). Not only must infants isolate the meaning of a word from a noisy, complex environment and learn to generalize it to new contexts, they must grasp the very concept of a symbol in the first place.

One cue infants may utilize to facilitate early word learning is iconicity - a degree of resemblance between the form of a signal and its meaning. For example, a person might represent 'small size' with an index finger-to-thumb pinching gesture, or in speech, by raising the pitch of their voice as they articulate the small-sounding word "itty-bitty". One proposal for how iconicity can help early word learning in spoken languages is the sound symbolism bootstrapping hypothesis (Imai and Kita, 2014). (The term "sound symbolism" is often used to refer to iconicity in spoken words.) On this idea, children are biologically endowed with a bias to recognize various cross-modal correspondences between sound and phenomena of the other senses - for example, between pitch and size or brightness, or between
the duration of a sound and the visual extension of a line (see Spence, 2011 for a review of crossmodal correspondences). These biases, which may also be learned by experience, might bootstrap children into the connection between the sounds of iconic words and their corresponding meanings (Imai \& Kita, 2014; Perniss \& Vigliocco, 2014). The sound of a word could help children identify its intended referent from a complex scene, recognize the invariance of its meaning across contexts, and apply it productively to new contexts. By helping children connect spoken words with their meanings, iconicity may help children gain the "referential insight" that speech sounds refer to entities and properties in the world.

## Laboratory studies of iconicity in word learning

Laboratory studies show that young children are indeed sensitive to iconicity in spoken words, and some studies suggest further that this iconicity can facilitate word learning. Maurer et al. (2006) found that 2.5 -year-old children were more likely to match nonsense words containing rounded vowels (e.g. bouba) with rounded shapes, and words containing unrounded vowels (kiki) with pointed shapes. Another study, using a preferential looking paradigm, found that infants as young as four months are sensitive to this bouba-kiki-type iconicity (Ozturk et al., 2012). There is also evidence that sound-shape correspondence can more directly facilitate word learning in infants (Imai et al., 2015). 14-month-old infants were habituated to combinations of a novel word and a picture of an object, in either an iconically matching or mismatching condition. When the children were then presented with the novel words along with a picture of the correct object and a distractor, they looked more at the correct object when its sound and shape were matching.

The sensitivity of infants to sound-shape iconicity has also been demonstrated using electroencephalography (Asano et al., 2015). Event related potentials were measured as 11 -month-old infants were presented with pictures of shapes followed by novel words that matched or mismatched the shape in iconicity. With mismatching wordshape pairs, subjects showed a response similar to the N400 effect, typically an index of difficulty with semantic
integration. Analysis of brain oscillations found an increase in early $\gamma$-band oscillations in the matching condition, which might indicate increased cross-modal integration between the sound of the word and its visual referent.

Importantly, children can benefit from iconicity in learning to associate sounds and meanings in domains outside of shape. Imai et al. (2008) presented 25-month-old Japanese toddlers with novel words along with two video clips of people performing two different manners of walking. Norming with adult Japanese and English speakers had determined that one of the videos, but not the other, was iconically congruent with the verb. Similarly, when the children were asked to select the manner of walking to which they thought the word referred, they were more likely to choose the one that matched the verb. A subsequent experiment found that 3 -year-old Japanese children were able to correctly generalize the iconic verbs to new agents, but were unable to generalize non-iconic verbs. Further work replicated the finding with 3-year-old English learners, indicating at least some level of universality in the iconicity of the sound-referent pairings (Kantarzis et al., 2011). A study by Yoshida (2012) found similar results with Japanese- and English-speaking toddlers.

## Iconicity in natural word learning

These laboratory studies show that young children are sensitive to certain forms of iconicity in spoken words, and under some conditions, they can learn iconic words faster than non-iconic words. However, if iconicity does play an important role in early word learning in the wild, then there should be evidence of this in natural language learning. In particular, children should learn more iconic words earlier, and caregivers should be more inclined to use iconic words with early learners.

A recent study of English and Spanish found that children do tend to learn more iconic words earlier (Perry et al., 2015). Perry et al. collected native speaker iconicity ratings of roughly 600 English and Spanish words that are learned earliest by children according to the respective MacArthurBates Developmental Inventories (MCDIs). They asked participants to rate the degree to which the words "sound like what they mean". The age of acquisition (AoA) of words was indexed by the proportion of children using the word at 30 months according to the MCDI database. Over multiple experiments in both languages, the results showed that words rated as more iconic were acquired earlier by children.

Notably, this relationship held after controlling for the systematicity of words as measured by Monaghan et al. (2014). Systematicity is an index of the degree to which similar meanings have similar forms in the lexicon of a language. Monaghan et al. found that, from the age of 2 to $13+$ years, children tended to learn more systematic words earlier. According to Monaghan et al., in theory, iconicity and systematicity are orthogonal properties. Words can be systematic but not iconic - a point they illustrate with the English consonant cluster sl- (e.g. slime, slow, slur, slum),
which systematically refers to negative or repellent properties, but bears no clear resemblance to this meaning. Yet, it is questioned whether spoken languages afford sufficient articulatory freedom for words to be iconic but not systematic. For instance, Monaghan et al. offers the example of onomatopoeic words for the calls of small animals (e.g. peep, cheep) compared to calls of big animals (roar, grrr), which both iconically and systematically reflect the animals' size. However, Perry et al.'s (2015) finding that the iconicity-AoA relationship held after controlling for systematicity shows some limited support for the independence of these properties in English - at least for the roughly 300 words for which these measures overlapped. In further support for their independence, Winter et al. (in press) examined the relationship between iconicity ratings and Monaghan et al.'s systematicity index for 1,104 words, and found only a weak correlation of $r=0.06$.

Following the study of Perry et al. (2015), a couple of subsequent studies have found comparable results. Massaro and Perlman (2017) used the same procedure to collect new iconicity ratings for the English MCDI words. They used these to examine the relationship between iconicity and the frequency with which children used the words from 6 to 47 months of age. The study found a gradual decrease in the influence of iconicity on children's production vocabulary with increasing age. An analysis of children's receptive and productive vocabularies with respect to increasing vocabulary size showed that the average iconicity of their vocabulary declined with increasing size.

Massaro and Perlman (2017) observed that the very first words that children produced were especially high in iconicity and included a relatively high number of onomatopoeic words. This observation is consistent with some other studies of early vocabulary, which indicate that a high proportion of children's first words are onomatopoeic or mimetic words. As reported by Laing (2015), a study of children's first five words across various languages found that about $20 \%$ were onomatopoeic (Menn \& Vihman, 2011). Another study found that 3 -year-olds used more mimetics to describe motion events than 5 -year olds (Kita et al., 2010).

In addition to the high level of iconicity in children's early spoken words, Perry et al. (in press) examined whether parents use more iconic words in child-directed speech. The study included iconicity ratings for approximately 2000 English words including Perry et al.'s (2015) prior ratings. First, the study replicated the finding of a relationship between the iconicity of words and their age of acquisition, which was indexed by norms based on adults' subjective ratings (Kuperman et al., 2012). Second, the study examined how iconicity influenced the frequency of words used in children's speech, as well as in the child-directed and adultdirected speech of adults. Word frequencies in childproduced and child-directed speech were calculated from the Child Language Data Exchange System (CHILDES), and word frequencies of adult-adult speech were from the American National Corpus. The results showed that younger
children tended to use higher iconicity words more frequently, but with age, they increasingly favored lower iconicity words. Analyses of adult speech found that adults used higher-iconicity words more frequently when talking to children, but used lower iconicity words more frequently with adults. Thus, as children became older and their vocabulary grew in size, their speech became more adultlike in the use of iconic words.

The finding that parents used more iconic words in child directed speech fits with some previous observations of Japanese-speaking parents. Imai and Kita (2014) described two studies published in Japanese that found that caretakers used more mimetics and onomatopoeia with younger children, but used these words less frequently as children became more language proficient (Saji \& Imai, 2013; Suzuki, 2013). However, caution should be applied in generalizing across languages: Japanese-speaking parents have been shown to use more onomatopoeia and mimetics than English speaking parents, who nevertheless do use some onomatopoeia and especially sound effects (Fernald \& Morikawa, 1993; Yoshida, 2012).

## Current study

In the current study, we examined how the use of iconic words in early conversations between children and caregivers develops within individual children-parent dyads, while controlling for production setting and individual differences in the children's verbal and nonverbal skills. The longitudinal data include about six observations for each of 35 dyads within the same semi-structured activity across children and ages. We examine the change in the use of iconic words in children's speech in comparison to the speech of their parents, allowing us to investigate how parents adapt their level of iconicity to their children's language proficiency. We also explore how individual differences of the children (verbal and nonverbal IQ) relate to the use of iconic words by children and parents over development.

## Methods

## Participants

As part of an ongoing longitudinal study investigating language acquisition in young children with autism spectrum disorder (Goodwin, Fein, \& Naigles, 2012; Tek, Mesite, Fein, \& Naigles, 2014), we recruited 35 typically developing children ( 6 girls, mean age at onset $=20.27$ months, $95 \%$ CIs: 19.78 20.93). All children were monolingual English learners. Their average verbal IQ at visit 1 (as measured by MSEL-EL, cf. below) was 19.89 ( $95 \%$ CIs: 18.421 .76 ) and perceptual IQ at visit 1 (as measured by MSEL-VR, cf. below) 26 ( $95 \%$ CIs: 24.83 27.09).

## Iconicity, systematicity, and concreteness

Iconicity ratings were taken from two previous studies, which collected ratings for 3001 English words (Perry et al.,

2015; Winter et al., in press). Approximately 600 of the words were selected from the MCDI (Fenson et al., 1994), and additional words were chosen to maximize coverage with relevant psycholinguistic datasets of age of acquisition and concreteness norms. Complete methodological details can be found in Perry et al. Native English speakers on Amazon Mechanical Turk rated the iconicity of the words on a scale from -5 to 5 , where 5 indicated that a word was highly iconic and sounds like what it means, -5 that it sounds like the opposite of its meaning, and 0 that it is completely arbitrary. The words "slurp" and "teeny" were suggested as examples of highly iconic words, "cat" and "dog" as arbitrary words (Pinker \& Bloom, 1989), and "whale" and "microorganism" as opposite-sounding words (Hockett, 1960). Each word was rated by at least 10 participants. The average iconicity rating across all words was 0.92 ( $\mathrm{SD}=1.13$ ).

Systematicity measures were taken from Monaghan et al. (2014). This study computed systematicity for a large set of monosyllabic English words by measuring the overall correlation between the degree of similarity between the forms of any two words in the set, and the degree of similarity between their corresponding meanings. Ratings for individual words consisted of their contribution to the overall form-meaning correlation across all the words. Concreteness ratings were taken from Brysbaert et al. (2014), which were collected for 40 thousand English words and short phrases via Amazon Mechanical Turk. Words were rated 1 'abstract' to 5 'concrete'.

## Speech data

The data were collected across six home visits, each separated by 4 months. For six children, data at one visit were missing. This generated a total of 204 visits. During each visit, children engaged in a $30-\mathrm{min}$ semi-structured parent-child play session. All sessions were transcribed at the word-level. The 204 transcripts analyzed consisted of 465,474 words ( 99,210 of children's speech, CS) and 4143 unique words ( 2185 in CS). 1334 unique iconicity-rated words were found ( 899 in CS), covering $32 \%$ of all unique words used ( $41 \%$ in CS) and $78 \%$ of all used words ( $72 \%$ in CS). The systematicity coding covered 699 employed unique words ( 515 in CS): $17 \%$ of all employed unique words ( $12 \%$ in CS) and $26 \%$ of all employed words ( $24 \%$ in CS). Altogether, the iconicity, systematicity, and concreteness coding covered 698 employed unique words (514 in CS): $17 \%$ of all employed unique words ( $12 \%$ in CS) and $26 \%$ of all employed words ( $24 \%$ in CS).

## Analysis

Separately for child-produced and child-directed speech, we produced mixed effects growth curve models assessing the development of iconicity over time in 4 steps. First we used iconicity as outcome measure, visit (linear and squared) as fixed factor, and child ID as random effect, including visit as random slope. Second, we controlled whether the results were preserved when controlling for measures of word
concreteness and systematicity by adding to the first model these measures as fixed effects. Third, we controlled for effects of verbal and nonverbal initial IQ: to the first model we added MSEL-EL and MSEL-VR at visit 1, both as main effects and as interactions with visit. Due to the high colinearity between verbal and nonverbal IQ ( $\mathrm{r}=-0.712$ ), high caution should employed in interpreting the results. Finally, we tested whether significant changes of iconicity over time were due to changes in iconic or in arbitrary words. Iconic words were defined as words with an iconicity score above 1 (531 unique words), arbitrary as words with a score between -0.5 and 0.5 ( 421 unique words). We employed a mixed effects Poisson regression with number of iconic words as outcome, visit (linear and squared) as fixed factor, overall number of words produced by the speaker as offset and child ID as random factor including visit as random slope. This analysis was repeated for unique iconic words and for overall and unique arbitrary words. All analyses were run employing R 3.3.2, RStudio 1.0.136, lme4 1.1-12 and tidyverse 1.1.0 (Bates et al., 2014; RCoreTeam, 2016; RStudioTeam, 2016; Wickham, 2017).

## Results

## Children's speech

First, we analyzed whether the iconicity in children's speech changed over the six visits. We found that iconicity decreases significantly over time (linear: $b=-0.63, \mathrm{SE}=0.11$, $p<0.001$; quadratic: $b=0.43, \mathrm{SE}=0.09, p<0.001$ ), cf. Figure 1 . When controlling for systematicity and concreteness, we still observed analogous results. Iconicity decreases over time (linear: $b=-0.19, \mathrm{SE}=0.05, p<0.001$; quadratic: $b=0.14$, $\mathrm{SE}=0.04, p<0.001)$. Concreteness is a significant predictor of iconicity $(b=0.06, \mathrm{SE}=0.007, p<0.001)$, but not systematicity ( $b=0.004, \mathrm{SE}=0.007, \mathrm{p}=0.565$ ).

Next, we examined whether individual cognitive skills play a role in the iconicity of children's speech. When verbal and nonverbal IQ were added to the model, we observed analogous effects, but modulated by these individual variables. Iconicity decreases over time (linear: $b=-0.63$, $\mathrm{SE}=0.1, p<0.001$; quadratic $b=0.44, \mathrm{SE}=0.09$, $p<0.001$ ). The higher the verbal IQ, the lower the iconicity ( $b=-0.11, \mathrm{SE}=0.03, p<0.001$ ), with only a marginal interaction with visit (linear: $b=0.23, \mathrm{SE}=0.12, p=0.07$; quadratic: $b=-0.11, \mathrm{SE}=0.11, p=0.3$ ). Nonverbal IQ did not have a main effect on iconicity ( $b=-0.002, \mathrm{SE}=0.03$, $\mathrm{p}=0.95$ ), and it marginally modulated the effect of time: the higher the nonverbal IQ, the bigger the linear iconicity decrease $(b=-0.22, \mathrm{SE}=0.12, \mathrm{p}=0.07)$ and the bigger the quadratic slowdown ( $b=0.19, \mathrm{SE}=0.11, \mathrm{p}=0.08$ ).

Finally, we examined whether the decrease in iconicity over time resulted from a decrease in the use of iconic words or an increase in the use of more arbitrary words. We observed no significant change over time in the frequency of iconic words used, either overall uses or by unique tokens ( $p$ 's>0.17). However, there was a significant increase over time in the overall use of arbitrary words $(b=1.07, \mathrm{SE}=0.1$,
$p<0.001$ ), though not in unique arbitrary words used ( $b=0.15, \mathrm{SE}=0.09, p=0.08$ ), cf. Figure 2.

## Adults' speech

Next we examined how iconicity in parents' speech changed over the six visits. Similar to children's speech, we found that iconicity decreased significantly over time (linear: $b=-$ 0.05 , $\mathrm{SE}=0.03, p=0.002$; quadratic: $b=0.03, \mathrm{SE}=0.02$, $p=0.08$ ), cf. Figure 1 . When controlling for systematicity and concreteness, we still observed analogous results. Iconicity decreases over time (linear: $b=-0.07, \mathrm{SE}=0.02$, $p<0.001$; quadratic: $b=0.04, \mathrm{SE}=0.02, p<0.001$ ). Like with children's speech, concreteness is a significant predictor of iconicity ( $b=0.1, \mathrm{SE}=0.003, p<0.001$ ). However, unlike children's speech, systematicity is also a significant predictor of iconicity ( $b=-0.06, \mathrm{SE}=0.003, p<0.001$ ).

Next, we examined the role of children's individual cognitive skills in the iconicity of parents' speech. With verbal and nonverbal IQ added to the model, we observed analogous effects, but modulated by the children's individual cognitive skills. Iconicity decreases over time (linear: $b=-0.06, \mathrm{SE}=0.009, p<0.001$; quadratic: $(b=0.03$, $\mathrm{SE}=0.009, p=0.001$ ). Verbal IQ did not affect the general level of iconicity ( $b=-0.004, \mathrm{SE}=0.005, \mathrm{p}=0.44$ ), but it interacted significantly with time: the higher the verbal IQ, the stronger the linear decrease in iconicity ( $b=-0.03$, $\mathrm{SE}=0.01, p=0.02$ ) and the smaller the slowdown ( $b=0.03$, $\mathrm{SE}=0.01, p=0.004$ ). Nonverbal IQ did not seem to affect iconicity ( $p$ 's>0.4).

Figure 1 - Average iconicity across visits in children and adults' speech

Figure 2 - Frequency across visits of highly iconic and arbitrary words in children and adults' speech

Finally, different from children, we observed a significant decrease over time in the overall frequency of iconic words ( $b=-0.7, \mathrm{SE}=0.03, p=0.012$ ), and a marginal decrease in the number of unique iconic words used ( $b=-0.09, \mathrm{SE}=0.05$, $p=0.058$ ), with no significant quadratic components ( $p$ 's>0.3). In contrast, we observed no significant change over time in the frequency of arbitrary words, either overall or by number of unique tokens ( $p \prime s>0.195$ ), cf. Figure 2.

Table 1 shows words with iconicity ratings of 1.5 or higher from the 100 most frequent words used by children and parents during visits 1 and 6 . Children produced 28 high-iconicity words during visit 1 and 18 during visit 6 . Parents produced 13 such words during visit 1 and 10 during visit 6 .

Table 1. Most frequent high-iconicity words.

| Group | Visit | Words |
| :---: | :---: | :---: |
| Children | 1 | no (2.8), baby (2.2), bye (1.6), one (1.8), vroom (3.5), cup (1.5), snake (2.0), balloon (1.7), help (1.5), pop (4.1), my (1.5), block (2.4), roar (3.9), beep (4.4), boom (3.8), fall (1.5), dump (2.9), shake (2.6), three (1.6), bowl (1.5), hello (2.1), mine (1.5), star (1.6), yes (2.2), yum (2.8), crash (3.7), look (1.8), bee (1.5) |
|  | 6 | no (2.8), one (1.8), three (1.6), snake (2.0), baby (2.2), my (1.5), look (1.8), elephant (2.1), yes (2.2), vroom (3.5), balloon (1.7), beep (4.4), knock (3.1), stop (2.5), pop (4.1), home (2), hiss (4.2), off (1.9) |
| Parents | 1 | look (1.8), one (1.8), baby (2.2), no (2.8), push (2.3), bye (1.6), block (2.4), snake (2.0), work (1.7), knock (3.1), vroom (3.5), help (1.5), hello (2.1) |
|  | 6 | look (1.8), one (1.4), no (2.8), baby (2.2), my (1.5), elephant (2.1), work (1.7), help (1.5), knock (3.1), block (2.4) |

Note. Words ranked in order of frequency. Iconicity ratings in parentheses. Underlined words among the most frequent for that group during the particular visit, but not for the other group. Italicized words among the most frequent during that visit for the particular group, but not for the other visit. E.g. "yum" was used frequently by children during visit 1 , but not by parents during that visit, nor by children during visit 6 .

## Discussion \& Conclusion

Developmental psychologists have proposed that iconicity may facilitate early word learning, helping children to bridge the sounds of words with their meanings. To investigate this hypothesis, we used iconicity ratings for a large set of English words to examine iconicity in the speech of children and parents.

We found that iconicity decreases over language development in both child-produced and child-directed speech. These patterns held after controlling for concreteness and systematicity of the words. In children, the overall decrease in iconicity is driven by an increase in the use of more arbitrary words, rather than a decrease in iconic words. This contrasted to parents, who decreased their use of iconic words, but maintained the frequency of arbitrary words. Our analysis of individual verbal and nonverbal IQ showed that children's level of cognitive ability modulated their transition to the more frequent use of arbitrary words. The results also suggest that parents may adapt their
iconicity more to the children' actual cognitive skills than to their age.

These findings, along with several other studies, show a robust relationship between the iconicity of spoken words as garnered from native speaker ratings, and their prevalence in early communication between children and caregivers (Massaro \& Perlman, 2017; Perry et al., 2015; Perry et al., in press; also see Thompson et al., 2012 for similar results with British Sign Language). They support the hypothesis that iconicity plays a role in facilitating early vocabulary learning. Additionally, they highlight the possible role of iconicity in children's production. Iconicity of words may not just facilitate comprehension of their meaning, but also foster "thinking for speaking" during the beginning phases of learning to produce meaningful words (cf. Slobin, 2006). However, it is also important to note that young children and their parents clearly use a high proportion of arbitrary words too, even as they show a relatively higher inclination to use iconic words.

Our findings suggest several directions for future research on iconicity in early word learning. One important question is whether iconic words actually help children gain the referential insight, which would then ease the way for learning more arbitrary words. Alternatively, iconic words might simply be more readily acquired and put to use, which potentially could still facilitate subsequent word learning by bolstering early vocabulary. A second direction for future research is to investigate the more fine-grained temporal dynamics of iconicity in the unfolding interaction. Do parents and children adapt to each other's level of iconicity, and if so, do they do that on a turn-by-turn base, or at a more general level? Finally, future research might examine how iconic words are used with other iconic devices, such as prosody and iconic gesturing. For example, parents might modulate the prosody of their speech in iconic ways, which could help children with comprehension and word learning (Nygaard et al., 2009).

The current study adds to accumulating research showing iconicity in the lexicons and grammars of spoken and signed languages alike (Dingemanse et al., 2015; Perniss et al., 2010). This research suggests that iconicity is a fundamental property of languages - a complement to arbitrariness. Our findings show how iconicity may play an important role in children's earliest conversations, even in a spoken language like English that lacks a large inventory of widely recognized iconic words.

## Acknowledgments

We are grateful for funding from the Language Evolution and Interaction Group at the Max Planck Institute for Psycholinguistics, and from the Interacting Minds Center (Aarhus university). We thank Padraic Monaghan for sharing his data on the systematicity of English words.

# Evidence for the size principle in semantic and perceptual domains 

Joshua C. Peterson (peterson.c.joshua@gmail.com)<br>Thomas L. Griffiths (tom_griffiths@berkeley.edu)<br>Department of Psychology, University of California, Berkeley

#### Abstract

Shepard's Universal Law of Generalization offered a compelling case for the first physics-like law in cognitive science that should hold for all intelligent agents in the universe. Shepard's account is based on a rational Bayesian model of generalization, providing an answer to the question of why such a law should emerge. Extending this account to explain how humans use multiple examples to make better generalizations requires an additional assumption, called the size principle: hypotheses that pick out fewer objects should make a larger contribution to generalization. The degree to which this principle warrants similarly law-like status is far from conclusive. Typically, evaluating this principle has not been straightforward, requiring additional assumptions. We present a new method for evaluating the size principle that is more direct, and apply this method to a diverse array of datasets. Our results provide support for the broad applicability of the size principle.

Keywords: size principle; generalization; similarity; perception

## Introduction

In the seminal work of Shepard (1987), the notion of stimulus similarity was made concrete through its interpretation as stimulus generalization. It was shown that, across species (including humans), generalization probabilities follow an exponential law with respect to an internal psychological space. Specifically, the probability that $y$ is in some set $C$ that contains $x$ (what Shepard terms a "consequential subset") is an exponentially decreasing function of distance ( $d$ ) in psychological space:

$$
\begin{equation*}
s_{x y}=e^{-d(x, y)} \tag{1}
\end{equation*}
$$

Shepard termed this phenomenon the Universal Law of Generalization, in that it should apply to any intelligent agent, anywhere in the universe. This result has been used in numerous cognitive models that invoke similarity (e.g., Nosofsky, 1986; Kruschke, 1992).

In spite of this, one could argue that generalization from a single stimulus to another does not adequately describe the full scope of human behavior. Indeed, in a concept learning task, people are asked to generalize from multiple examples of a concept. To capture this, Tenenbaum and Griffiths (2001) extended Shepard's original Bayesian derivation of the law to rationally integrate information about multiple instances. The resulting model defines the probability of generalization (that $y$ is in $C$ ) as a sum of the probabilities of all hypotheses $h$ about the true set $C$ that include both $x$ and $y$,

$$
\begin{equation*}
p(y \in C \mid x)=\sum_{h: y \in h} p(h \mid x) . \tag{2}
\end{equation*}
$$

The posterior probability of each hypothesis is given by Bayes' rule,

$$
\begin{equation*}
p(h \mid x)=\frac{p(x \mid h) p(h)}{p(x)} \tag{3}
\end{equation*}
$$

The prior $p(h)$ represents the learner's knowledge about the consequential region before observing $x$. The likelihood $p(x \mid h)$ depends on our assumptions about how the process that generated $x$ relates to the set $h$. The key innovation over Shepard's model is the use of the likelihood function

$$
p(x \mid h)=\left\{\begin{array}{cc}
\frac{1}{|h|} & x \in h  \tag{4}\\
0 & \text { otherwise }
\end{array}\right.
$$

where $|h|$ is the number of objects in the set picked out by $h$. The motivation for this choice of likelihood function is the size principle, which uses the assumption of random sampling to justify the idea that smaller hypotheses should be given greater weight (see Tenenbaum and Griffiths, 2001, for a demonstration of this when $x$ represents multiple examples).

The value of the size principle lies in the fact that it allows for the benefit of multiple examples of a concept to influence generalization. Assuming samples are drawn independently, the likelihood of a hypothesis for $n$ samples is simply the likelihood of that hypothesis for a single sample to the power of $n$. From this, it can be shown that generalization tightens as the number of examples increases, consistent with human judgments (see Tenenbaum \& Griffiths, 2001).

The size principle thus plays an important role in understanding generalization, placing equal importance on determining whether it actually describes human similarity judgments in a wide range of settings. If the size principle is disconfirmed, an alternative augmentation of Shepard's model is needed to explain generalization from multiple instances. If it can be confirmed to hold broadly, it is a good candidate for a second law of generalization, or an amendment of the original law. In this paper we build on previous work evaluating the evidence for the size principle (Navarro \& Perfors, 2010), providing a novel and more direct methodology and a broader empirical evaluation that includes rich perceptual feature spaces.

## Evaluating the Size Principle

In this section we describe previous work evaluating the size principle and provide the details of our approach.

## Previous work

Navarro and Perfors (2010) made three important contributions towards understanding the scope of the size principle. First, they made explicit a link between the Bayesian model of generalization and a classic model of similarity judgment. The similarities between a set of objects can be summarized in a similarity matrix $\mathbf{S}$, where the entry in the $i$ th row and $j$ th column gives the similarity $s_{i j}$ between objects $i$ and $j$.

Figure 1: Feature Size/Weight Relationships in Semantic Dataset Group 1.

The additive clustering model (Shepard \& Arabie, 1979) decomposes such a similarity matrix into the matrix product of a feature-by-object matrix $\mathbf{F}$, its transpose, and a diagonal weight matrix $\mathbf{W}$,

$$
\begin{equation*}
\mathbf{S}=\mathbf{F W F}^{T} \tag{5}
\end{equation*}
$$

The feature matrix $\mathbf{F}$ is binary and can represent any of a broad set of structures including partitions, hierarchies, and overlapping clusters, and can either be inferred by a number of different models or generated directly by participants. The individual entries of $\mathbf{S}$ are defined as

$$
\begin{equation*}
s_{i j}=\sum_{k=1}^{N_{f}} w_{k} f_{i k} f_{j k} \tag{6}
\end{equation*}
$$

Navarro and Perfors (2010) pointed out that each feature could be taken as a single hypothesis $h$, as it likewise picks out a set of objects with a common property. Having made this link, the degree of generalization between objects $i$ and $j$ predicted by the Bayesian model can be put in the same format as Equation 6: a weighted sum of common features (a similar point was made by Tenenbaum \& Griffiths, 2001). The equivalence can be seen if we let $w_{k}$ represent the posterior $p(h \mid x)$ and $f_{k}$ be the $k^{\text {th }}$ hypothesis $\left(h_{k}\right)$, since $f_{i k} f_{j k}$ selects only the features that contain both objects. If the prior probabilities of the different hypotheses are similar, the likelihood (and the size principle) will dominate and

$$
\begin{equation*}
w_{k} \propto \frac{1}{\left|h_{k}\right|} . \tag{7}
\end{equation*}
$$

Using the link between hypotheses and features, Navarro and Perfors (2010) made their second contribution: an alternative derivation showing that the relationship predicted by the size principle can hold even in the absence of random sampling. They argued that learners encode the similarity structure of the world by learning a set of features $\mathbf{F}$ that efficiently approximate that structure. Under this view, a "coherent" feature is said to be one for which all objects that possess that feature exhibit high similarity. If a learner seeks a set of features that are high in coherence, the size principle emerges even in the absence of sampling since the variability in the distribution of similarities between objects sharing a feature is a function of $\left|h_{k}\right|$.

The third contribution that Navarro and Perfors (2010) made was to evaluate this prediction using data from the Leuven Natural Concept Database (LNCD; De Deyne et al., 2008). This database consists of human-generated feature matrices for a large number of objects, as well as pair-wise similarity ratings for those objects. Navarro and Perfors (2010) observed that, under some simplifying assumptions, the size principle predicts that the similarity between objects that share a feature will be inversely related to the size of that feature. They showed that this prediction was borne out in 11 different domains analyzed in the LNCD.

## Directly testing the size principle

The method adopted by Navarro and Perfors (2010) depends on the derived relationship between the similarity of objects that share a feature and the number of those objects. However, the link that they established between Bayesian clustering and

Figure 2: Feature Size/Weight Relationships in Semantic Dataset Group 2.
the additive clustering model (Equations 5-7) can also be used to directly test the size principle. Since both models take the same mathematical form, we can directly test the size principle by estimating the weights $w_{k}$ for a set of features $\mathbf{F}$ and verifying that Equation 7 holds. If we take the logarithm of both sides of this equation, we obtain the linear relationship

$$
\begin{equation*}
\log w_{k}=-\log \left|h_{k}\right|+c \tag{8}
\end{equation*}
$$

which can be evaluated by correlating $w_{k}$ with the number of objects that possess feature $k$. Given a feature matrix $\mathbf{F}$ and similarity matrix $\mathbf{S}$, the weights $w_{k}$ can be obtained through linear regression (Peterson, Abbott, \& Griffiths, 2016). In additive clustering the weights are often constrained to be nonnegative. To obtain such weights, we employ a non-negative least squares algorithm (Lawson \& Hanson, 1995). We can thus directly test the size principle in any domain where a feature matrix and a corresponding similarity matrix are available. In the remainder of the paper we consider two different sources of such matrices: semantic feature norms and perceptual neural networks.

## Semantic Hypothesis Spaces

We first evaluate evidence for the size principle using two groups of datasets in which people judge the similarity of words. Both datasets contain human similarity ratings of noun pairs corresponding to concrete objects (e.g., "zebra" and "lion") and lists of binary feature labels associated with each object that can be filtered by frequency of mention. We
call these features "semantic" because they are linguistic descriptions of general concepts that exclude perceptual-level information associated with actual instances of that concept or brought to mind when the instance is perceived.

## Semantic Dataset Group 1

Following Navarro and Perfors (2010), the first evaluation dataset is comprised of similarity and feature matrices from the Leuven Natural Concept Database (De Deyne et al., 2008). It includes data for 15 categories (Kitchen Utensils, Clothing, Vegetables, Professions, Fish, Sports, Birds, Fruit, Reptiles, Insects, Tools, Vehicles, Musical Instruments, Mammals, and Weapons), each containing $\sim 20-30$ exemplars. Binary feature matrices for each category contain $\sim 200-300$ unique features each. The feature descriptions are much broader than merely visually apparent features (e.g., "has wings", "eats fruit", "is attracted by shiny objects").

## Semantic Dataset Group 2

The second dataset group consisted of 17 similarity matrices from a variety of sources throughout the literature. The experimental contexts and methodologies differed considerably compared to the those in group 1 . All but one of these datasets (SIMLEX) were taken from the similarity data repository on the website of Dr. Michael Lee (http://faculty.sites.uci.edu/mdlee/similarity-data/). SIMLEX was taken from a larger word similarity dataset (Hill, Reichart, \& Korhonen, 2016). The majority of the datasets (Birds, Clothing1, Clothing2, Fish, Fruit1, Fruit2, Furniture1,

Furniture2, Tools, Vegetables1, Vegetables2, Weapons1, and Weapons2) are from Romney, Brewer, and Batchelder (1993). For dataset pairs such as (Vegetables1, Vegetables2), the first contains more prototypical items than the second. Since none of these datasets contain corresponding object-feature data, we matched objects from each set to the feature norms reported in McRae, Cree, Seidenberg, and McNorgan (2005).

## Analysis \& Results

For each dataset, we computed the element-wise multiplication of each pair of rows in $\mathbf{F}$ and used non-negative least squares to regress this matrix onto the corresponding empirical similarity values. We then computed the $\log$ of all nonzero weights, as well as the log of the feature sizes (column sums of the $\mathbf{F}$ matrix for which there was a corresponding non-zero weight). The resulting $\log$ weights and $\log$ feature sizes are z -score normalized and plotted in Figures 1 and 2 for each category in each subgroup. Red lines indicate perfect -1 slopes as predicted by the size principle, whereas black lines are best fitting lines to the actual data. The corresponding correlation coefficients are reported in Tables 1 and 2 along with a number of other statistics to be discussed.

Average Pearson and Spearman correlations were -0.43 and -0.47 , respectively for group 1 , and -0.63 and -0.61 for group2. For nearly all individual datasets in all groups, coefficients are consistently negative, with the exception of Animals11 in group 2, which along with Animals5 are the only datasets with no published method. Correlations were generally stronger for group 2. All correlations in group 1 were significant at the $\alpha=0.05$ level except for the Reptiles and Mammals datasets. In contrast, virtually no correlations were significant in group 2 given the small number of features with non-zero coefficients, however one-sample $t$-tests confirmed that the mean slopes were significantly less than 0 for both Pearson $(t(16)=-7.65, p<0.0001)$ and Spearman $(t(16)=-7.65, p<0.0001)$ correlations.
The $F R$ (feature ratio) column indicates how many coefficients were positive out of the total possible. Although there were many more features overall in group 1 , the average percentage of features with non-zero weights was comparable ( $28 \%$ and $23 \%$ respectively).
Finally, model performance in predicting similarity $\left(R^{2}\right)$ is reported in the $R_{M P}^{2}$ column, and indicates the degree to which the feature sets are sufficient to accurately predict human similarity judgments. ( $R^{2}$ ) values for group 1 are markedly higher than group 2 (which have many fewer features) and match reliability ceilings reported in the original experiments.

## Perceptual Hypothesis Spaces

While evidence for the size principle seems apparent from studies of semantic hypothesis spaces, there has been no work attempting to verify the operation of the principle for concrete objects, especially with complex, real-world instances of these objects such as natural images. The featural representations of such instances are complex and include innumerable details not contained in semantic descriptions of the
general case, rendering explicit feature descriptions difficult. Here, we offer a method to overcome this challenge by leveraging representations learned from deep neural networks.

## Perceptual Features

Recent work (Peterson et al., 2016) has provided evidence that deep image feature spaces can be used to approximate human similarity judgments for complex natural stimuli. For our analysis, we extracted image features from an augmented version of Alexnet with a binarized final hidden layer ( Wu , Lin, \& Tang, 2015). This allows for a comparison both to non-

Table 1: Correlations between feature size and feature weight (Semantic Datasets Group 1)

| Set | Pearson | Spearman | $\boldsymbol{F} \boldsymbol{R}$ | $\boldsymbol{R}_{\boldsymbol{M P}}^{2}$ |

Figure 3: Feature Size/Weight Relationships for Convolutional Neural Network Representations.

Figure 4: Examples of stimuli from each of the 5 natural image categories
perceptual binary feature sets (i.e., features from the previous section) and non-binary perceptual feature sets (i.e., previous work on similarity prediction).

## Stimuli \& Data Collection

We obtained pairwise image similarity ratings for 5 sets of 120 images (animals, fruits, furniture, vegetables, vehicles) using Amazon Mechanical Turk, following Peterson et al. (2016). Examples of images in each dataset are given in Figure 4. The image sets represent basic level categories, with 20-40 subordinate categories in each.

Subjects rated at least 4 unique pairs of images and we required that at least 10 unique subjects rate each possible pair. Each experiment yielded a $120 \times 120$ similarity matrix.

## Analysis \& Results

As before, we computed the pairwise multiplication of each pair of rows in $\mathbf{F}$ (120 images $\times 4096$ neural features) and regressed this matrix onto the corresponding empirical similarity values. The resulting weights and feature sizes are plotted in Figure 3 for each category, and the corresponding correlations are reported in Table 3.

Like the previous semantic datasets, only a small portion of the total features obtained non-zero weights, although the average percentage was much smaller ( $\sim 4 \%$ ). Given that the

Table 3: Correlations between feature size and feature weight (Perceptual Dataset)

| Set | Pearson | Spearman | $\boldsymbol{F R}$ | $\boldsymbol{R}_{M P}^{2}$ |
| :--- | ---: | ---: | :---: | :---: |
| Animals | -0.32 | -0.34 | $122 / 4096$ | 0.56 |
| Fruits | -0.43 | -0.44 | $302 / 4096$ | 0.41 |
| Furniture | -0.48 | -0.51 | $170 / 4096$ | 0.38 |
| Vegetables | -0.41 | -0.34 | $295 / 4096$ | 0.45 |
| Automobiles | -0.46 | -0.49 | $125 / 4096$ | 0.31 |

full feature set is meant to characterize 1000 mostly qualitatively distinct categories from which they were learned (Deng et al., 2009), whereas features from the semantic datasets were relevant only to the objects in each group, this discrepancy is to be expected.

In all five datasets, correlation coefficients are moderate, negative, and significant at the $\alpha=0.001$ level. Average Pearson and Spearman correlation was 0.42 in both cases. Variance explained in similarity matrices was comparable to previous work on predicting similarity from deep features, but was generally reduced given the constraint of binary features and non-negative weights.

## Discussion

We have attempted to provide a direct evaluation of the size principle in both semantic and perceptual hypothesis spaces. In some cases, the correlations we report using our method are weaker overall than those reported in past work (Navarro \& Perfors, 2010), but are consistently negative nonetheless. If anything, this discrepancy serves as a caution to trusting a single method for evaluating the size principle.

Across all datasets, variance explained in similarity judgments ranged from .03 to .94 , however these fluctuations don't appear to vary systematically with the magnitude of the size principle effect, This may indicate that the size principle should emerge with respect to both "good" and "bad" feature sets, so long as they are related to the objects and vary in their inclusiveness.

Furthermore, it appears that the size principle can be shown to operate in more ecologically valid stimulus comparisons
such as visual image pairs. In cases such as these, the specific visual details of the image are relevant, and our feature sets derived from convolutional neural networks included only these features. There may be hundreds of small visual details that are only present in novel instantiations of familiar objects that we encounter on a daily basis and that actually represent the more abstract concepts used in semantic datasets. These results may also have implications for the method of estimating human psychological representations recently proposed by Peterson et al. (2016). In this work, it was shown that human similarity judgments for natural images can be estimated by a linear transformation of deep network features, and the current results imply that this transformation is perhaps partly accounted for by the size principle. This finding may lead to better methods for approximating complex human representations based on psychological theories.

It is apparent from the $F R$ columns of each table that few of the total features were used in the actual models. This may be due in part to useless features, or features associated with too many or too few objects. It may also be due to multicollinearity in our feature matrices (some columns are linear combinations of others). These are unique consequences of using a regression model. For this reason, our method may be less susceptible to over-representing certain features that are redundant. On the other hand, the size principle is meant to address the problem of redundant hypotheses directly, and it may be an undesirable property of our model that these hypotheses are eliminated through other means, which is perhaps the cost of direct estimation of the weights in the additive clustering framework. In any case, this variability in the amount of non-redundant features does not appear to co-vary with the size principle in any systematic way.

The only notable discrepancy between our results and the predictions of the size principle is the variation in the magnitude of the negative slopes obtained, which does not appear to depend on model performance, number of features, or even aspects of the dataset groups or individual datasets. Semantic dataset group 2 had more large slopes (e.g., SIMLEX) than group 1, but also had many small slopes. Similar datasets from group 1 (e.g., Fruit and Vegetables) had fairly dissimilar slopes, and nearly identical datasets from group 2 (e.g., Fruit1 and Fruit2) had widely varying slopes. Prototypicality doesn't seem to matter either, since Fruit1 and Vegetables1 have smaller slopes than Fruit2 and Vegetables2, but Clothing1 and Vehicles1 have larger slopes than Clothing 2 and Vehicles2. Furthermore, we can find examples of both natural and artificial stimuli with comparable slopes. For these reasons, it is unclear what the source of these deviations could be. It is possible that certain experimental contexts encourage a focus on certain featural comparisons that can be represented by a weighting of our feature sets, and so still allow for good model fit. Alternatively, it may be an artifact of the weight estimation algorithm, in which case it will be useful to compare alternative methods.

Our results provide broad evidence for the size principle
regardless of the assumptions that are employed to derive it. Thus, the size principle is a good candidate for a second universal law of generalization, and can be motivated both by rational theories based on strong sampling and feature learning. Further, a $\frac{1}{|h|}$ law can provide a solid basis for generalizing from multiple instances, a behavior that we should expect to find in any intelligent agent, anywhere in the universe.

# Modeling the Ellsberg Paradox by Argument Strength 

Niki Pfeifer (niki.pfeifer@Imu.de)<br>Munich Center for Mathematical Philosophy, LMU Munich, Germany

Hanna Pankka (hanna.pankka@helsinki.fi)<br>Department of Philosophy, History, Culture and Art Studies, University of Helsinki, Finland

#### Abstract

We present a formal measure of argument strength, which combines the ideas that conclusions of strong arguments are (i) highly probable and (ii) their uncertainty is relatively precise. Likewise, arguments are weak when their conclusion probability is low or when it is highly imprecise. We show how the proposed measure provides a new model of the Ellsberg paradox. Moreover, we further substantiate the psychological plausibility of our approach by an experiment $(N=60)$. The data show that the proposed measure predicts human inferences in the original Ellsberg task and in corresponding argument strength tasks. Finally, we report qualitative data taken from structured interviews on folk psychological conceptions on what argument strength means.

Keywords: argument strength; coherence; Ellsberg paradox; probability logic

## Introduction

## Measuring Argument Strength

Probabilistic models of argumentation became popular in cognitive science and its subfields including psychology, philosophy, and computer science in recent years (see, e.g., Hahn \& Oaksford, 2006; Haenni, 2009; Zenker, 2013). Like logicbased nonmonotonic approaches for defeasible argumentation (see, e.g. Prakken \& Vreeswijk, 2002), probabilistic approaches allow for dealing with exceptions and retracting conclusions in the light of new evidence. However, in contrast to qualitative logical approaches, probability allows for managing degrees of belief in the sentences involved in common sense argumentation. Moreover, degrees of belief can be used to model the strength of arguments (Hahn \& Oaksford, 2006; Oaksford \& Hahn, 2007; Pfeifer \& Kleiter, 2006; Pfeifer, 2007, 2013b).
The concept "argument" is ambiguous. In logic, it denotes a triple consisting of a (possibly empty) premise set, a conclusion indicator, and a conclusion set. Consider, for example, the following argument, which is an instance of modus ponens:
(P1) If I take the train at five ( $T$ ), I'll be home at six $(H)$.
(P2) I take the train at five $(T)$.
(C) Therefore, I'll be home at six $(H)$.

Here, (P1) and (P2) are the premises, "Therefore" the conclusion indicator and the sentence "I'll be home at six" is the conclusion. In argumentative contexts, "argument" may also denote a premise which speaks for or against a conclusion. For example "The train conductors are on strike", can serve as an argument for concluding that it is better to take the bus. In what follows, however, we will focus on arguments in the logical sense only.

How can we measure the strength of an argument? There are at least two formal approaches to study (probabilistic) argument strength. In the first approach argument strength is based on uncertain consequence relations, i.e., by presupposing that the conclusion follows to some degree from the premises. Usually, this is modeled by a conditional probability of "the conclusion given (some combination of) the premises" of the argument (see, e.g. Hahn \& Oaksford, 2006; Oaksford \& Hahn, 2007). As pointed out by Osherson, Smith, Wilkie, López, and Shafir (1990), measures of confirmation can serve as models for argument strength (for an overview of measures of confirmation see Crupi, Tentori, \& Gonzales, 2007). Measures of confirmation and previous attempts to model argument strength by uncertain consequence relations are problematic when arguments involve conditionals, like the modus ponens above (see premise ( P 1 )): it is far from clear to give a precise meaning of conditionalizing on a combination of premises, when the premise set contains conditional events. There is ample formal and experimental evidence that uncertain conditionals are best modeled by conditional probabilities (see, e.g., Evans \& Over, 2004; Oaksford \& Chater, 2007; Over \& Cruz, in press; Pfeifer, 2014, 2013a). Therefore, conditionals should be modeled by conditional probabilities. However, this requirement would imply to measure the uncertainty of a conclusion given (some combination of) the premises. Unfortunately, satisfactory semantics of expressions like $\overbrace{C}^{\text {conclusion }} \mid \overbrace{(A \text { and }(C \mid A))}^{\text {premises }}$ do not exist yet. Such semantics would, however, be necessary to capture the underlying logical structure of the modus ponens (for an approach which deals with nested conditionals and which avoids Lewis' triviality results, see Gilio, Over, Pfeifer, \& Sanfilippo, 2017; Sanfilippo, Pfeifer, \& Gilio, 2017). Modus ponens is just a relatively simple example here: there are, of course, many other argument forms involving conditionals. The inability to deal with conditionals seems to us to be one of the main reasons, why currently no formally satisfactory measure of argument strength exists within the first approach: measures based on uncertain consequence relations do not seem to be able to deal with the logical form of the argument.

In this paper, we advocate the second approach to argument strength. It satisfies the requirement of doing justice to the logical form of arguments involving conditionals (Pfeifer, 2007, 2013b). Specifically, we define argument strength based on the following ideas: (i) keep the consequence relation deductive, (ii) assign probabilities to the premises, and
then (iii) define the measure of argument strength based on the propagated coherent lower and upper probability bounds on the conclusion (Pfeifer, 2007, 2013b). Probability propagation from the premises to the conclusion is governed by coherence based probability logic (see, e.g. Coletti \& Scozzafava, 2002; Pfeifer \& Kleiter, 2009; Gilio, Pfeifer, \& Sanfilippo, 2016). The coherence approach to probability was originated by Bruno de Finetti (de Finetti, 1970/1974). It conceives probabilities as subjective degrees of belief. Conditional probabilities $(p(C \mid A))$ are primitive. This allows for zero probabilities of the conditioning event $(A)$. Note that in standard approaches to probability, $p(C \mid A)$ is undefined if $p(A)=0$, which is problematic in many argument forms (see, e.g. Pfeifer, 2014; Gilio et al., 2016). Moreover, coherence allows for managing imprecise probabilities (set-valued probabilities involving lower and upper probability bounds), which is relevant for formalising arguments under incomplete probabilistic knowledge. The above mentioned modus ponens, for example, is formalised as follows (see, e.g. Pfeifer \& Kleiter, 2009, Example 1, p. 209):
(P1') $\quad p(H \mid T)=x$
(P2') $\quad p(T)=y$
(C') Therefore, $z^{\prime} \leq p(H) \leq z^{\prime \prime}$, where $z^{\prime}=x y$ and $z^{\prime \prime}=x y+1-y$ are the best possible coherent probability bounds on the conclusion.
Following Pfeifer (2013b), we define the measure of argument strength $\mathfrak{s}$ on an argument $\mathcal{A}$ as follows:

Let $z^{\prime}$ and $z^{\prime \prime}$ denote the coherent lower and upper probability bounds, respectively, on the conclusion of argument $\mathcal{A}$. Then,

$$
\begin{equation*}
\mathfrak{s}(\mathcal{A})={ }_{\text {def. }} \overbrace{\left(1-\left(z^{\prime \prime}-z^{\prime}\right)\right)}^{\text {precision }} \times \overbrace{\frac{z^{\prime}+z^{\prime \prime}}{2}}^{\text {location }} . \tag{1}
\end{equation*}
$$

Intuitively, measure $\mathfrak{s}$ combines the precision and the location of the coherent conclusion probability interval. Specifically, strong arguments are arguments with low imprecision of the conclusion probability (measured by the one-complement of the distance between the upper and the lower probability bounds, $\left.1-\left(z^{\prime \prime}-z^{\prime}\right)\right)$ and with conclusion probabilities close to one (measured by the mean of the lower and upper probability bound, $\left.\left(z^{\prime}+z^{\prime \prime}\right) / 2\right)$. Weak arguments are characterized by a large conclusion interval (i.e., high imprecision) or by a low-probability conclusion (i.e., the center point of the conclusion interval is close to 0 ). For a discussion of how logical validity relates to whether the degree of belief in the conclusion is constrained by the assessment of the premises see, e.g., Pfeifer and Kleiter (2009). Of course, precision and location could be modeled differently (e.g., by using the geometric or the harmonic mean instead of the arithmetic mean). Moreover, in contexts where the location is more important than the precision of the conclusion probability interval (or vice versa), adding suitable weights to formula (1) can adjust the measure for such cases. However, for the purpose of our paper it is sufficient to keep the measure as simple as possible.

Measure $\mathfrak{s}$ has a number of plausible consequences: it ranges always from zero to one (i.e., $0 \leq \mathfrak{s} \leq 1$, since $z^{\prime}$ and $z^{\prime \prime}$ are probability values, which are also in the unit interval, $[0,1]$ ). The extreme " 0 " denotes weak arguments and " 1 " denotes strong arguments. Arguments with conclusion probability 1 , are strong arguments, since $\mathfrak{s}=1$ if $z^{\prime}=z^{\prime \prime}=1$. Arguments with conclusion probability 0 (i.e., $z^{\prime}=z^{\prime \prime}=0$ ) are weak arguments, since $\mathfrak{s}=0$. Likewise, probabilistically non-informative arguments (i.e., $z^{\prime}=0$ and $z^{\prime \prime}=1$ ) are weak arguments, since $\mathfrak{s}=0$.

Interestingly, measure $\mathfrak{s}$ also provides a new solution to the Ellsberg paradox (Ellsberg, 1961), ${ }^{1}$ which we describe in the next section.

## Modeling the Ellsberg Paradox by Measure $\mathfrak{s}$

Ellsberg described the following situation (Ellsberg, 1961):
An urn contains 90 balls, of which 30 are red $(R)$ and 60 are black or yellow. The ratio of the black and yellow balls is unknown-there might be anything between 0 to 60 black (or yellow) balls. One ball is drawn at random from the urn and you are asked to choose a bet between two bets. If you take Bet $\mathbf{1}$, you will win $\$ 100$, if the ball drawn from the urn is red. If you take Bet 2, you will win $\$ 100$, if the ball drawn from the urn is black.

Ellsberg predicted that most people choose Bet $\mathbf{1}$ when asked to decide which of the two bets they prefer. Then, considering again the same urn, Ellsberg predicted that people will choose Bet 4, when they are asked to decide between the following two alternative bets:

If you take Bet 3, you will win $\$ 100$, if the ball drawn from the urn is red or yellow. If you take Bet 4, you will win $\$ 100$, if the ball drawn from the urn is black or yellow.

Ellsberg's predictions create a well-known paradox as they violate the independence axiom of rational choice (see, e.g., Briggs, 2016). Moreover, Ellsberg's predictions were experimentally confirmed in many studies (see, e.g., Becker \& Brownson, 1964; Slovic \& Tversky, 1974; MacCrimmon \& Larsson, 1979).
We propose to frame the Ellsberg paradox in terms of probability logical arguments. Specifically, the premises represent the probabilistic information given in the description of the urn, and the conclusions represent the respective bets involved in the Ellsberg paradox. Thus, we obtain four arguments. Each argument speaks for choosing the corresponding bet. The associated argument to Bet 2, for example, is argument $\mathcal{A}_{2}$ (where " $\vee$ " denotes disjunction ("or") and $R, B$ and $Y$ are mutually exclusive):
$p(R)=.33$
$p(B \vee Y)=.67$
Therefore, $0 \leq p(B) \leq .67$ is coherent.

[^171]The strength of this argument is denoted by $\mathfrak{s}\left(\mathcal{A}_{2}\right)$ and by applying equation (1) equal to . 11 (i.e., $\mathfrak{s}\left(\mathcal{A}_{2}\right)=.11$ ). Table 1 lists the conclusions and the argument strengths $\mathfrak{s}$ for each argument for the corresponding four bets involved in the Ellsberg paradox.

Table 1: Conclusions and normative strengths (s) of Arguments $\mathcal{A}_{1}, \ldots, \mathscr{A}_{4}$ associated with the four bets involved in the Ellsberg paradox. The premises are always $p(R)=.33$ and $p(B \vee Y)=.67$.

|  | Conclusion | Argument strength |
| :--- | :---: | :---: |
| Bet 1 | $p(R)=.33$ | $\mathfrak{s}\left(\mathcal{A}_{1}\right)=.33$ |
| Bet 2 | $0 \leq p(B) \leq .67$ | $\mathfrak{s}\left(\mathcal{A}_{2}\right)=.11$ |
| Bet 3 | $.33 \leq p(R \vee Y) \leq 1$ | $\mathfrak{s}\left(\mathcal{A}_{3}\right)=.22$ |
| Bet 4 | $p(B \vee Y)=.67$ | $\mathfrak{s}\left(\mathcal{A}_{4}\right)=.67$ |

The four argument strength values in Table 1 induce the following preference orders in the classical Ellsberg task: Bet $1 \succ$ Bet 2, since $\mathfrak{s}\left(\mathscr{A}_{1}\right)=.33>\mathfrak{s}\left(\mathscr{A}_{2}\right)=.11$, and Bet $4 \succ$ Bet 3, since $\mathfrak{s}\left(\mathscr{A}_{4}\right)=.67>\mathfrak{s}\left(\mathcal{A}_{3}\right)=.22$ (where $X \succ Y$ denotes $X$ is preferred over $Y$ ). This preference order corresponds to Ellsberg's predictions and matches the data (see, e.g., Becker \& Brownson, 1964; Slovic \& Tversky, 1974; MacCrimmon \& Larsson, 1979). The functions of the four arguments can be understood in an epistemic and in a persuasive sense. The epistemic function of the arguments is to gain knowledge about which bet should be preferred. The persuasive function of the arguments is to convince someone which bet should be preferred.

In the following section we further investigate the psychological plausibility of $\mathfrak{s}$ by an experiment.

## Method

## Participants

In this experiment 60 university students (mean age 25.9 years ( $S D=5.6$ ), 48 females, 12 males) participated for a compensation of $15 €$. All of the participants were Finnish native speakers and none of them had studied psychology, mathematics, statistics or philosophy as their major.

## Design and Materials

We used three target task types: argument ranking tasks, argument rating tasks, and the (original) Ellsberg tasks. The argument ranking tasks first instructed the participants to rank the strength of arguments $\mathcal{A}_{1}$ and $\mathcal{A}_{2}$ (see Table 1). Second, the participants were instructed to rank the strength of arguments $\mathcal{A}_{3}$ and $\mathcal{A}_{4}$. The argument rating tasks instructed the participants to rate the strength of each of the four arguments. In the original version of the Ellsberg task, participants had to rank which bets they preferred as described in the Introduction. We investigated the following questions which relate argument strength to the Ellsberg problem:

- Do the results of the argument strength rating tasks predict the responses in the Ellsberg tasks?
- Do the results of the argument strength rating tasks predict the responses in the argument strength ranking tasks?

Moreover, we explored empirically, whether argument strength formulated in epistemic or in persuasive terms impacts participants' reasoning. Finally, we systematically manipulated the information conveyed in the argument rating and in the argument ranking tasks by the following independent variables: (i) only the uncertainty of the conclusion was presented, (ii) only the uncertainties of the premises were presented, and (iii) uncertainties of the premises and the conclusion were presented. The instructions introduced the following symbol for marking not conveyed information in the respective conditions which correspond the variables (i) and (ii): $\mathbb{4}$. By using a $2 \times 3$ between-participant design we fully crossed epistemic versus persuasive formulations and the manipulated information conveyed in the arguments. In the epistemic booklets we used knowledge-oriented phrasings like "Which argument is stronger to know which bet to choose?", whereas in the persuasive booklets we used according phrasings like "Which argument convinces stronger which bet to choose?". The experimental conditions are explained in Table 2.

Table 2: Experimental conditions ( $\mathrm{Cd} 1-\mathrm{Cd} 6 ; N=60$ ).

| Presented probabilities | Epistemic | Persuasive |
| :--- | :--- | :--- |
| Premise \& conclusion | $\operatorname{Cd} 1\left(n_{1}=10\right)$ | $\operatorname{Cd} 2\left(n_{2}=10\right)$ |
| Conclusion only | $\operatorname{Cd} 3\left(n_{3}=10\right)$ | $\operatorname{Cd} 4\left(n_{4}=10\right)$ |
| Premise only | $\operatorname{Cd} 5\left(n_{5}=10\right)$ | $\operatorname{Cd} 6\left(n_{6}=10\right)$ |

Argument ranking tasks In these tasks, the participants were instructed to imagine two friends arguing about which bet the participant should choose. Then, argument $\mathcal{A}_{1}$ for Bet 1, and argument $\mathcal{A}_{2}$ for Bet 2 were presented to the participant, e.g.:

## Argument 2 for Bet 2

I am $\times \%$ sure that the ball drawn from the urn is red.
I am $\times \%$ sure that the ball drawn from the urn is black or yellow.
Therefore, I am at least $0 \%$ and at most $67 \%$ sure that the ball drawn from the urn is black

The participants were then presented with the question "Which argument is stronger to know which bet to choose?" (Kumpi argumentti on vahvempi sen tietämiseen, kumpi veto kannattaisi valita?) in the epistemic condition. In the persuasive condition, they were asked "Which argument convinces you stronger which bet to choose?" (Kumpi argumentti vakuuttaa sinut vahvemmin siitü, kumpi veto kannattaisi valita?). Then, the participants were instructed to indicate
their choice by ticking the respective box for Argument 1 (i.e., $\mathcal{A}_{1}$ ) or Argument 2 (i.e., $\mathcal{A}_{2}$ ). Finally, the participants ranked Argument 3 (i.e., $\mathcal{A}_{3}$ ) and Argument 4 (i.e., $\mathcal{A}_{4}$ ).

Argument rating tasks In these tasks participants were presented with the same four arguments as in the argument ranking tasks. They were asked to carefully reconsider each. Instead of using forced choice response formats, each argument was followed by a question, e.g., "How strong is Argument 2 for choosing Bet 2?" (Kuinka vahva Argumentti 2 on Vedon 2 valitsemiseksi?; original epistemic formulation) or "How strong is Argument 2 for convincing to choose Bet 2?" (Kuinka vahva Argumentti 2 on vakuuttamaan Vedon 2 valitsemisesta?; original persuasive formulation). The participants were asked to mark their responses on a ten point rating scale (see Figure 1).

Figure 1: Answer scale used in the argument rating tasks.

Ellsberg tasks Here, as explained in the introduction, the participants had to choose which rankings among bets they preferred (Bet 1 or Bet $\mathbf{2}$ and Bet $\mathbf{3}$ or Bet 4). All participants were presented with the same Ellsberg tasks.

## Procedures

Participants completed the booklets individually in a quiet room. At the beginning of the testing, participants were informed to take as much time as needed for completing the tasks. Furthermore, they were instructed not to look back on their previous responses. After reading the introduction the participants worked on tasks which differed from the Ellsberg problem (and which are not in the scope of the present paper). After that, the target tasks were presented in the following order: (i) argument ranking tasks, (ii) argument rating tasks, and (iii) the Ellsberg tasks. The easier argument ranking tasks (rankings require less cognitive effort than ratings) appeared prior to the argument rating tasks to further help participants to familiarize themselves with the task materials. To avoid any influences of the Ellsberg tasks on the argument strength tasks and to see whether our samples replicate the findings in the literature, the Ellsberg tasks were presented at the end of the booklet. Then, the participants filled in demographic data and rated the difficulty and clearness of the tasks. Participants used 9.6 minutes $(S D=2.8)$ on the average to work on the booklets. Each session concluded by an interview to further explore argument strength from a qualitative point of view: we asked how the participants solved

Table 3: Percentages of argument preferences in the argument ranking tasks $(\operatorname{rnk}(\mathcal{A}))$ and in the Ellsberg tasks $(N=60)$.

| \% | $\operatorname{rnk}(\mathcal{A})$ | Ellsberg | \% | $\operatorname{rnk}(\mathcal{A})$ | Ellsberg |
| :---: | :---: | :---: | :---: | :---: | :---: |
| Bet1 | 73,3 | 93,3 | Bet3 | 25,0 | 23,3 |
| Bet2 | 26,7 | 6,7 | Bet4 | 75,0 | 76,7 |

the tasks and what they thought determined the strength of an argument.

## Results and Discussion

We performed Fisher's exact tests to compare the impact of the different booklets on the response frequencies in the argument ranking tasks and in the Ellsberg tasks. Moreover, we tested influences of the different conditions in the argument rating tasks by analyses of variance. After performing Holm-Bonferroni corrections we did not observe any significant differences. We therefore pooled the data for further analysis $(N=60)$.

Ellsberg's predictions The majority of responses in all three types of tasks (i.e., argument ranking, argument rating and Ellsberg task) are consistent with Ellsberg's predictions. Our findings also replicate empirical findings reported in the literature (see, e.g., Becker \& Brownson, 1964; Slovic \& Tversky, 1974; MacCrimmon \& Larsson, 1979). Moreover, our data suggest that classical findings in Ellsberg tasks carry over to (isomorphic) problems formulated in terms of argument strength.

Table 3 shows how the participants ranked the arguments in the argument ranking tasks and how they ranked the bets in the Ellsberg tasks. Bet 1 (resp., argument $\mathcal{A}_{1}$ supporting Bet 1 ) is more frequently chosen than Bet 2 (resp., $\mathcal{A}_{2}$ supporting Bet 2). Likewise, Bet 4 (resp., argument $\mathscr{A}_{4}$ supporting Bet 4 ) is more frequently chosen than Bet 3 (resp., $\mathcal{A}_{3}$ supporting Bet 3).

Moreover, we constructed the underlying preference orders of the argument strengths and the bets from the participants' responses in all the three task types. This allows one to see which choice strategies were most commonly used. In all tasks, strategies consistent with the independence axioms of rational choice were less frequently preferred, as can be seen in Table 4. For constructing the preference orders based on the responses in the argument strength ratings tasks, we made the following assumption: if the strength of an argument $\mathcal{A}_{x}$ was rated higher than the strength of an argument $\mathcal{A}_{y}$, then the corresponding Bet $x$ is preferred over Bet $y$. Again, our findings replicate the predictions of Ellsberg and the previous empirical findings (see, e.g., Becker \& Brownson, 1964; Slovic \& Tversky, 1974; MacCrimmon \& Larsson, 1979).

Table 5 shows the mean argument strength rating responses. As predicted by measure $\mathfrak{s}$, the mean argument strength ratings reflect the Ellsberg predictions, i.e.,

Table 4: Percentages of responses consistent with Ellsberg's predictions $(E)$, the independence axiom of rational choice $(I)$. The preference order $R$ can be interpreted as a reversed version of $E$. " $(x, y) \succ(u, v)$ " means "arguments (resp. bets) $x$ and $y$ are preferred over arguments (resp. bets) $u$ and $v$ ". Preference order responses consistent with $\mathfrak{s}$ are in bold.

| Preference | Tasks $(N=60)$ |  |  |
| :---: | :---: | :---: | :---: |
| Order | $\mathcal{A}$ Ranking | Ellsberg | $\mathcal{A}$ Rating |
| $(1,4) \succ(2,3)^{E}$ | $\mathbf{5 6 . 6 7}$ | $\mathbf{7 1 . 6 7}$ | $\mathbf{5 6 . 1 0}$ |
| $(2,3) \succ(1,4)^{R}$ | 8.33 | 1.67 | 4.88 |
| $(1,3) \succ(2,4)^{I}$ | 16.67 | 21.67 | 21.95 |
| $(2,4) \succ(1,3)^{I}$ | 18.33 | 5.00 | 17.07 |

mean rating $\left(\mathcal{A}_{1}\right)>$ mean rating $\left(\mathcal{A}_{2}\right)$ and mean rating $\left(\mathcal{A}_{4}\right)>$ mean rating $\left(\mathcal{A}_{3}\right)$.

Table 5: Means and standard deviations (SD) of the argument strength ratings on a scale from 0 ("extremely weak") to 10 ("extremely strong"; $N=60$ ).

|  | $\mathcal{A}_{1}$ | $\mathcal{A}_{2}$ | $\mathcal{A}_{3}$ | $\mathcal{A}_{4}$ |
| :---: | :---: | :---: | :---: | :---: |
| Mean | 5,20 | 3,98 | 5,77 | 6,95 |
| $S D$ | 2,64 | 2,58 | 1,74 | 1,87 |

Consistency among the data Based on the argument strength ratings, we predicted the participants' choices in the ranking and in the Ellsberg tasks. The data support our predictions: the argument strength rating responses predict the ranking responses in the Ellsberg tasks. The rating responses also predict the responses in the argument strength ranking tasks (see Table 6 and Table 7).

As some participants had rated the arguments for the bets equally strong, no predictions could be derived in these cases. When taking into account only those cases, in which making predictions was possible, the responses of roughly $3 / 4$ of the participants were consistent with their responses in the ranking tasks. In the argument strength ranking tasks, $77.3 \%$ of the participants chose as predicted between the first two bets and $75.0 \%$ chose as predicted between the second two bets. For the Ellsberg tasks, we observed similarly high percentages (i.e., $75.0 \%$ and $70.8 \%$ of the participants, for the first and the second bet rankings, respectively). This is again experimental support for the psychological plausibility of measure $\mathfrak{s}$.

Finally, we discuss qualitative data taken from structured interviews on folk psychological conceptions on what argument strength means.

Interview results After the participants completed the paper and pencil tasks, we collected folk psychological conceptions on what "argument strength" (argumentin vahvuus)

Table 6: Predictions of bet rankings in Ellsberg tasks based on responses in the argument strength rating tasks $(N=60)$.

|  | Ranking |  |
| :--- | :---: | :---: |
| $\%$ | Bet 1 vs. Bet 2 | Bet 3 vs. Bet 4 |
| Chose as predicted | 55.00 | 56.67 |
| Did not choose as predicted | 18.33 | 23.33 |
| No prediction made | 26.67 | 20.00 |

Table 7: Predictions of argument strength rankings based on the responses in argument strength rating tasks $(N=60)$.

| $\%$ | Ranking |  |
| :--- | :---: | :---: |
|  | $\mathcal{A}_{1}$ vs. $\mathcal{A}_{2}$ | $\mathcal{A}_{3}$ vs. $\mathcal{A}_{4}$ |
| Chose as predicted | 56.67 | 60.00 |
| Did not choose as predicted | 16.67 | 20.00 |
| No prediction made | 26.67 | 20.00 |

means by structured interviews. We asked the participants how they would define argument strength in their own words. Participants who had received the persuasive booklets, we hypothesized, mentioned persuasive aspects (like how convincing arguments are) more frequently than those of the epistemic condition. Moreover, participants who had received the epistemic booklets focused more on epistemic aspects (like truth and knowledge) than those of the persuasive condition. However, the interview responses do not confirm these hypotheses.

The responses to the interview question concerning the meaning of "argument strength" reflected features of our measure $\mathfrak{s}$. Specifically, the location of the coherent conclusion probability interval was referred to by almost all of the participants. For many participants the location seemed to be more important than the precision of the coherent conclusion probability interval. They had, for example, focused solely on the lower probability bound of the interval and ignored the upper bound or responded based on the mean value of the interval.

However, a few participants also referred to the precision of the coherent conclusion probability interval by sentences like:
"The size of this gap between 33 [\%] and 100 [\%] is so big that it increases the uncertainty." (Epävarmuиtta lisää se, että väli 33:n ja 100:n välillä on niin suuri)

Some participants also talked about the truth or correctness of the probability bounds of the conclusion. For them, the arguments were strong, when the probabilities in the conclusions were correct, almost regardless of the values in them.

The interview responses provide folk psychological evidence for using location and precision of conclusion probability intervals for evaluating the strength of uncertain argu-
ments. Location and precision are the key ingredients of our argument strength measure $\mathfrak{s}$.

Finally, we note that Bet $\mathbf{1}$ is usually not compared directly against Bet 3 in the traditional Ellsberg task. The corresponding $\mathfrak{s}\left(\mathscr{A}_{1}\right)$ is a bit higher compared to $\mathfrak{s}\left(\mathcal{A}_{3}\right)$ : epistemically, this makes sense since the conclusion of $\mathcal{A}_{3}$ is highly imprecise while the conclusion of $\mathcal{A}_{1}$ is perfectly precise (see Table 1 above). However, it seems plausible to assume that people would prefer Bet $\mathbf{3}$ over Bet 1. To accommodate $\mathfrak{s}$ for this prediction, one could reduce the impact of the precision by adding suitable weights to the definition of $\mathfrak{s}$.

## Concluding Remarks

Based on the location and the precision of the conclusion's probability interval, we proposed a formal measure of argument strength $\mathfrak{s}$ and showed how $\mathfrak{s}$ predicts responses in Ellsberg tasks. Specifically, we framed choices among bets in terms of probability logical argument forms. Our data support the hypothesis that Ellsbergs predictions can be justified by argument strength rankings and argument strength ratings.

Since the proposed measure exploits tools available in coherence-based probability logic and since it is based on a deductive consequence relation, it allows for dealing with arguments involving conditionals. The proposed measure has many plausible consequences, which calls for future formalnormative and experimental research for modeling also other argument types, like the conditional syllogisms.

Understanding argument strength is important for theories about reasoning and argumentation in general. Our paper sheds formal and experimental light on what argument strength can mean.

# Causation and norms of proper functioning: Counterfactuals are (still) relevant 

Jonathan Phillips (phillips01@g.harvard.edu) \& Jonathan Kominksy (jkominsky@g.harvard.edu)<br>Department of Psychology, Harvard University, 33 Kirkland St. Cambridge, MA, 02138

#### Abstract

Causal judgments are well-known to be sensitive to violations of both prescriptive moral and descriptive statistical norms. There is ongoing discussion as to whether both effects are best explained through changes in the relevance of counterfactual possibilities, or if moral norm violations should be independently explained through a potential polysemy whereby 'cause' may simply mean 'is morally responsible for'. In support of the latter view, recent work has pointed out that moral norm violations affect judgments of agents, but not inanimate objects, and that these effects are moderated by agents' knowledge states. We advance this debate by demonstrating that judgments of counterfactual relevance exhibit precisely the same patterns, and that judgments of inanimate objects are actually highly sensitive to whether the object violated a prescriptive norm by malfunctioning. The latter finding is difficult to account for through polysemy, but is predicted by changes in the relevance of counterfactual alternatives. Finally, we show that direct (non-moral) interventions on the the relevance of counterfactual alternatives affect causal judgments in precisely the same way as functional and moral norm violations.

Keywords: causation; norms; counterfactuals; morality; teleology

## Introduction

A central question in research on causal cognition concerns the role of norms. It is well-known that both descriptive norms (e.g., the probability of an event occurring) and prescriptive norms (e.g., the morality of an event occurring) influence judgments of actual causation, that is, a judgment that some event, $e$, was the cause of some outcome, $o$ (Alicke, 2000; Gerstenberg \& Tenenbaum, in press; Hitchcock \& Knobe, 2009; Kominsky, Phillips, Gerstenberg, Lagnado, \& Knobe, 2015). Specifically, people are more inclined to judge that $e$ was the cause of $o$ if $e$ was either very unlikely to happen or morally prohibited. Despite widespread agreement on the existence of the phenomenon, there has been little corresponding agreement on how these effects should be explained.

Most researchers take the impact of descriptive statistical norms to reveal part of the basic underlying processes that support causal reasoning (e.g., Gerstenberg \& Tenenbaum, in press; Icard, Kominsky, \& Knobe, in press; Samland \& Waldmann, 2016). They differ, however, in whether they treat the impact of prescriptive moral norms similarly, or argue that it arises from a fundamentally different set of processes.

On one side, researchers have argued that the impact of both descriptive and prescriptive norms is best explained by changes in the relevance of counterfactual possibilities. These accounts propose that when a norm violation occurs, it increases the relevance of counterfactual alternatives wherein the norm violations are replaced by norm-conforming events (e.g., Halpern \& Hitchcock, 2015; Kominsky et al., 2015; Bello, 2016). In support of this account, recent work demonstrated that norm violations affect explicit assessments of
counterfactual relevance in precisely the same way that they affect causal judgments (Phillips, Luguri, \& Knobe, 2015).

On the other side, other researchers have argued for separate explanations of the two effects. The most recent approach has suggested that the term 'cause' is polysemous: It can be used to talk about whether an agent is morally responsible for an outcome, or it can be used to talk about whether some event causally contributed to an outcome (Samland \& Waldmann, 2016). On this approach, the impact of violations of moral norms can instead be accounted for by arguing that participants are more likely to interpret the word 'cause' as being about moral responsibility in cases where moral norms have been violated.

Advancing this debate, Samland and Waldmann (2016) (S\&W hereafter) reported two important new data points: First, the violation of moral norms selectively influences causal judgments about whether agents caused an outcome, but not causal judgments of whether inanimate objects used by the same agents caused the outcome. Second, factors that affect the moral responsibility of the norm violator (such as their knowledge states) also affect causal judgments (see also Samland, Josephs, Waldmann, \& Rakoczy, 2016). S\&W suggest that these findings are best accounted for by assuming that participants were interpreting the causal question to be about moral responsibility when asked about an agent, but about simple causal contribution when asked about an object.

In arguing that these results provide evidence against a unified counterfactual account, S\&W rely on the assumption that when a norm violation occurs, people consider counterfactual alternatives to the event in its entirety. That is, they consider a counterfactual alternative that involves both the agent who violated a norm and the inanimate object used by that agent. If this assumption is correct, then a polysemy account seems to better capture S\&W's results, since a unified counterfactual account would predict that causal judgments of the agent and the inanimate object would both be affected.

At the same time, though, it is possible that the counterfactual alternatives people represent are more granular. That is, when a moral norm violation occurs, people may consider a counterfactual alternative that involves the norm-violating agent, but not the inanimate object used by that agent. If this turns out to be correct, then S\&W's findings should be understood as perfectly compatible with a unified counterfactual explanation, as this accounts would then predict that causal judgments of the agent, but not the object, would be affected.

To distinguish these possibilities, we begin by asking whether the effects uncovered by S\&W also arise in participants' assessments of which counterfactuals are relevant. One possibility is that, because moral norms apply to agents but not inanimate objects, participants will regard counter-
factual alternatives to what the agent did as relevant, but not alternatives to what the inanimate object did. If so, it would suggest that they are represented somewhat independently of one another. Furthermore, changes to agents' mental states may affect both the agent's moral responsibility and similarly whether it is relevant to consider counterfactual alternatives to their actions, which may help explain why changes to agents' mental states affect causal judgments (see, e.g., Lombrozo, 2010 on how intentions affect causal judgments in doubleprevention scenarios).

## Experiment 1

## Methods

Participants. 610 participants $\left(M_{\text {age }}=37.28, S D_{\text {age }}=\right.$ 12.14; 338 females, 1 unreported) from Amazon Mechanical Turk participated for a $\$ 0.25$ compensation. Participant recruitment was automated through TurkPrime (www.turkprime.com) to prevent repeat participation and limit recruitment to participants with a high approval rating.

Stimuli and procedure. This experiment was nearly identical to S\&W's Experiment 4, but with an additional DV. The overall design was 4 (norm condition) x 3 (question) and administered fully between-subjects. Participants read one of four vignettes (see Supplementary Materials available at https://github.com/phillipsjs/stillRelevant). In all conditions, Tom owns a garden and has two gardeners, Alex and Benni, who each take care of $1 / 3$ of the plants on their own, and jointly tend to the remaining $1 / 3$. Additionally, Alex and Benni always use two fertilizers "A-X200®" and "B-Y33®". Tom reads that fertilizers are good for plants, but using more than one kind of fertilizer could damage his plants, so Tom decides he wants both gardeners to use only fertilizer A-X200. In all cases, however, Alex applies fertilizer A-X200 and Benni applies fertilizer B-Y33, and the plants cared for by both of them are damaged.

The four conditions varied the reason that Benni used BY33. In the Standard norm-violation condition, Benni simply decides to use B-Y33; in the Unintended norm-violation condition, Benni believed he was applying A-X200, but accidentally applied B-Y33; in the Ignorant norm-violation condition, Tom neglects to tell Benni to use only A-X200, and he uses B-Y33 instead; and in the Deceived norm-violation condition, Alex deliberately lies to Benni about which fertilizer he is supposed to use to get him in trouble. We additionally varied the focus of the questions. Participants were either asked questions that focused on the two agents ("Alex" and "Benni"), the two actions ("the application of fertilizer by Alex" and "the application of fertilizer by Benni"), or the two chemicals ("the application of chemical A-X200" and "the application of chemical B-Y33").

After reading the vignette, participants were asked whether it was relevant to consider counterfactual alternatives to some aspect of the event, following Phillips et al., (2015). For example, in the Agent condition, participants indicated both whether they thought it was relevant or irrelevant to consider
what Alex could have done differently and also whether it was relevant or irrelevant to consider what Benni could have done differently. Subsequently, as in S\&W, participants were asked to judge who or what caused the plants to dry up (again depending on the Question condition). In the Agent condition, participants indicated both whether they thought Alex was a cause and also whether they thought Benni was a cause. Because the causal question was simply a replication of S\&W (who did not include a counterfactual question), the counterfactual question was always presented first and mirrored S\&W's causal question as closely as possible.

Following these question, participants received two check questions that tested their understanding of which chemicals were applied by which gardener, and which chemicals Tom wanted each gardener to use. Following S\&W, they were also asked to estimate the proportion of the flowers that dried when (1) only fertilizer A-X200 was applied, (2) only fertilizer B-Y33 was applied, and (3) both were applied.

## Results

We excluded participants who did not answer both of the check questions correctly, and analyzed the remaining 439 participants' judgments. (Note that here and throughout the following experiments, all of the key results remain when these exclusion criteria are relaxed.) To examine the effects of our manipulation on both causation and relevance judgments, we categorized participants' responses as assigning causal responsibility (or counterfactual relevance) to (1) only the norm-violating agent, (2) both agents, or (3) only the normconforming agent, and then subjected both kinds of judgments to a proportional odds logistic regression using the probit function in the MASS package in R. For causal judgments, we observed an effect of the norm-condition $(L R T=20.49$ $[d f=3], p<.001)$, an effect of question $(L R T=44.53$ $[d f=2], p<.001)$, and critically, a norm-condition $\times$ question interaction effect $(L R T=19.94[d f=6], p=.003)$. This precisely replicates the pattern of data observed in S\&W (the complete information on the replication of the key statistical tests reported in S\&W is available in the Supplementary Materials). Importantly, this direct replication of S\&W provides evidence that answering the counterfactual question first did not unduly influence participants' causal judgments.

We next analyzed participants' relevance judgments, and observed a highly similar pattern of results: an effect of norm-condition $(L R T=13.93[d f=3], p=.003)$, an effect of question $(L R T=73.34[d f=2], p<.001)$, and a norm-condition $\times$ question interaction effect $(L R T=14.15$ $[d f=6], p=.028$. Critically, because participants answered this question first, the observed pattern cannot have been influenced by participants' causal judgments. All the same, at the level of each participants' responses, judgments of the causal responsibility were highly correlated with judgments of whether it was relevant to consider alternatives to the agents' actions. This was true both for judgment of the norm-violating agent/action/object, (Pearson's $r=0.553$, $p<.001$ ), and for the norm-conforming agent/action/object
(Pearson's $r=0.406, p<.001$ ), and moreover, held whether participants were making judgments about agents (Pearson's $r=0.651, p<.001$ ), actions (Pearson's $r=0.262, p<$ .001), or simply inanimate objects (Pearson's $r=0.280, p<$ .001).The similarity in the overall pattern of these judgments across all of the conditions can be seen in Figure 1.

Figure 1: Depiction of the relationship between participants' causal ratings and relevance ratings. Judgments related to the norm-conforming agent are marked with a ' C '; Judgments related to the norm-violating agent are marked with a ' V '.

## Discussion

In sum, we replicated S\&W's causal judgments, and found a corresponding pattern for which counterfactual alternatives participants regarded as relevant. These findings mirror those in observed in Phillips et al. (2015), which used a continuous rather than dichotomous measure of counterfactual relevance, and more importantly are predicted by a unified counterfactual account of the impact of norms on causal judgments.

## Experiment 2

We next investigated whether causal judgments of inanimate objects are sensitive to violations of prescriptive norms of proper functioning (e.g., a machine malfunctioning). According to a unified counterfactual account, when a machine malfunctions, it should become more relevant to consider the counterfactual possibility that the machine could have instead functioned as intended, and thus the machine should be judged as more causal. Polysemy accounts do not predict such an effect, as participants should not interpret the word 'cause' to mean 'morally responsible' when discussing an inanimate object. We test these two predictions.

## Methods

Participants. 403 participants $\left(M_{\text {age }}=34.96, S D_{\text {age }}=\right.$ 11.90; 205 females, 1 unreported) from Amazon Mechanical Turk participated for a $\$ 0.25$ compensation. Participant recruitment was again automated through TurkPrime.

Stimuli and procedure. This experiment used a 3 (Norm violation; norm-conforming vs. moral violation vs. malfunction) x 2 (Question: agent vs. object) design, administered fully between-subjects.

Participants read one of three vignettes involving a vending machine in an academic department. In every condition, the machine has three levers (red, black, and white): two produce pencils and one produces an eraser but frequently malfunctions and also produces a broken pencil. There were also two agents: an administrative assistant, and Professor Smith (a recent hire who did not know about the malfunctioning lever). Prof. Smith always pulls the red lever, and the assistant always pulls the black lever. This later results in a problem for a student who needs a pencil to take a test but cannot get one.

In the norm-conforming condition, the red lever and black lever both produce pencils, and the white lever produces erasers (but also consistently malfunctions). Additionally, both administrators and faculty were allowed to take pencils from the machine. Both agents request pencils using the black and red levers, which both function appropriately. The moral violation condition was identical to the normconforming condition, except that the faculty are not allowed to get pencils from the machine (but administrative assistants are allowed), and this rule was known by Prof. Smith. Lastly, the malfunction condition was identical to the normconforming condition except that it was the red lever that produced erasers (and malfunctioned), and Prof. Smith wanted an eraser, so Prof. Smith pulled the red lever and got an eraser and a broken pencil.

Participants were then asked a question about the relevance of counterfactual alternatives and a causal question in random order on separate pages. The relevance of alternatives question was worded and presented the same way as Experiment 1, and either focused on the agents (Prof. Smith, administrative assistant) or the objects (red lever, black lever). The causal question similarly asked either who caused the problem (agent condition) or what caused the problem (object condition), and participants could select one or both.

These were followed by three comprehension check questions and two additional manipulation-check questions. The comprehension questions ensured that participants understood the key facts about the levers, agents, and outcome of the scenario. Additionally, participants rated, on a 0 100 scale, how likely the malfunction was to occur, in order to verify that participants did not think the malfunction also violated a descriptive (statistical) norm. Finally, participants rated their agreement with the statement "It was morally wrong for Prof. Smith to pull the red lever" on a 7-point Likert scale, with the expectation that ratings should be higher in the moral violation condition than the other two conditions, which should not differ from each other. The predictions for both manipulation-check questions were overwhelmingly confirmed (see Supplementary Materials). Thus, any effect of the functional norm violation cannot be explained by appealing to statistical or moral norms.

## Results

We excluded participants who did not answer all three of the check questions correctly, and analyzed the remaining 258 participants' judgments. To facilitate comparison of participants' judgments, we computed a measure of participants' preference for selecting the norm-violating event as a cause. Participants who selected only the norm-violating event as a cause were assigned a score of 1 ; participants who selected both or neither events as causes were assigned score of 0 ; and participants who selected only the norm-conforming event were assigned a score of -1 . We then analyzed participants' causal preference scores with a 2 (Causal Question: Agent vs. Object) $\times 3$ (Norm condition: Immoral vs. Malfunction vs. Normal) proportional odds logistic regression, as in Study 1. This analysis revealed a main effect of Norm condition, $(L R T=71.49[d f=2], p<.001)$, no main effect of Causal question $(L R T=0.045[d f=1], p=.832)$, and critically a Norm condition $\times$ Causal question interaction effect ( $L R T=31.42[d f=2], p<.001$ ).

We decomposed this interaction effect by separately analyzing participants' causal preference scores for each of the different conditions. When the relevant norm was moral and thus applied to the agent but not the object, participants tended to prefer the norm-violating agent as a cause, but did not similarly prefer the norm-violating object as a cause ( $L R T=15.33[d f=1], p<.001$ ). When the relevant norm was functional, and thus the norm applied to the object but not the agent, this pattern was reversed: participants tended to prefer the norm-violating object as a cause, but did not similarly prefer the norm-violating agent as a cause $(L R T=12.36$ $[d f=1], p<.001)$. When there was no norm that applied to either the agent or the object, there was small and nonsignificant preference for the norm-conforming agent but not the object ( $L R T=1.13[d f=1], p=.288$ ).

We next analyzed participants' judgments of the relevance of counterfactual alternatives in exactly the same way. Just as with participants' causal judgments, we observed a main effect of Norm condition, $(L R T=40.53[d f=2], p<.001)$, no main effect of Relevance question $(L R T=0.10[d f=1]$, $p=.747$ ), and critically a Norm condition $\times$ Relevance question interaction effect ( $L R T=33.70[d f=2], p<.001$ ). We decomposed this interaction effect by separately analyzing participants' counterfactual preference scores for each of the different conditions. When a moral norm was salient, participants tended to prefer counterfactuals for the agent, but not the object $(L R T=16.63[d f=1], p<.001)$. When the relevant norm was functional, this pattern was reversed: participants preferred counterfactuals for the object, but not the agent $(L R T=11.20[d f=1], p<.001)$. When there was no norm violation that applied to either the agent or the object, there was a small and significant preference for the normconforming agent, but not the object $(L R T=4.48[d f=1]$, $p=.034)$. A similar pattern is found when only participants' first responses are analyzed, allowing for a between-subjects analysis (see Supplementary Materials).

Figure 2: Average preference score for the norm-violating event in causal judgments (top) and counterfactual relevance judgments (bottom), as a function of which norms were relevant (split into panels). Grey bars depict responses to questions about agents; Red bars depict responses to questions about inanimate objects. Error bars depict +/- 1 SEM.

## Discussion

Experiment 2 found that judgments of inanimate objects are sensitive to violations of prescriptive norms of proper functioning, even though they are not sensitive to violations of moral norms. Specifically, we found that when an inanimate object violated a functional norm, participants' thought it was relevant to consider counterfactual alternatives to that malfunction, and that this effect was mirrored by a corresponding change in participants' causal judgments. This pattern is uniquely predicted by a unified counterfactual accounts of the impact of norms on causal judgments, and is not predicted by an account on which the term 'cause' is polysemous.

## Experiment 3

Previous research (Phillips et al., 2015) has demonstrated that causal judgments are also sensitive to more direct counterfactual manipulations: participants tend to judge an event to be more causal after they generate relevant alternative ways that the event could have occurred. In Experiment 3, we extend this method by asking participants to generate alternatives to one particular aspect of the causal structure that contributes to the outcome (i.e., to the agent or to the inanimate object). We then measure how their causal judgments are affected by this manipulation. This allows us to test a precise prediction of a unified counterfactual account: participants causal judgments should be affected by the generation of counterfactual alternatives primarily for the part of the causal structure that the counterfactual alternative focused on.

## Methods

Participants. 601 participants $\left(M_{\text {age }}=35.96, S D_{\text {age }}=\right.$ 15.58; 304 females, 2 unreported) from Amazon Mechanical Turk participated for $\$ 0.35$ in compensation. Participant recruitment was again automated through TurkPrime.
Stimuli and procedure. This experiment used a 3 (AgentCounterfactual vs Object-Counterfactual vs No Counterfactual) $\times 2$ (Agent Question vs Object Question) design. Counterfactual condition was manipulated between-subjects and Question was manipulated within-subjects.

All participants read the norm-conforming condition from Experiment 2, where the red lever and black lever both produce pencils, and the white lever produces erasers (but also consistently malfunctions). In this scenario, both the administrators and the faculty are allowed to take pencils from the machine, both the administrative assistant and Professor smith request pencils using the black and red levers respectively, and both levers function appropriately to produce pencils. A problem then arises from a lack of pencils.

After reading the vignette, participants underwent the counterfactual manipulation. In the Agent-Counterfactual condition, for example, participants were asked to think about Professor Smith's decision to take a pencil from the vending machine, and then to consider and describe one relevant way that things could have gone differently such that the professor would not have taken one of the pencils from the vending machine. In the Object-Counterfactual condition, by contrast, participants were instead asked to consider and describe a relevant way in which the red lever could have functioned differently such that it didn't produce a pencil from the vending machine. In the No Counterfactual condition, participants were simply asked to describe the story they read.

After completing this task, they rated their agreement (on a scale from 0 ('Completely disagree') to 100 ('Completely agree') with a statement that the Professor caused the problem, and separately with a statement that the red lever caused the problem. The statements were presented in counterbalanced order and on separate pages. Participants then completed a series of control questions that asked them about

Figure 3: Agreement with the causal statement concerning the agent (left bars) and the object (right bars) as a function of Counterfactual condition). Error bars depict +/- 1 SEM.
which levers were actually pulled and about who actually received a pencil in the original story.

## Results

We excluded participants who did not answer both of the check questions correctly, and analyzed the remaining 423 participants' judgments. First, we analyzed the agreement with the two causal statements by comparing a series of linear mixed-effects models using the lme4 package in R (Bates, Maechler, Bolker, Walker, et al., 2014). This analysis revealed a main effect of Question $\left(\chi^{2}(1)=53.135\right.$, $p<.001)$ and a main effect of Condition $\left(\chi^{2}(2)=13.492\right.$, $p=.001$ ). Critically, however, these were qualified by a significant Question $\times$ Condition interaction $\left(\chi^{2}(2)=23.04\right.$, $p<.001$ ). We decomposed this interaction using a series of planned comparisons. These analyses revealed that participants strongly agreed that Professor Smith was a cause of the problem when they considered alternatives to Professor Smith's action ( $M=32.99, S D=33.33$ ), but in comparison, agreed significantly less both when they did not consider counterfactual alternatives ( $M=18.22, S D=27.28$ ), $t(282.48)=4.12, p<.001, d=0.482$, and when they only considered alternatives to the way the lever functioned ( $M=$ $24.43, S D=29.12$ ), $t(279)=2.27, p=.024, d=0.272$.

We also observed a corresponding pattern in participants' agreement with the statement that the red lever caused the problem: participants agreed that the lever was more of a cause when they considered alternatives to the way the lever functioned ( $M=20.11, S D=33.34$ ), than when they did not generate any relevant counterfactual alternatives, $(M=8.62$, $S D=19.64), t(211.21)=3.42, p<.001, d=0.421$, or when they considered alternatives to what Professor Smith $\operatorname{did}(M=10.05, S D=20.59), t(213.65)=2.99, p=.003$, $d=0.367$.

## Discussion

In short, we found that directly manipulating the relevance of counterfactual alternatives affected participants' causal judgments. Moreover, in line with the predictions of a unified counterfactual account, we found this effect was specific to the factor that was altered in the counterfactual alternative.

## General Discussion

The results of these three experiments favor a counterfactual relevance account of the impact of norms on causal judgments. Experiment 1 replicated S\&W's finding that moral norm violations primarily affect causal judgments of intentional agents and not inanimate objects. Experiment 2 further found that violations of norms of proper functioning primarily affect judgments of inanimate objects but not intentional agents. In both experiments, judgments of counterfactual relevance tracked the impact of different norm violations on causal judgments for both intentional agents and inanimate objects. Finally, Experiment 3 demonstrated that nonnormative manipulations of counterfactual relevance produce an analogous pattern in participants' causal judgments. These results support work on causal cognition that provides a central role for counterfactuals (Gerstenberg \& Tenenbaum, in press; Kominsky et al., 2015; Icard et al., in press).

The extant literature on causal judgment now provides evidence for three distinct types of norms that all show similar effects: descriptive statistical norm violations (e.g., Kominsky et al., 2015), prescriptive moral norm violations (e.g., Hitchcock \& Knobe, 2009), and prescriptive functional norm violations (demonstrated here). The demonstration of additional norms that have similar a impact on causal judgments makes a parsimonious explanation increasingly desirable. To extend the polysemy account, for example, one would now have to propose three independent explanations for three qualitatively similar effects. By contrast, an account that appeals to the relevance of counterfactual alternatives provides a unified explanation and predicts that these various norms should all have a qualitatively similar impact.

At the same time, many aspects of the relationship between counterfactual representation and causal cognition remain poorly understood. For example, a critical insight which arises in both $\mathrm{S} \& \mathrm{~W}$ and in the current studies is that norms have a highly specific effect on causal judgments: they preferentially affect causal judgments of the entities to which the norm applies and typically do not extend to other aspects of the same event. Across three experiments, we find a similar pattern in participants' reasoning about counterfactual alternatives. Collectively, these findings suggest that, rather than representing a counterfactual alternative to an event in its entirety, participants' causal and counterfactual cognition represents events more granularly.

Not only does this shape our interpretation of S\&W's original result, it opens an exciting new frontier in the study of causal cognition. How events are represented in causal and counterfactual cognition, and which aspects of an event are
represented as distinct variables, are almost completely unexplored topics (e.g. Halpern \& Hitchcock, 2015 explicitly acknowledge this issue). However, as emerging research makes clear, it will be difficult to make precise predictions about the impact of norms without a more well worked-out theory of how events are represented in causal reasoning.

This opportunity cuts in both directions. These results are, to our knowledge, the first empirical investigation of which events are represented as distinct variables. Yet, as much as we need to build precise theories of how these events are represented in order to understand how norms will affect causal judgments, we can also use the effect of norms on causal judgments to determine which causes are distinct. We look forward to exploring these questions in future work.

## Acknowledgments

We would like to thank Harvard's Moral Psychology Research Lab, D. Lagnado, T. Gerstenberg, and J. Knobe for helpful discussion. This work was supported by Grant N00014-14-1-0800 from the Office of Naval Research to JP.

# Assessing the Linguistic Productivity of Unsupervised Deep Neural Networks 

Lawrence Phillips (Lawrence.Phillips@pnnl.gov)<br>Pacific Northwest National Laboratory

Nathan Hodas (Nathan.Hodas@pnnl.gov)<br>Pacific Northwest National Laboratory

#### Abstract

Increasingly, cognitive scientists have demonstrated interest in applying tools from deep learning. One use for deep learning is in language acquisition where it is useful to know if a linguistic phenomenon can be learned through domain-general means. To assess whether unsupervised deep learning is appropriate, we first pose a smaller question: Can unsupervised neural networks apply linguistic rules productively, using them in novel situations? We draw from the literature on determiner/noun productivity by training an unsupervised, autoencoder network measuring its ability to combine nouns with determiners. Our simple autoencoder creates combinations it has not previously encountered and produces a degree of overlap matching adults. While this preliminary work does not provide conclusive evidence for productivity, it warrants further investigation with more complex models. Further, this work helps lay the foundations for future collaboration between the deep learning and cognitive science communities.

Keywords: Deep Learning; Language Acquisition; Linguistic Productivity; Unsupervised Learning; Determiners

## Introduction

Computational modeling has long played a significant role within cognitive science, allowing researchers to explore the implications of cognitive theories and to discover what properties are necessary to account for particular phenomena (J. L. McClelland, 2009). Over time, a variety of modeling traditions have seen their usage rise and fall. While the 1980s saw the rise in popularity of connectionism (Thomas \& McClelland, 2008), more recently symbolic Bayesian models have risen to prominence (Chater \& Oaksford, 2008; Lee, 2011). While the goals of cognitive modelers have largely remained the same, increases in computational power and architectures have played a role in these shifts (J. L. McClelland, 2009). Following this pattern, recent advances in the area of deep learning (DL) have led to a rise in interest from the cognitive science community as demonstrated by a number of recent workshops dedicated to DL (Saxe, 2014; J. McClelland, Hansen, \& Saxe, 2016; J. McClelland, Frank, \& Mirman, 2016).

As with any modeling technique, DL can be thought of as a tool which is best suited to answering particular types of questions. One such question is that of learnability, whether an output behavior could ever be learned from the types of input given to a learner. These types of questions play an integral role in the field of language acquisition where researchers have argued over whether particular aspects of language could ever be learned by a child without the use of innate, language-specific mechanisms (Smith, 1999; C. D. Yang, 2004; Chater \& Christiansen, 2010; Pearl,
2014). The success of a domain general learner does not necessarily imply that human learners acquire the phenomenon in a similar fashion, but it does open the possibility that we need not posit innate, domain-specific knowledge.

The crux of these learning problems typically lies in making a particular generalization which goes beyond the input data. One major type of generalization that DL models would need to capture is known as linguistic productivity. A grammatical rule is considered productive when it can be applied in novel situations. For example, as a speaker of English you may never have encountered the phrase a gavagai before, but you now know that gavagai must be a noun and can therefore combine with other determiners to produce a phrase such as the gavagai. Before DL might be applied to larger questions within language acquisition, the issue of productivity must first be addressed. If DL models are not capable of productivity, then they cannot possibly serve to model the cognitive process of language acquisition. On the other hand, if DL models demonstrate basic linguistic productivity, we must explore what aspects of the models allow for this productivity.

## The Special Case of Determiners

For decades, debate has raged regarding the status of productive rules among children acquiring their native language. On the one hand, some have argued that children seem hardwired to apply rules productively and demonstrate this in their earliest speech (Valian, Solt, \& Stewart, 2009; C. Yang, 2011). On the other, researchers have argued that productivity appears to be learned, with children's early speech either lacking productivity entirely or increasing with age (Pine \& Martindale, 1996; Pine, Freudenthal, Krajewski, \& Gobet, 2013; Meylan, Frank, Roy, \& Levy, 2017). Of particular interest to this debate has been the special case of English determiners. In question is whether or not English-learning children have acquired the specific linguistic rule which allows them to create a noun phrase (NP) from a determiner (DET) and noun ( N ) or if they have simply memorized the combinations that they have previously encountered. This linguistic rule, $\mathrm{NP} \rightarrow$ DET N, is productive in two senses. First, it can be applied to novel nouns, e.g. a gavagai. Second, consider the determiners $a$ and the. If a singular noun can combine with one of these determiners, it may also combine with the other, e.g. the wug.

This type of rule seems to be acquired quite early in acquisition, making it appropriate to questions of early productivity, and provides an easy benchmark for a DL model. Yet answering such a simple question first requires addressing
how one might measure productivity. Most attempts to measure productivity have relied on what is known as an overlap score, intuitively what percentage of nouns occur with both $a$ and the (C. Yang, 2011). This simple measure has been the source of some controversy. C. Yang (2011) argues that early attempts failed to take into account the way in which word frequencies affect the chance for a word to "overlap". Because word frequency follows a Zipfian distribution, with a long tail of many infrequent words, many nouns are unlikely to ever appear with both determiners. He proposes a method to calculate an expected level of overlap which takes into account these facts. Alternatively, Meylan et al. (2017) propose a Bayesian measure of productivity which they claim takes into account the fact that certain nouns tend to prefer one determiner over another. For instance, while one is more likely to hear a bath than the phrase the bath, the opposite is true of the noun bathroom which shows a preference for the determiner the (Meylan et al., 2017).

The literature is quite mixed regarding whether or not children show early productivity. Differences in pre-processing have lead researchers to draw opposite conclusions from similar data, making interpretation quite difficult (C. Yang, 2011; Pine et al., 2013). Indeed, most corpora involving individual children are small enough that Meylan et al. (2017) argue it is impossible to make a statistically significant claim as to child productivity. For analyzing whether or not text generated by a DL model is productive or not, we thankfully do not need to fully address the problem of inferring child productivity. Ideally, the model would demonstrate a similar level of overlap to the data it was exposed to. We make use of the overlap statistic from Yang because it is more easily comparable to other works and has been better studied than the more recent Bayesian metric of Meylan et al. (2017).

## Deep Learning for Language Acquisition

Deep learning, or deep neural networks, are an extension of traditional artificial neural networks (ANN) used in connectionist architectures. A "shallow" ANN is one that posits a single hidden layer of neurons between the input and output layers. Deep networks incorporate multiple hidden layers allowing these networks in practice to learn more complex functions. The model parameters can be trained through the use of the backpropogation algorithm. The addition of multiple hidden layers opens up quite a number of possible architectures, not all of which are necessarily applicable to problems in cognitive science or language acquisition more specifically.

While the most common neural networks are discriminative, i.e. categorizing data into specific classes, a variety of techniques have been proposed to allow for truly generative neural networks. These generative networks are able to take in input data and generate complex outputs such as images or text which makes them ideal for modeling human behavior. We focus on one generative architecture in particular known as a deep autoencoder (AE) (Hinton \& Salakhutdinov, 2006).

While AEs have been used for a variety of input data types,
most prominently images, we describe their use here primarily for text. The first half, the encoder, takes in sentences and transforms them into a condensed representation. This condensed representation is small enough that the neural network cannot simply memorize each sentence and instead is forced to encode only the aspects of the sentence it believes to be most important. The second half, the decoder, learns to take this condensed representation and transform it back into the original sentence. Backpropogation is used to train model weights to reduce the loss between the original input and the reconstructed output. Although backpropagation is more typically applied to supervised learning problems, the process is in fact unsupervised because the model is only given input examples and is given no external feedback.

AEs have been shown to successfully capture text representations in areas such as paragraph generation (Li, Luong, \& Jurafsky, 2015), part-of-speech induction (Vishnubhotla, Fernandez, \& Ramabhadran, 2010), bilingual word representations (Chandar et al., 2014), and sentiment analysis (Socher, Pennington, Huang, Ng, \& Manning, 2011), but have not been applied to modeling language acquisition. While any number of DL architectures could be used to model language acquisition, the differences between ANNs and actual neurons in the brain make any algorithmic claims difficult. Instead, DL models might be used to address computationallevel questions, for instance regarding whether or not a piece of knowledge is learnable from the data encountered by children. Before this can be done, however, it remains to be seen whether DL models are even capable of creating productive representations. If they cannot, then they do not represent useful models of language acquisition. This work attempts to address this not by creating a model of how children acquire language, but by using methods from the psychological literature on productivity to assess the capability of DL to learn productive rules.

## Methods

## Corpora

To train our neural network, we make use of child-directed speech taken from multiple American-English corpora in the CHILDES database (MacWhinney, 2000). In particular, we make use of the CDS utterances in the Bloom 1970, Brent, Brown, Kuczaj, Providence, Sachs, and Suppes corpora (Bloom, 1970; Brent \& Siskind, 2001; Brown, 1973; Kuczaj, 1977; Demuth \& McCullough, 2009; Sachs, 1983; Suppes, 1974). The combined corpora contain almost 1 million utterances and span a wide age range, including speech directed to children as young as 6 months and as old as 5 years. Relevant information about the used corpora can be found in Table 1.

Because we are interested in seeing what the AE can learn from data similar to that encountered by children, we train the model only on child-directed utterances. These can be produced by any adult in the dataset, including parents and researchers. Although a comparison with child-produced text

Dense Softmax Layer
GRU Layer (20 dim)
Latent Representation (20 dim)
GRU Layer (20 dim)
Embedding Layer (30 dim)

Figure 1: Visual representation of the autoencoder model.
holds great interest, it is not clear whether child-produced speech is rich enough to support robust language learning on its own. It therefore provides a poor basis upon which to train the AE.

Text from the various corpora is processed as a single document. Child-directed utterances are cleaned from the raw files using the CHILDESCorpusReader function of the Python Natural Language Toolkit (NLTK). Utterances from all nonchildren speakers are included and not limited just to the primary caregiver. Each utterance is split into words according to the available CHILDES transcription and then made lowercase. The model represents only the most frequent 3000 words, while the remainder are represented as a single out-of-vocabulary (OOV) token. This step is taken both to reduce computational complexity but also to mimic the fact that young children are unlikely to store detailed representations of all vocabulary items encountered. Because the neural networks require each input to be of the same length, sentences are padded to a maximum length of 10 words. Sentences that are longer than this are truncated, while short sentences are prepended with a special $P A D$ token.

| Corpora | Age Range | N. Utterances |
| :--- | ---: | ---: |
| Bloom 1970 | $1 ; 9-3 ; 2$ | 62,756 |
| Brent | $0 ; 6-1 ; 0$ | 142,639 |
| Brown | $1 ; 6-5 ; 1$ | 176,856 |
| Kuczaj | $2 ; 4-4 ; 1$ | 57,719 |
| Providence | $1 ; 0-3 ; 0$ | 394,800 |
| Sachs | $1 ; 1-5 ; 1$ | 28,200 |
| Suppes | $1 ; 11-3 ; 3$ | 67,614 |
| Overall | $0 ; 6-5 ; 1$ | 930,584 |

Table 1: Descriptive statistics of CHILDES corpora. Ages are given in (year;month) format and indicate the age of the child during corpus collection.

## Neural Network Architecture

Our autoencoder model was implemented using Keras and Tensorflow. The words in each sentence are input to the model as a one-hot vector, a vector of 0 s with a single 1 whose placement indicates the presence of a particular word. This is
an inefficient representation because it assumes all words are equally similar, e.g. that $d o g$ is equally similar to dogs as it is to truck. To deal with this, the model passes the onehot vector to an embedding layer. Neural word embeddings, as popularized by the word2vec algorithm (Mikolov, Chen, Corrado, \& Dean, 2013), are a way to represent words in a low-dimensional space without requiring outside supervision. Words are placed within the space such that words that are predictive of neighboring words are placed closer to one another. Because our training data is relatively small, we keep the embedding dimensionality low, at only 30 . Standard embeddings trained on much larger NLP corpora tend to use 100 or 200 dimensions.

Once each word has been transformed into a 30dimensional embedding vector, the sequence of words is passed into a gated-recurrent unit (GRU) layer (Cho et al., 2014). The GRU is a type of recurrent (RNN) layer which we choose because it can be more easily trained. RNN layers read in their inputs sequentially and make use of hidden "memory" units that pass information about previous inputs to later inputs, making them ideal for sequence tasks such as language. As such, the model creates a representation of the sentence which it passes from word to word. The final representation is the output of the encoder, a latent representation of the full sentence.

This 20-dimensional latent vector serves as the input to the decoder unit. The first layer of the decoder is a GRU layer of the same shape as in the encoder. For each timestep, we feed into the GRU the latent vector, similar to the model proposed in Cho et al. (2014). Rather than producing a single output, as in the encoder, the decoder's GRU layer outputs a vector at each timestep. Each of these vectors is fed into a shared dense softmax layer which produces a probability distribution over vocabulary items. The model then outputs the most likely word for each timestep.

The model loss is calculated based on the model's ability to reconstruct the original sentence through categorical crossentropy. Model weights are trained using the Adam optimzer over 10 epochs. During each epoch the model sees the entire training corpus, updating its weights after seeing a batch of 64 utterances. While this process does not reflect that used by a child learner, it is a necessary component of training the neural network on such a small amount of data. If the network had access to the full set of speech that a child encounters such a measure likely would not be necessary. Future work might also investigate whether optimizing the dimensionality of the network might lead to better text generation with higher levels of productivity.

## Baseline Models

Because the AE is learning to reproduce its input data, one might wonder whether similar results might be achieved by a simpler, distributional model. To assess this, we also measure the performance of an n-gram language model. We train bigram and trigram language models using the modified Kneser-Ney smoothing (Heafield, Pouzyrevsky, Clark,
\& Koehn, 2013) implemented in the KenLM model toolkit to estimate the distributional statistics of the training corpus. Sentences are generated from the n-gram language model by picking a seed word and then sampling a new word from the set of possible $n$-grams. The smoothing process allows for the model to generate previously unseen n-grams. Sampling of new words continues for each utterance until the end-ofsentence token is generated or a maximum of 10 tokens is reached (the same maximum size as for the AE).

Since the AE is able to generate sentences from a latent representation, it would be inappropriate to generate $n$-gram sentences from random seed words. Instead, for every sentence in the test set we begin the n-gram model with the first word of the utterance. While this allows the model to always generate its first token correctly, this does not directly impact our measure of productivity as it relies on combinations of tokens.

## Productivity Measures

We measure the productivity of our autoencoders through the overlap score described in C. Yang (2011). Words both in the child-directed corpus and the autoencoder-generated output are tagged using the default part-of-speech tagger from NLTK. The empirical overlap scores are simply calculated as a percentage of unique nouns that appear immediately after both the determiners $a$ and the. The expected overlap score is calculated based off of three numbers from the corpus under consideration, the number of unique nouns $N$, the number of unique determiners $D$, and the total number of noun/determiner pairs $S$. The expected overlap is defined as in Equation 1:

$$
\begin{equation*}
O(N, D, S)=\frac{1}{N} \sum_{r=1}^{N} O(r, N, D, S) \tag{1}
\end{equation*}
$$

where $O(r, N, D, S)$ is the expected overlap of the noun at frequency rank $r$ :

$$
\begin{equation*}
O(r, N, D, S)=1+(D-1)\left(1-p_{r}\right)^{S}-\sum_{i=1}^{D}\left[\left(d_{i} p_{r}+1-p_{r}\right)^{S}\right] \tag{2}
\end{equation*}
$$

$d_{i}$ represents the probability of encountering determiner $i$, for which we use the relative frequencies of $a$ and the calculated from the training corpus ( $39.3 \%$ and $60.7 \%$, respectively). The probability $p_{r}$ represents the probability assigned to a particular word rank. The Zipfian distribution takes a shape parameter, $a$ which C. Yang (2011) set equal to 1 and which we optimize over the training corpus using least squares estimation and set at 1.06 :

$$
\begin{equation*}
p_{r}=\frac{1 / r^{a}}{\sum_{n=1}^{N}\left(\frac{1}{n^{a}}\right)} \tag{3}
\end{equation*}
$$

It should be noted that Zipfian distributions are not perfect models of word frequencies (Piantadosi, 2014), but assigning empirically-motivated values to the determiner probabilities
and Zipfian parameter $a$ represents an improvement upon the original measure.

## Results

We analyze our overlap measures for the adult-generated (i.e. child-directed) as well as the autoencoder and n-gram modelgenerated text and present these results in Figure 2. We analyze overlap scores across 10 training epochs with three levels of dropout, $10 \%, 20 \%$, and $30 \%$. Dropout is typically included in neural models to encourage the model to better generalize. We hypothesized that a certain level of dropout would encourage the model to generate novel combinations of words that might lead to higher overlap scores. We find that with only two training epochs the AEs have already begun to near their maximum overlap performance. The $30 \%$ dropout AE achieves the highest level of performance, matching the empirical overlap score of the original corpus. The $10 \%$ and $20 \%$ dropout models perform somewhat worse suggesting that high levels of dropout may be necessary for good text generation.

In Table 2, we present the results for the final epoch of the AE models as well as for the adult-generated and $n$ gram generated text. We note that the expected overlap measure consistently overestimates the productivity of all learners, including the adult-generated text. It is unclear why this should be the case, but could be a result of capping the model vocabularies, resulting in lower $N$ values. In particular, the autoencoders tend to produce a relatively limited set of nouns. Looking at empirical overlap measures, the worstperforming models are the bigram and trigram models with overlap scores below $30 \%$. The AEs fair much better all producing overlap scores over $50 \%$. The $30 \%$ dropout AE is actually able to match the overlap score of the original adultgenerated corpus ( $59.4 \%$ vs. $59.3 \%$ ).

Looking at the number of unique nouns following a determiner $(N)$ and the total number of determiner-noun pairs $(S)$, it becomes clear there are large differences between the n-gram and AE models. The n-gram models tend to produce very few determiner-noun pairs (low $S$ ) but are likely to choose from any of the nouns in the corpus, leading to high $N$. This fact accounts for the low overlap scores that they achieve. In contrast, the AEs follow a pattern which mirrors the adult corpus with few unique nouns but a large number of noun-determiner pairs. In all cases, however, the AEs produce both fewer unique nouns and fewer noun-determiner pairs than the original corpus.

One possible problem for calculating the expected overlaps comes from the difficulty of part-of-speech tagging text generated by the neural network. Whereas adult-generated speech follows set patterns that machine taggers are built to recognize, the neural network does not necessarily generate well-formed language. Examples of AE-generated text can be found in Table 3. In some cases, the tagger treats items that occur after a determiner as a noun regardless of its typical usage. For example, in the generated sentence let put

Figure 2: Empirical overlap scores. Adult-generated speech is marked by the solid black line while autoencoder-generated speech is marked by the dashed colored lines. Results are presented for three levels of dropout, $10 \%, 20 \%$, and $30 \%$. The x -axis represents the training epoch of the model.

|  | $\boldsymbol{N}$ | $\boldsymbol{S}$ | Exp. Over. | Emp. Over. |
| :--- | ---: | ---: | ---: | ---: |
| Adult | 1,390 | 34,138 | $77.5 \%$ | $59.3 \%$ |
| AE 10\% | 861 | 29,497 | $88.4 \%$ | $53.3 \%$ |
| AE 20\% | 870 | 28,817 | $87.6 \%$ | $53.4 \%$ |
| AE 30\% | 816 | 31,181 | $90.8 \%$ | $59.4 \%$ |
| Bigram | 1,780 | 5,177 | $17.6 \%$ | $28.6 \%$ |
| Trigram | 2,506 | 4,595 | $11.2 \%$ | $22.1 \%$ |

Table 2: Expected and empirical overlap scores for adultand autoencoder-generated language with varying levels of dropout. Expected overlap scores were calculated as in Yang (2011). Empirical overlap was calculated as the percent of unique nouns that appeared immediately following both $a$ and the.
put the over over here, the phrase the over is tagged as a $\mathrm{DET}+\mathrm{N}$ pair. These type of errors are further evidenced by the fact that the trigram language model produces a larger set of words tagged as nouns than the original adult-generated corpus ( 2,506 vs. 1,390 ).

Another explanation for the difference between expected and empirical overlaps may come from deviation from a true Zipfian distribution of word frequencies. If word frequencies are Zipfian, we should expect a perfect correlation between log ranks and log counts. C. Yang (2011) report a correlation of 0.97, while our larger corpus deviates from this with $r^{2}=0.86$. Although we attempt to take this into account by fitting the Zipfian distribution's shape parameter, this divergence clearly indicates that further work is needed.

The success of the AE model in generating productive text serves as a confirmation that unsupervised neural models might be used in future work to investigate other cognitive phenomena. This work does not directly address the question of how infants might learn to produce productive speech, it does represent one possible approach. AEs can, for instance, be thought of as information compression algorithms which learn to represent high-dimensional data into a low-
dimensional latent space (Hinton \& Salakhutdinov, 2006). If the brain likewise attempts to find efficient representations of the stimuli it encounters then it may prove fruitful to investigate how these representations compare to one another.

| Adult | Autoencoder |

Table 3: Example adult and AE-generated language. The AEgenerated text is from the final epoch of the AE with $20 \%$ dropout. In bold is a $\mathrm{DET}+\mathrm{N}$ combination that does not appear in the AEs input.

## Conclusion

While there is great interest regarding the inclusion of deep learning methods into cognitive modeling, a number of major hurdles remain. For the area of language acquisition, deep learning is poised to help answer questions regarding the learnability of complex linguistic phenomena without access to innate, linguistic knowledge. Yet it remains unclear whether unsupervised versions of deep learning models are capable of capturing even simple linguistic phenomena. In this preliminary study, we find that a simple autoencoder with sufficient levels of dropout is able to mirror the productivity of its training data, although it is unclear whether this proves productivity in and of itself.

Future work will need to investigate whether more complex models might be able to generate text with higher productivity as well as further investigating how particular model choices impact performance. It would also be worthwhile to compare AEs against simpler models such as a basic LSTM language model. While additional work needs to be done to motivate the use of deep learning models as representations of how children might learn, this preliminary work shows how one might combine techniques from deep learning and developmental psychology.

# Opinion Cascades and Echo-Chambers in Online Networks: A Proof of Concept Agent-Based Model 

Toby D. Pilditch (t.pilditch@ucl.ac.uk)<br>Department of Experimental Psychology, University College London<br>WC1E 6BT, Gower Street, London, United Kingdom

#### Abstract

In online networks, the polarization of opinions (e.g., regarding presidential elections or referenda) has been associated with the creation of "echo-chambers" of likeminded peers, secluded from those of contrary viewpoints. Previous work has commonly attributed such phenomena to self-regarding preferences (e.g., confirmation bias), individual differences, and the pre-dispositions of users, with clusters forming over repeated interactions. The present work provides a proof of concept Agent-Based Model that demonstrates online networks are susceptible to echo-chambers from a single opinion cascade, due to the spatiotemporal order induced by lateral transmission. This susceptibility is found to vary as a function of degree of interconnectivity and opinion strength. Critically, such effects are found despite globally proportionate levels of opinions, equally rational agents (i.e. absent conformity, confirmation bias or pre-disposition architecture), and prior to cyclical interactions. The assumptions and implications of this work, including the value of Agent-Based Modelling to cognitive psychology, are discussed.

Keywords: Information cascades; opinion dynamics; belief updating; Agent-Based Models

## Introduction

As online networks, such as social media, have developed and increased in popularity, research regarding the spread of false information, the polarization of opinions (Dandekar, Goel, \& Lee, 2013), and echo-chamber phenomena (Del et al., 2016) have become increasingly pertinent topics. Such phenomena pose a problem to society, and democracy as a whole, given the average user's exposure to only the information and opinions of their local (i.e. direct) network, leading to a break-down in informed debate and consensus.

Recently, questions regarding how individuals on a network receive new information and form or adopt opinions has come to the fore. Whether on topics of national referenda, deciding between presidential candidates, or interpreting news events (e.g., who is at fault in the annexation of Crimea, the shooting down of passenger aircraft, the political correctness of a reported comment or behavior), it has become more and more common for such information to be ascertained via social media ${ }^{1}$. In this way, an agent's source of information comes through a filter of network-acquaintances, presenting an unprecedented degree

[^172]of lateral, peer-to-peer dissemination of information. Such peer-to-peer transference of information, in a time where the information itself (whether "fake news", political memes, or posted opinion) carries a bias in its view of the world, presents a problem that psychology and multi-agent modelling is well-placed to answer.

The purpose of the present paper is two-fold: Firstly, this work provides a novel demonstration of the dangers of lateral propagation of opinions in online networks, based solely on the level of interconnectivity and the inherent way in which interpreted events (i.e. opinions) travel through them. This results in high levels of false consensuses and echo-chambers on a local level within the network. Critically, such localized clustering is shown to occur before any repeated interaction behaviors, and is robust to both different opinion strengths and propensities to communicate. Secondly, this work presents an argument that cognitive science is readily placed to lend insight into these interactive, societal level phenomena, and the superaggregate behaviors. Such insight can be lent by the ready application of cognitive models taken from individual-based empirical work and theory, to multi-agent simulations, known as Agent-Based Models (ABMs), so as to uncover and explain phenomena beyond the scope of individualbased experiments.

## Cascades and Opinions

How information is communicated between individuals on a societal (or multi-agent) scale, and its consequences, has been formally approached in two main areas; information cascades and opinion dynamics.

Research in information cascades has focused on the way in which information is spread through a system. This has included how networks may be resistant to cascading influence, such as the spread of cultural fads (Watts, 2002). Such work has typically characterized "information" as a singular, memetic entity that is propagated or hindered by either the properties of individuals within the network (such as the proportion of "easily influenced individuals", see Watts \& Dodds, 2007), or the structure of the network itself (e.g., hierarchical influencers; see Watts, 2002). This work has illustrated power law effects in information propagation across networks, an effect akin to percolation theory in physics (for a review, see Essam, 1980), wherein the clustered structure of a system leads to a critical singularity event (i.e. cascade). These cascades result in cluster size distribution effects, where smaller, more numerous clusters
occur as systems become more interconnected (Amar \& Family, 1995; Meakin, Vicsek, \& Family, 1985).

Research in opinion dynamics has instead focused on the cyclical interactions of individuals within a network. In particular, it has looked at the ways in which individuals and groups interact so as to either reach a consensus (Acemoglu \& Ozdaglar, 2011; Hegselmann \& Krause, 2002) or segregate into polarized sub-groups of homogenous opinion-holders (Dandekar et al., 2013; Duggins, 2016; Zanette \& Gil, 2006). Critically, this research has focused on groups of pre-existing opinion-holders. This work has yielded insights into belief-updating via repeated interaction (such as through the use of the Bounded Confidence Model; Deffuant, Neau, Amblard, \& Weisbuch, 2000), along with psychologically based models of behaviors including network pruning (Ngampruetikorn \& Stephens, 2015), which provides a plausible pruning mechanism of network contacts, based on a confirmation bias (self-regarding) principle.

The present paper interweaves elements of these two lines of literature, in conjunction with cognitive architecture brought forth from models of learning and communication in cognitive psychology. In particular, agents are encoded with three pieces of cognitive machinery: attention (detecting the public declarations of others); learning (incorporating a communication into a belief-state, and evaluating it against evidence); and decision-making (each choosing whether to make their opinion public based on a decision rule). In this way, all agents within the network are equally rational.

By focusing on universal cognitive architecture on the part of agents (and instead introducing stochasticity to the evidence against which an opinion is evaluated), this work argues that echo-chambers may result solely from the way in which networks are structured, and the spatiotemporal order of lateral opinion transference (i.e. an opinion cascade).

The semi-random way in which networks are structured (my relational position to the global network is random, but my method of forming my proximal (direct) connections is rule-based (those whom I know)), runs parallel to work on "small-worlds" (Watts \& Strogatz, 1998), which have shown susceptibility to cascades and synchronizability. As such, echo-chambers may occur without reliance on repeated interaction (Acemoglu \& Ozdaglar, 2011; Duggins, 2016), or individual differences encoded in agents, such as differences in susceptibility, or pre-dispositions towards an opinion (Watts \& Dodds, 2007) or hierarchy (see Quattrociocchi, Caldarelli, \& Scala, 2014).

## Agent-Based Modeling

ABMs are multi-agent, dynamic simulations which use combinations of three central components; agents, patches, and links. Agents are the individual actors within a model, and in the present paper, represent individuals within a network. Agents may be encoded cognitive rules (e.g., learning models), simple behaviors (e.g., signaling to
neighboring agents, movement), and values (e.g., prior beliefs, physical positioning). Agents are ascribed various forms of heterogeneity (such as occupying different positions within a network), as multiple agents are generated within the system. As the simulation runs, agents enact behaviors and update their values according to the specific rules ascribed to them, interacting with other agents and the environment accordingly.
Similarly, both links, which represent connections between agents, and patches, which represent the environment, may be encoded with behaviors and values, and the capacity to dynamically interact and update as the simulation runs. In the present paper, links are used to represent the connections between individuals within a network, and are thus used for signaling between agents. Given the network representation (requiring only agents and the links between them), the present model does not require the use of patches.

ABMs have been used to explore and assess how behaviors on an individual level, when placed within a dynamic, multi-agent, heterogeneous system, can lead to societal level, super-aggregate behaviors (Epstein, 1999, 2006; Schelling, 2006). For example, by encoding a preference in individuals to be neighbors with others who are similar (whether, on racial, socio-economic, or cultural lines), and assuming some stochasticity in signaling such similarity, Thomas Schelling (1971) was able to show the evolution of segregation on a community, and even citywide level. In a similar manner, the previously mentioned research on information cascades and opinion dynamics (Duggins, 2016) has used this technique to demonstrate a number of phenomena, with relatively few assumptions, that are difficult with traditional, equation-based cognitive modelling.

## A Model of Opinion Cascades

The aim of the current model is to provide a proof that the inherent structure of an online network is susceptible to high degrees of opinion segregation (i.e. false consensuses or echo-chambers). Critically, this segregation does not require repeated interaction, and can instead occur as a consequence of a single "cascade" across a network of rational agents (i.e. assuming no individual differences in cognitive architecture), despite equal proportions of opinion-holders on a global level.

A network of agents is created whereby agents are randomly assigned an XY coordinate, and each outfitted with the cognitive architecture and values outlined below. Each agent then forms links with its neighbors based on proximity in terms of Euclidean distance - representative of relational proximity in online networks (see Duggins, 2016). The number of links agents form is manipulated, and based on the percentage of the total number of agents in the system, from $.5 \%$, to $50 \%$. This is calculated by dividing the number of links per agent by the total number of agents in the network. Thus, given a population of 1000 agents, for an interconnectivity of $.5 \%$, all agents form links with their
nearest 5 neighbors; for $10 \%$, the nearest 100 agents, and so on. Accordingly, given a fixed population size across simulations, interconnectivity is manipulated via the number of links each agent possesses. In a similar manner, a neutral "event" node is placed in the geographical center of the simulation, and connected to the nearest agents according to the above rules for interconnectivity. Thus, increasing interconnectivity beyond $50 \%$ serves no purpose, given that every other agent will have been exposed to the neutral event (i.e. is $1^{\text {st }}$ generation), and thus no cascade can occur beyond two time points. Similarly, in the current model, interconnectivity below $.5 \%$ (i.e. 5 links per Agent) starts to risk fracturing the network into separate entities.

## Cognitive Architecture

Each agent is outfitted with simple cognitive architecture that can be classified into three branches: attention, learning, and propagation.

All agents within the network attend to their linkedneighbors, in that they are sensitive to the first of their neighbors to "declare" an opinion. Having seen such a declaration, the agent then moves into a learning phase to evaluate it.

The communicated opinion thus forms a prior for the evaluating agent. As mentioned previously, the opinions in the model are categorized into a binary division (Opinion A, Opinion B). Thus, from a neutral prior (.5), moving towards Opinion A is assigned a positive direction, whilst moving towards Opinion B a negative direction. In this way, a prior indicating Opinion A should shift the neutral recipient agent positively (e.g., $0.5+0.1=0.6$ ), and negatively for Opinion B. The strength of this shift is accordingly manipulated as a proxy of opinion strength / influence.

To represent the relationship between the strength of an opinion and the likelihood of a recipient adhering to that opinion, a learning model is used that allows agents to evaluate the opinion against stochastic evidence.
Specifically, a reinforcement learning model is used (Rescorla \& Wagner, 1972), in which agents evaluate an opinion in light of new evidence, such that the prediction error ( $\delta$ ), multiplied by the learning parameter ( $\beta$ ), is added to the value associated with the opinion (prior) for the current trial $(\mathrm{Q}(\mathrm{t}))$, leading to an updated opinion value $(\mathrm{Q}(\mathrm{t}$ $+1)$ ).

$$
\begin{equation*}
Q(t+1)=Q(t)+\beta \delta(t) \tag{1}
\end{equation*}
$$

Such models have been adapted (with added complexity) successfully to model the impact of instruction in reinforcement learning (Doll, Jacobs, Sanfey, \& Frank, 2009; Staudinger \& Büchel, 2013) and are thus considered a suitable placeholder for the proof of concept model. To evaluate the belief, agents then experience a number of evidence trials (arbitrarily set to 10), where evidence values are binary $\{0,1\}$, and are drawn with equal likelihood (i.e. $\mathrm{P}(\mathrm{E}=1)=.5)$. To reiterate, the learning process herein serves as a representation for the relationship between prior strength, and its likelihood of acceptance/rejection. Thus, if
the communicated opinion is represented by a weaker prior, it is more likely to be rejected by the learning / evaluation process. Similarly, increasing the amount of available evidence has the equivalent effect of converging the agent to the .5 (neutral) true state of the event (i.e. reducing the likelihood of passing on the original opinion). In this way, stronger opinions make the cascade more deterministic. Further, using a stochastic sampling process to dictate opinion uptake serves as a useful baseline model, to which complexity may be added directly to learning processes.

Having evaluated, agents declare for one of the two opinions, based on a decision rule: if Q (posterior) > .5, hold Opinion A; if $<.5$, hold Opinion B. This declaration is then made public (and thus may act as a prior to attending linkedneighbors) with a probability that is manipulated between systems. For example, a $\mathrm{P}($ Declaration $)$ of 1 means all agents will make their opinions public, whilst a P (Declaration) of .1 means there is a $10 \%$ probability of agents making their opinion public. This $\mathrm{P}($ Declaration $)$ bears a parallel to Watts and Dodds (2007) "individual threshold", found to impact spreading phenomena.

## Dynamics

Given the above architecture has been established, simulations commence with the initial, neutral "event" being witnessed by a portion of the network (based on manipulated interconnectivity). These agents (termed $1^{\text {st }}$ generation) start with a neutral prior, and so, based on the stochastic nature of the evidence, half should arrive at each opinion post-evaluation. From this point, if an agent of the $1^{\text {st }}$ generation makes their opinion public (based on manipulated $\mathrm{P}($ Declaration), their attentive (presently neutral) linked-neighbors ( $2^{\text {nd }}$ generation) then take this opinion as a prior, and evaluate it according to the procedure above. This $2^{\text {nd }}$ generation agents, having come to $a$ decision, then similarly each choose whether to make their opinion public (based on $\mathrm{P}\left(\right.$ Declaration)), and thus the $3^{\text {rd }}$ generation is exposed. This process continues until there has been no change in the number opinion-holders (of either type) for two consecutive time periods (i.e. if no one has made an opinion public, and thus the opinions have "died out", or if the network is now completely saturated).

Importantly, for the proof of concept model, having decided upon an opinion, an agent is no longer attentive to further information. This is purposeful to prevent cyclical effects beyond an initial cascade, as the goal of the present paper is to show the susceptibility of interconnected neutral agents to an opinion cascade, without resorting to explanations of homophily (Dandekar et al., 2013) and localized consensus reaching (Ngampruetikorn \& Stephens, 2015).

For the purpose of the present paper, the behaviors of interest are constrained to two, related measures. Firstly, the global proportion of opinions across the system (i.e. the proportion of agents with Opinion A , and the proportion with Opinion B) is of interest before inferring anything about localized clustering. For example, whether localized
clustering is simply a by-product of a dominant, networkwide opinion. This leads to the second measure: the average percentage of likeminded neighbors an agent possesses. In other words, of an agent's visible network, what percentage are in agreement with the agent (e.g., $50 \%$ indicates agents directly linked to equal proportions of each opinion-type). The manipulated variables are summarized in table 1 below:

Table 1. System variables

| Variable | Description | Levels |
| :--- | :--- | :--- |
| Interconnectivity (\%) | (Links per Agent / Total | $0.5,1,1.5$, |
| Opinion Strength | Agents in Network) $* 100$ <br> Added to (or subtracted from) | $\ldots 50$ |
|  | neutral agent prior $(\mathrm{P}(\mathrm{H})=.5)$ |  |
| P (Declaration) | Probability of making opinion <br> public | $0.1,0.5,1$ |

## Central Findings

The above model was implemented in NetLogo (5.2.1). Each system specification (Interconnectivity (100) x Opinion Strength (3) x P(Declaration) (3)) was run independently 100 times, taking an average set of values for each specification. The total number of agents in each simulation was set to 1000 .
Figs. 1a \& 1b show example outcomes of opinion cascades (A in red, B in blue) across a sparsely connected ( $1 \%$ interconnectivity) and a more densely connected (10\% interconnectivity) system, respectively.

Figures 1a and 1b: Sparsely and densely connected networks, post cascade (grey represents unused links).

Importantly, as Fig. 2 illustrates, irrespective of opinion strength, $\mathrm{P}($ Declaration ), or interconnectivity, the global proportion of different opinion holders consistently approximates 50/50.

Figure 2: Proportion of opinion holders across network

Figure 3: Degree of Clustering. Calculated as the average percentage of like-minded neighbors an agent possesses (panels represent $\mathrm{P}($ Declaration) conditions).

The degree of clustering (Fig. 3) can be broken down into several key findings. First, and central to the present paper, localized clustering increases as a function of decreasing interconnectivity and opinion strength, with stronger opinions and low interconnectivity ( $<1 \%$ ) resulting in the local (directly visible) networks of agents consisting of $>90 \%$ likeminded individuals ${ }^{2}$. Second, this effect occurs irrespective of the propensity for individuals within the network to make their opinions public ${ }^{3}$. In other words, whether $\mathrm{P}($ Declaration ) is at $100 \%$ or $10 \%$, localized clustering occurs regardless.
Finally, localized clustering is mitigated by the degree of stochasticity (i.e. as opinion strength moves towards neutral, thus having no communicative impact) and increasing interconnectivity. However, it is important to note that to prevent local clustering requires either no opinion impact or moving towards high (and arguably unrealistic) levels of interconnectivity.

## Discussion

The central finding of the present paper is that the fundamental way in which networks are constructed, when combined with the temporal dynamics of how information travels through them, and the cognitive representation of opinions as a prior, inherently leads to false consensus effects and echo-chambers. Thus, the more deterministic peer-to-peer communications are (i.e. how likely is a recipient to adopt the opinion of a sender), and the lower the relative density of connections within the network, the greater the impact of the spatiotemporal order (i.e. the larger the cascade sequence) on clustering. ${ }^{4}$

[^173]Critically, this effect occurs prior to any repeated interactions between agents, separating the present work from opinion dynamic literatures (Acemoglu \& Ozdaglar, 2011; Allahverdyan \& Galstyan, 2014), and without assuming individual differences on the part of agents (e.g., differences in susceptibility) or singular information types, common to information cascade literatures (Watts, 2002). Further, work in these areas including social network pruning (Ngampruetikorn \& Stephens, 2015) and polarization effects (Dandekar et al., 2013; Duggins, 2016), when looking at cyclical interactions, illustrate that repeated interaction is likely to only exacerbate the already high levels of localized clustering.

## False Consensus and Echo-chambers

The effects described in the present work are found to be broadly independent of the propensity to communicate, and robust across the degree of interconnectivity (requiring approximately $50 \%$ interconnective density to negate, something unfeasible in online networks approaching billions). Putting this into concrete terms, Facebook has an estimated 1.79 billion active users ${ }^{5}$. The average (median) number of "friends" or links is approximately $200^{6}$, meaning the average user is connected to $.000011 \%$ of the overall network. To fully negate the effects demonstrated here would require either the severance of lateral transmissions (or decreasing the deterministic capacity of communications sufficiently), or having each user share direct connections with approximately 900 million other users.

The formation of echo-chambers and the polarization of opinions is typically attributed to repeated interaction with a self-regarding preference (Ngampruetikorn \& Stephens, 2015) or a signaling of like-mindedness (e.g., trust; see Li, Scaglione, Swami, \& Zhao, 2013). This work instead shows that the structure of the network, and the way in which opinions emanate across it, are sufficient to result in false consensus effects and echo-chambers. To put this in more pragmatic terms; regardless of who you know, why you know them, or how you have repeatedly interacted / pruned your network, the fact that you do not, and arguably cannot know enough people, no matter who they are, is sufficient to leave you highly susceptible to echo-chambers.

It should be noted that this proof of concept model carries with it several assumptions. Most notably, opinions are classified in a binary fashion, so as to replicate the target
> opinion strength, then clustering severity is reduced. However, this relies on the strong assumption that there is independence of opinions across a self-selecting network. If one incorporates instead a degree of dependence in neighbouring opinion-holders, then one has in effect shifted echo-chamber formation to precede opinion transmission, and have thus "baked-in" the result.
${ }^{5}$ Figure taken from monthly active users as of the $3{ }^{\text {rd }}$ quarter of 2016. Source: https://www.statista.com/statistics/264810/number-of-monthly-active-facebook-users-worldwide/
${ }^{6}$ Figure taken from Pew Research Center survey of Facebook users in 2014. Source: http://www.pewresearch.org/fact-tank/2014/02/03/6-new-facts-about-facebook/
opinion types under investigation, and associated with echochambers (e.g., referenda, or political campaigns). Future work is proposed to incorporate variance as they move across a network (i.e. do they dissipate, or become stronger). Secondly, agents attend and evaluate based on the first exposure to an opinion in their immediate network (i.e. those they are directly connected to). Although future work is suggested to incorporate the influence of multiple sources (e.g., via social conformity), such architecture is initially precluded to avoid "baking in" localized clustering effects.

Finally, the present model assumes a flat hierarchy of individuals. Although the argument can be made that fixing the level of interconnectivity for all individuals in a network is an artificial constraint, in terms of the degree of interconnectivity in target systems (e.g., Facebook) the functional difference in interconnectivity among users is between approximately $.000011 \% ~(200$ friends) and $.00028 \%$ ( 5000 friends; Facebook user limit). Although structural hierarchy, such as media influencers, may have an impact on dissemination (along with their own motives, such as following pre-existing opinion trends; see Quattrociocchi et al., 2014), the present work serves to illustrate that localized clustering can result from the spatiotemporal order of lateral transmission across a network.

## Further Work

The present work, in serving as a proof of concept for an increasingly important phenomenon, and providing some initial assumptions to illustrate the effects in a straightforward manner, leaves the door open for further, more psychologically informed modelling opportunities.

Further work should start to incorporate additional complexity on the part of agent (cognitive) architecture, such as the inclusion of social conformity (Latané, 1981), which is predicted to increase clustering tendencies (and feasibly increase the strength of opinions as they spread throughout the system. Similarly, work on confirmation bias suggests a similarly exacerbating role (Allahverdyan \& Galstyan, 2014; Doll et al., 2009; Nickerson, 1998; Staudinger \& Büchel, 2013). Finally, the inclusion of Bayesian models of source credibility (Harris \& Hahn, 2009; Harris, Hahn, Madsen, \& Hsu, 2015; Madsen, 2016) are of interest (Bayesian models of social learning have already started being applied to opinion dynamics; see Acemoglu \& Ozdaglar, 2011), given the way in which people form networks (i.e. we tend to select those we know / trust / like when forming our "direct" network). These suggestions are by no means exhaustive, but serve as examples of the promising (and readily applied) further additions to the framework laid out in the present work.

The present work purposefully precludes such psychological elements, which are expected to exacerbate the effects illustrated in this proof of concept model. This choice was made both for reasons of parsimony, and to provide a demonstration that the effects herein do not rely on such processes or explanations.

In conclusion, the present paper demonstrates that rational agents (i.e. absent special functionality of cognition or individual differences), through the way in which online networks are structured, are intrinsically susceptible to high levels of localized clustering (i.e. echo-chambers) when opinions are transmitted laterally. Further, it is hoped that the present paper serves as an example of how psychological principles taken from the individual level may be applied to a societal level through the use of AgentBased Models.

# Make-or-break: chasing risky goals or settling for safe rewards? 

Pantelis P. Analytis ${ }^{1}$ (pp464@cornell.edu),<br>Charley M. Wu² (cwu@mpib-berlin.mpg.de), Alexandros Gelastopoulos ${ }^{3}$ (gelas@bu.edu)<br>${ }^{1}$ Department of Information Science, Cornell University<br>${ }^{2}$ Center for Adaptive Behavior and Cognition (ABC), Max Planck Institute for Human Development<br>${ }^{3}$ Department of Mathematics and Statistics, Boston University

#### Abstract

Humans regularly invest time towards activities characterized by dramatic success or failure outcomes, where criti-cally, the outcome is uncertain ex-ante. How should people allocate time between such make-or-break activities and other safe alternatives, where rewards are more predictable (e.g., linear) functions of time? We present a formal framework for studying time allocation between these two types of activities, and explore (optimal) behavior in both one-shot and dynamic versions of the problem. In the one-shot version, we illustrate the striking discontinuous relation between peoples skill and optimal time allocation to the make-or-break task. In the dynamic version, we formulate both fully rational and boundedly rational strategies, both defined by a giving up threshold, which adaptively dictates when one should cease pursuit of the make- or-break goal. Comparing strategies across environments, we investigate the cost of sidestepping the computational burden of full rationality.

# A computational decomposition of task-irrelevant perceptual learning 

Angelo Pirrone (apirrone1 @sheffield.ac.uk)<br>Department of Psychology \& Department of Computer Science, University of Sheffield, UK<br>Tom Stafford (t.stafford@sheffield.ac.uk)<br>Department of Psychology, University of Sheffield, UK

#### Abstract

Change in motion discrimination was assessed after seven days training on a rapid serial visual presentation training task, which included exposure to below-threshold coherent motion that was irrelevant to the task the participant was involved in. Post-training, participants had improved sensitivity for supra-threshold motion discrimination, which was specific to the direction exposed during training. A computational decomposition of the effect shows that the improvement is a combination of (i) an increase in rate at which participants accumulate evidence for the direction to which they were exposed and (ii) a decrease in their criterion for a response. Together with these differences (consistent across participants) other cognitive processes vary non-systematically between the pre-test and the post-test session making an analysis only based on accuracy or reaction times potentially misleading. Our analysis shows the benefits of isolating the different processes that are involved in perceptual decision making and are affected by perceptual learning.

Keywords: task-irrelevant perceptual learning; drift diffusion model; speed-accuracy trade-off

## Introduction

During task-irrelevant perceptual learning (TIPL), participants learn to better discriminate stimuli to which they are merely exposed but that are irrelevant to the purpose of the experiment (Watanabe et al., 2001; Seitz \& Watanabe, 2008). The first example of TIPL comes from Watanabe et al. (2001), in which authors, after testing participants on a motion discrimination task, exposed participants to many days of a rapid serial visual presentation (RSVP) task, on the background of which was presented a random-field motion stimulus with a below threshold coherence in a constant direction across all days of training. Watanabe et al. (2001) found that participants showed an improvement in a post-test motion discrimination task, only for the supra-threshold coherence level in the direction to which they were exposed. Results from TIPL research suggest that the brain, even in the presence of subliminal exposure, adapts to specific features of the environment. As discussed in Watanabe et al. (2001), this result has important implications for modern everyday life in which we are constantly subject to high amounts of information that we try to ignore. TIPL research suggests that such ignored information could still affect our behaviour.

Focusing only on RT or accuracy for a perceptual task has some limitations, since different components contribute to those aspects of the decision which can be eas-
ily measured, RT and accuracy: (1) the difficulty of the decision, (2) the decision criteria adopted by the participant, which can be more or less conservative, (3) the nondecision time, which includes time to encode the stimulus and to execute the motor response, (4) the bias towards a response, (5) across trials variation in the above mentioned mechanisms. If the participant is performing a task on many different days, since the experimenter is interested in the effect of learning over different sessions, it is reasonable to expect that all the above mechanisms could also vary across different days on the basis of factors not related to the experiment (e.g., on one day the participant could be more tired or less collaborative). In some cases, an approach focusing only on RTs or accuracy has even been misleading in generating theories from data (for a discussion and examples, see Ratcliff \& McKoon, 2008).

Here, we use the Drift Diffusion Model (DDM; Ratcliff \& McKoon, 2008) as a tool to isolate different components of the processes that contribute to a decision. The DDM (Ratcliff \& McKoon, 2008) is a computational model of decision making that, over the years, has been applied in a wide variety of tasks (for a review see Ratcliff \& McKoon, 2008). In the DDM the decision maker accumulates evidence supporting two alternatives until a threshold for a decision is reached. In its arguably most used formulation (Ratcliff \& McKoon, 2008), the DDM is composed of seven parameters. The first, denoted by $a$, is the boundary separation and it describes the distance between the two decision boundaries. This parameter is related to the speed-accuracy trade-off. When the boundaries are near, the decision is faster but less accurate; conversely, when the distance between the two boundaries increases, the decision is slower but more accurate. The rate at which noisy information is accumulated over time within a trial is defined by the drift rate, $v$. This parameter reflects the difficulty of the task with respect to the sensitivity of the observer, with easier conditions (and/or more sensitive observers) resulting in faster and more accurate decisions. When the decision maker starts to integrate difference in evidence at an equal distance from the two decision boundaries, the process is defined as unbiased. However, the decision maker can start to integrate evidence nearer one of the two boundaries so that a third parameter affect the decision, the starting point
of evidence accumulation, $z$. When the decision maker is biased towards one of the two boundaries, fast RTs for that boundary but slow RTs for the opposite boundary are predicted, and at the same time the decision is more likely to end at the nearer boundary. The decision time is the time required to cross one of the two boundaries; however, for each reaction time it is present also a component that incorporates the non-decision time component of a decision, ter, which is the time to encode the stimulus and execute the motor response (e.g., pressing a button on the keyboard). Three further parameters of the DDM are: inter-trial variability in drift rate defined as $e t a$, in the starting point, $s z$, and in the non-decision time, st.

Despite widespread success in other domains, the DDM has not been consistently applied in the domain of perceptual learning. In Petrov et al. (2011), the authors performed a DDM decomposition of a fine motion discrimination task. In their study, authors found that perceptual learning was best explained by an increase in drift rate, a decrease in boundary separation and a decrease in both the non-decision time component and its inter-trial variability. In Liu \& Watanabe (2012), participants performed a three day perceptual learning coherent motion direction task (i.e., is the random dot kinematogram all noise or is there some signal?) and authors found an improvement in drift rate but with boundary separation decreasing across the days of training. In Dutilh et al. (2009), participants performed a 5 days lexical decision task and authors found that the learning led to an increase in drift rate, a decrease in boundary separation, as well as a significant decrease in non-decision time. As it is clear from these investigations, RTs and accuracy alone cannot give a full description of the cognitive processes that are most likely to have generated the data. Considering both measures and their distribution can lead to a better understanding of the cognitive processes involved in such tasks. In particular, if perceptual learning is associated with a decrease in the boundary separation, as other studies of task-relevant perceptual learning have found, then assessing perceptual learning via measurement of accuracy will systematically underestimate the true size of perceptual learning (since decreased boundary separation will tend to decrease accuracy, all other things being equal).

Although task-relevant perceptual learning has been decomposed by using the DDM, to our knowledge, no studies have focused on a DDM decomposition of TIPL. In our study, we ran an experiment similar to that presented in Watanabe et al. (2001), and we performed a DDM decomposition of TIPL. Because of the aforementioned multi-component nature of perceptual decisionmaking, our expectation is that use of the DDM will allow a more accurate assessment of perceptual learn-
ing than attention to solely RT or accuracy. Further, the DDM allows us to isolate the component of decision making that reflects a true change to stimulus sensitivity - a change in the drift rate parameter. Because of the potential for non-stimulus related parameters to alter across sessions due to non-experimentally caused factors (such as fatigue or motivation) and because, by their nature, perceptual learning experiments involve testing participants on different days or even weeks, we isolate perceptual learning as an increase in the drift rate for the exposed stimulus (for one participant also the drift of the not exposed direction increased but the increase was greater for the exposed stimulus than for the not exposed stimulus). In this way, we use each participant as their own control, testing them for changes in perceptual decision making for both exposed and not exposed stimuli and thus accommodating non-training related changes in decision parameters.

## Material and methods

Participants Four right-handed healthy university students (2 females, ages: 30, 21, 20, 22 years), with no history of neurological or psychiatric disorders, with normal vision and naïve to the purpose of the study participated voluntarily in the experiment and received a compensation of $£ 50$ for their participation. The experiment was approved by the University of Sheffield, Department of Psychology Ethics Sub-Committee, and carried out in accordance with the University and British Psychological Society ethics guidelines. Participants gave their informed consent.

Apparatus The stimuli were generated on a personal computer using PsychoPy (Peirce, 2009). During the whole experiment, participants had to put their head on a chin rest at a viewing distance of 57 cm from a SONY Multiscan CPD-200ES 17" monitor with a resolution of $1280 \times 1024$ pixels at a refresh rate of 60 Hz . The experiment was conducted under binocular viewing conditions and participants used a keyboard to make a response.
Motion-Direction Stimuli We used stimuli similar to those adopted by other studies on task-irrelevant perceptual learning (Watanabe et al., 2001; Seitz \& Watanabe, 2008): on a grey background, within a black annulus aperture of $1^{\circ}-10^{\circ}$, white dots with a size of $2 \times 2$ pixels were moving with a speed of $6 \%$ and a density of 16.7 $d o t s / d e g^{2} / s$ on a black background. Signal dots were randomly chosen in each frame, and on each frame, noise dots had a random position. Dots had a limited lifetime of three frames after which they were redrawn in random locations. If any of the signal dots were to move out of the annulus, they were replaced randomly in the stimulus field. The stimuli were generated in real time and two non-cardinal directions were employed in this study, $45^{\circ}$
and $135^{\circ}$.
Procedure The experiment consisted of nine sessions; a pre-test to measure sensitivity for various strengths of motion coherence in the two directions, then seven training sessions consisting of a RSVP task with on the background a random dot motion, and finally a post-test that measured sensitivity for various coherence levels in the two directions, that was equal to the pre-test. Participants came on different days for each session, and could take a maximum of three-days break between sessions.

Pre/post Motion-Direction Sensitivity Tests Participants were instructed to pay attention to the stimulus that would be presented for 500 ms and then report as quickly and accurately as possible if the coherent motion was towards up-left ( $45^{\circ}$ on the left with respect to an imaginary vertical reference line) or up-right ( $45^{\circ}$ on the right with respect to a imaginary vertical reference line) by button press. They were instructed to use their right hand index finger to press left on the keyboard for 'up-left', and their middle finger to choose 'up-right'. Participants were instructed that there was always a correct response and were required to fixate the cross at the centre of the screen during the whole task and minimise as much as possible eye movements. In each trial, a fixation cross in the central circle was presented for 333 ms , followed by the presentation of moving dots for 500 ms , followed by two arrows showing the possible direction of the dots and the text 'Answer:' presented on top of the screen until participants made a response. Each test stage consisted of 10 blocks x 2 directions ( $45^{\circ}$ and $135^{\circ}$ ) x 10 motion coherence levels ( $5 \%, 10 \%, 20 \%, 30 \%, 40 \%, 50 \%, 60 \%$, $70 \%, 80 \%, 90 \%) \times 9$ repetitions for a total of 1800 trials and took about 1 hour to complete. Coherence levels were chosen so that for each direction we would have accuracy levels that range from chance to ceiling based on the results of previous pilot studies. During each block the order of presentation of trials was randomised and no accuracy feedback was given to the participants. After a block of 180 consecutive trials participants were required to take a self-paced break to rest before continuing with this task.

Training sessions In the training sessions, participants performed a RSVP character identification task and were asked to report in order of presentation two white capital letters (height about $.9^{\circ}$ ) in a sequence of 10 capital letters presented in the central circle. All letters of the alphabet were used. Distractors consisted of eight capital black letters. The first and second white letters were presented in one of the first five serial positions and in one of the second five serial positions, respectively. They were determined randomly in each trial. Within the annulus aperture of $1^{\circ}-10^{\circ}$ participants were presented a mo-
tion stimulus in one of the two directions, constant across all training sessions, at a coherence level 5\% below their chance level at pre-test, in order to ensure a level reasonably below threshold. For each participant, we computed the motion strength at $50 \%$ accuracy by interpolating the psychometric curve predicted by the model free estimation of the psychometric curve described in Zchaluk \& Foster (2009), and using MATLAB scripts made available by those authors. In each trial, a fixation cross in the central circle was presented for 333 ms followed by the presentation of the stimulus for 500 ms followed by a grey screen and the text 'Type in the two white letters' presented on top of the screen until participants responded. Each test stage consisted of 10 blocks x 108 repetitions for a total of 1080 trials and took about 45 minutes to complete. No accuracy feedback was given to the participants. After a block of 108 consecutive trials, participants were required to take a self-paced break to rest before continuing with this task.

## Results

## Behavioural analyses

The performance of participants in the RSVP was mostly stable across the seven days of training. We did not perform any analysis on the RSVP task as our interest is in the TIPL, hence in the change in performance between pre-test and post-test for the exposed and not exposed directions.

For all analyses, both behavioural analyses and model fitting, we removed, for each participant, the $2.5 \%$ of slowest responses, given that a first inspection of data showed the presence of extremely slow outliers. In the following analyses, each subject is analysed separately. Participants 1 and 2 were exposed to $45^{\circ}$ while participants 3 and 4 were exposed to $135^{\circ}$. T-tests were conducted to investigate overall differences for each participant between the pre-test and the post-test in mean RT and accuracy levels for the exposed and the not exposed directions. Bonferroni corrections were applied on the p-values.

All subjects had a significant decrease in RTs between the pre-test and post-test, for the exposed and the not exposed direction ( $\mathrm{p}<.001$ in all cases). Participant 1 did not have a change in accuracy for the exposed direction between the pre-test and post-test $(\mathrm{t}(9)=-0.34, \mathrm{p}=1)$ while all other participants had a significant increase ( $p$ $<.001$ in all cases). Regarding accuracy of the not exposed direction, there was not a significant change between pre-test and post-test for any subject ( $\mathrm{p}>.07$ in all cases).

## Model fitting

For fitting the diffusion model to RT distributions and proportion of correct and incorrect responses, we used
the Diffusion Model Analysis Toolbox (DMAT; Vandekerckhove \& Tuerlinckx, 2007) for MATLAB. Parameters were estimated by using as the objective function a multinomial likelihood function, which expresses the likelihood of observing a certain proportion of responses in a given number of RT bins and is maximised in order to find the parameter estimates. We decided to represent the reaction time distributions of responses in terms of the classical $.1, .3, .5, .7$ and .9 quantiles that divide the RT distribution. For each participant we fitted a model in which the drift rates were free to vary across all conditions while all other parameters were fixed across conditions within the pre-test and the post-test but could vary between pre-test and post-test. In this way, for each session, a model with 26 parameters was fitted for each individual. However, the high number of parameters, rather than over-fitting, reflects the high number of conditions of this experiment. In fact, the only stimulus-contingent parameter allowed to vary is the drift, which varies according to the difficulty of each coherence level and according to the direction (exposed vs not exposed). Since participants were presented with trials in random order they could not adjust their boundary separation or their starting point of evidence accumulation before the presentation of each trial, hence the assumption of constant boundary and starting point parameters within each session is reasonable, together with stimulus-independent variability in starting point across trials. We assumed as constant the non-decision time component (i.e., stimulus encoding and motor response) between the two directions since it is unlikely that subject would have higher non-decision time (e.g., pressing a button on the keyboard) for one direction compared to the other. DMAT allows to calculate estimates of the parameters' standard errors. For each participant, we performed Wald tests for the difference in parameters between pre-test and posttest using the parameter estimates and their standard errors. Also here, results are presented by participant, Figure 1. Here we focus on within-subjects variation, hence for visibility we do not report consistent scaling and range across the same parameters fitted to different subjects.

Participant 1 had a significant decrease in boundary separation ( $Z=-7.38, p<.001$ ), in non decision time ( $\mathrm{Z}=-11.46, \mathrm{p}<.001$ ) and in starting point $(\mathrm{Z}=-10.36$, $\mathrm{p}<.001$ ). Regarding drift rates, t -tests showed an increase in drift for the exposed direction $(t) 9)=-2.75$, $\mathrm{p}=.045$ ), while the drift of the not exposed direction did not vary between pre-test and post-test $(t)(9)=-.42$, $p=$ 1). Participant 2 had a significant decrease in boundary separation ( $Z=-13.14, p<.001$ ), non-decision time ( $Z=$ $-6.64, \mathrm{p}<.001$ ) and starting point ( $\mathrm{Z}=-7.15, \mathrm{p}<.001$ ). This subject had an increase in drift for the exposed direction $(\mathrm{t}(9)=-3.36, \mathrm{p}=.02)$, while the drift of the not
exposed direction did not vary significantly between the pre-test and the post-test $(\mathrm{t}(9)=-1.15, \mathrm{p}=.56)$. Participant 3 had a significant decrease in boundary separation ( $\mathrm{Z}=-9.18, \mathrm{p}<.001$ ), an increase in non-decision time ( $Z$ $=1.98, \mathrm{p}=.02)$ and a decrease in starting point $(\mathrm{Z}=-$ $5.46, \mathrm{p}<.001$ ). Between the pre-test and the post-test, the drift of the exposed direction increased significantly $(\mathrm{t}(9)=-4.83, \mathrm{p}=.002)$ while the drift of the not exposed direction stayed the same $(\mathrm{t}(9)=-1.61, \mathrm{p}=.28)$. Participant 4 had a significant decrease in boundary ( $\mathrm{Z}=$ $-5.81, \mathrm{p}<.001$ ), an increase in non decision time ( $\mathrm{Z}=$ 2.33, $\mathrm{p}=.01$ ) and a decrease in starting point. $(\mathrm{Z}=-1.37$, $\mathrm{p}=.08$ ). The drift of the exposed direction increased significantly $(\mathrm{t}(9)=-6.25, \mathrm{p}=<.001)$ as well as the drift of the not exposed direction $(\mathrm{t}(9)=-3.85, \mathrm{p}=.01)$. Although the drift rates for both directions increased between pre-test and post-test, the relative change between pre-test and post-test for the exposed direction was significantly higher than the relative change between pretest and post-test for the not exposed direction $(t)(9)=$ $3.72, \mathrm{p}=.01$ ). None of the participants had a significant change between the two sessions in the parameters capturing across trials variability in drift, starting point or non-decision time. The goodness of fit of the model was assessed graphically through quantile-probability plots (not shown for brevity). The quantile probability plots showed that the model on which our analyses are based fits the data well and without mismatches.

## Discussion

Here, using the DDM (Ratcliff \& McKoon, 2008), we have modelled for the first time the processes underlying TIPL in healthy individuals. The results indicate that: (i) TIPL affects the drift rate at which participants accumulate evidence for the exposed direction meaning that their sensitivity for the exposed direction is increased, (ii) TIPL affects the conservativeness of participants' response (iii) non-systematic variations (i.e., the direction of the change varied between subjects) in parameters between the two sessions (e.g., variations in non-decision time, variations in starting point) do not allow a direct comparison of the decision process only based on accuracy and/or RT.

These findings have important implications for the interpretation of perceptual learning data, both taskrelevant and task irrelevant, and, we hope, for the analysis of data collected on different days or for which learning is involved. First, every decision is a mixture of different cognitive processes that can be isolated by this analysis for a more principled interpretation of results. Interpreting learning in terms of latent cognitive variables allows for a more precise investigation of its effect and gives a proper measure of 'true' perceptual learning - change in the drift rate which is related to the qual-

Figure 1: DDM parameters for each participant: top-left (Participant 1), top-right (Participant 2), bottom-left (Participant 3), bottom-right (Participant 4). For each participant, in order from top left to bottom right: boundary separation (a), non decision time (ter), starting point ( z ) and drift rates (v). The x -axis for the drift rate reports, for both the exposed and the not exposed directions, the 10 coherence levels by decreasing difficulty. Bars are standard errors of parameters' estimates.
ity of input information - while weighting for systematic or random variations in other parameters. In particular, caution should be exercised when comparing data across different sessions. As in previous studies of perceptual learning, participants in our study showed evidence of a change in their speed-accuracy trade-off. Not taking this factor into account can lead to wrong conclusions from data. In theory, decreased boundary should result in decreasing accuracy for the not exposed direction. In our investigation, participants had to view the stimuli for 500 ms before giving their response; given this constraint, participants had a relatively long time window to make a decision and as a consequence this might have obscured a decrease in accuracy between the pre-test and the posttest that should result from a decreased boundary. For future investigation, we recommend using a shorter presentation of the stimuli (e.g., 200 ms ) that is more likely to reveal stronger variations in accuracy and RTs of the not exposed direction between the pre-test and the posttest.

Our results show the risk of directly comparing sessions performed on different days without considering the role of each single parameter. Take for example participant 1: by testing for differences in accuracy, a researcher may be tempted to conclude that this subject did not have any TIPL since there is not a difference be-
tween the accuracy of the first and second session both for the exposed and the not exposed direction. However, the model fitting shows that this participant had higher drift rates for the exposed direction, which is likely to be the signature of TIPL, which is accompanied by a decrease in boundary and variations in the bias towards a response. An increase in drift (faster and more accurate responses) accompanied by a decrease in boundary (faster and less accurate responses) can have as output that accuracy levels stay the same.

Previous studies have shown that perceptual learning is associated with a decrease in boundary separation (Petrov et al., 2011; Liu \& Watanabe, 2012; Dutilh et al., 2009) and we replicated this result also here for TIPL showing consistency across four participants. It has been proposed (Liu \& Watanabe, 2012) that this decrease in boundary separation is due to the fact that participants are trying to maximise their reward rate, operatlionalised as the proportion of correct responses divided by the average time between them. In other words, if the quality of information increases (i.e., hence the task becomes 'easier') participants can decrease the time spent on each decision in order to finish the task sooner without sacrificing accuracy too much given the increase in drift rate. To the best of our knowledge, this is the first study to report a DDM decomposition of TIPL and the first study
to show the systematic parameter variations associated with TIPL. Regarding other parameters there is not consistency in the literature regarding the effects of learning, and also here we do not observe a clear pattern across participants. For example, regarding the non-decision time component, in previous studies investigating perceptual learning, Petrov et al. (2011) and Dutilh et al. (2009) found a decrease associated with learning, while Liu \& Watanabe (2012) found that, although not significant overall, some participants showed an improvement. Here we did not find a consistently decreasing non-decision time component between the two sessions, given that only two out of four participants have a decrease in non-decision time. Our only consistent result is that of decreasing boundary related to learning and an effect on the drift; result that shares some similarities with that by Liu \& Watanabe (2012). Regarding the drift, we show that there is an increase in the drift of the exposed direction, compared to the pre-test, and compared to the drift of the not exposed direction of the post-test when the drift of the not exposed direction increases as well in the post-test. Ideally, we would expect that the drift of the not exposed direction would not vary between pre and post-test. For one participant however the drift of the not exposed direction varies as well; this is unlikely to be an effect of TIPL but rather a random variation in participants' performance that further highlights the importance of a DDM decomposition of learning data.

Although the sample size $(\mathrm{N}=4)$ is low, this is in line with similar studies that have performed a DDM decomposition of learning data (e.g., Dutilh et al., 2009), and it is common practice in perceptual learning research. Furthermore the consistency in results across participants reassures us about our conclusions. It is to be mentioned that the training that our participants performed is relatively 'short' if compared with the usual TIPL training of about 20 days, during which TIPL reaches its asymptotic level (Watanabe et al., 2001). Future work, employing more participants and longer training regimes is clearly warranted in order to quantify the rate at which each component is affected by learning, and to quantify the distortion that focusing only on accuracy could lead to; if the days of training increase, the effect on boundary and drift reported here might increase and have even stronger consequences on accuracy and RT.

Here we used the DDM as a model of decision making and in order to analyse our data, but it is to be mentioned that other models of decision making could have been applied (Bogacz et al., 2006). However, given the model mimicry between models of decision making (Bogacz et al., 2006), we predict that our results are likely to be replicated if another model is applied.

Overall, a consideration of the different components in decision making shows that the two components which
are found to vary systematically all have independent effects on speed and/or accuracy. Whilst increased drift will tend to increase speed and accuracy, decreased boundary separation will tend to decrease both. For these reasons, a decomposition of decision making from these observed variables allows us not only to focus on the different effects of perceptual learning individually, but allows us a more accurate assessment of the extent of increased stimulus sensitivity in perceptual learning. Our study is the first to show this increased sensitivity in taskirrelevant perceptual learning, and does so demonstrating that the other components of decision making are affected in a similar way to as in task-relevant perceptual learning.

#### Abstract

A key challenge for cognitive neuroscience is to decipher the representational schemes of the brain. A recent class of decoding algorithms for fMRI data, stimulus-feature-based encoding models, is becoming increasingly popular for inferring the dimensions of neural representational spaces from stimulusfeature spaces. We argue that such inferences are not always valid, because decoding can occur even if the neural representational space and the stimulus-feature space use different representational schemes. This can happen when there is a systematic mapping between them. In a simulation, we successfully decoded the binary representation of numbers from their decimal features. Since binary and decimal number systems use different representations, we cannot conclude that the binary representation encodes decimal features. The same argument applies to the decoding of neural patterns from stimulus-feature spaces and we urge caution in inferring the nature of the neural code from such methods. We discuss ways to overcome these inferential limitations.

## Introduction

A key challenge for cognitive neuroscience is to decipher the representational schemes of the brain, to understand the neural code that underlies the encoding and representation of sensory, motor, spatial, emotional, semantic and other types of information. To address these issues researchers often employ neuroimaging techniques like functional magnetic resonance imaging (fMRI), which measures the blood oxygenation leveldependent (BOLD) activation in the brain that is elicited when participants engage with different stimuli. A common assumption has been that the underlying neural representation of each stimulus has measurable but complex effects on the BOLD activation patterns. In order to understand what those patterns of activity can tell us about how the brain processes and represents information, researchers have used various analytical tools such as univariate subtraction methods, multivariate pattern (MVP) classification, representational similarity analysis (RSA) and, recently, explicit stimulus-feature-based encoding and decoding models (for reviews, see Davis \& Poldrack, 2013, Haxby, Connolly, \& Guntupalli, 2014, or Naselaris, Kay, Nishimoto, \& Gallant, 2011). Despite their differences, these methods aim to quantify how changes in task conditions and the properties of the stimuli relate to changes in BOLD activation and vice versa. Where these methods differ is in how they achieve that mapping and in what inferences they allow us to draw.

In this article, we review some of the known inferential limitations of existing fMRI analysis methods and we highlight a previously unrecognized issue in interpreting results from stimulus-feature-based encoding and decoding models. The latter are steadily becoming the de facto gold standard for investigating neural representational spaces (Haxby et al. 2014, Naselaris \& Kay, 2015).

## Univariate vs. multivariate analysis

Before the advent of the more advanced techniques we review below, the main fMRI analysis tool was based on comparing how activity in a single voxel or averaged activity in a contiguous area of voxels differs between task conditions or stimuli. These univariate subtraction methods have been informative about the relative engagement of certain brain areas in specific tasks. Unfortunately, the coarse nature of this method precludes fine-grained inferences about the underlying representational content and computations that give rise to the observed BOLD signal. By ignoring the possibility that information might be represented in a distributed manner across voxels, the assumptions underlying univariate subtraction methods limit their use in understanding neural representations. In addition, these methods cannot tell us whether changes in activation are due to representational preferences, processing differences, or attentional variation among conditions (Coutanche, 2013).

In contrast, multivoxel pattern analysis (MVPA) techniques have attempted to overcome this limitation by looking at how various categories of stimuli or task conditions lead to differences (i.e. MVP classification) or similarities (i.e. RSA) in distributed patterns of activity over multiple voxels. These methods have become popular because they allow researchers to study neural representational spaces with increasing sensitivity and resolution. For example, a seminal study by Haxby et al. (2001) found that visual object categories can be classified based on the pattern of activation that their exemplars elicited in the ventral temporal cortex. The classification was successful despite the lack of overall activation differences in that region. Similar methods have been used to show that concepts have language-invariant representations in the anterior temporal lobe (Correia et al., 2014), that very similar visual scenes can be discriminated in the hippocampus (Bonnici et al., 2012) and that during their retrieval from memory, the shape, color and identity
of visual objects can be differentially decoded across several cortical areas (Coutanche \& Thompson-Schill, 2015).

Despite early enthusiasm that MVPA methods could be used to understand the structure of the neural code and the nature of the underlying representations (Norman, Polyn, Detre, \& Haxby, 2006), conventional MVP classification and RSA techniques share one of the same fundamental inferential limitations of univariate methods. Successful classification or careful inspection of confusions/similarity matrices can indicate that some relevant information about the stimulus class is present in the population of analyzed voxels, but it cannot identify exactly what that information is, or how it is represented and organized (Naselaris \& Kay, 2015; Poldrack, 2011; Tong \& Pratte, 2012). Because neural data is correlational, many different properties of the stimuli might lead to successful classification of the stimulus category, the task condition, or the brain state in question. For example, successfully categorizing whether a word represents an animate or an inanimate object does not necessarily mean that the region of interest encodes that category distinction. There are many differences between animate and inanimate objects, such as differences in their sensory and functional features (Farah \& McClelland, 1991) that could be responsible for the successful classification.

Another limitation of conventional MVP classifiers is that they cannot generalize and predict behavioral responses to novel types of stimuli or task conditions. To understand why, we can conceptualize classifiers in terms of types and tokens. An MVP classifier is usually trained on stimuli that are tokens from several types. For example, the stimuli tokens might be different category exemplars, and the classifier is trained to predict the type of category to which they belong. Alternatively, the tokens might be multiple presentations of the same word in different modalities or languages and the types are the unique words themselves. In the first case, the classifier can only be used to predict category membership of words that belong to one of the categories on which it was trained. In the second case even though the classifier could be used to predict exemplars in novel languages or modalities, it is again restricted only to exemplars of the words on which it was trained in the first place. In general, while the tokens being tested might be novel, they will be potentially decoded only if they are exemplars of a type that has already been trained on.

For example, if one trains a classifier to predict the color of objects and trains it on yellow and orange objects (Coutanche \& Thompson-Schill, 2015), one will not be able to predict the color of novel objects that are green. This methodological limitation is important - just as understanding how the decimal system represents numbers allows people to understand and manipulate numbers they have never seen before, a complete understanding of any neural representational system should allow researchers to use the neural pattern associated with novel stimuli to predict their identity, even if those stimuli are not exemplars of the types on which a particular model was trained on.

## Stimulus-feature-based encoding models

To overcome this limitation many researchers are turning to a novel analysis method that is known by a few different names voxelwise modelling (Naselaris \& Kay, 2015), stimulus-model based encoding and decoding (Haxby et al., 2014), voxel-based encoding and decoding models (Naselaris et al., 2011), and forward models (Brouwer \& Heeger, 2009; Fernandino, Humphries, Conant, Seidenberg, \& Binder, 2016). This approach can decode the identity of novel types of stimuli from neural activity by predicting activity not for the stimuli themselves, but for a set of simpler features into which they can be decomposed. In a seminal study, Mitchell et al. (2008) predicted the neural activity associated with individual novel words based only on the activation of other words. To achieve that, they decomposed each word into a vector of weights on 25 sensory-motor semantic features (verbs such as "eat", "taste", "run", "fear", etc.). The weights were estimated from cooccurrence statistics of the word with each verb feature in a large corpus. They trained a classifier to predict the neural activity associated with each constituent feature of a training set of words, which resulted in separate neural activation maps for each feature. Neural activity for novel test words was then predicted highly accurately as a linear combination of the semantic feature activation maps weighted by the association of the word with each feature. Based on these results, Mitchell et al. (2008) concluded that the neural representation of concrete nouns might be based on sensory-motor features.

Similar approaches have been used to predict the neural response to novel natural images using Gabor filter features (Kay, Naselaris, Prenger, \& Gallant, 2008), to novel colors based on color tuning curve features (Brouwer \& Heeger, 2009), to novel music clips based on acoustic timbre features (Casey, Thompson, Kang, Raizada, \& Wheatley, 2012), to natural sounds based on frequency, spectral and temporal modulations (Santoro et al., 2014), to novel faces based on a PCA decomposition of face features (Lee \& Kuhl, 2016), to novel words based on subjective sensory-motor ratings (Fernandino et al., 2016). The motivating question behind the majority of these studies has been about the nature of the representations used by the brain in encoding the experimental stimuli, and the results have been used to argue that the neural representation is based on the constituent features of the stimuli used in the model.

To summarize, stimulus-feature encoding models generally use the following analysis procedure: 1) Specify a set of features and dimensions that hypothetically underlie the representation of a stimulus set in brain. 2) Decompose a set of stimuli into vectors of weights for each feature. 3) Select a region of interest (ROI) in the brain from which to analyze neural activation. 4) Train a model to predict activity in each voxel for a training set of stimuli, using the weights of their features as predictors. 5) Derive activation pattern maps (e.g. regression coefficients) associated with each feature. 6) Predict neural activity in the ROI for novel stimuli, based on their feature weights and the activation pattern maps for each feature. 7) Compare predicted neural activity for each novel stimulus with their observed neural activity and derive a measure of fit and accuracy. In essence, stimulus-feature-based encoding models attempt to map a
stimulus feature representational space, where each feature is a separate dimension, and each stimulus is a point in that space, to a neural activation space, where each voxel is a separate dimension, and the activation pattern elicited by each stimulus is a point in that space.

## What can we infer about neural representations?

What can a successful mapping between a stimulus feature space and a neural activation space tell us about the nature of the representation used by the brain? A common inference in these studies has been that if you can predict the identity of novel stimuli based on that mapping, then the neural representation is likely based on the feature set used by the model. Put formally, the inferential claim goes as follows:

1) We can represent certain stimuli as a combination of lower-level features
2) We can show that it is possible to predict the neural pattern caused by a novel stimulus in brain area A from an encoding model based on these features
3) Therefore, brain area A encodes those features and uses a representational scheme based on them.
This claim has been made to different degrees both in theoretical and methodological papers reviewing the approach (e.g., Haxby et al., 2014; Naselaris \& Kay, 2015; Naselaris et al., 2011; Norman et al., 2006; Tong \& Pratte, 2012), as well as in empirical studies that use it to address representational questions (Fernandino et al., 2016; Kay et al., 2008; Mitchell et al., 2008; Santoro et al., 2014; although some are more cautionary, e.g. Lee \& Kuhl, 2016). If this inference is valid, then encoding models could be an extremely powerful tool for understanding the nature of neural representations.

A useful illustrative example of this inference in practice comes from a recent study by Fernandino et al. (2016). The authors wanted to understand how conceptual information is represented in a set of higher-order non-modality-specific brain regions in General Semantic Network (Binder, Desai, Graves, \& Conant, 2009). An encoding model based on subjective ratings for 5 sensory-motor features of training words ("color", "motion", "sound", "shape", "action") was used to predict activation patterns related to novel individual words. The model successfully predicted above chance the brain activity patterns for concrete words in the semantic network regions ( $61 \%$ mean accuracy), but not in a set of control regions associated with visual word form processing. Based on this finding, Fernandino et al. (2016) suggested that "the brain represents concepts as multimodal combinations of sensory and motor representations" and that "heteromodal areas involved in semantic processing encode information about the relative importance of different sensory-motor attributes of concepts, possibly by storing particular combinations of sensory and motor features".

[^174]Here lies the problem - this inference is not formally valid. We need to consider what the data would have looked like if the underlying neural representation was actually different (Mahon, 2015). In this example, the successful decoding of conceptual identity in the GSN based on an encoding model of sensorymotor features does not necessitate the representational format in the GSN to be sensory-motor in nature. The results might be obtained even if the GSN uses amodal representations, as long as there is a non-arbitrary mapping between representations in the GSN and sensory-motor features. To illustrate, let us hypothetically assume that the GSN literally encodes word cooccurrence statistics. As co-occurrence statistics correlate with sensory-motor feature ratings, it would be possible to predict GSN activity patterns based on these features, even if they are not driving the activity patterns. In contrast, successful decoding would be impossible if the mapping between the GSN representations and sensory-motor features was arbitrary. Thus, Fernandino et al.'s (2016) results constitute evidence against the possibility that conceptual representations in heteromodal areas bear an arbitrary relation to sensory-motor features, as has been argued by some proponents of symbolic systems (Fodor \& Pylyshyn, 1988), but should not be taken as conclusive evidence that the GSN encodes multimodal sensory-motor information.

This issue is not limited to the specific study discussed above. To put the claim more generally, we argue that information in one representational system might be decoded based on features from another, even if they use different representational schemes, as long as there is at least a partially systematic mapping between them. Specifically, while such encoding models should be able to predict the neural activation from the features of a stimulus if the brain uses a representational scheme based on those features, the reverse is not guaranteed ${ }^{1}$. A successful prediction can also occur when the stimulus feature space is systematically related to the features that underlie the neural representational scheme. However, that relationship need not be one of equivalence. There are at least three ways in which mappings between representational systems can be made and successful prediction can occur in two of those cases.

## Types of mappings

Arbitrary mappings between representations. First, items from two representational systems might be related in an entirely arbitrary way. For example, the meaning of words is mostly unrelated to their orthographic features ${ }^{2}$, and the geographic locations of countries are not predictive of their names, etc. More generally, consider two unordered sets of items, $A=$ $\left\{A_{1}, A_{2}, \ldots, A_{n}\right\}$ and $B=\left\{B_{1}, B_{2}, \ldots, B_{n}\right\}$. An arbitrary mapping between these two sets exists when the mapping from a specific item in set $A$ to a corresponding item in set $B$ is unrelated to the mappings between the remaining items in the sets. In the context of encoding models and the brain, decoding of novel items from one set would be impossible based on a feature model from the other set, if these two sets are arbitrarily related.
in this domain (e.g., Monaghan et al., 2014), word meanings cannot be systematically predicted based on their orthography and vice versa.

Table 1 Examples of studies that use feature encoding models

| Source | Item | Features | Response vector |
| :---: | :---: | :---: | :---: |
| Mitchell et al., (2008) | Concrete words (dog) | Co-occurrence statistics with 25 sensory-motor verbs | Pattern of activation in all cortical voxels |
| Fernandino et al., (2016) | Concrete words (dog) | 5 sensory-motor relevance ratings | Pattern of activation in the GSN (Binder et al., 2009) |
| Current simulation | Numbers (3497) | 5 decimal digits [030497] | 17 binary digits $[000000000000$ 00000000110110101001 ] |

Sets that use the same representational format. In contrast, a successful prediction can occur if the two sets use the same representational format. Consider the set of multi-digit numbers in the decimal system, $A=\{10,11, \ldots, 427, \ldots\}$, and the set of 10 digits in the decimal system, $B=\{0,1,2,3,4,5,6,7,8,9,10\}$. These sets use the same representational format to represent quantities (the decimal system), and there is a systematic linear mapping from the features (the digits), to the multi-digit numbers, such that:

$$
\begin{gathered}
\overline{d_{n} d_{n-1} \ldots d_{1} d_{0}}=\sum_{i=0}^{n}\left(d_{i} \times 10^{i}\right) \\
3491=3 \times 1000+4 \times 100+9 \times 10+1 \times 1
\end{gathered}
$$

When we have such systematic mappings between systems that use the same representational format, knowing the mapping function allows us to decompose any item from set A as a combination of features from set B . An example of such a mapping would be Fernandino et al.'s (2016) suggestion that the general semantic network encodes multimodal combinations of sensory-motor features by integrating information from modality-specific sensory-motor areas. If this were true, then you could predict the neural pattern of novel items from their featural representations, which is what that study found as well.

Sets that use different but systematically related representational formats. However, there is an alternative, which would also allow you to make a successful prediction from encoding models. Two sets can use different representational schemes, while maintaining a systematic mapping between themselves that allows us to predict the mapping of any one pair of items from knowledge of the mapping function. Within the context of conceptual representations in the brain, higher-level heteromodal areas might use a representational code that is different from the one used by sensory-motor cortices, but there might be a systematic mapping between representations in each system ${ }^{3}$.

For a simplified example, consider the relation between the decimal and the binary systems for representing numeric values. A binary represented value can be transformed into a decimal number by applying the following formula:

[^175]\[

$$
\begin{gathered}
\left(\overline{d_{n} d_{n-1} \ldots d_{0}}\right)_{2} \rightarrow\left(\sum_{i=0}^{n}\left(d_{i} \times 2^{i}\right)\right)_{10} \\
10011_{2} \rightarrow 1 \times 2^{4}+0 \times 2^{3}+0 \times 2^{2}+1 \times 2^{1}+1 \times 2^{0} \\
=16_{10}+2_{10}+1_{10}=19_{10}
\end{gathered}
$$
\]

Clearly, there is a systematic but non-linear mapping between the decimal and the binary system, and yet, these two systems use different codes to represent numbers. If our argument is correct then it should be possible to predict the binary representation of a number based on a decimal feature encoding model. Below we present a simulation that achieves this by applying the encoding model approach often used in neuroimaging studies. Within the simulation, binary vectors are analogous to voxel activation patterns, and the encoding model is based on decimal representations (Table 1).

## Simulation: Decoding binary representations with a decimal feature encoding model

As detailed previously, encoding models predict stimulus identity from brain activation by modelling the relationship between the constituent features of the training stimuli and their corresponding BOLD activation in a group of voxels. Then they use that relationship to estimate the expected neural activation patterns for novel test items based on their feature representations. The predicted activation pattern for each stimulus is compared to the observed patterns for all test stimuli. For the following simulation, let us consider the numbers from 0 to 99999 as our stimulus set. They can be decomposed into 5dimensional feature vectors where each feature is a decimal digit (e.g., 3497 can be decomposed as [0 349 7]. These features can be considered analogous to the 5 sensory-motor relevance ratings of words used by Fernandino et al. (2016) or to the cooccurrence statistics with sensory-motor verbs used by Mitchell et al. (2008). Further, let us consider the binary representation numbers as 17-dimensional vectors (e.g. [000000000000 00000000110110101001 ], to be analogous to the BOLD activation pattern in a set of 17 voxels in an ROI under investigation. The correspondence between these patterns and actual neuroimaging studies using this approach is demonstrated in Table 1.

We trained an encoding model to predict the binary activation pattern for a given number, based on its 5-dimensional decimal
limitations we will briefly cover this issue in the general discussion, but a more in-depth treatment is needed
feature representation. The modelling followed 4 steps: 1) splitting the stimuli into a training ( $90 \%$ ) and a test ( $10 \%$ ) set, 2) fitting multiple linear regression models on the training set with the 17 binary features as response variables, and the 5 decimal features as predictors, 3 ) calculating predicted activation pattern (predicted maps, PMs) for each test item from its decimal features and the multivariate regression model, 4) comparing the PMs with the actual binary patterns for all test items (observed maps, OMs). In the comparison stage, we computed the Euclidean distance between each PM and the OMs for all test items, and we calculated the percentile rank of the similarity between the PM and the OM of each item. For example, if the PM for the number 29782 were most similar to OM for that number, then the percentile rank for it would be $10000 / 10000$ $=1$. However, if it were more similar to the OMs of 1000 other items, then its percentile rank would be $9000 / 10000=0.9$.

The encoding model was successful in decoding the binary representation of untrained items based only on their decimal features. The prediction accuracy of the linear regression model was $0.7(\mathrm{SD}=0.24)$ and a wilcoxon signed rank test showed that it was above chance ( $p<.0001$ ). Since by definition binary and decimal number systems use different representational formats, we cannot conclude that the representation of binary numbers encodes decimal features. By analogy, the successful decoding of patterns of neural activation based on a stimulus feature space, cannot be used to infer that the brain encodes information about these features or that its neural representational space is organized along the dimensions of that feature space.

## Discussion

Stimulus-feature based encoding models (Haxby et al., 2014, Naselaris et al., 2011) are a powerful new tool for studying how the constituent features of stimuli relate to the neural activation patterns elicited by these stimuli. They represent a significant methodological advance over more traditional MVPA methods because they allow us to predict neural activation for novel items and because they can be used to decode the identity of such items from neural data alone. While this is an impressive feat and an incredibly useful tool, we have to be cautious in interpreting what such successes mean for our understanding of the representational system of the brain. Both theorists (e.g., Haxby et al., 2014; Naselaris \& Kay, 2015; Naselaris et al., 2011; Norman et al., 2006; Tong \& Pratte, 2012) and practitioners (e.g. Fernandino et al., 2016; Kay et al., 2008; Mitchell et al., 2008; Santoro et al., 2014) have suggested that we can infer that the brain uses a certain set of features to encode information, if we can successfully decode the activity of novel items from such features. However, as we have argued here, this inference is not formally valid. Successful decoding might be the result of a systematic relationship between the representational system of the brain and the stimulus feature set, even if those utilize different representational schemes.

How do we know whether two representational systems are truly different? It could be argued that in our example, both

[^176]binary and decimal number systems share many properties, and that they are merely different implementations of the same fundamental representation. For example, both systems use the position of a digit to encode its magnitude, and as a result, all arithmetic procedures that can be performed with decimal numbers can be applied to binary numbers as well. We propose that the key issue in determining whether two representations are the same is whether you can establish a one-to-one mapping relation between features at different levels of representation in each system. For example, if you substitute each decimal digit with a unique letter, the resulting system would appear different from the decimal system only on the surface, but the relation between multi-digit numbers and their features would be the same in both cases ${ }^{4}$ In contrast, decimal and binary features have a qualitatively different relation to the numbers they represent. Despite this, binary representations can be decoded based on decimal features, illustrating the inferential problem of encoding models we address here.

It is important to clarify that the "one-to-one" mapping is an abstract requirement. We are not claiming that to establish representational equivalence between the brain and a certain set of features that it is necessary to find a one-to-one mapping between the basic feature components of stimuli and activation in individual voxels or groups of voxels. The brain does not compute and represent information at the voxel level - voxel activations are the result of averaged activity over hundreds of thousands of neurons. The general lack of access to large-scale neural level activity in the living human brain makes it even more important to not only discover analytical tools that helps us relate voxel activation to possible representations, but also to understand the limitations of those tools and what they can and cannot tell us.

An important question that naturally arises from the caveats we discussed is how one can maximize confidence in the outcome of a forward encoding model approach, or conversely, guard oneself against unjustified inferences. We propose that it is crucial to compare the performance of several possible encoding models. To that aim, it is not sufficient to use a "baseline model" that is unrelated to the domain of interest (i.e., compare a semantic feature model to a low-level visual word form model). Instead, one or several alternative representational models should be tested that are derived from competing theories (i.e., semantic model A vs. semantic model B). To illustrate, an elegant comparison of a sensory-based vs. non-sensory-based semantic model was achieved by Anderson et al. (2015). These authors contrasted a visual model with a word cooccurrence model to investigate which brain regions represent modality-specific visual features, and which do not (using differential correlation in RSA rather than an encoding model). The relative superiority of a particular model at predicting activation patterns in a brain region makes it more likely that the brain is using the representational scheme of the better performing model rather than the alternative. However, it is important to keep in mind that such comparisons only provide
perfect decoding accuracy; compare that to the 0.7 decoding accuracy for the decimal-to-binary model
evidence for the relative likelihood of each model, but, due to the limitations discussed above, still do not allow us to infer that the winning model is the "true" model.

For that reason, besides the assessment of relative model performance based on model comparison, a second crucial step is to evaluate absolute prediction performance. In particular, the observed decoding accuracy can be compared to the "noise ceiling", or to the "upper limit of prediction accuracy" (Naselaris et al., 2011), reflecting the maximal performance that can be feasibly achieved given the noise present in the signal. The gap between the two can be thought of as the variance that is not explained by the current model, which should motivate and guide the search for an improved or alternative version of the model. Until such maximal performance is obtained, we should be careful in making strong representational inferences about the brain from the currently available analytic methods.

Ultimately, many of these inferential caveats exist because fMRI data is correlational. Comparing alternative models and evaluating absolute prediction performance might eventually converge on the true underlying feature model, but this is not guaranteed. We propose that an even better way to test representational hypotheses might be to introduce experimental manipulations that affect the hypothesized representational dimensions. For example, one could prime participants to weight some features of the stimuli more than others. If that leads to changes in the performance of a classifier based on the primed features, this would constitute much stronger evidence that these features underlie the neural representational scheme in question. This proposal is logical but it has not been experimentally tested yet, and we look forward to seeing how it will fare in practice.

# The Relational Luring Effect: False Recognition via Relational Similarity 

Vencislav Popov<br>Carnegie Mellon University, Pittsburgh, PA, USA<br>Penka Hristova<br>New Bulgarian University

#### Abstract

We present evidence for a novel relational luring effect (RLE) in recognition memory. Participants performed a continuous associative recognition task in which they had to discriminate between new, old and recombined word pairs. Participants made more false alarms and responded more slowly to lures (TABLE CLOTH) that were relationally similar to studied pairs (FLOOR CARPET). RTs and false alarms for lures increased linearly as the number of previously studied different exemplars of the relation increased (e.g., 0 to 4 previous exemplars). The RLE effect was stronger for relations that were represented by exemplars that were more typical of the relation. These results suggest that semantic relations exist as independent representations in LTM, and that during associative recognition these representations can be a spurious source of familiarity. The RLE has implications for models of semantic and episodic memory, unitization in associative recognition, analogical reasoning, and constructive memory research.

# Target-to-distractor similarity can help visual search performance 

Vencislav Popov (vencislav.popov@gmail.com)<br>Lynne Reder (reder@cmu.edu)<br>Department of Psychology, Carnegie Mellon University, Pittsburgh, PA, USA

#### Abstract

We found an unexpected positive effect of target-to-distractor similarity (TD) in a visual search task, despite overwhelming evidence in the literature that TD similarity hurts visual search performance. Participants with no prior knowledge of Chinese performed 12 hour-long sessions over 4 weeks, where they had to find a briefly presented target character among a set of distractors. At the beginning of the experiment, TD similarity hurt performance, but the effect reversed during the first session and remained positive throughout the remaining sessions. We present a simple connectionist model that accounts for that reversal of TD similarity effects on visual search and we discuss possible theoretical explanations.

Keywords: visual search; learning; similarity; connectionist model; neural network

## Introduction

Intuitively, the more similar two objects are to each other, the more difficult it should be to say whether they are the same object or not. Research with the visual search task has confirmed this intuition repeatedly - when a target is more similar to distractors in the search array accuracy decreases and response times (RTs) increase (Treisman \& Gormican, 1988; Duncan \& Humphreys, 1989; Treisman, 1991), and more errant saccades are made to the highly similar distractors (Bichot \& Schall, 1999). Despite the ubiquity of this negative target-to-distractor (TD) similarity effect, in a recent experiment that explored how frequency of exposure affects a variety of tasks, including a visual search task, we discovered by accident a positive TD similarity effect in visual search (Reder, Xiaonan, Keinath \& Popov, 2016). We found that greater TD similarity eventually lead to greater accuracy and faster RTs.

The visual search task was performed with Chinese characters over 12 hour-long sessions and the participants were US undergraduates with no previous knowledge of Chinese characters. Interestingly, during the initial stages of the visual search task we observed a negative TD similarity effect, as is expected from prior research, but this effect reversed quickly. After a single training session, higher TD similarity lead to better performance. Since this result was not reported in Reder et al. (2016), we will first describe the experiment and the key results with respect to frequency and similarity.

[^177]
## Method

## Participants

Twenty U.S. college students with no prior experience learning Chinese participated in this experiment.

## Materials

The stimuli for the visual search task were 64 Chinese characters. We grouped the characters based on their visual similarity in 16 sets of four characters. Characters within a set had a higher similarity with each other compared to characters from other sets. This was determined by a native Chinese speaker and was subsequently confirmed by analyzing orthographic vector representations of the characters (Xing et al, 2004; Yang et al 2009) ${ }^{1}$. We used highly similar distractors in order to force participants to encode the entire character rather than a subset of diagnostic features. For each participant, half of the sets were randomly assigned to the high-frequency condition and were presented 20 times more often during the visual search task.

## Procedure

The visual search task was performed over 12 sessions. There were three session per week and each lasted for about 1 hour. Each trial began with a sample character presented in the middle of the screen for 2 seconds. The sample character was followed by a display of 3 to 5 characters. On half of the trials, the display included the target character and participants were to respond whether the target was present. Three of the characters were from the same similarity set as the target character. Additionally, 0-2 characters from different sets of the same frequency class as the target were also present as distractors. After participants made their response, they received immediate accuracy feedback.

## Results and Discussion

We analyzed the accuracy data via logistic mixed-effects regressions and RTs via linear mixed-effects regressions, both with participants and items ${ }^{2}$ as random intercept effects. All effects discussed below were significant ( $\mathrm{p}<.05$ ) as determined by likelihood ratio tests that compared alternative regression models with and without each effect. Most results concerned with effects of frequency are described in Reder et al. (2016; see also Reder et al., 2007); here we focus primarily on the role of similarity.

[^178]

Fig 1. Accuracy and RTs to search the display as a function of target presence or absence, week of training and frequency of exposure.

Figure 1 shows the effect of frequency of exposure on accuracy and RTs for finding the target character. Overall, accuracy was greater and RTs faster for characters from high frequency sets. There was a two-way interaction between frequency and whether the target was present or absent. For accuracy, the effect of frequency was evident only when the target was absent. In Reder et al. (2015), we proposed that frequent exposure facilitates the development of unitized representations of each character. That is, a character seen less often has a weaker chunk representation and is more likely to be encoded as a configuration of some of its features rather than as a single higher-level unit. Thus, when a participant is searching for a LF character the probability of partially matching some of the target's features with features of the distractors is much greater compared to HF characters. This leads to more false alarms in the absent condition, but does not affect the present condition. The interaction was also evident in RTs, although there was still a small effect of frequency in the present trials, likely reflecting the differential efficiency of encoding high and low frequency characters.

A number of previous versions of this experiment had failed to show the hypothesized frequency effects. In those experiments, the distractors in each search array were chosen at random and thus were not very similar to the targets on each trial. In contrast, in the current experiment we ensured that targets were paired with highly similar distractors. We believe that the discrimination required in the prior versions of our visual search task was too easy and as a result, participants were able to perform the task by noting and remembering individual features that distinguish the target from its distractors. As a result, participants did not have to develop stable chunks for each character.

If that is the correct interpretation, then we expected to see an analogous effect within this experiment based on the discriminability (similarity) of the target character to its distractors in the search array. We should see that greater TD similarity leads to a better performance over time, because the increased difficulty in discriminating the target from the distractors forces people to develop stronger and more stable representations of each character as a whole unit/chunk. Note that this prediction is contrary to an intuitive and classic result in the visual search literature - usually, the more similar a target to its distractors, the more difficult it is to perform the task (Duncan \& Humphreys, 1989).

TD similarity was calculated based on vector representations obtained from Yang et al. (2009). Each character was represented as a vector of 270 binary features for five dimensions - simple features, shapes, structure, position and strokes. These vector representations are based on an orthographic analysis of the characters and prior behavioral work (Xing et al, 2004). These representations have been already used successfully to model print-to-sound mappings in Chinese (Yang et al, 2009) with a connectionist model similar to those used in modeling English print-tosound mappings (Harm \& Seidenberg, 1999). For each search array, we calculated the mean Euclidean distance between the target and each distractor. Low and high similarity groups were defined as being below or above one SD around the mean similarity of all search arrays.

Figure 2 shows that our prediction was confirmed. During the first session, initially greater TD similarity lead to slower RTs. However, by the end of the first session the effect had reversed and throughout the remaining sessions high similarity between the target and distractors lead to faster RTs and greater accuracy.

Fig 2. Accuracy and RTs for visual search as a function of similarity of target to distractors within the search array. Right panel shows performance over time during the first session. Left panel shows performance over all 12 sessions.

Contrary to our findings, visual search tasks usually show that high TD similarity leads to lower accuracy and slower response times. Why is it that we found exactly the opposite? A trivial explanation would be that TD similarity in our study was confounded with distractor-to-distractor similarity. The latter consistently shows positive similarity effects. We discounted this explanation by showing that the positive effect of target-to-distractor similarity remained even after controlling for distractor-to-distractor similarity in the regression model.

A theoretical explanation is that most visual search studies use simple stimuli that have pre-existing representations in long-term memory and no additional learning is required. Our study instead used Chinese characters, which are a complex configuration of features for participants who do not know Chinese. Since these characters did not have preexisting representations, participants had to develop them while doing the visual search task. We suggest that those representations were influenced by the demands of the task - to make highly similar patterns more distinct from one another so as to be better suited to support future performance. In essence, we argue that over time when the target is presented along highly similar distractors, the cognitive system builds more distinctive and stable representations of these targets.

Additional support from this argument comes from the fact that (as it was with frequency) the similarity effect is mostly observed in the absent condition (Figure 3, left panel). That is, the benefit from gaining more distinct and stable representations is mostly to prevent the partial matching of shared features between the target and distractors on absent trials.

Fig. 3. Effect of TD similarity on visual search accuracy as a function of training session and whether the target was absent (left panel) or present (right panel).

## A connectionist model

The reversal of the similarity effect is something of a challenge from a modeling perspective. How exactly are more distinct representations built over time and what mechanism drives that differentiation?

In order to capture the reversal of similarity effects, we decided to apply a novel connectionist model that will be able to perform a visual search task while continuously modifying its internal representations of the stimuli. Connectionist
models that represent stimuli as distributed patterns of activity are well suited for exploring the time-dependent changes in the structure of conceptual representations that consist of multiple features. In line with our theoretical interpretation of the data, we expected that in the beginning of training, the model will behave similarly to our human participants and will make more errors for highly similar distractors. However, since this initial behavior would lead to more errors, over time the error-dependent learning might cause the model to alter its internal representations of each stimulus so as to make them more distinct from one another.

In this way, the problem that a connectionist model of this task has to solve is akin to the XOR problem. Specifically, how should the representation of the input patterns be transformed so that similarity is reversed through the transformation? One possibility is for our model to have at least one layer that intervenes between the input layer and a layer that computes similarity between patterns. After a number of failed attempts using a single hidden layer we tried two separate hidden layers, which allowed the network to more gradually change the similarity structure in the input.

The visual search task here requires that participants are able to initially encode the sample character and keep it active in short term memory while comparing it in turn with each candidate character in the search array. To model the task as fully as possible, a model was implemented with a single input layer that can send activation through two different pathways - either to a working memory (WM) module (implemented as a kind of a long short-term memory module), or directly to the comparison layer. This dual pathway represents two ways to use information coming through the senses. One pathway can store the representation of the target in short-term memory and then manipulate it in the absence of the stimulus itself. The other pathway can directly use the incoming information (i.e. the candidates for comparison in the search array).

We assumed that the visual search is performed serially, because the RTs increased linearly with the search array size, and because the slope in the absent condition was twice as large as the slope in the present condition (Treisman \& Gelade, 1980). As a simplification, the model presented below will deal only with this serial search case.

## Architecture

The network consisted of the following layers (the architecture is presented in Figure 4):

- Input: 20 units
- Hidden1: 15 sigmoid units
- Hidden2: 10 sigmoid units
- LSTM module 1
- LSTM_Input: 10 linear units
- LSTM_Buffer: 10 linear units
- LSTM_Context: 10 linear units
- LSTM_Output: 10 linear units
- LSTM_Input_gate: 1 input unit
- LSTM_Context_gate: 1 input unit
- LSTM_Output_gate: 1 input unit
- Direct_output: 10 linear units
- Direct_output_gate: 1 linear unit
- Comaprison: 20 units
- Response: 2 softmax units (output layer)

The input was connected in a feedforward manner to hidden1, which in turn was connected to hidden2. We expected the two hidden layers to progressively extract higher order features of the input. Initial weights between these layers were randomized with a mean of 0 and $\operatorname{sd}$ of 0.5 . Each unit of the hidden 2 layer was connected with the corresponding unit in the input layer of the LSTM module, as well as with the direct_output layer with a frozen weight of 1. The same applied to the connections from LSTM_Input to LSTM_Buffer and from LSTM_Buffer to LSTM_Output. Thus, the output of the hidden2 layer was copied forward to the output layer of the LSTM module, and to the direct_output layer. The LSTM module also had a recurrent context layer that was connected bi-directionally to the LSTM_Buffer layer.

The purpose of the four gates was to control the flow of activation through these two modules. There was a fixed negative bias of -1 to the LSTM_input and LSTM_output layers, and a fixed positive connection of 1 with their corresponding gates. Since they were all linear units that were cropped at 0 and 1 , when a gate was off, no activity was copied to corresponding and subsequent layers. When a gate was on, it negated the bias and the layer copied the output of the preceding layer and passed it forward.

## Network functioning

Each example trial was composed of four events (i.e., presenting different input patterns):

1. Presentation of the target
2. First candidate from the search array
3. Second candidate from the search array
4. Final candidate from the search array

When the target was presented to the input, only the LSTM_input gate was on. Thus, the activity in hidden 2 layer that corresponds to the sample input was copied to the LSTM1_input, LSTM_buffer and LSTM1_context layer. All other gates were off, thus preventing the sample input from transferring to the direct_output layer.

When each candidate from the search array appeared, the LSTM_input gate was off, preventing the candidate representation from entering LSTM module. All the other gates were on. This meant several things happened. The candidate representation on hidden 2 was copied to the direct_output layer. The representation of the sample that was encoded in the LSTM_context layer on the previous time step was transfered back on to the LSTM_buffer, and from there it was transfered to the LSTM_output. At this point, the network had the hidden 2 representation of the sample instantiated on the LSTM_output layer, while the hidden2 representation of the first candidate was active on the direct_output layer.

Both the LSTM_output and the direct_output layers were connected with free random weights with sd 0.1 to the comparison layer, which integrated the representations of the sample and the first candidate input. The comparison layer was connected to the response layer, which consisted of two units - 1 for responding that the two representations are the same, and the other for responding that they are different.

Fig 4. The network architecture. Arrows with stars (*) represent copy connections, where each unit in the sending layer is connected with a single connection with fixed strength 1 to the corresponding unit in the receiving layer.

## Training

To mimic the experiment's stimuli, 64 input patterns of length 20 were created with binary values that were grouped into 16 sets, which had greater similarity within sets than between sets. On average, $50 \%$ of the features in each input vector were "on". The randomization and conditions were equivalent to those in the experiment.

Mean similarity in a set was calculated using Euclidean distance. The groups in the lower $25 \%$ quantile of the distance distribution were designated as "Low distance / High similarity" sets, while groups in the higher $25 \%$ quantile were designated as "High distance / Low similarity" sets.

When a distractor was present, the network was trained to activate the "mismatch" response unit, while when a target was present it was trained to activate the "match" response unit. Therefore, the goal of the network was to discover a suitable combined representation in the comparison layer such that it will be able to discriminate when the LSTM_output and the direct_output layers had the same or different patterns of activation.

We used a back-propagation training algorithm with a learning rate of 0.01 and a momentum descent with a momentum rate of 0.9 . The network was trained for 4000 passes through the training set and the weights were updated at the end of each pass. After every 100 updates, we recorded the output activation of the hidden1, hidden 2 and the response layer.

## Results and discussion

Frequency effects. The main results of the simulation are presented in Figures 5 and 6, which show the activation of the "match" response unit over training time. Since the response layer had softmax units this value can be directly interpreted as the proportion of "match" responses the network would give in response to a pattern. In Figure 5 we can see that the training patterns that were presented more often lead to greater accuracy.

Fig 5. Activation of the Match output unit as a function of training time, stimulus type and frequency of the input pattern.

Several things should be noted about this pattern. We can see that initially the network deactivated the match response unit for both types of stimuli. We can also see that overall the effect of frequency was much greater on target stimuli compared to distractor stimuli, which is exactly the opposite effect than the one we found in the behavioral data. This was probably because there were 5 times more distractor items than target items ( 3 in absent conditions, 2 in the present conditions). In the actual experiment, this too was the case, but participants got feedback only for their final response, thus they had equal amounts of "present" and "absent" feedbacks. On the other hand, the network was trained as if each individual comparison required a response, which causes the discrepancy between distractor and target stimuli.

Thus, while the network captures the overall effect of frequency, its training regimen causes it to miss the specific pattern of frequency for different types of stimuli. This could
possibly be solved by considering the current response layer to be an internal response, reflecting whether there is a match or not. Then a secondary motor response layer can be added which outputs a 'present' response if the internal match response is higher than a threshold, or stays inactive until all candidates have been compared. If by the last one none of them had elicited a match response, it produces an 'absent' response. In this way the network would reflect the actual behavior more closely, and weight updating would be affected only by the final response in each example.

Similarity effects. As can be seen from Figure 6, initially the network performance is better for input stimuli that are less similar to their distractors. This is a normal behavior of connectionist networks, and it is also what is expected by previous behavioral data from the visual search paradigm (Duncan \& Humphreys, 1989). However, after about 2300 weight updates the effect reverses and stimuli that are closer to each other in the input space lead to better performance. Importantly, this reversal happens very shortly after the behavior of the network starts to approximate the behavioral result levels ( $\sim 70 \%$ accuracy), which is exactly the pattern we have seen from the behavioral session - greater similarity impairs performance during the first session of training, but the effect reverses by the end of that session. Indeed, if we limit our attention to the window between updates 2200 and 3000, which is immediately after the pre-training, and before the performance saturates at ceiling, there is a close correspondence between the network performance both in terms of frequency and similarity structure.

Fig 6. Activation of the 'Match' output unit as a function of training time, type of stimulus and Euclidean distance between the target and distractor input in each array.

What could be causing this reversal of the distance/similarity effect? A possible answer comes from examining the input-output mappings, as well as the hidden representations the network develops during training.

If we split the candidate input patterns into targets, similar distractors and dissimilar distractors, then the network is supposed to produce the following outputs. For targets, which are identical to the sample item (thus 0 distance or perfect correlation) the network has to produce a match response, but for distractors that are highly similar as well, it has to produce mismatch responses. Thus, a major conflict during training comes from the fact that when distance is high, the network has to produce only one type of response, but when it is low,
it has to either respond with a match or a mismatch. One way to achieve these contradictory goals would be to develop such hidden representations of the input that cause highly similar patterns to be represented as less similar to each other.

To test this explanation we looked at the distance between the sample item and its distractors in activation patterns in each of the two hidden layers, split by the distance in the input layer. In right panel of Figure 7, we can see that in the first hidden layer the distance structure in the input has been preserved. In the second hidden layer, however, in the beginning there is no difference in distance due to the two layers of random weights and the sigmoid nature of the stimuli. As training progresses, stimuli that were low in distance in the input and the first hidden layer become more distant to one another, compared to stimuli that were highly distinct to begin with.

Fig 7. Distance between the hidden layers representations of the target and the distractors in each training set as a function of training time. Left panel shows distance in the first hidden layer, right panel shows the second hidden layer.

## General Discussion

The current paper present preliminary data on a novel counter-intuitive finding that the usual target-to-distractor similarity effect in visual search reverses after a short training with previously unfamiliar Chinese characters. Namely, while targets that are highly similar to distractors in a search array are usually more difficult to detect, when the stimuli are complex visual objects, this effect reverses after about 20 repetitions of each object as a target. We propose that visual discrimination and learning interact in such a way that greater difficulty in discriminating the stimuli causes the development of more distinct and stable representations.

To test this idea of differentiation in the character representation over time, we fit a novel connectionist model. When it comes to frequency, the network successfully captured the overall effect that more frequently exposed stimuli led to better performance (although see the preceding discussion for some limitations). Theoretically, this was presumably because low frequency made it more likely that people depend on representing the characters as a configuration of features, rather than on its weak chunked representation. This caused them to be more likely to partial match constituent features and confuse distractors with targets. In contrast, the network showed exactly the opposite
effect, because distractors were present 5 times more than targets and had a greater influence over the weight updates.

The most interesting aspect of the model is that it was able to successfully capture the reversal of the similarity effect on visual search performance. It achieved this by transforming the input through multiple hidden layers, which allowed it to change the similarity structure in the input so that highly similar distractors became more and more differentiated in the second hidden layer as training progressed.

This explanation was further supported by a model that involved direct connections from the input to the comparison layer without hidden layer representations (not shown here). This model did not show the similarity reversal effect. This model is analogous to performing the task without having to develop novel representations. One novel prediction from the comparison of these two models and task versions would be that people who learned the Chinese characters under a visual search task would rate highly similar characters as less similar after the training.

Finally, while we simulated the input patterns in this model to resemble as closely as possible how our stimuli were structured, the simulation results might be specific to the interaction between the model architecture and the generated stimuli. Initial modeling results using the actual 270 -length vector representations of the Chinese characters show the same pattern as the simplified model presented here.

# Timing Time: Why Early Vision is Cognitively Impenetrable 

Athanassios Raftopoulos (raftop@ucy.ac.cy)<br>Department of Psychology, University of Cyprus, P.O. Box 20537<br>Nicosia 1678, Cyprus

#### Abstract

Newen and Vetter (2016) argue that cognitive penetration (CP) of perceptual experience is the most possible account of the evidence. They target both the weak impenetrability thesis that only some early visual processes are cognitively impenetrable (CI), and the strong impenetrability thesis that all perceptual processes are CI. Since I agree that perceptual processing as a whole is CP, I will concentrate on their arguments against the weak CI thesis. In attacking weak CI, the authors take aim at Raftopoulos' arguments supporting the CI of early vision. Their main argument comes from studies that, Newen and Vetter think, show that early vision is CP by demonstrating the existence of cognitive effects on early vision. I examine the same empirical evidence that Newen and Vatter discuss and argue this same evidence strongly supports the view that early vision is CI.

## 1. Introduction

Newen and Vetter (2016) argue that the CP of perceptual experience is the most possible account of the available evidence. They target both the weak impenetrability thesis that only some early visual processes are CI, and the strong impenetrability thesis that all perceptual processes are CI. Since I agree that perceptual processing, as a whole, is CP, I concentrate on weak CI. The authors criticize Raftopoulos' (2001, 2014) arguments in support of the view that early vision, defined by temporal criteria, is CI. They maintain that top-down influences from higher-level cognitive areas to early visual cortex occur very early. Thus, it is unjustified to conclude from an early timing of a visual process that it is unaffected by top-down cognitive influences.

The authors' main argument against weak CI, given that weak CI holds that during the timing of early vision no direct cognitive effects modulate the ongoing perceptual processes, comes from studies that, Newen and Vetter think, demonstrate the existence of cognitive effects on visual processing that occur within the time frame of early vision.

Furthermore, Newen \& Vetter $(2016,5)$ argue that even if it exists a stage of perceptual processing that is unaffected by cognition, it lasts for so few ms that it could not be a plausible candidate for a perceptual module and it would be of almost no importance to philosophical discussions about the CP of perception. In other words, even if such a CI stage exists, the information it processes and outputs would be too poor to be categorized as a properly speaking perceptual content.

Here, I concentrate on Newen and Vetter's arguments from temporal processing. The main reason is that if it turns out that this evidence does not support the CP of early vision, the rest of the arguments against weak CI are moot.

I argue that the evidence Newen and Vetter adduce if properly examined strongly supports weak CI. The evidence that emerges from these studies shows that all visual brain areas at some time are affected by top-down cognitive signals that usually drive spatial or object/feature based attention. They also show that within the time frame of early vision there is a confluence of top-down, lateral, and bottom up interactions. These interactions, however, do not involve any cognitive signals. These studies do not show that during the first $120-140 \mathrm{~ms}$ of perceptual processing there are direct cognitive top-down effects on early vision. What Newen and Vetter consider as evidence for top-down cognitive effects on early vision is, in effect, evidence for top-down and bottom up interactions that do not involve any cognitive effects.

In the first section, I define early vision and examine most of the studies cited by Newen and Vetter (2016) and argue that they do not show that early vision is CP. I also take up Newen and Vetter's claim that even if a CI stage of visual processing exists it is too impoverished to be deemed a perceptual stage and claim that the output of early vision has a rich structure. In the second section, I examine the rest of the evidence used by Newen and Vatter and argue that in effect it supports the claim that early vision is CI. All recurrent processing during early vision is restricted within the visual areas of the brain and does not involve any causal influences from cognitive states.

## 2. Early Vision and why it is CI, Part 1.

Early vision includes a feed forward sweep (FFS) in which signals are transmitted bottom-up. In visual areas (from LGN to FEF) FFS lasts for about 100 ms . Early vision also includes a stage at which lateral and recurrent processes that are restricted within the visual areas and do not involve signals from cognitive centers occur. Recurrent processing starts at $80-100 \mathrm{~ms}$ and culminates at $120-150 \mathrm{~ms}$. Lamme (2003) calls it local recurrent processing (LRP). The unconscious FFS extracts high-level information that leads to categorization, and results in some initial feature detection. LRP produces further binding and segregation. The LRP is needed because,
owing to the small receptive fields of the neurons in V1 and V2, only local information can be coded at this level. The segmentation and recognition of the objects in a visual scene requires a more global analysis of the visual scene that can be achieved in higher areas, such as V4 or MT/V5, where the neurons' receptive fields o are larger and integrate information across longer distances in the visual field.

The feedback projections provide this global analysis that allows object segmentation, figure/ground separation, and object recognition. In the case of the MT/V5 feedback to V1, there is evidence (Pomp et al, 2015) that this feedback increases the responsiveness of the neurons in V1 especially for low-salience, small signals, which means that the recurrent signals from MT/V5 may serve to disambiguate sub-optimal visual input with respect both to the spatial location and motion of the sub-optimal signals and to their content. In addition, the feedback signals may be used to inform V1 where a change has happened in the visual scene. By not involving signals from the cognitive areas of the brain, FFS and LRP are cognitively impenetrable since the transmission of signals within the visual system is not affected by top-down signals produced in cognitive areas.

The processes of early vision retrieve from the environment information that allows the perception of a visual scene with as much accuracy as possible. To do so, early vision gradually constructs representations of increasing complexity (from variations in light intensities it extracts edges, from edges blobs, from blobs it extracts twodimensional surfaces, and from these the $21 / 2$ sketch). The output of early vision consists in the dynamic structural description of a visual scene corresponding to Marr's 21/2 sketch to which one could add the affordances of objects.

Current research on predictive coding sheds light on the nature of the processes implicated in vision. Applying this to early vision, one gets the following. The top-down and lateral effects in early vision aim to test hypotheses concerning the putative distal causes of the sensory data encoded in the hierarchically lower neuronal assemblies. In this testing, predictions made on the basis of hypotheses about the sensory information that the lower levels should encode assuming that the hypotheses are correct, are tested against the actual sensory information encoded at the lower levels. The hypothesis that best matches the sensory data is selected.

To form hypotheses concerning the probable cause of the sensory data at a certain level, at a specific spatial, and temporal scale, the neuronal assembly at the next level uses information not only about the sensory data at the previous level (or, to be precise, information regarding its prediction error) that is transmitted bottom-up, but also higher-level information that is transmitted either laterally, that is, from neuronal assemblies at the same level (neurons in V1 processing wave-lengths inform other neurons in V1 processing shape information), or top-down from levels higher
in the hierarchy (neurons in V4 are informed about the color of incoming information from neurons in IT). This lateral and top-down processing provides the context in which each neuronal assembly constructs the most probable hypothesis that would explain the sensory data at the lower level.

Since $90 \%$ of the information transmitted by neurons is transmitted within the first 100 ms of the neurons' activation as a response to a stimulus, information to neurons transmitted from other assemblies can affect their activity only if it arrives within the 100 ms time frame (Bullier 2001, 98). In order for the recurrent signals to modulate the activity at the reentered sites, they should reenter them during these crucial 100 ms . Thus, for some signal from V4 or MT/V5, which receive feedforward signals from V 1 , to reenter V 1 in time to influence the activation of the V1's neurons, the loop consisting of feedforward signals from V1 to V4 or MT/V5 and the recurrent signals from V4 or MT/V5 back to V1 must have been completed in less than 100 ms .

To put things into perspective, let us revisit Bullier's (2001) 'reintroinjection' view as it pertains to early vision and involves MT/V5 and its interaction with the lower visual areas V1 and V2. Low spatial frequency (LSF) signals precede high spatial frequency (HSF) signals. LSF information is transmitted through fast magnocellular pathways, while HSF information is transmitted through slower parvocellular pathways; the information transmitted through M-channels reaches V1 from LGN 20 ms earlier than the information transmitted from LGN to V1 through P-channels.

The mean activation latency of the neurons in MT/V5 of the brain is 75 ms after stimulus presentation respectively. Signals arrive at these areas at about the same time as, or a bit later than, they arrive in V1 ( $50-80 \mathrm{~ms}$ ) and V2 ( 85 ms ) and much earlier than they arrive in V4 despite the fact that MT/V5 is anatomically higher than V4 (Bullier (2001, 98). MT/V5 (and FEF) are parts of the 'fast brain' and belong to the dorsal system. MT/V5 is situated in the parietal cortex. Signals from V1 can reach the MT/V5 at about the same time they reach V2, that is, within 1-2 ms. It takes less than 20 ms for the recurrent signals from MT/V5 to affect the activation of neurons in V1 and V2. So, when HSF information transmitted through the P-channels reaches V1, 20 ms after LSF information transmitted through M-channels had reached V1, the responses of the V1 neurons have been modified as a result of the top-down signals from MT/V5 that had received earlier LSF information. In addition to the fast transmission of signals through the M-channels, MT/V5 also receives fast signals directly from LGN bypassing V1 through the koniocellular pathway. Thus, under certain conditions, MT/V5 could be activated earlier that V1 (Foxe \& Simpson 2002).

Bullier $(2001,100)$ concludes "the first wave of activity that invades the visual cortex following a visual stimulus appearing in the visual scene is carried by the M channel . . . the characteristics of the M channel are well suited for such a
first-pass analysis of the visual scene." This entails that even the earliest ERP component, C1, which is elicited between 4060 ms , is not an indice of the activity of V1 alone but also likely reflects top-down influences to V1 from areas as high as MT/V5. These bottom-up and top-down interactions take place within early vision (they have latencies up to 140 ms ), but all these studies bear evidence to the existence of topdown flow of information within early vision that involves stimulus driven signals reprocessed in higher visual areas and no evidence for cognitive effects in early vision.

The reason that the picture described thus far bears no evidence to support the existence of cognitive influences at these early latencies is that the top-down signals are transmitted from MT/V5 and are part of the processing along the dorsal system. The picture presented thus far posits early latencies of the signals arriving to MT/V5 from LGN either directly or through V1, that is, it dictates a bottom-up early activation of MT/V5 that, in turn, sends feedback to V1 affecting the activations of the neurons there. At these latencies there are no top-down cognitive signals to MT/V5 and, therefore, there are no cognitive signals affecting V1.

This conclusion is reinforced by the results of a study by Plomp et al (2015). The researchers combined EEG sourceimaging and Granger-causal modeling with high temporal resolution to "investigate whether recurrent and top-down interactions between visual and attentional brain areas can be identified and distinguished at short latencies in humans." Their results confirm the fast interaction between V1 and MT/V5 reported by Bullier (2001). Their results also show that the C1 ERP waveform ( 50 ms (onset)- $80 / 90 \mathrm{~ms}$ (peak)) reflects both V1 activity and also activity in highly distributed areas situates at the occipital, parietal, and frontal lobes (FEF is in the pre-frontal lobe in an area where the dorsal pathway projects). This activity reflects the early bottom-up and topdown interactions described by Bullier that includes the V1/MT feedback loop. In contradistinction to this early recurrent activity, the parietal cortex and FEF (the later cycle of activity there), which are known to modulate perceptual processing so as to help adapt behavior to the demands of a task and context, affect posterior activity around the latency of N1 ( 170 ms after stimulus onset). Thus, top-down interactions that reflect task-specific processing of the stimuli arise at longer latencies after stimulus onset. Pomp et al. (2015, 4-5) synopsize their results as follows "at the N1 latency, driving from MT no longer showed a stimulus effect, indicating that stimulus-specific driving from MT is confined to earlier latencies, in line with its fast response properties."

As Plomp et al., $(2016,1)$ write "stimulus-evoked activity at latencies before 100 ms is traditionally considered a bottom-up process. Even at these short latencies, however, there is mounting evidence of fast recurrent interactions between visual areas, obtained from direct recordings of neural activity in animal models." This agrees with Bulier's
conclusion that during the early interaction between MT/V5 and V1 (latencies earlier than 100 ms ) the signals are stimulus driven (since the signals entering MT and processed there originate from the stimulus only), while only in the later interactions that involve cognitively driven attention, whose commands are issued according to the task demands, do cognitive factors modulate the activation of neurons in V1.

Suppose that early vision is CI. Newen and Vetter could be right that the perceptual processes within this narrow time frame produce states with such poor contents that they are not properly speaking perceptual states; they could be at most sensory states. As we have seen, however, FFS and local RP allow, in about $120-140 \mathrm{~ms}$ after stimulus onset, the construction of fairly complex representations of stimuli. There is some form of perceptual organization, which certainly includes information regarding the presence of discrete objects in a scene, their orientations, sizes, shapes or forms, motions; these features determine the structural description of objects. Thus, the output of early vision consists of information about spatio-temporal and surface properties, 3D shape viewed from the perspective of the viewer, color, texture, orientation, motion, and affordances of objects, in addition to the representations of objects as bounded, solid entities that persist in space and time (Raftopoulos 2014). I disagree, thus, with Newen and Vetter that the content of CI perceptual states is related to the perception of impoverished black and white pictures. Early vision retrieves from the visual scene an extensive range of information.

## 3. Timing the Cognitive Effects: Why Early Vision is CI, Part 2

Let us examine the evidence that Newen \& Vetter employ to substantiate their claim.

Time-resolving electrophysiological evidence showed that visual cortex is activated within 50 ms and prefrontal areas within 80 ms after visual stimulus onset. This leaves plenty of time for iterative top-down processing between 'cognitive", e.g. frontal and parietal, areas and sensory, e.g. occipital, areas, within the first $100-200 \mathrm{~ms}$ after visual stimulation (Foxe \& Simpson, 2002). Thus, complex high level and reiterative processing can happen very fast and can influence visual processing very early on (. . . Plomp, Hervais-Adelman, Astolfi, \& Michel, 2015). (Newen \&Vetter 2016, 4-5)
Newen and Vetter talk about recurrent signals that involve cognitive activity affecting visual areas at latencies 100-200 ms . Thus, they accept that the available evidence suggests that cognitive effects on visual areas are registered after 100 ms post stimulus. We discussed Plomp et al. (2015) work and their conclusion that the recurrent early activity (before the elicitation of N1) is restricted within visual areas and only after that latency does recurrent activity involving cognitive
centers register in visual areas. Thus, the early recurrent activity (up to about 170 ms ) does not involve cognitive signals and this supports the view that the processes of early vision (that lasts up to about $120-140 \mathrm{~ms}$ ) are not affected by cognitive signals. Thus, when Newen and Vetter conclude "complex high level and reiterative processing can happen very fast and can influence visual processing very early on", this very early on is not early enough to be within early vision.

Indeed, as Foxe and Simpson $(2002,139)$ state
There is clearly sufficient time for multiple iterations of interactive processing between sensory, parietal, and frontal areas during brief (e.g., 200 ms ) periods of information processing preceding motor output . . . These data strongly suggest that activity represented in the "early" ERP components such as P1 and N1 (and possibly even C1) is likely to reflect relatively late processing, after the initial volley of sensory afference through the visual system and involving topdown influences from parietal and frontal regions.
Notice, first, that the reference is to the time frame up to 200 ms and that the recurrent interactions at earlier latencies that Foxe \& Simpson report concern interactions within visual areas. In addition, the top-down signals that are generated in the higher visual areas and reenter the early visual areas within these earlier latencies result from the processing of sensory signals that arrive very quickly, through PM-channels or the koniocellular pathway, to the higher areas; "The rapid activation of prefrontal cortex following initial visual activation (within 30 ms ) suggests that this input is mediated through the faster dorsal visual stream" (Foxe \& Simpson 2002,147-148). This is in line with Bullier's views that we examined earlier. All these suggest that the higher areas at these latencies have not received as yet any signals from cognitive areas and, in this sense the signals that constitute the feedback loop are bottom-up sensory signals and top-down reprocessed and modified sensory signals. In fact, it could hardly be otherwise; since all this very early recurrent activity involves the dorsal system, there is up to date no evidence to support the existence of any cognitive effects on the dorsal system when it functions on line to support fast action.

Furthermore, and in reference to Foxe and Simpson's mention of parietal and frontal regions involved in the early recurrent processing, which may be taken as evidence for the existence of cognitive influences, MT/V5 is in the parietal cortex and FEF is in the prefrontal cortex. Our discussion concerning the role of MT/V5 shows that there are no cognitive effects in the early latencies we discuss and, as our examination of the role of FEF will show, neither are such cognitive effects found in the early activation of FEF and in its role in the early stages of perceptual processing. Foxe and Simpson $(2002,146)$ confirm this analysis by concluding that "multiple visual areas begin to contribute substantially to the surface potential and C 1 begins to reflect contributions from a
number of visual areas other than, but is likely also to include V1 (emphasis added)." Moreover, Foxe and Simpson (2002, 147), after their claim that "that sustained activation patterns within cortical areas are consistent with feedback modulation of 'lower' visual areas by 'higher' areas, as well as local intrinsic processing", add that their findings conform with the findings of Lamme (1995) and Lamme et. al. (1998) about the time frame of feedback modulation in figure-ground segregation studies with monkeys. It is well known that these studies confirm that the recurrent processes that occur at early latencies do not involve cognitive signals.

Newen and Vetter $(2016,5)$ argue that in the visual system there is strong evidence for fast top-down processing within the first 50 ms after stimulus onset, certainly between motion area V5 and primary visual cortex V1 during motion perception (Silvanto, et al., 2005). The reference to the interaction between V5 and V1 during motor perception brings into mind the foregoing discussion of LRP that is restricted within the visual areas. Let use examine these studies to see if this assumption is substantiated.

Silvanto et al., (2005) studied the role of V1 in the visual awareness of motion. Their experiments show that backprojections from extrastriate cortex influence the activations of neurons in V1 and that it is the activation in V1 that determines which information reaches awareness. Since our interest is in the latencies at which the back projections affect V1 and the sites of origin of the top-down signals, I will ignore the findings concerning motion awareness. Silvanto et al., (2005) applied TMS on V1 and V5 at different times to examine the perception of phosphenes. When subthreshold TMS (that is, TMS producing no phosphene on its own) was applied over V5 followed by a subthreshold pulse to V1, subjects did not report any phosphene. When a subthreshold pulse was applied over V5 followed $10-40 \mathrm{~ms}$ later by a suprathreshold pulse over V1, subjects reported a phosphene, which was not merely the suprathreshold V1 phosphene. Instead, it acquired features of a suprathreshold V5 phosphene since subjects reported the perception of movement, and the shape and size of their percept was a mixture of V1 and V5 phosphenes. This shows that activity in V5, which on its own is insufficient to induce a moving percept, can produce such a percept if the level of induced activity in V1 is high enough.

Silvanto et al. $(2005,143)$ conclude that the fact "that moving phosphenes are perceived only when suprathreshold V1 stimulation follows, but not precedes, subthreshold V5 stimulation, together with the gradual increase in motion perception from the $10-50 \mathrm{~ms}$ period, precludes a simple feedforward summation account and points instead to a critical time of backprojection arrival in V1." They also note that the narrow time window for V5-V1 interaction ( $10-50 \mathrm{~ms}$ ) is consistent with previous reports of extrastriate-striate feedback interactions in motion during this time interval. Indeed, this accords with Bullier's (2001) and Plomp et al. (2016) finding
that there is an early (up to 100 ms ) phase of recurrent activity between V1 and MT/V5, but as in these studies, so in Silvanto et al. (2005) report, there is no evidence to suggest top-down cognitive effects at these early latencies, because the recurrent signals from MT/V5 are stimulus driven, or, to use Plomp et al. (2016) term, they are a stimulus-evoked activity.

Next, Newen and Vetter $(2016,5)$ examine the interaction between FEF and V1.
[T]he frontal eye fields (FEF), a higher-level area in frontal cortex involved in motor planning of eye movements, exerts its influence to V5 within 30 ms (Silvanto, Lavie, \& Walsh, 2006). Therefore, a feedback loop from a frontal region to an early occipital region can take as little as 80 ms or less . . . when the task requires face recognition, FEF signals are sent to face-sensitive regions and when the task requires motion discrimination, FEF signals are sent to motion area V5, both within a time frame of $20-40 \mathrm{~ms}$ after FEF activity (Morishima et al., 2009).
FEF is situated in the prefrontal cortex at a site that is heavily interconnected with the parietal cortex and is considered a part of the dorsal system. The mean activation latency of the neurons in FEF is 70 ms after stimulus presentation. Signals arrive at FEF with a slight time delay time with respect to the signals arriving at V1 (50-80 ms) and V2 ( 85 ms ) and much earlier than they arrive at V4 despite the fact that FEF is anatomically higher than V4 (Taylor and Nobre 2007). FEF TMS affects the detection of targets in arrays of distractors and these effects are apparent when pulses are applied early ( 40 and 80 ms ) after presentation of the visual array (O'Shea et al. 2004). HSF signals from V1 can reach FEF in 50-100 ms.

FEF contains visual and movement neurons. Studies (see O'Shea et al. $(2004,1060)$ for a discussion) show that there are two dissociated processing operations in FEF; the target selection by FEF visual neurons and saccade programming by movement neurons. Studies (O'Shea et al., 2016; Silvanto et al., 2006; Taylor \& Nobre 2007) show that some FEF responses are independent of saccades to targets and respond to the visual stimuli. Some of the FEF feedback signals play a role in the perception of a visual scene by affecting in a topdown manner the earlier visual areas. FEF plays a crucial role in visual target discrimination that is independent of saccade programming, as TMS applied to FEF impairs performance in target discrimination tasks if applied between $40-80 \mathrm{~ms}$ after stimulus onset (O'Shea et al. 2004). In addition, these visual neurons of FEF are thought to be associated with top-down or endogenous attention (Taylor and Nobre 2007).

Accepting O'Shea et al. (2004) early latencies of FEF neurons in discriminating targets from non targets (100-120 ms ), in view of the fact that, as Newen and Vetter $(2016,5)$ also accept, FEF exerts its influence to V5 within 30 ms and, therefore, a feedback loop from FEF to an early occipital
region can take as little as 80 ms or less, the total time it takes for the FEF neurons that have distinguished the targets from non targets to affect via top-down feedback projections the early visual areas is about $180-200 \mathrm{~ms}$, considering that the target discrimination in FEF reported by O'Shea t al. (2004) occurs at $100-120 \mathrm{~ms}$. This means that the FEF effects the activation of the neurons in early visual areas with a latency that places these effects outside early vision.

Concerning the finding that FEF neurons effectively discriminate targets from non targets as early as $100-120 \mathrm{~ms}$ after stimulus onset, one could argue that since this discrimination is task relevant and involves cognitive factors, cognition affects a visual area, FEF, within the timing of early vision. O'Shea et al. (2004), think it very likely that the early latency they report is the result of feature pre cueing, which means that the early activity in FEF occurs as the result of a cognitive demand issued before the appearance of the stimulus. I have argued (Raftopoulos 2014) that the cognitive effects on perception through pre-cueing are not cases of CP because they do not affect directly early vision and do not affect its epistemic role in grounding empirical beliefs.

Silvanto et al., (2006), whose study is cited by Newen and Vetter (2016) as showing that early vision is CP, found that stimulation applied to FEF $20-40 \mathrm{~ms}$ prior to the stimulation of MT/V5 decreases the intensity of the MT/V5 stimulation required to elicit phosphenes, which entails that the activity of MT/V5 is modulated by the activity in FEF. FEF has also been found to modulate top-down V4. Silvanto et al (2006, 944) claim that the content of to-down control may be either spatial or feature related, which means that they think that FEF affects the control of top-down attention; "an area involved in control would be expected to be active early and by responding to target features, the FEF could increase the sensitivity of extrastriate neurons to task relevant parameters." (Silvanto et al. 206, 944) With regards to how FEF exerts topdown control, it is possible that FEF activity occurs prior to sensory stimulation as opposed to rapid responses to visual stimuli since FEF neurons may also play a role in visual priming (Silvanto et al. 2006, 944). Thus, as Taylor and Nobre (2007), so Silvanto et al., (2006) think that FEF controls the allocation of top-down attention prior to stimulus presentation.

The discrimination between targets and non-targets depends on the task at hand and is cognitively driven. Thus, the top-down effects that result from this discrimination are also cognitively-driven and the visual processes that are thus affected are clearly CP. Accepting O'Shea et al. (2004) early latencies of FEF neurons in discriminating targets from non targets, since FEF exerts its influence to V5 within 30 ms and, therefore, a feedback loop from FEF to an early occipital region can take as little as 80 ms , the total time it takes for the FEF neurons that have distinguished the targets from non targets to affect via top-down feedback projections MT/V5 is $130-150 \mathrm{~ms}$, and the effects on the early visual areas is about

180-200 ms, considering that the target discrimination in FEF in O'Shea t al. (2004) occurs at $100-120 \mathrm{~ms}$. All of these are outside the timing of early vision and do not entail its CP.

Finally, Newen and Vetter (2016, 5), appeal to a study by Drewes et al. (2016) that shows that object recognition involves recurrent processing with a time constant of 60 ms . Drewes et al. (2016) examine the view that since the visual system extracts from object information, for example, the shape of objects, very fast this entails that the underlying cortical processing should be strictly feedforward. Against this, their study suggests that in shape perception there is a recurrent circuit, which is not an attentional cueing effect but reflects "the time course of feedback processing underlying the rapid organization of shape." (Drewes et al. 2016, 185)

In their introduction, they mention work by Heinen et al. (2005) suggesting that the figure-ground segregation requires two distinct periods of information processing in the early visual areas, an early one around $130-160 \mathrm{~ms}$ and a later one around $250-280 \mathrm{~ms}$ after stimulus onset, and by Wokke et al. (2012) showings that recurrent processing engages the early visual areas (V1/V2) to participate in more complex visual tasks. In an early time window (96-119 msec), detection of figure stimuli and of neural correlates of figure border detection and border ownership occurs. Later (236-259 msec) V1 and V2 participate in surface segregation. Drewes et al. (2016) accept these latencies as a general framework.

Drewes et al. $(2016,190)$ claim that "the extent of facilitation between two shape stimuli depends nonmonotonically on the delay between their presentations, peaking at a delay of 60 ms ." This suggests a recurrent circuit underlying shape processing in the cortical object pathway. They remark that in Wokke's et al. (2012) study TMS was applied to the occipital pole to disrupt processing in V1/V2 or to the lateral occipital lobe to disrupt processing in the LOC. TMS disrupted performance at both locations but at different latencies. In LOC, TMS disrupted processing when the pulse occurred $100-122 \mathrm{~ms}$ post stimulus, while in V1/V2, processing was disrupted when the pulse was applied 160-182 ms post stimulus. This shows a feedback process in the grouping of contour fragments to form shape with a one-way feedback time constant (LOC to V1/V2) of $40-80 \mathrm{~ms}$. Given the 60 ms time constant, the top-down signals reenter V1 and V2 at latencies outside early vision.

## 4. Conclusion

I examined the evidence Newen and Vetter (2016) adduce to support the claim that early vision is CP. None of it supports the existence of direct cognitive effects on early vision. Finally, concerning the claim that a stage of visual processing that is CI is so impoverished that it would not be worthy to be called a stage of perception, I claimed that early vision delivers a rich structure.

# The Wason Selection Task: A Meta-Analysis 

Marco Ragni (ragni@,informatik.uni-freiburg.de)<br>Cognitive Computation Lab, University of Freiburg, 79110 Freiburg, Germany<br>Ilir Kola (kola@informatik.uni-freiburg.de)<br>Cognitive Computation Lab, University of Freiburg, 79110 Freiburg, Germany

P. N. Johnson-Laird (phil@princeton.edu)<br>Princeton University, Princeton NJ 08540 USA and New York University, New York, NY 10003, USA

#### Abstract

In Wason's selection task, participants select whichever of four cards could provide evidence about the truth or falsity of a conditional rule. As our meta-analysis of hundreds of experiments corroborates, participants tend to overlook one of the cards that could falsify the rule. 15 distinct theories aim to explain this phenomenon and others, but many of them presuppose that cards are selected independently of one another. We show that this assumption is false: Shannon's entropy for selections is reliably redundant in comparison with those of 10,000 simulated experiments using the same four individual probabilities for each real experiment. This result rules out those theories presupposing independent selections. Of the remaining theories, only two predict the frequencies of selections, one (due to Johnson-Laird \& Wason, 1970a) provides a better fit to the experimental data than the other (due to Klauer et al., 2007). We discuss the implications of these results.

Keywords: Conditional reasoning; Entropy; Falsity, Selection task; Mental models.

## Introduction

Human beings are able to evaluate whether assertions are true, and to select evidence relevant to such evaluations. The late Peter Wason (1968) carried out a paradigmatic study to test whether naive individuals grasped the relevance of falsification. In his original "selection" task, the experimenter explains to the participants that there is a pack of cards in which each card has a letter on one side and a number on the other side. Four cards are taken at random from the pack, and placed in front of the participant (see Fig. 1). The experimenter then presents the rule:

If there is a $D$ on one side of a card, then there is a 3 on the other side.
The participants' task is to select just those cards that, if turned over, would show whether or not the rule is true or false of the four cards. The task is a demonstration, not an experiment, because it has no independent variable.

Participants tend to select the $D$ card alone, or the $D$ and 3 cards, but rarely the $D$ and 7 cards. Yet, if the 7 has D on its other side, the rule would be false. This failure to falsify was shocking. Perhaps as a consequence more than 300 experiments investigating the task have been published over the last 50 years.

In order to try to understand performance, psychologists developed various versions of the task. They explored rules of different sorts, such as disjunctions and rules framed

Rule: If a card has a $D$ on one side, then it has a 3 on the other side
Figure 1. The four cards in Wason's selection task. Each has a number on one side and a letter on the other side. The participants' task is to select just those cards that, if turned over, would show whether or not the rule shown above holds for the four cards. The letters $p, q$, etc. are added for illustrative purposes as the rule is of the sort, if $p$ then $q$.
with "every" in place of "if" (Wason \& Johnson-Laird, 1969; Wason \& Shapiro, 1971), cards with all the information on one side but partly masked, choices of just two cards (e.g., Johnson-Laird \& Wason, 1970b), or choices of multiple cards, with repetitions of one or more cards (e.g., Oaksford \& Chater, 1994). But, two main versions elicited better performance than abstract rules, such as the one in Fig. 1. One version used everyday rules, such as one about destinations and modes of transport (Wason \& Shapiro, 1971). The other version switched the task around so that participants had to select those cards representing individuals who might be violating a deontic rule (e.g., Griggs \& Cox, 1982), such as:

If a person is drinking beer, then the person must be
over 19 years of age.
The efficacy of some deontic rules, such as one about the amount of postage on letters (Johnson-Laird, Legrenzi, \& Legrenzi, 1972), depended on the participants' familiarity with them, but not all do so.

As the number of experimental studies grew, so too did the number of theories. By our reckoning, there are at least 15 distinct theories of the selection task including ones based on the meaning of conditionals, on formal rules of inference for them, on heuristics such as "matching" in which participants merely select those cards referred to in the rule (Evans, 1977), on content-specific rules of inference, and on the probabilities with which the various items on the cards occur in reality (Oaksford \& Chater, 1994). Given that the selection task has been under investigation
for half a century, the existence of 15 theories about it is embarrassing for cognitive science. Our aim in what follows is therefore to describe meta-analyses of the experiments that aimed to eliminate as many theories as possible.

## Meta-analyses

## The reliability of the results

We searched the literature for experiments on the selection task with the proviso that they used a conditional rule of the sort: if $p$ then $q$, and that they reported at least the frequencies of the four canonical selections of $\mathrm{p}, \mathrm{pq}$, $\mathrm{pq} \overline{\mathrm{q}}$, and $\mathrm{p} \bar{q}$, which the early studies had reported. Henceforth, we abbreviate selections in the preceding way, stating which of the 4 cards they included, e.g., pq denotes a selection of the p and q cards (see Fig. 1). We divided the resulting experiments into three categories according to the nature of the rule they used: abstract, everyday, or deontic. We also classified them according to whether they reported the frequencies of only the 4 canonical selections and a category of "other" selections, or the frequencies of all 16 possible selections. The studies can be found at http://www.cc.uni-freiburg.de/data.
Because the first studies were carried out half century ago and subsequent ones in many countries, their results might be too heterogeneous for an informative test of the theories. We assessed the overall homogeneity of the results for the three categories of task from the reliability of the rank orders of the frequencies of their canonical selections. Table 1 reports Kendall's coefficient of concordance, W, which ranges from 0 for no consensus to 1 for perfect consensus, for the three categories of task. The results show a reasonable and robust consensus over the experiments. Table 2 presents the overall percentages of each of the four canonical selections for the three sorts of selection task. It shows why the deontic task yielded a greater concordance, W: the majority of participants selected cards denoting potential violations of the rule.

Table 1. The concordance across different experiments examining the three main sorts of selection tasks as assessed with Kendall's coefficient of concordance, W, and stating its $\chi^{2}$ and $p$ values.

| Three sorts of <br> selection task | Number of <br> experiments | Kendall's | $\chi^{2}$ and p value |
| :---: | :---: | :---: | :---: |
| Abstract | 104 | $\mathrm{~W}=.34$ | $107, \mathrm{p}<.001$ |
| Everyday | 44 | $\mathrm{~W}=.25$ | $33, \mathrm{p}<.001$ |
| Deontic | 80 | $\mathrm{~W}=.54$ | $29, \mathrm{p}<.001$ |

## The redundancy of the selections

Many studies of the selection task report only the four separate probabilities with which participants selected each of the cards (e.g., Evans, 1977). These results, however, make sense only if the selection of each card is independent of the others. Some investigations have reported this independence (e.g., Evans, 1977). But, others have refuted it by establishing correlations between the selections (Pollard,

1985; Oaksford \& Chater, 1994). Correlations, however, are only among pairs of cards in selections. A better assessment would take into account each selection as a whole

Table 2. The percentages of each of the four canonical selections for the three sorts of selection task

|  | The canonical selections |  |  |  |
| :---: | :---: | :---: | :---: | :---: |
|  | p | pq | $\mathrm{pq} \overline{\mathrm{q}}$ | $\mathrm{p} \overline{\mathrm{q}}$ |
| Abstract | 36 | 39 | 5 | 19 |
| Everyday | 23 | 37 | 11 | 29 |
| Deontic | 13 | 19 | 4 | 64 |

and all the selections made in an experiment. We therefore introduced a new procedure that combines Shannon's measure of entropy (or informativeness) with the computer simulation of thousands of experiments. The underlying intuition is straightforward. Suppose the selections in an experiment are more redundant - more predictable - than a prediction made solely from the frequencies of selecting each of the four individual cards in the experiment. It follows that the cards in selections are, not independent of one another, but interdependent. And some aspect in the process of selecting cards yields the redundancy.

The first step in our procedure is to compute the amount of information in the selections in an experiment, i.e., the difficulty of predicting them. We use Shannon's measure of entropy:

$$
\mathrm{H}=-\Sigma \mathrm{P}_{\mathrm{i}} \log _{2} \mathrm{P}_{\mathrm{i}}
$$

for the set of selections, where $P_{i}$ denotes the probability of the i-th selection, and $\log _{2}$ denotes a logarithm to the base 2. In general, the greater the number of different selections, and the more evenly distributed the frequencies over them, so the value of H increases, and it is harder to predict the selections. If participants chose each card independently of the others, the value of H for the experiment would not differ reliably from its value for selections derived from sampling according to the four probabilities for selecting each card. But, if the value of H for the selections in the experiment is reliably smaller than this theoretical value, then we can reject the null hypothesis of independent selections. In other words, the redundancy reflected in a smaller value of H reflects interdependence in the selections.

As an illustrative example, consider the selections in Experiment 2 of Stahl et al. (2008), which we choose because of its large number of participants: 351 . Here are the frequencies of the selections, in which 6 participants selected none of the cards:

$$
\text { p 92, pq 99, pq } \bar{q} 2, p \bar{q} 20, p \bar{p} q \bar{q} 19, \bar{p} q 6, p \bar{p} \bar{q} 2,
$$

$\bar{p} q \bar{q} 2, \bar{q} 18, \bar{p} \bar{q} 22, p \bar{p} 7, q \bar{q} 6, \bar{p} 7, q 43$, none 6 .
They show that the probabilities of selecting each of the four cards were as follows:

$$
\mathrm{p} 0.69, \mathrm{q} 0.49, \overline{\mathrm{q}} 0.26, \overline{\mathrm{p}} 0.19 .
$$

The value of H for the selections in the experiment is 2.8 bits. Could this value have occurred by chance? We used a resampling procedure to find out its chance probability (see, e.g., Good, 2001). We ran a computer program to carry out 10,000 simulated experiments based both on the
number of participants in the original study and on its probabilities above of selecting the four individual cards. The resulting mean value of H was 3.13 , which shows that the observed selections in the experiment have a redundancy of 0.33 . More important, however, is that not one of the simulated experiments yielded an entropy as low as 2.8 bits, and so the difference is statistically significant ( $\mathrm{p}<.0001$ ). The redundancy in the original experiment did not occur by chance. In summary, a statistically significant degree of redundancy in selections in an experiment is evidence for their interdependence.

We programmed an algorithm based on the same idea. Its key difference from our analysis of Stahl's data above is that it concerns only the four canonical selections. This constraint is necessary because so many experimental reports state the results only for them. Four selections have a maximum entropy of 2 bits if they are each equiprobable. The mean over the 228 experiments (in Table 1) is 1.27 bits (with a standard deviation of 0.48 ). The input to the program states the number of participants and the frequencies of the four selections for each experiment in the set. Its main steps are as follows. For each experiment:

1. Compute N , the number of participants, and the probabilities with which each of the 4 cards occurred in the experiment's selections.
2. Compute Shannon's entropy H for the experiment.
3. Carry out 10,000 simulated experiments based on the probabilities of selecting each card, assigning a selection to each of the N participants.
4. Return the number of simulated experiments with a higher entropy than the actual experiment and the number of them with the same or a lower entropy.

Table 3. The mean entropies (in bits) of 228 experiments on three sorts of selection task, the mean entropies of sets of 10,000 simulations of each experiment, and Wilcoxon's tests ( W , and its p -value) of the difference between them.

| The three <br> sorts of selec- <br> tion task | Mean entropy <br> of experiments of sets of <br> simulations | Mean entropy | Wilcoxon's <br> W and p-value |
| :--- | :---: | :---: | :---: |
| Abstract | 1.32 | 1.42 | $\mathrm{~W}=469, \mathrm{p}<.001$ |
| Everyday | 1.51 | 1.66 | $\mathrm{~W}=28, \mathrm{p}<.001$ |
| Deontic | 1.06 | 1.21 | $\mathrm{~W}=68, \mathrm{p}<.001$ |

Table 3 presents the mean entropies of the 228 experiments investigating the three sorts of selection task, the mean entropies of each of their 10,000 simulations, and the results of Wilcoxon's W test and its p -value comparing the pairs of means. These results allow us to reject the null hypothesis of independent selections. The redundancy shown in the smaller entropies of real experiments over simulated ones shows that the cards in selections are not selected independently of one another. They are selected in an interdependent way. This result eliminates any theory that predicts that selections are independent.

## Theories of the selection task

Some theories of the selection task are informal and make only qualitative predictions about selections (e.g., Wason, 1968). Some predict only whether the correlations between selecting the possible pairs of cards are positive or negative (Oaksford \& Chater, 1994). Some predict only the probabilities of selecting each of the four cards (Evans, 1977; Hattori, 2002; Oaksford \& Wakefield, 2003). We discount all of these theories as insufficiently powerful to make quantitative predictions about the frequencies of the canonical selections, let alone all 16 possible selections. There remain just two theories, which we now outline.

## The insight model

The first algorithms to model the mental processes underlying the selection task were due to Johnson-Laird and Wason (1970a). Their principal algorithm posits three levels of insight into the importance of falsification: no insight, which implies that reasoners select only cards referred to in the rule - an anticipation of "matching" bias (Evans, 1972); partial insight, which implies that reasoners consider all the cards, adding any further cards that verify the rule, or, failing that, that falsify the rule; and complete insight, which implies that reasoners select only cards that can falsify the rule. The algorithm was published as a flow chart, but not implemented, because of a lack of access to a main-frame computer. We recently programmed it, replacing its use of truth tables with mental models and fully explicit models, simplifying its processes, but keeping its original functionality so the program makes the identical predictions to the original version.

Given a rule of the sort if $p$ then $q$, the program begins by compiling a list of cards to select, and its first step is to scan its mental model of the conditional, and as a result to put $p$ on this list. If the program also scans the model in the opposite direction, it adds q to the list. With no insight into the task, these selections verify the rule. However, the program implements two interrelated levels of insight. Partial insight is to assess all the cards, and to add any further card that verifies the rule, or, if none does, to add any that falsifies the rule. So, if $q$ is already in the list, partial insight adds $\bar{q}$, because it can falsify the rule, yielding the selection $\mathrm{pq} \overline{\mathrm{q}}$. Complete insight is to select only cards that can falsify the rule, and yields the selection $\mathrm{p} \overline{\mathrm{q}}$. Complete insight occurs only if all the cards are examined. An explicit biconditional as an input yields a selection of all four cards in certain cases, e.g., when it scans its model in both directions with partial insight.

Fig. 2 presents, not the algorithm, but a tree diagram summarizing its parameters and its predictions for conditionals and biconditionals. As it illustrates, the algorithm produces the same selections as a result of different processes, and it is not deterministic, i.e., nothing in the algorithm determines the level of insight (pace Evans, 1977, who took the algorithm to be deterministic). The predictions in Fig. 2 explain why selections should be interdependent, e.g., verifying cards include q only if they include p and falsifying cards include $\overline{\mathrm{q}}$ if and only if they include
p. The only exceptions to the algorithm's outputs should be the result of guessing or haphazard errors. In fact, these exceptions occur at a rate less than chance in the 288 experiments.

Figure 2. The predictions of the insight model (JohnsonLaird \& Wason, 1970a) as a binary decision tree. Each decision is controlled in its recent implementation by a parameter (see text). Participants with no insight select only cards referred to in the rule. Those with partial insight consider all cards, selecting any further card that can verify the
rule, or, failing that, that can falsify it. Participants with complete insight select only cards that can falsify the rule.

Our implementation of the algorithm contains three probabilistic parameters in the unit interval from 0 to 1 . The first parameter, $c$, is the probability of scanning the model in both directions as opposed to scanning in only one direction. The second parameter, $e$, is the probability of examining all four cards, and if the result fails to add any card that verifies the rule, adding any card that falsifies it. This corresponds to partial insight. The third parameter, $f$, is the probability of complete insight, which makes only a falsifying selection.

## The inference-guessing model

Klauer et al. (2007) proposed a set of related theories, including one with a heuristic component allowing for guessing, and an inferential component. There is no algorithm the implements the theory's underlying processes, but its predictions were modeled in a binary tree. This model has 10 parameters, which are each the probability that one sort of process occurs rather than another, and so each is in the unit interval from 0 to 1 . The model's first parameter is the probability that the inference governs the selection as opposed to guessing. The guessing component makes independent selections of each of the four cards according to four parameters that are the respective probabilities of selecting each of them independently as a result of guessing or any heuristic factor such as "matching" (Evans, 1977). The theory assumes that selections are governed, not by the meaning of the rule, but by inferences from the rule. The particular inferences depends on five parameters:

1. The probability that the rule, if $p$ then $q$, is interpreted as a conditional as opposed to a biconditional.
2. The probability that the inference is forwards from the if-clause: modus ponens (MP) or denial of the antecedent (DA), as opposed to backwards from the then-clause: modus tollens (MT) or affirmation of the consequent (AC).
3. Given the biconditional interpretation, the probability that the interpretation is bidirectional, if $p$ then $q \&$ if $q$ then $p$, as opposed to a case distinction, if $p$ then $q$ \& if not- $p$ then not- $q$. With the bidirectional interpretation, the distinction between forwards and backwards inferences does not apply - both are made, but with a case distinction interpretation, the distinction still applies.
4. The probability that an inference from a conditional or a bidirectional biconditional is a sufficient one as opposed to a necessary one. Normally, $p$ is judged sufficient to infer $q$ from if $p$ then $q$, but sometimes $p$ is judged necessary to infer $q$, as when the conditional is interpreted as stating an enabling condition akin to only if $p$ then $q$. A forward sufficient inference is MP, whereas a forward necessary inference is DA; and a backward sufficient inference is AC, whereas a backward necessary inference is MT.
5. The probability that inferences are made only about the visible sides of cards as opposed to the invisible sides of cards too, i.e., individuals can envisage items on them.

The model contains 10 parameters but the data are the frequencies of the four canonical selections. Hence, to ensure that the process of fitting model to data converges and does not overfit the data, we implemented a restricted in-ference-guessing model that makes the four canonical selections. Fig. 3 summarizes the predictions of this restricted inference-guessing model. The reasoning component in the original model makes no more than two inferences on a trial, and so it cannot make the canonical selection of three cards: $\mathrm{pq} \overline{\mathrm{q}}$. We therefore changed the original guessing component to make this selection.

Figure 3. A restricted version of the binary decision tree of the inference-guessing model (Klauer et al., 2007) for the 4 canonical selections. Each decision is controlled by a parameter (see text).

The two models are based on the only theories that we could find in the literature that can be programmed with parameters that fit data about the frequencies of selections.

## An evaluation of the two models

We evaluated the insight model with 3 parameters (John-son-Laird \& Wason, 1970a) and the restricted inferenceguessing model with 4 parameters (cf. Klauer et al., 2007). Their respective predictions can be represented as trees of
binary decisions (see Fig. 2 and Fig. 3). Both models invoke alternative sequences of processes depending either on three decisions in the insight model or four decisions in the inference-guessing model. Because each model's predictions correspond to a tree of decisions, we evaluated each of them as a multinomial processing tree (MPT) in which the probability of a particular cognitive state is estimated from the observed frequencies of selections (Riefer \& Batchelder, 1988). A program fitted each of the two models to the frequencies of the canonical selections of the three sorts of selection task: 104 experiments with the abstract task, 44 experiments with everyday task, and 80 experiments with deontic task (see Tables 1-3 above). We used the maximum-likelihood method from the R-package for multinomial processing trees (the MPTinR of Singmann \& Kellen, 2012). We calculated three measures to compare the goodness of fits of the two theories:-

- The root mean square errors (RMSEs) of the fits.
- The Bayesian information criterion (BIC), which indicates how much information is lost when a model represents the process that generates the data, taking into account both its goodness of fit and its number of parameters. It penalizes models according to the number of their parameters, and the smaller its value, the better the fit between a model and the data.
- The Bayes factor (BF; Schwarz, 1978), which is a Bayesian method to compare different models. It uses an approximation of the difference between the BIC value of model 1 and BIC value of model 2 as computed by MPTinR. The higher its value between 30 and 100 , the stronger the support for model 1 over model 2 (Wagenmakers et al., 2011).

Table 4 presents the three measures for each of the two models. As it shows, the insight model with three parameters has a closer fits, and lower BIC values, than the restricted inference-guessing model. The Bayesian factor likewise shows stronger evidence for the insight model than for the restricted inference-guessing model. The insight model has the advantage of fewer parameters. As a theory, it is simpler because it relies on the meaning of the rule rather than inferences from it, and because it has no machinery to account for selections that occur at a rate less than chance. But, it is not a paragon, and we explain why below.

## General Discussion

Half a century of research and over 300 articles should have led to a single unique theory of a cognitive task rather than to 15 different theories. That was the situation for Wason's selection task. The present research, however, has eliminated all but one theory. And it did so using the following strategy. It established a large but representative set of experiments investigating rules of the sort if $p$ then $q$ that had a reliable concordance in their results (Table 1). These results established the rarity of falsifying selections,
$p \bar{q}$, except when they violate a deontic rule Table 2). The four canonical selections ( $\mathrm{p}, \mathrm{pq}, \mathrm{pq} \overline{\mathrm{q}}$, and $\mathrm{p} \overline{\mathrm{q}}$ ) are reliably redundant in most experiments in comparisons of each experiment's entropy (informativeness) with the entropy of its

Table 4. The insight model's and the restricted inferenceguessing model's goodness of fit with the individual canonical selections for 288 experiments overall and for the three sorts of selection task: the root mean square errors (RMSE) for their predictions, their Bayesian information criteria (BIC), and the Bayes factors for the better-fitting model.

| The 3 sorts <br> of the sele- <br> ction task | Cognitive <br> model | RMSE | Bayesian <br> Information <br> Criterion (BIC) | Bayes <br> factor |
| :--- | :--- | :---: | :---: | :---: |
| Overall | Insight | 2.69 | 27.7 |  |
|  | Inference- <br> guessing | 19.35 | 37.0 | 99.5 |
| Abstract | Insight | 1.97 | 25.7 | 73.7 |
|  | Inference- <br> guessing | 3.28 | 34.3 | 47 |
| Everyday | Insight | 1.7 | 23.2 | 49.4 |
|  | Inference- <br> guessing | 2.18 | 30.9 | 23.5 |
| Deontic | Insight 0.8 31.4  <br>  Inference- <br> guessing 1.05  |  |  |  |

10,000 simulations based on its four probabilities of selecting each card (Table 3). Not all experiments yield redundant selections, but the vast majority do. This result ruled out theories that imply that selections of cards are independent of one another. Above all, theories therefore need to predict the frequencies of the canonical selections. Perhaps surprisingly, this criterion rules out nearly all the remaining theories. Klauer et al. (2007) had programmed an MPT of their inference-guessing model using 10 parameters to make predictions for the frequencies of all 16 possible selections - most of which do not occur more often than chance. More than twice as many experiments reported the frequencies only of the four canonical selections than reported them for all 16 selections. Hence, we produced an MPT for a restricted version of the model that used four parameters to predict the frequencies of the canonical selections. To do so, we reduced the original parameters for guessing to one, which made a selection of three cards, otherwise impossible for the model to select. For the insight model, we programmed an algorithm that carried out its processes (Johnson-Laird \& Wason, 1970a), and we used it to construct an MPT model with three parameters. The insight model yielded a better fit with fewer parameters (Table 4).

The story of the selection task does not end here. But, the success of the insight theory tells us that we have returned to how it was conceived after only a handful of studies. Naive individuals focus on those cards mentioned in the rule, and select them if they can verify the rule. With a little bit of insight, they consider all the cards, and may select additional cards. With complete insight, they select only cards that can falsify the rule (Johnson-Laird \& Wason,

1970a). We now know that various factors - the competence of participants, the contents of the rule, and the framing of the task - can all enhance insight. An account along these lines seems to be correct, except perhaps when experiments implicate probabilities in their contents or framing (e.g., Oaksford \& Chater, 1994).

The excellent fit of the insight model must be viewed with caution. The number of parameters in a model is a measure of our ignorance. Those for guessing seem to be dispensable. Indeed, some selections are very odd, as we saw earlier in our analysis of the results from Stahl et al. (2008). They are so odd that they must count as irrational on any criterion: the participants erred or guessed. Introducing parameters to model guessing has no theoretical value other than to index the difficulty of a task. The insight theory has three essential parameters, and the original infer-ence-guessing model has five. The difference reflects an crucial distinction: whether people determine the truth value of an assertion based on its meaning (the insight model) or based on inferences from it (the inference-guessing model). Therein may lie the advantage of the insight model. But, we are bound to ask what mechanisms might replace its parameters. We now know that the insight to make falsifying selections depends on various factors, including intellectual ability (e.g., Stanovich \& West, 1998). Hence, it may be feasible to replace the parameter for the probability of complete insight with a measure of ability. It is even conceivable that the parameter of partial insight might reflect a lesser but above average intellect. The parameter for scanning a model of the conditional in both directions is more problematic. It may depend on the processing capacity of working memory. These speculations in no way rule out the possibility of some quite different theory of the selection task outperforming the insight model.
If our research has any general moral, it is an old one: cognitive theories should be effective procedures (JohnsonLaird, 1983, p. 6). They should be programmable.

## Acknowledgements

This research was supported by a DFG-Heisenberg fellowship DFG RA 1934/3-1, and DFG projects RA 1934/2-1 and $4-1$. We thank Linden Ball, Ruth Byrne, Nick Chater, Jonathan Evans, Keith Holyoak, Sangeet Khemlani, Ken Manktelow, Mike Oaksford, Klaus Oberauer, Lance Rips, Carlos Santamaría, Walter Schaeken, Walter Schroyens, Dan Sperber, Christoph Stahl, and Valerie Thompson, for their help. We thank Christoph Klauer for his advice and sending us his algorithm,. We dedicate this paper to the memory of Peter Wason (1924-2003), a unique and most extraordinary researcher.

#### Abstract

Words frequently acquire new senses, but the mental process that underlies the historical emergence of these senses is often opaque. Many have suggested that word meanings develop in non-arbitrary ways, but no attempt has been made to formalize these proposals and test them against historical data at scale. We propose that word meaning extension should reflect a drive towards cognitive economy. We test this proposal by exploring a family of computational models that predict the evolution of word senses, evaluated against a large digitized lexicon that dates back 1000 years in English language history. Our findings suggest that word meanings not only extend in predictable ways, but also that they do so following an historical path that tends to minimize cognitive cost - through a process of nearestneighbor chaining. Our work contributes a formal approach to reverse-engineering mental algorithms of the human lexicon.

Keywords: Word meaning; semantic change; polysemy; chaining; nearest neighbor algorithm; lexicon

Over history, words have frequently acquired new senses, and become polysemous (Bréal, 1897). But the mental process that underlies the historical emergence of word senses is often opaque. Wittgenstein's notion of family resemblance (Wittgenstein, 1953, p31-32) highlights the challenge for researchers, showing that the many senses of the word game form "a complicated network of similarities overlapping and criss-crossing" with nothing identifiably in common (as for board games, card games, ball games, Olympic games, and so on). The network is presumably a reflection of the complex path the word game took in the historical development of its meaning. Decades of research have suggested possible ways that word meanings might be mentally structured or extended over time, but none has been tested formally against historical data at scale. We propose that word meanings should develop historically in ways that minimize cognitive effort, hence reflecting a drive towards cognitive economy (Zipf, 1949; Rosch, 1975). We test this proposal by formalizing previous theories in computational models that predict how word senses might emerge over time, contributing a principled approach to reverse-engineering mental algorithms of the human lexicon.

Our starting point is a set of influential ideas from cognitive science and linguistics suggesting that word meanings or categories might be structured in non-arbitrary ways. For example, pioneering work by Rosch (Rosch, 1975) showed that common semantic categories signified by words such as bird and furniture tend to exhibit a prototype structure, such that certain members of a category are more representative than others (e.g., robins and sparrows are more representative as birds than penguins or bats are). Although this theory has since been adapted to describe how word meanings might be structured (Lakoff, 1987) or extended over time (Geeraerts, 1997), it has not been computationally specified or evaluated broadly in accounting for historical patterns in how word senses emerge. A prominent alternative proposal is exemplar theory (e.g., Medin \& Schaffer, 1978; Nosofsky, 1986), which suggests that all encountered members of the category are stored and used in categorization judgments, although different members may be weighted differently. This proposal has also been used to describe how language might change over time, particularly concerning phonological and semantic representation (Bybee, 2006). To our knowledge, however, there has been no formal comparison of prototype and exemplar theories with respect to their ability to explain the historical emergence of word senses.

A critical addition to this theoretical terrain is the idea of chaining - popularized by Lakoff and other scholars (Lakoff, 1987; Malt, Sloman, Gennari, Shi, \& Wang, 1999) - as a possible mechanism that constrains word meaning extension. Chaining operates by linking an emerging idea (an incipient word sense) to a highly-related, already lexicalized word sense. When this process repeats over time, a chained structure in meaning space results. Recent work by Xu et al. (2016) has explored a preliminary version of this proposal via a nearest-neighbor model in a single semantic domain - household containers - but no systematic formalization or evaluation of chaining has been applied to explain the historical emergence of word senses more broadly. Further, al-
though chaining seems plausible as a mechanism, its theoretical value has been limited in two respects: 1) No work has formally specified why chaining might be a preferred mechanism for the development of word meanings; 2) No largescale assessment of chaining vs. alternative mechanisms has been performed against historical records of word sense extension, leaving open how chaining fares with respect to alternatives. These issues leave open the question of whether the evolution of word meanings follows a cognitively predictable path, and if so, what principles explain this process.

In the current work, we hypothesize that the emergence of word meanings should follow an historical path that minimizes collective cognitive effort. In particular, we propose that chaining should be a preferred algorithm for extending word meanings across history because it tends to minimize the cognitive cost of linking novel ideas with existing ones - a critical property not previously considered with regard to historical sense extension. To test the validity of this argument, we motivate nearest-neighbor chaining with tree-based computer algorithms that minimize edge lengths in a graph. We then formalize the process of chaining as a cognitively economical strategy for encoding novel ideas into an existing lexicon (cf. Xu, Malt, \& Srinivasan, 2016).

We critically assess our proposal by developing a family of computational algorithms of word meaning extension - inspired by the previous literature that described above - and evaluate them against a large historical database of wordmeaning records in English, spanning over 1,000 years. Our research extends a growing body of work which suggests that structures of language conform to efficient design principles (Zipf, 1949; Rosch, 1975; Piantadosi, Tily, \& Gibson, 2011; Kemp \& Regier, 2012; Kirby, Tamariz, Cornish, \& Smith, 2015), by bringing the perspective of cognitive economy to bear on the evolution of polysemy.

## Modeling the emergence of word meanings

## Computational formulation

We present here a formulation of five cognitive algorithms that might predict the historical emergence of word meanings, along with a null model. Given the initial, progenitor meaning of a word, each non-null algorithm postulates a distinct chaining mechanism by which novel word senses might emerge over time by "attaching to" existing meanings. Each algorithm generates a prediction of the historical order through which the meanings for any given word should emerge, which we then test against the historical record. In effect, we reverse-engineer the mental mechanisms of sense extension.

Table 1 summarizes the full set of proposed algorithms. Here $m$ stands for meaning or word sense, and $t$ stands for time. Each algorithm infers the word sense that emerges at time $t+1\left(m_{t+1}\right)$, based on existing senses of a word up to time $t\left(m_{1}, \ldots, m_{t}\right)$. The inferred sense is drawn from the candidate pool of senses (denoted by $m^{*}$ ) that appear after $t$ for a given word. A perfect model would fully recapitulate the

Table 1: Proposed models of word meaning extension.

| Name | Description |
| :--- | :--- |
| Random (null) | $m_{t+1} \sim \operatorname{random}$ draw $m^{*}$ |
| Exemplar | $\left.m_{t+1} \sim E_{m_{i}} \operatorname{sim}\left(m^{*}, m_{i}\right)\right]$ |
| Prototype | $m_{t+1} \sim \operatorname{sim}\left(m^{*}\right.$, prototype $\left.\left(m_{1}, \ldots, m_{t}\right)\right)$ |
| Progenitor | $m_{t+1} \sim \operatorname{sim}\left(m^{*}, m_{1}\right)$ |
| Local | $m_{t+1} \sim \operatorname{sim}\left(m^{*}, m_{t}\right)$ |
| Chaining | $m_{t+1} \sim \max _{i=1}^{t} \operatorname{sim}\left(m^{*}, m_{i}\right)$ |

historical emerging order of all senses of a word. All of our models are parameter-free and thus make minimal assumptions in the computational formulation.

1. The random algorithm - or null model - predicts the historical emergence of a word's senses to be random. This would only be plausible if word senses emerge purely based on immediate communicative needs with no further cognitive constraints.
2. The exemplar algorithm adapts from work by Nosofsky (1986), whereby the emerging sense at $t+1$ is predicted to be the one that bears the highest semantic similarity on average (or the highest sum of semantic similarities, which is equivalent in our case) with existing senses of a word at time $t$. We define semantic similarity identically in all algorithms, and we defer its formal definition to a later section.
3. The prototype algorithm is adapted from work by Rosch (1975) and Geeraerts (1997) and predicts the emerging sense at $t+1$ to be the one that bears the highest semantic similarity with the prototypical sense at time $t$. The prototype at $t$ is defined as the sense that bears the highest semantic similarity with existing senses of a word prototype $\left(m_{1}, \ldots, m_{t}\right) \leftarrow$ $\max _{i} \sum_{j \neq i} \operatorname{sim}\left(m_{j}, m_{i}\right)$. Thus, this algorithm allows the most representative sense of a word to change as a function of time, as more word senses develop.
4. The progenitor algorithm is a variant of the prototype model that assumes a fixed prototype that is always the initial, progenitor word sense (i.e., the earliest sense recorded in history). It predicts the emerging sense at $t+1$ to be the one that bears the highest semantic similarity (among all candidate senses) with respect to the progenitor sense.
5. The local algorithm assumes that word meanings emerge in a temporal linear chain, where the emerging sense at $t+1$ is the one that bears the highest semantic similarity with the sense that appears at time $t$. Critically, senses that appear prior to $t$ have no influence on the emerging sense at $t+1$ on this model. This algorithm posits that sense extension will yield minimal cost locally between consecutive time points, as opposed to yielding globally minimal cost (described below).
6. The chaining (or nearest-neighbor) algorithm is closely related to Prim's algorithm for constructing a minimal spanning tree (Prim, 1957) - but with a fixed (as opposed to random) starting point, i.e., it always begins with the progenitor sense of a word. In essence, this algorithm predicts the

Figure 1: Simulation of the proposed algorithms of word sense extension. The solid red circle symbolizes the progenitor sense of a word. The blue circles represent emerging word senses, and the arrows indicate the predicted path that each algorithm makes about order of emergence. The time labels indicate the predicted sequence of emergence. The cost is the aggregated Euclidean distances traversed by the arrows.
emerging sense at $t+1$ to be the one that bears the highest semantic similarity to any of the existing senses up to $t$, hence rendering a chain that connects nearest-neighboring senses over time. In contrast with the other algorithms described above, this chaining algorithm is also similar to single linkage clustering (Gower \& Ross, 1969) which tends to yield a tree (i.e., each tree node is a sense in this case) with minimal edge lengths among nodes of a graph (i.e., the graph is a network of senses of a word, developed in history). Due to this property, the chaining algorithm assumes the least cumulative historical cognitive effort for the extension of word senses (where effort is inverse to the degree of association between emerging and existing senses of a word), providing the computational implementation of our hypothesis.

## Simulation of sense extension algorithms

To illustrate how nearest-neighbor chaining would yield a near-minimal-cost historical path, we provide a simulation for the proposed algorithms of sense extension as follows.

We generated 15 randomly placed points in a twodimensional plane that represents the meaning space for a hypothetical word (see Figure 1). We took Euclidean distance between-points as a proxy for semantic distance (or inverse semantic similarity) between two senses. We also designated the bottom-right point in the space as the progenitor sense, i.e., it is the earliest seeding sense for the word that is a given to any algorithm. We then applied the family of sense extension algorithms to the remaining data points and visualized the path of emerging senses predicted by each algorithm. Figure 1 shows that these algorithms yield distinct typologies and paths in the simulated meaning space. Specifically, the exemplar algorithm links novels senses to all existing senses based on average distances between them (illustrated by chains that develop from spaces between senses as opposed to those that
stem off directly from senses). The prototype algorithm predicts a dynamic radial structure (Lakoff, 1987), where temporal chains are established by linking novel senses to prototype senses, while allowing the prototype to change over time. The progenitor algorithm predicts a strict radial structure where all senses stem from the earliest progenitor meaning. The local algorithm predicts a linear temporal chain of senses by attaching each emerging sense to the existing sense that appears one time point earlier. Finally, the chaining algorithm renders a tree structure that branches off as needed to preserve nearest-neighbor relations between emerging and existing senses. Importantly, the chaining algorithm yields the minimal aggregated edge lengths, hence rendering a minimal cost in semantic space. This result is robust to variations in simulation parameters and is a consequence of the close link between the nearest-neighbor chaining algorithm and the concept of a minimal spanning tree.

Below, we test the extent to which these algorithms can recapitulate the emergence of word senses, as recorded in a large historical lexicon of English.

## Treatment of data

## Historical lexicon

To evaluate our proposed algorithms, we used the Historical Thesaurus of English (HTE) (Kay, Roberts, Samuels, Wotherspoon, \& Alexander, 2015) - a unique large-scale historical lexicon constructed from the Oxford English Dictionary. This database includes approximately 800,000 word forms and their senses, dated and recorded over a span of over 1,000 years - from Old English to the present day. Each word sense in the HTE is annotated with the date of its emergence (and, where applicable, obsolescence) and part of speech, and is structured in a fine-grained semantic hierarchy that features about a quarter of a million concepts. Consecutive tiers of the hierarchy typically follow a IsA or Partof relation. For example, one sense of the word game under the HTE code "01.07.04.04" is defined in terms of a four-tier hierarchy: The world (01) $\rightarrow$ Food and drink (01.07) $\rightarrow$ Hunting (01.07.04) $\rightarrow$ Thing hunted/game (01.07.04.04).

## Measure and validation of semantic similarity

To quantify similarity between word senses, we defined a measure using the semantic hierarchy in the HTE and then validated it against human judgments. Specifically, we approximated psychological similarity between a pair of word senses $\operatorname{sim}\left(m_{i}, m_{j}\right)$ by a common measure of similarity used in psychology that is bounded in the range of $(0,1)$ (Nosofsky, 1986; Shepard, 1987):

$$
\begin{equation*}
\operatorname{sim}\left(m_{i}, m_{j}\right)=e^{-d\left(m_{i}, m_{j}\right)} \tag{1}
\end{equation*}
$$

Here $d\left(m_{i}, m_{j}\right)$ represents thesaurus-based conceptual distance between two meanings, which we defined by the inverse of a conceptual similarity measure $(s(\cdot, \cdot))$, commonly used in
natural language processing (Wu \& Palmer, 1994; Jurafsky \& Martin, 2009):

$$
\begin{equation*}
d\left(m_{i}, m_{j}\right)=1-s\left(m_{i}, m_{j}\right)=1-\frac{2 \times|p|}{l\left(m_{i}\right)+l\left(m_{j}\right)} . \tag{2}
\end{equation*}
$$

Here $|p|$ is the number of parent tiers shared by senses $m_{i}$ and $m_{j}$, and $l(\cdot)$ is the depth of a meaning in the semantic hierarchy. This measure gives 1 if two meanings are identical, and 0 if they have nothing in common. Table 2 illustrates the calculation of this measure with a concrete example.

Table 2: Illustration of conceptual similarity based on two senses of game recorded in the HTE. Since the two senses share two parent tiers (i.e., The social world $\rightarrow$ Leisure) in the hierarchy, the conceptual similarity is $s(\bullet, \star)=\frac{2 \times 2}{5+6}=\frac{4}{11}$.

We validated this measure of semantic similarity via standard techniques in natural language processing, by evaluating its performance in predicting human judgments of word similarities. Following Resnik (1995), we approximated word similarity by using the pair of senses for the two words that results in maximum sense similarity, defined as follows: $\operatorname{wordsim}\left(w_{i}, w_{j}\right)=\max _{m_{i} \in \operatorname{senses}\left(w_{i}\right), m_{j} \in \operatorname{senses}\left(w_{j}\right)} s\left(m_{i}, m_{j}\right)$.

Our measure of semantic similarity yielded a Spearman's correlation of 0.43 ( $p<0.001$ ) on Lex-999 (Hill, Reichart, \& Korhonen, 2015), which provides a well-known data set of human word similarity judgments. The performance of our measure of semantic similarity is better than the corpusbased skipgram (Word2Vec) model, which has been trained on 1 billion words of Wikipedia text (Mikolov, Chen, Corrado, \& Dean, 2013) and roughly on par with the same model trained on 300 billion words (Faruqui \& Dyer, 2015). In addition, our measure of semantic similarity obtained a Spearman's correlation of $0.52(p<.001)$ on Sim-353 (Finkelstein et al., 2001), another common data set of human word relatedness judgments, which is comparable to the state-of-the-art

GLOVE word vector model, which has been trained on 6 billion words (Faruqui \& Dyer, 2015; Pennington, Socher, \& Manning, 2014).

Having validated our measure of semantic similarity, we used it to assess the mental algorithms described above.

## Choices of words

We focused our analyses on explaining word sense extension in a set of the most common English words. Specifically, we worked with the most frequent 6318 words in the British National Corpus (BNC). Some of the word forms are duplicated in this set because one word can function in multiple part-of-speech categories. However, our results were robust regardless of whether we collapsed these words by form or distinguished them by part-of-speech.

## Model evaluation and results

We used model likelihood to assess the performance of each proposed algorithm. ${ }^{1}$ We defined likelihood as a probability function that specifies the degree to which a model accounts for the entire sequence of senses that historically emerged for a given word. To be concrete, for a sequencce of senses $m_{1}, m_{2}, m_{3}, \ldots, m_{t}$, the likelihood $\mathcal{L}$ is the joint probability of observing such a sequence under a certain model $\mathcal{M}$ :

$$
\begin{equation*}
\mathcal{L}_{\mathcal{M}}=p\left(m_{1}\right) p\left(m_{2} \mid m_{1}\right) p\left(m_{3} \mid m_{1}, m_{2}\right) \ldots p\left(m_{t} \mid m_{1}, \ldots, m_{t-1}\right) \tag{3}
\end{equation*}
$$

We assumed that the progenitor sense is always given, so $p\left(m_{1}\right)=1$. For all remaining emerging senses, the set of algorithms can be evaluated by calculating likelihood based on their specifications in Table 1. For example, the progenitor model would yield a likelihood for the emerging sense at $t=2$ (conditioned on that appeared at $t=1$ ) as follows:

$$
\begin{equation*}
p\left(m_{2} \mid m_{1}\right)=\frac{\operatorname{sim}\left(m^{*}, m_{1}\right)}{\sum_{m^{*} \in\left\{m_{2}, \ldots, m_{t}\right\}} \operatorname{sim}\left(m^{*}, m_{1}\right)} . \tag{4}
\end{equation*}
$$

The algorithm then steps through each point in time and the likelihood correspondingly calculates the degree to which the algorithm predicts the true emerging sense at that point, among a candidate pool of senses that appear after.

Because our null hypothesis is that there exists no predictability in how word senses develop in history, we evaluated each cognitive algorithm against the random null algorithm, using the log likelihood ratio $(L L R)$ - a standard metric for model comparison in statistics: $L L R=\log \left(\mathcal{L}_{\mathcal{M}} / \mathcal{L}_{\text {null }}\right)$. This quantity should be greater than 0 if a given model accounts for word sense extension better than the null, and the converse if the null does better. For any given word, the likelihood function of the null can be determined theoretically, and it is simply the inverse of factorial of $N-1$ for a word with $N$ senses: $\mathcal{L}_{\text {null }}=1 \times \frac{1}{N-1} \times \frac{1}{N-2} \times \ldots \times \frac{1}{1}=\frac{1}{(N-1)!}$. Thus the log likelihood ratio indicates whether a model predicts the sequence of emerging word senses better than chance.

[^179]

Figure 2: Summary of model performances against the null. " 0.0 " on the y -axis indicates performance of the null model. Bar height indicates the mean log likelihood ratio averaged over the entire pool of most common words from the BNC corpus. Error bars indicate $95 \%$ confidence intervals.

Figure 2 summarizes the results. The bar plot shows that each of the proposed algorithms accounts for the historical data that we examined significantly better chance ( $p<0.001$ from 1-tailed $t$-tests), reflected in the positive log likelihood ratios. This observation suggests that the null hypothesis can be rejected: The emerging order of word senses in the English lexicon is not purely random.

Critically, the nearest-neighbor chaining algorithm yielded the highest overall likelihood among all models, and this result was statistically significant according to paired $t$-tests between the chaining model and each of the remaining models ( $p<0.001$ in all four comparisons). This observation provides evidence that word senses emerge in cognitively efficient ways by approximating a minimal spanning tree over the course of history. As such, these data support our hypothesis about nearest-neighbor chaining as the dominant mental algorithm for the historical emergence of word senses.

To illustrate the nearest-neighbor chaining process, we visualized the predicted chaining path for the English word game. Figure 3 shows a low-dimensional projection (via multi-dimensional scaling with a random starting point) of all senses of game as a noun, taken from the HTE database. As can be seen, the chaining algorithm forms a minimal spanning tree among the senses of game, by linking neighboring nodes that are semantically close. Importantly, this process of meaning extension tends to support branching and the formation of local clusters, identified roughly in this case by the three sense groups of "hunting game" (upper-left cluster), "scheme" (middle cluster), and "sports and entertainment" (upper-right cluster) in Figure 3. This offers a computational basis for family resemblance (Wittgenstein, 1953) and polysemy, by allowing words to develop both related and distinct
senses over time.

## Conclusions

We presented the first large-scale computational investigation of the mental algorithms that determine how words evolve new senses over time. We found that the historical emergence of word senses in English is not arbitrary; Instead, it has exhibited a high degree of predictability over the past millennium. Our findings indicate that the order in which word senses emerge can be best accounted for by a process of nearest-neighbor chaining, which supports the view that the historical development of the lexicon follows a trajectory that tends to minimize cognitive effort. Our current analysis focuses on sense extension within individual word forms, but it would be useful to extend our analysis to examine how different words compete to express novel meanings. Our exploration of the mental algorithms that underlie historical sense extension opens new, interdisciplinary venues for reverse engineering the evolution of the human lexicon.

## Acknowledgments

We thank Marc Alexander for helping with data licensing, and the University of Glasgow and the Oxford University Press for making the Historical Lexicon of English available. We thank Charles Kemp and Terry Regier for discussions on chaining and the Computational and Experimental Methods group in Linguistics at UC Berkeley for constructive comments. This project was partly funded by NSF award SBE-1041707 to the Spatial Intelligence and Learning Center (SILC) and NSF award SBE-16302040 to MS.

#### Abstract

When the interests of interlocutors are not aligned, either party may wish to avoid truthful disclosure. A sender wishing to conceal the truth from a receiver may lie by providing false information, mislead by actively encouraging the receiver to reach a false conclusion, or simply be uninformative by providing little or no relevant information. Lying entails moral and other hazards, such as detection and its consequences, and is thus often avoided. We focus here on the latter two strategies, arguably more pernicious and prevalent, but not without their own drawbacks. We argue and show in two studies that when choosing between these options, senders consider the level of suspicion likely to be exercised on the part of the receiver and how much truth must be revealed in order to mislead. Extending Bayesian models of cooperative communication to include higher level inference regarding the helpfulness of the sender leads to insight into the strategies employed in non-cooperative contexts.

Keywords: deception; Inductive inference; communication; pragmatics

## Introduction

"You can tell he's lying because his lips are moving."
If only detecting lies were that simple! Despite its importance, people generally perform at chance when classifying liars and truth tellers (C. Bond \& DePaulo, 2006). Indeed, most verbal and nonverbal cues have only marginal diagnostic value (DePaulo et al., 2003). Instead of focusing on cues to deception, a promising new approach considers how the cognitive processes involved in deception may differ from telling the truth. It has been suggested, for example, that deception imposes higher cognitive demands on liars, who may find it more difficult to furnish details when interviewed (Vrij \& Granhag, 2012). A good understanding of the cognitive mechanisms underlying deception, taking into account the complexities of the strategies employed, would be a tremendous asset (G. D. Bond, 2012; Blandon-Gitlin, Fenn, Masip, \& Yoo, 2014).

In the present research we analyse the challenge faced by would-be deceivers seeking to conceal the truth. We begin with a brief analysis of the deceiver's perspective, identifying the main deceptive strategies, and outline a preliminary study which illustrates people's preferences for these strategies. We then present two studies where we ask people to conceal the
truth, manipulating the level of suspicion of the hypothetical receiver and the information content of the available message options.

## How to deceive in ten steps (with pictures)

Communication relies on principles of cooperation (Grice, 1989). The intended meaning of a sender rarely coincides perfectly with the "literal" content of a message, but by making assumptions about why the sender chose that particular message, the receiver may infer the intended meaning. By assuming that a sender is cooperative and produces messages that follow the Gricean maxims (described below), a receiver can increase the speed and strength of the inferences they draw from those messages (Horn, 2004).

But what if the sender is not trying to be cooperative? In that case, there are three main strategies the sender can rely on, each corresponding to different violations of the Gricean maxims. Consider the following scenario: You shot your neighbour's hamster with your shotgun while she was away for the weekend. Obviously, you'd prefer that she didn't learn the truth. However, you were given the key to her house to take care of her pet, so you are definitely a person of interest in her investigation. How can you conceal the truth from her?

- Lying: You might try an outright lie: "I did not shoot your hamster". Lying involves communicating a proposition to the receiver with the full knowledge that it is false. From a Gricean perspective, lying is a violation of the supermaxim of quality, stating that your contribution should be true.
- Being uninformative: It seems very sensible to be uninformative. Neighbour: "Did you shoot my hamster?" You:"Have you heard the new Justin Bieber album? It's fantastic!" ${ }^{1}$ With this kind of utterance, it would seem that the receiver can infer nothing beyond her prior beliefs. But this violates the Gricean maxims of relevance and quantity, and these violations can themselves be informative about the sender's intentions even if not the actual facts of the matter.
- Misleading: A third option is to mislead your neighbour by implicature. "I was not at home when your hamster was shot!" You tell her a truth very relevant to the issue at hand, but from which you believe a false conclusion will be drawn (you were not at home when you shot the hamster; you took it with you to a nearby park for target practice). Misleading involves covertly violating the maxims of quantity, but may be harder to detect.

[^180]In a preliminary study, we asked 96 first year psychology students ( 87 women) at the University of Leuven to imagine seven different scenarios like the following:

> A man arrives home after a weekend in Vegas, during which he won $\$ 2000$ playing Poker, but lost $\$ 500$ at the slot machines and $\$ 4000$ on Blackjack. When he returns, he does not know how to tell his wife. His wife knows that he has had gambling problems in the past, but is convinced that they are resolved. Their relationship is currently strained, so the man would rather not cause any additional problems. His wife asks him directly if he has gambled. Which of these answers would you give if you were in his situation?

Participants selected a response from seven options comprised of two lies (e.g. "I didn't gamble"), two uninformative statements (e.g. "there were a lot of people gambling"), two misleading statements (e.g. "I won $\$ 2000$ playing Poker"), and the truth. Figure 1 presents the preference of the participants (collapsed across scenarios and equivalent response options).

Figure 1: When choosing how to communicate in a variety of different scenarios with a clear motivation to deceive, participants showed a strong tendency to mislead rather than be uninformative.

Two important conclusions emerge from Figure 1. Firstly, people were uncomfortable with deception: $37 \%$ of responses involved telling the full truth and only $10 \%$ were outright lies: a surprising number perhaps given that each scenario provided a clear motivation to deceive. However, this finding is consistent with previous research showing that in general people avoid lying through concerns regarding self-image, guilt, and anxiety (Aquino \& Reed, 2002). Of more relevance to our present purposes, we found that among those who chose not to tell the truth, people showed a clear preference for misleading over lying or being uninformative (37\%, 10\% and $15 \%$ respectively). This finding is consistent with earlier work on the topic (Montague, Navarro, Perfors, Warner, \& Shafto, 2011; Rogers, Zeckhauser, Gino, Schweitzer, \& Norton, 2014).

## Balancing suspicion and information

So, why do people seem to prefer to actively mislead rather than be entirely uninformative? At first glance, it seems rational to be as uninformative as possible: the receiver cannot revise her beliefs on the basis of your utterances. Misleading on the other hand, involves salting your statements with a grain of truth - something which the receiver may build upon to infer the whole truth.

An important motivation for choosing a misleading utterance over a strictly uninformative one is because the latter
raises suspicion. Consider the likely response of choosing to be uninformative, as in the Las Vegas scenario:

```
Spouse: Did you gamble?
Gambler: Where shall we go for dinner? I'm hungry.
Spouse: You lost money didn't you?
Gambler: Some of the guys won big.
Spouse: How much did you lose?
```

As Sperber et al. (2010) points out, people have a toolbox of cognitive mechanisms for epistemic vigilance that reduce the risk of being deceived. One such tool supports tracking the cooperation of others; as a result, obvious departures from that cooperation are noted (e.g., Mills, 2013). Responding in an uninformative way violates the principle of cooperation so blatantly that the deception is revealed.

A deceiver, sensitive to the epistemic vigilance of his counterpart may prefer instead to provide truthful but misleading utterances, but in doing so faces a delicate trade-off. Chosen well, such utterances may not only allay the receiver's suspicion, but by virtue of the inferential boost accorded to cooperative speakers, the receiver may be led to a false conclusion, terminating the search for further information. Yet if suspicion is already raised, the receiver is unlikely to fall for the false implicature, which relies on her assumption of cooperation (Dynel, 2011), and may use the information to get closer to the truth.

This analysis points to two opposite forces, balanced in the selection of one strategy over another. On one hand, the knowledge that the receiver may engage in inference about the helpfulness of the statement may lead the sender to opt for a misleading yet informative statement. On the other hand, if the sender considers that the receiver will be suspicious a priori, he may resort to being uninformative. We examine these factors in two experiments.

## Experiment 1: The deception game

As the basis for our empirical investigation, we use a simple two person communication game in which the interests of the sender and receiver are opposed. In the game, the sender (cast in the role of a pirate) and the receiver (cast as an explorer) see four alternative maps, only one of which is genuine. Each map purports to show the true extent of a contiguous region where treasure is buried. The pirate, who knows the identity of the genuine map and must seek to protect it, is required to provide a hint to the explorer in the form of a small number of locations that lie within the region. The explorer must use this information to guess the identity of the genuine map. Both players know that lying is not allowed; so the pirate can only reveal locations where treasure is actually buried.

An example trial faced by participants, who took the role of the pirate in this experiment, is shown in Figure 2. Figure 2(a) illustrates the four maps shown to the pirate and (hypothetical) explorer for an example trial. In providing a hint to the explorer, participants were restricted in their choice to one of three kinds of hints : one uninformative, one mislead-

(a) Four maps provided to the pirate and explorer.

(b) The pirate chooses one of three hints.

Figure 2: Experiment 1: The deception game.(a) Both the pirate and explorer see the same four maps; the shaded area marks the region where treasure be buried. Only one of the four maps is genuine: the pirate seeks to conceal its identity, the explorer seeks to discover it. (b) The pirate must provide a hint to the explorer, and is given three hints from which to choose: a MisLEADING, Uninformative, or Helpful hint. Each hint marks a subset of locations where treasure is buried (blue dots). Since lying is not permitted all marked points lie within the shaded area when overlaid on the genuine map. The hints vary in their potential to drive inference. The MisLEading hint appears to clearly point out the wrong map, despite being consistent with all of them. The Uninformative hint neither points to nor excludes any of the maps. The Helpful hint excludes all of the maps except the genuine one.
ing, and one genuinely helpful. Figure 2(b) shows examples of the three options, and illustrates the likely effect that each hint would have on the inference of a trusting explorer.

The informativeness of a hint was manipulated by varying the number of treasure maps (out of four) that were excluded by the hint. When maximally informative (Helpful), a hint excludes all treasure maps, except the true one (bottom row of Figure 2b). When maximally Uninformative, it excludes no treasure maps (middle row). The Misleading hints were designed to closely resemble one of the three false maps (top row), and to exclude none (as in the example shown), one or two of the treasure maps.

People's beliefs about the suspicion level of the receiver (the hypothetical explorer) were manipulated by changing the proportion of deceivers in the population that were supposedly providing information. Participants were told that they were part of a crew of six sailors providing a hint to the explorer. Participants were also told that the explorer knew that the hint came from an unknown (but randomly selected) crew member and knew the proportion of deceptive crew members. Varying the number of deceivers in the crew from one to five was intended to raise the perceived suspicion level of the explorer. Our question was whether the pirate would track and use this information when providing hints, being more likely to mislead when the suspicion level was lower. When facing
a trusting receiver, we expect people to be more inclined to mislead, provided that the amount of information disclosed is acceptable. But if the receiver is likely to be suspicious or too much information would otherwise be revealed, we expect people to be uninformative.

Participants were 120 undergraduates from the University of Leuven ( $86 \%$ female, ages 18-24, median 18) participating for course credit. Participants faced 30 trials in all: six sets of four maps were presented in conjunction with each of five crew configurations.

## Results and discussion

Our first question was whether people's decision to mislead or not depended on how much information the misleading option gave away. To address this, we examined whether the proportion of participants choosing each kind of hint depended on the number of treasure maps that were excluded by the Misleading one. A chi-square test confirmed the dependency shown in Figure $3\left(\chi^{2}(4,3600)=93.31, p<\right.$ 0.001 ): as the amount of information revealed by the MisLEADING hint increased, people were less willing to select it, preferring instead to choose the Uninformative option. Indeed, in contrast to the pilot data in Figure 1, the UninFORMATIVE option was the most favoured in this task. This is unsurprising perhaps, since a hint that excludes even one of four maps is extremely informative.

Figure 3: Experiment 1: Informativeness. The $y$-axis shows the number of times each type of hint (given by column label) was selected as a function of the number of treasure maps excluded by the misleading hint ( $x$-axis): $0 \%$ means none were excluded, $25 \%$ means one was, and $50 \%$ means that two were. People were sensitive to informativeness: when the misleading hint was more informative, people were less likely to mislead.

Our second question was whether people's decision was affected by their estimate of how suspicious the receiver (the hypothetical explorer) was likely to be. In light of this, we examined the relationship between participants' choice of hints and the number of deceptive crew members providing hints for the explorer. Curiously, as Figure 4 illustrates, there was no evidence for a relation between the level of suspicion and the type of hint selected $\left(\chi^{2}(8,3600)=12.96, p=0.11\right)$. Even when people knew that the explorer thought that five out of the six possible senders was acting deceptively, they did not alter their selection of hints.

Figure 4: Experiment 1: Suspiciousness. The $y$-axis shows the number of times each type of hint (given by column label) was selected as a function of the implied suspicion level of the explorer. The numbers on the $x$-axis represent the number of deceptive members in the crew that provides the explorer with a hint (more members suggests that the explorer should be more suspicious). There was no dependency between choice of hint and number of deceptive crew members.

## Experiment 2: Increasing suspicion

Experiment 1 found convincing evidence for the influence of informativeness on the decision to mislead. If too much information would be revealed with a true but misleading statement, people are more inclined to be uninformative. Surprisingly, we did not find an effect of suspicion. What might be going on here?

One possible explanation is simply that our manipulation was ineffective. Perhaps changing the number of deceptive crew members was not salient enough or required too much effort for participants to interpret or keep in mind.

Experiment 2 was identical to Experiment 1, but rather than have people infer how suspicious the explorer might be from the composition of the crew, we instead gave participants explicit information about the explorer's beliefs. In the Low SUSPICION condition, participants were told that the explorer suspected that the hint came from a teammate, whereas in the High Suspicion the explorer suspected the hint came from an opponent. The experiment was similar in all other respects except for a control condition in which participants were asked to help the explorer (used to identify participants who were not trying or did not understand the task). There were also a number of filler items in which there was no obviously misleading option.

Participants were 98 adults recruited via Amazon Mechanical Turk and paid $\$ 1.25$ USD for 15 minutes participation. Data from 22 participants who failed to demonstrate a sufficient understanding of the experiment were excluded from subsequent analysis. ${ }^{2}$ The remaining 76 participants were $46 \%$ female and aged 20-63 (median age 28.5). Participants faced 30 trials in all: 10 map sets (six experimental, four fillers) were presented in each of the three condition blocks.

[^181]

Figure 5: Experiment 2: Informativeness. The $y$-axis shows the number of times each type of hint (given by column label) was selected as a function of the number of treasure maps excluded by the misleading hint ( $x$-axis). As in Experiment 1, people were sensitive to informativeness: when the misleading hint was more informative, people were less likely to mislead. Data from the control condition are excluded.

Figure 6: Experiment 2: Suspiciousness. The $y$-axis shows the number of times each type of hint (given by the column label) was selected as a function of the implied suspicion level of the explorer. The $x$-axis reflects whether people were told that the explorer was expecting a hint from a member of another team (the HIGH SUSPICION condition) or from a teammate (the LOW SUSPICION condition). When participants knew that the explorer was apt to be suspicious of them, they were less inclined to be misleading, opting instead to be uninformative.

## Results and discussion

As before, our first question was whether people were sensitive to informativeness when choosing which hint to provide. Once again, there was a significant effect of informativeness $\left(\chi^{2}(4,912)=18.04, p=0.001\right)$. As Figure 5 shows, the more maps the misleading option excluded, the less inclined people were to select it, favouring instead the uninformative option.

In light of the null effect in Experiment 1, a perhaps more interesting question is whether people were sensitive to the suspicion level of the explorer when deciding what to tell them. As Figure 6 reflects, when the suspicion level of the explorer is made more obvious, people are indeed sensitive to it. Although the Uninformative hint was still the most popular overall, the MisLEADING option was chosen far more when the explorer was expecting a hint from a trusted teammate $\left(\chi^{2}(2,912)=85.95, p<0.001\right)$. This suggests that people acting as senders are indeed attentive to the level of trust presumed by the receiver; although, taken together with the results from Experiment 1, tracking suspicion may be too cognitively challenging where it is not especially salient.

## Towards a computational model

Experiments 1 and 2 manipulated two important factors: the information content of the messages that deceivers could
choose and their beliefs about the degree of suspicion with which their messages would be received. Taken together, our results show that both factors were important considerations. In this section we present a computational model whose goal is to aid our understanding of these results and generate new testable predictions. While an in-depth analysis of the model is beyond the scope of this paper, here we briefly describe the relevant features.

A convenient starting point for a model of the deception game employed here - and for communication in general is rational inference (e.g., Goodman \& Frank, 2016). In this framework, a receiver faces the challenge of updating her beliefs on the basis of information disclosed by a sender. The sender, for his part, selects information designed (according to his goal) to help or hinder the receiver in her efforts.

We first evaluate things from the perspective of the receiver, who is confronted with a hint $x$ (or, more generally, an utterance). The receiver is assumed to update her beliefs $h$ according to:

$$
\begin{equation*}
P_{\text {Receiver }}(h \mid x) \propto \sum_{s \in \mathcal{S}} P_{\text {Sender }}(x \mid h, s) P(h) P(s) \tag{1}
\end{equation*}
$$

where $s$ represents a sampling strategy employed by the sender and $S$ represents the range of such strategies considered. As a simplifying assumption, we assume that the receiver considers the sender's sampling strategy to be independent of the true hypothesis.

This inference thus depends on the sender, who selects information according to a sampling strategy:

$$
\begin{equation*}
P_{\text {SENDER }}(x \mid h) \propto\left(P_{\text {RECEIVER }}(h \mid x)\right)^{\alpha} \tag{2}
\end{equation*}
$$

where $\alpha$ reflects the goals of the sender, and $P_{\text {Receiver }}(h \mid x)$ the sender's assumptions about how the receiver updates her beliefs. A sender who wishes to reveal the truth to the receiver (i.e., to increase the receiver's posterior probability for the correct hypothesis $h$ ) will have an $\alpha$ with a positive value; one who wishes to conceal the truth has a negative $\alpha$; one who behaves somewhat randomly has an $\alpha=0$. There are other ways to capture conflicting goals, like assigning separate utility functions for the sender and receiver with regard to truth-predicated action, but we chose this for its relative simplicity.

To capture the patterns observed in our deception game, both equations have to be considered simultaneously. That is, both sender and receiver must recursively consider the assumptions and strategies used by the other party. Importantly, from the receiver's perspective the inferential potential of a message depends not only on the information as such, but also on the "sampling strategy" of the sender, which reflects the sender's goals and assumptions about the receiver. For example, sampling procedures that follow the principle of cooperation and the Gricean maxims have a stronger inferential potential (e.g., Bergstrom, Moehlmann, \& Boyer, 2006; Shafto, Goodman, \& Griffiths, 2014; Voorspoels, Navarro, Perfors, Ransom, \& Storms, 2015). Crucially, the receiver

Figure 7: Model predictions for sender actions. Model predictions for the preference of a sender in the deception game for the misleading, uninformative and helpful message options. From left to right, the panels present scenarios with increasingly suspicious receivers (modelled through different kinds of inference about the sender's goals and assumptions). The $x$-axes indicate how informative the misleading option is (in terms of the proportion of hypotheses excluded by it). The model predicts a decrease in preference for the misleading option as it becomes increasingly informative, as well as an increase in preference for misleading when the receiver is less suspicious.
not only updates her beliefs about what is true, but simultaneously makes inferences about the sender's sampling strategy: learning whether the sender is helpful and knowledgeable play a critical role in epistemic vigilance, and has a substantial impact on how rational agents reason (e.g., Shafto, Eaves, Navarro, \& Perfors, 2012).

In Equations (1) and (2), the universe of sampling strategies $S$ evaluated by the receiver is defined in terms of two things that she presumes about the sender: what does the sender assume about her (reflected by $P_{\text {Receiver }}(h \mid x)$ ), and what are his goals (reflected in $\alpha$ ). Many scenarios may be modelled in this way, but here we consider three. If the receiver is TRUSTING, this means that she is performing inference over two possibilities: either the sender is trying to be helpful ( $\alpha=1$ ), or he is inattentive and thus not selecting information with care $(\alpha=0)$. If the receiver is UNTRUSTING, this means that she believes that the sender is trying to conceal the truth from her $(\alpha=-1)$, under the mistaken assumption that he is trusted. Lastly, if the receiver is SUSPICIOUS, this means that she is performing inference over whether to be trusting or untrusting.

How well does this approach capture the main qualitative patterns in the deception game? To answer this, we simulate outcomes for the three scenarios we have outlined. In the leftmost panel of Figure 7, the receiver trusts the sender, but is not sure how attentive he is: he may be acting helpfully ( $\alpha=1$ ) or he may be providing poor but not actively misleading data, perhaps due to lack of motivation, attention, or information ( $\alpha=0$ ).

If the receiver updates her beliefs (concerning the true treasure map) at the same time as her assumptions about the helpfulness of the information received ( $\alpha$ ) then there is reason for the sender to choose a hint that seems informative. That
the message appears informative supports the receiver's assumption that it has been carefully selected, which further fuels inference. This recursive process may lead the receiver to draw a misleading conclusion if the sender is not actually helpful (as in our experiments). However, as the information content of the hint increases, so too does the risk that the receiver will inadvertently arrive at the truth. Consequently, the model captures the fact that the sender's preference for the misleading hint declines with its information content.

In the rightmost panel of Figure 7, in contrast, the receiver is certain that the sender is not to be trusted. If the sender is aware of this, there is little to be gained by attempting to mislead, and so the uninformative hint is preferred. The extent of this preference is, once again, moderated by the information content of the misleading option.

In many situations, a receiver will not be predisposed to regard the sender with complete trust, nor complete distrust, but rather will remain open to either possibility. We model this case by assuming that the receiver is performing inference about whether the sender should be trusted ( $\alpha=1$ or 0 ) or not $(\alpha=-1)$. The preferences of an antagonistic sender facing a suspicious receiver are shown in the center panel of Figure 7. The two conflicting forces are most pronounced here, dividing the sender's preference between the two strategies. On the one hand, the sender may convince the receiver that he is actually trying to help by appearing informative, yet the (real) information can be used by the receiver to rule out previously plausible (but false) hypotheses.

Overall, there are two clear patterns that were found in our experiments and were also predicted by our model. Firstly, as the information content of the misleading option increases, there is an increasing preference for choosing the uninformative hint. Secondly, the more trusting the receiver is assumed to be, the more popular the misleading option becomes. This pattern of results is consistent with the idea that people may be performing some kind of recursive inference over how suspicious their interlocutor is when deciding how to deceive. Furthermore, our results are consistent with the notion posited here and elsewhere (e.g., Goodman \& Frank, 2016; Shafto et al., 2012), that receivers (from the sender's perspective at least) perform joint inference over the goals of the sender and the truth of the matter at hand given the information received.

## Conclusion

"There is nothing more deceptive than an obvious fact." - Arthur Conan Doyle

In two studies we have demonstrated that people's preference for a deceptive strategy hinges on their assumption of whether cooperative norms are expected to apply. In situations where high levels of trust and cooperation are warranted, deceivers are more inclined to actively mislead than to simply withhold information. In this scenario, the deceiver seeks to leverage the inferential boost of cooperative communication. In contrast, when the deceiver believes the false implication will not
be inferred - when the receiver is already suspicious - then preference shifts towards limiting the information disclosed.

# Connecting stimulus-driven attention to the properties of infant-directed speech Is exaggerated intonation also more surprising?

#### Abstract

The exaggerated intonation and special rhythmic properties of infant-directed speech (IDS) have been hypothesized to attract infant's attention to the speech stream. However, studies investigating IDS in the context of models of attention are few. A number of such models suggest that surprising or novel perceptual inputs attract attention, where novelty can be operationalized as the statistical predictability of the stimulus in a context. Since prosodic patterns such as F0 contours are accessible to young infants who are also adept statistical learners, the present paper investigates a hypothesis that pitch contours in IDS are less predictable than those in adultdirected speech (ADS), thereby efficiently tapping into the basic attentional mechanisms of the listeners. Results from analyses with naturalistic IDS and ADS speech show that IDS has lower overall predictability of intonation across neighboring syllables even when the F0 contours in both speaking styles are normalized to the same frequency range.

Keywords: language acquisition; infant-directed speech; statistical learning; attention; stimulus predictability

## Introduction

Infant-directed speech (IDS) is a speaking style that talkers often use when interacting with young infants. In contrast to adult-directed speech (ADS), IDS tends to have exaggerated intonational contours with higher fundamental frequency (F0) and larger frequency range (e.g., Grieser \& Kuhl, 1988), hyperarticulated vowels (Kuhl et al., 1997; but see also Martin et al., 2015), and shorter utterances with a higher token/type ratio (Phillips, 1973). In addition to serving as language input tuned to the developmental stage of the listener (Snow, 1977), one hypothesized role of the exaggerated nature of IDS is that it may engage infants' attention to the speech stream more efficiently than ADS (e.g., Garnica, 1977; Fernald, 1989; see Soderstrom, 2007, for an overview), thereby facilitating language learning from speech.

Although the exaggerated intonation of IDS is often implicitly assumed to be the cause for higher attentional attractiveness, according to our knowledge, no study has systematically evaluated properties of IDS in the context of what is known about perceptual mechanisms for stimulusdriven attention. Instead, the evidence for higher attentional capture of IDS largely comes from behavioral studies that show that infants prefer to listen to IDS over ADS (Fernald,

1985; Cooper \& Aslin, 1990; Pegg, Werker \& McLeod, 1992). In addition, based on acoustic analyses and their perceptual correlates, IDS is often characterized as more salient or prominent than ADS, therefore also potentially being more interesting to the listeners (e.g., Garnica, 1977; Fernald, 1989). Since stimulus-driven attention and prominence of the perceived speech input seem both to be driven by unpredictability of the stimuli in the given context (see the next sub-section; but see also Kidd et al., 2012), the existing knowledge suggests that IDS might be more attractive to the listeners simply because it has different predictability properties over time than ADS. For instance, larger variability of F0 in IDS already implies, but does not guarantee ${ }^{l}$, higher uncertainty regarding the realization of the intonation at any moment in time. However, no study has systematically compared the prosodic predictability of IDS and ADS from a statistical learning point of view, even though infants are known to be sensitive to statistical regularities in their perceptual experience (c.f., Saffran et al., 1996; Soderstrom et al., 2009, and references therein) and to the prosodic structure of their native language already from an early age (e.g., Nazzi et al., 1998).

In the present paper, a quantitative investigation is carried out in order to test whether IDS is indeed not just more variable, but also less predictable than ADS, thereby being in line with the recent predictability-based accounts of perceptual attention. Importantly, we assume that the listener is able to learn the typical behavior of intonational contours from speech experience and this creates the basis for prosodic expectations for new speech input. In order to do this, a straightforward computational model of statistical learning is applied to F0 trajectories of naturalistic IDS and ADS and tested in its ability to predict intonational contours on speech utterances from both speaking styles.

## Stimulus-driven attention and statistical learning

A number of models for stimulus-driven perceptual attention suggest that attention is drawn to stimuli that are low-probability, or unpredictable, in the given context (Itti \& Baldi, 2009; Zhang et al., 2008; Tsuchida \& Cottrell,

[^182]2012; Zarcone et al., 2016), basically enabling the perceptual system to focus on aspects of the environment with the highest information content (Shannon, 1948), i.e., input that is not yet learned and thereby accurately predicted by the brain. However, infants are also known to prefer stimuli that are surprising or novel only as long as the input is not too unlikely in the given context, also known as the Goldilocks effect (Kidd et al., 2012). This suggests that the input should still be structured enough to support learning, thereby providing the basis for statistical expectations and evaluation of the relative information value of the inputs.

Earlier work with prosody perception suggests that lowprobability intonation patterns in the context of otherwise predictable prosody are associated with higher perceptual prominence of the concurrent words (Kakouros \& Räsänen, 2016a) and alter semantic processing of speech (e.g., Magne et al., 2005), having the same consequences as lowprobability words in the given context (see Kakouros et al., submitted, for a discussion). Recent evidence also suggests that adult listeners are sensitive, and rapidly adapt, to changing statistical properties of the intonation patterns, leading to experience-based expectations for prosody whose violations give rise to the subjective impression of prominence (Kakouros \& Räsänen, 2016b; Kakouros et al., submitted). Overall, the earlier research indicates that auditory attention and perceptual prominence are connected to the predictability of the prosodic patterns, and this may play a role also in the perception of IDS.

Importantly, the concept of predictability necessitates some type of mechanism for learning regularities from experience, thus connecting attention and prominence with the concept of statistical learning. The most parsimonious assumption would be that the prosodic learning utilizes the same statistical learning mechanisms hypothesized to play a role in other aspects of language acquisition, but now operating at the level of prosodic features such as F0 contours and energy envelopes instead of the phonemic units of the language. Since infants are known to be adept statistical learners, and since prosodic cues are perceptually accessible to them (e.g., Hawthorne, Mazuka \& Gerken, 2016), it is likely that infants are sensitive to statistical regularities present at the prosodic level similarly to adults.

If predictability of the stimulus in a given context is a major factor in controlling stimulus-driven attentional orientation, as also exemplified by the widely used preferential head-turn or looking-time paradigms to probe infants' learning, we would expect IDS to have different predictability properties than ADS. In the present study, we will look into one specific aspect of IDS, namely, intonation, and test how well F0 contours can be predicted over time for the two speaking styles in question.

## Data

The speech material used in the present experiments comes from the ManyBabies study that aims to replicate IDS preference across a large number of labs (The ManyBabies Consortium, 2017). In the context of that study, naturalistic
speech from female caregivers to their infants or from caregivers to other adults was recorded in central Canada and Northeastern US. All caregivers had infants aged 122250 days. The recordings were carried out in an infantfriendly greeting area/testing room using lapel clip-on microphones connected to smartphones. The task involved describing a closed set of labeled objects by asking the mother to take each object out of a bag one at a time and talk about it to her baby (IDS) or to an experimenter (ADS). In addition, there were two types of objects: those supposedly familiar to the infants (e.g., a ball or a block) and those considered as novel (e.g., a sieve or a whisk). After rough manual segmentation of the recordings into utterances, the utterances were also classified into three categories: utterances containing the familiar object word, those containing the unfamiliar object word, and utterances without naming of the object.

In the present study, we used the Canadian section of the recordings, containing speech from a total of 11 mothers. The US recordings ( 4 mothers) were excluded due the significant presence of room reverberations that could have impacted automatic F0 estimation. All utterances shorter than 1 s or with less than five syllables (see Methods) were discarded, leading to a total of $N=882$ utterances (504 IDS, 378 ADS) with an average of $80.2 \pm 29.9$ utterances per talker. Average utterance length was $4.0 \pm 2.5$ seconds (3.1 $\pm 1.1$ for IDS, $5.2 \pm 3.1 \mathrm{~s}$ for ADS).

## Methods

The overall goal of the analysis was to compare predictability of F0 trajectories in the IDS and ADS utterances using a statistical model. This was done by first syllabifying and estimating F0 trajectories for all speech, parametrizing F0 trajectories during each syllable, clustering the syllable-specific parameters into a finite number of categories ("F0 shapes") in an unsupervised manner, and then modeling the temporal evolution of these F0 states across time. By training the predictive model from a set of utterances and then computing the likelihoods of F0 trajectories on a set of held-out utterances, measures of F0 predictability can be estimated from the data. Fig. 1 shows a schematic picture of the processing pipeline for an individual utterance. All experiments were conducted in MATLAB unless mentioned otherwise.

## Pre-processing of F0 trajectories

F0 trajectories were estimated at a $100-\mathrm{Hz}$ sampling rate with YAAPT-algorithm (Zahorian \& Hu, 2008; version 4.0), constraining F0 estimates to the range of $100-600 \mathrm{~Hz}$ and using YAAPT's ptch_fix() tool for post-processing of the pitch tracks for potential estimation errors and for interpolation of the trajectories across unvoiced regions. For the predictability analysis, utterance-level F0 tracks were zscore normalized to zero mean and unit variance in order to focus on temporal behavior instead of the absolute mean or range of the pitch. In addition, the original non-normalized F0 contours were used as baseline features in the analyses.

Figure 1: A schematic view of the F0 predictability analysis. The output is the probability of F0 in syllable $s$ given the observed F0 in $m$ preceding syllables (after training the statistical model on a number of training utterances).

All utterances were syllabified using a sonority envelopebased automatic syllabifier described in Räsänen, Doyle and Frank (submitted; see also Räsänen, Doyle \& Frank, 2015, for an earlier but similar version). All syllables without any frames with reliable voicing (as determined by YAAPT) and syllables shorter than $50-\mathrm{ms}$ were merged with the neighboring syllables, leading to a total of 8056 syllables in the data set. Note that although this type of acoustic syllabification is not perfectly accurate in terms of the phonological rules of the language, it still provides systematic chunking of speech into syllable-like units with each unit consisting of a sonorous peak surrounded by lesssonorous onsets and coda (see also, e.g., Villing, Ward \& Timoney, 2006, and references therein). Importantly, such acoustic-signal based chunking can be argued to better match the syllabification capabilities of pre-linguistic infants that also must rely on non-phonological acoustic cues in their perception of speech before they master the sound system of their native language (Räsänen et al., submitted).

Following the syllabification, F0 trajectories during each syllable were parametrized by fitting a second order polynomial to the trajectory in time (Fig. 2) and using the polynomial coefficients without the constant term as a parametric description of the F0 during the syllable. Parameters across all syllables in the data were then vector quantized into $Q$ discrete categories using standard k-means clustering with random initialization. In practice, these $Q$ shapes correspond to different F0 patterns with varying curvature and rate of change as a function of time, larger $Q$ simply meaning more fine-grained distinction between F0 patterns that occur during the syllables.

## Temporal modeling of $\mathbf{F 0}$ state sequences

As a result of the pre-processing, the F0 trajectory of each utterance was described as a sequence of discrete states $q_{s} \in$ $Q$, one state per syllable $s$. In order to quantify the predictability of F0, a mixed-order Markov chain model, or MOCM, was trained for the sequences (Saul \& Pereira, 1997). Instead of computing $n$-gram statistics for different $n$-gram orders and then choosing and/or merging the models with best predictive capability, MOCM allows modeling of varying order Markov chains with a single set of model parameters. In MOCM, the probability of an F0 shape $q_{s}$ in syllable $s$, given the preceding $m$ syllables, is calculated as

Figure 2: An example of syllable-wise $2^{\text {nd }}$ order polynomial approximation of the F0 trajectory. Top: The original speech waveform. Bottom: YAAPT-estimated and z-score normalized F0 trajectory with interpolation across unvoiced segments (blue solid line) and the corresponding $2^{\text {nd }}$ order polynomial least-squares fit for F0 during each syllable. Syllable boundaries are shown with vertical lines.

$$
\begin{align*}
& P\left(q_{s} \mid q_{s-1}, \ldots, q_{s-m}\right)= \\
& \sum_{k=1}^{m} \lambda_{k}\left(q_{s-k}\right) \mathbf{M}_{k}\left(q_{s-k}, q_{s}\right) \prod_{j=1}^{k-1}\left[1-\lambda_{j}\left(q_{s-j}\right)\right] \tag{1}
\end{align*}
$$

where lag-specific transition matrices $\mathbf{M}$ and transition weights $\boldsymbol{\lambda}$ are estimated from training data using the Expectation Maximization (EM) algorithm (Saul \& Pereira, 1997). In the context of the present study, $\mathbf{M}_{k}$ describes the transition probabilities between syllabic F0 contours at different lags $k$ while $\lambda$ weighs these probabilities from different distances based on the reliability of the probability estimates in the context of the observed shapes.

In the experiments, a third order $(m=3)$ MOCM model was trained using the syllabic F0 sequences from $90 \%$ of the combined pool of IDS and ADS utterances. This was followed by syllable-by-syllable estimation of F0 likelihoods on the remaining held-out utterances using Eq. (1). The procedure was repeated in a 10 -fold manner until all utterances had been used in the training and test sets. The division of utterances into training and testing sets was purely random, and therefore both contained speech from the same 11 unique talkers. We decided not to use speakerspecific models for F 0 due to the modest number of utterances per talker that would have caused data sparsity issues in the model estimation. As a result, the obtained probability estimates describe how expected is the F0 behavior in the given context given a preceding exposure to a large number of F0 trajectories, low probability reflecting unexpected and thereby attention capturing intonation.

Note that the choice of $Q$, the number of quantization levels for the F0 shapes, contains an inherent tradeoff between the resolution of the F0 trajectory modeling and the amount of data required for model estimation. Although there is no a priori reason to consider any $Q$ specifically favoring IDS or ADS due to the z-score normalization of all F0 values, we wanted to minimize the impact of $Q$ in our
findings. Therefore the simulation was conducted for $Q=6$, 12 , and 24 with syllable-specific likelihood estimates averaged across all these runs. In addition, all likelihoods were averaged across five runs of the entire experiment to diminish variation caused by random initialization of the k means clustering process, even though the k-means clustering results for the two dimensional features were found to be highly consistent across individual runs.

## Data analysis

Five utterance-level statistical descriptors, namely, the mean, SD, min, max, and range ( $\max -\min$ ) were calculated for the F0 likelihoods across all syllables and for the original F0 trajectories in Hz in each utterance. Talker and style-specific (IDS vs ADS) means for the descriptors were then averaged across all the utterances from the given talkers. Before any statistical analysis, the statistical descriptors for F0 likelihoods were corrected for the variable amount of matching training data for the speaker and speaking style in question. This was done by first fitting a speaker-independent linear regression model from the number of matching training samples to the statistical descriptors, and then subtracting the prediction from the original values, basically decorrelating the measures with respect to the amount of training data.

In order to test differences between IDS and ADS, the normalized descriptors for F0 predictability and descriptors for the original F0 values were then compared between the IDS and ADS conditions using the paired t-test with significance level of $p<0.05$ (Holm-Bonferroni corrected for the ten comparisons and $d f=10$ for all reported stats).

## Results

Fig. 3 shows a summary of the results together with markers and $t$-statistics for significant differences between IDS and ADS. As expected, the mean frequency of F 0 in the utterances is higher in IDS $(210.9 \mathrm{~Hz} \pm 29.0 \mathrm{~Hz})$ than in ADS ( $189.9 \pm 23.9 \mathrm{~Hz}$ ). In addition, the average utterancelevel maximum and minimum F0 are significantly higher in IDS, but the overall variability and absolute range (in Hz ) are not different between the speaking styles.

As for the predictability, the mean predictability of F0 in IDS was significantly lower than in $\operatorname{ADS}(t(10)=4.82$, Cohen's $d=1.93$ ). In addition, maximum predictability during each utterance was also lower $(t(10)=5.46, d=2.10)$ and so was the range of predictability values across the syllables in the utterances $(t(10)=5.19, d=1.88)$. In contrast, variability of predictability across the utterances was not different between IDS and ADS. Notably, the average F0 probabilities are within a similar range to what was found to be optimal stimulus complexity for attentional capture in the visual perception experiments of Kidd et al. (2012) and significantly above chance-level ( $p=0.0972$ ). This suggests that the F0 trajectories might be in a suitable complexity region for triggering novelty preference, enabling predictive learning but also leaving room for unpredictable patterns and events.

Figure 3: Top: Utterance-level statistical descriptors of F0 predictability, averaged across all ADS/IDS utterances. Middle: F0 predictability after controlling for the amount of matching training data (speaker \& style) for each utterance. Bottom: Utterance-level descriptors of original F0 in Hz, averaged across all utterances. Error bars denote $\pm 1 \mathrm{SE}$ across all talkers. Significant differences between IDS and ADS are denoted with asterisks and related t -values (paired t-test, $d f=10$, and using significance level $p<0.05$ with Holm-Bonferroni correction for the ten comparisons).

We also repeated the entire analysis but now using linear instead of the 2 nd order model for the syllabic F0 contours (i.e., encoding only the average direction and rate of change in F0 during the syllable). This replicated all the main findings (significantly lower mean, max, and range for the predictability of F0 in IDS; not shown separately). We also tested whether there were differences in the predictability descriptors between the three sentence types (familiar object, unfamiliar object, no labeling) but none of the tests were significant after controlling for multiple comparisons. In addition, the predictability difference is not simply due to a larger quantization error for IDS parameters, since the reported pattern of results persists also if only the IDS data are used for the k-means codebook creation leading to lower quantization errors (RMSE) for the IDS F0 trajectories.

Overall, the main result confirms the hypothesis that the intonation contours in IDS are less predictable than in ADS, at least for the present data set in question.

As a follow-up validation of the findings, we also ran binary logistic regression to classify all the individual utterances into IDS or ADS classes using the utterance-level descriptors for probabilities and raw F0 values as features and using likelihood ratio as the criterion for forward stepwise feature selection (using SPSS version 23.0, IBM Corp., Armonk, NY). The resulting model achieved IDS/ADS utterance classification rate of $74.8 \%$ using a final
set of four features: SD of likelihood (Wald statistic $=$ $31.28, p<0.001 ; d f=1$ for all features), mean likelihood ( $W$ $=23.08, p<0.001$ ), likelihood range $(W=88.34, p<$ 0.001 ), together with max of original F 0 in $\mathrm{Hz}(W=66.24, p$ $<0.001$ ). This further shows that the predictability differences of intonation in IDS and ADS do not simply appear as aggregate measures across a large number of utterances, but can be also used to effectively classify individual utterances into ADS or IDS.

Finally, a subset of the utterances used in the present study had been previously rated for their IDS-likeness using a low-pass version of the recordings as part of the ManyBabies project (see The ManyBabies Consortium, 2017, for details). These utterances were rated on a 7-point Likert scale by several naïve raters recruited from Amazon's mechanical Turk. We therefore calculated the correlation between all the utterance-level F0 descriptors and the human IDS-likeness ratings for all the IDS utterances with ratings $(N=442)$. The human judgments of IDS-likeness correlated with the mean (Spearman's $r=0.25, p<0.001$ ), SD ( $r=0.31, p<0.001$ ), min $(r=0.154, p=0.002)$, max $(r$ $=0.35, p<0.001)$, and range $(r=0.32, p<0.001)$ of the original F0 values, i.e., with all of them. Surprisingly, all the descriptors of F0 trajectory likelihoods were uncorrelated with the human ratings ( $p>0.05$ for all comparisons).

Since predictability was nonetheless a reliable cue in our classification of utterances into IDS and ADS based on the original study labels, the finding with the naïve ratings data suggests a dissociation between perceptual correlates of IDS-like speech in naïve listeners (e.g., high and variable pitch) and the lower predictability of intonation in IDS as a potential attractor of listeners' attention. Notably, an earlier study by Singh, Morgan \& Best (2002) has also reported that higher and more variable pitch alone was not sufficient to capture infants' attention when pitted against affective speech. This suggests that the properties that make an utterance sound IDS-like to a naïve listener may be unrelated to those that lower the predictability of IDS. How those properties relate to the attentional attractiveness of IDS is currently unclear and requires further investigation.

## Discussion and conclusions

This study aimed to test whether the exaggerated intonation in IDS also translates into less predictable prosody over time. The results support this idea, even when the actual mean and range of F0 values in the predictive analysis was normalized between the IDS and ADS utterances. In addition, while IDS intonation is less predictable than ADS, it is still relatively structured as indicated by the mean predictability that is significantly above the chance-level given the analyzed quantization levels. These findings provide initial support to the idea that IDS may be more attentionally attractive simply because it is more surprising without being too chaotic (c.f., Kidd et al., 2012), thereby tapping to the basic attentional mechanisms causing orientation towards unfamiliar inputs.

In addition, some evidence for a dissociation between human ratings of IDS-likeness and predictability of the utterances was also discovered, warranting further research in the issue. In fact, a dissociation between F0 variability and F0 predictability is expected on the basis of predictability-based accounts to prominence and attention in speech. More specifically, it has been argued that the perceptual system should allocate processing resources to the aspects of the input that are not yet predicted by the brain independently of the physical magnitude or other absolute property of the input. In contrast, highly predictable inputs, by definition, have low information value and are therefore low priority targets for sensing and learning even if they have large magnitude on some scale such as loudness or pitch (e.g., Kakouros \& Räsänen, 2016b; Kakouros et al., submitted; see also, e.g., Friston \& Kiebel, 2009). In the context of speech, the talker can control the listener's attention by freely using non-canonical prosodic forms on any word or words of choice without changing the literal meaning of the utterance (Kakouros et al., 2016b; Kakouros et al., submitted). The present study suggests that caregivers may (implicitly) utilize a similar strategy to maintain infants' attention on the speech stream or highlighting certain segments of speech.

However, the present work only provides an initial investigation into the predictability aspects of IDS using a certain modeling approach. Much more work is needed to understand the underpinnings of IDS and how it relates to learning and attention mechanisms of the human cognition. This also includes the need to replicate the present investigation on different speech data and also preferably with alternative approaches to quantifying suprasegmental statistical structure. In addition, prosody is much more than F0 trajectories, and therefore aspects such as timing, utterance duration, and intensity should be investigated from the predictability point of view independently and in conjunction with F0.

## Acknowledgments

O.R. was funded by Academy of Finland project titled "Computational modeling of language acquisition" (274479). All MATLAB scripts for syllabification, mixedorder Markov chains, and reported analyses can be found at https://git.io/vDT0N. # When does a 'visual proof by induction' serve a proof-like function in mathematics? 

Josephine Relaford-Doyle (jorelafo@ucsd.edu) Rafael Núñez (rnunez@ucsd.edu)<br>Department of Cognitive Science, University of California - San Diego<br>9500 Gilman Drive, La Jolla, CA 92093 USA

#### Abstract

A proof by mathematical induction demonstrates that a general theorem is necessarily true for all natural numbers. It has been suggested that some theorems may also be proven by a 'visual proof by induction' (Brown, 2010), despite the fact that the image only displays particular cases of the general theorem. In this study we examine the nature of the conclusions drawn from a visual proof by induction. We find that, while most university-educated viewers demonstrate a willingness to generalize the statement to nearby cases not depicted in the image, only viewers who have been trained in formal proof strategies show significantly higher resistance to the suggestion of large-magnitude counterexamples to the theorem. We conclude that for most university-educated adults without proof-training the image serves as the basis of a standard inductive generalization and does not provide the degree of certainty required for mathematical proof.

Keywords: mathematical reasoning; proof; mathematical induction; visual proof; induction; generalization

## Introduction

Mathematics has been defined as "the science which draws necessary conclusions" (Peirce, 1881). To this end, proofs are indispensible to formal mathematics. A mathematical proof uses deductive logic to establish the truth of a general theorem - for instance, that a property holds for all triangles, or all natural numbers. Relative to the logical system being used, the conclusion of the proof is certain; if the premises are true, then the conclusion is necessarily true as well. The certainty of results obtained through formal, deductive proof is a defining feature of mathematics.

Mathematical induction, despite what its name suggests, is a well-established deductive proof method that can be used to prove that a theorem holds for all natural numbers. It has been suggested that some general theorems that can be formally proved using mathematical induction may also be proved using specially designed images known as 'visual proofs' (Brown, 2010). The claim that a 'visual proof by induction' can prove a general theorem is an interesting one, since any image is necessarily finite and thus can only display a particular set of cases of the theorem. Case-based argumentation falls under the umbrella of inductive reasoning, which does not provide certain conclusions and is not accepted in formal mathematical justification. However, visual proofs contain additional structure that could be leveraged to demonstrate that a theorem necessarily holds in all cases, even those not depicted in the image. Thus, it is possible that a visual proof, despite displaying only a finite number of cases, could serve a proof-like function for some viewers.

Although the status of visual proofs is at the center of a debate in the philosophy of mathematics (see, e.g., Brown, 2010; Doyle, Kutler, Miller, \& Schueller, 2014; Folina, 1999), they have been largely ignored within Cognitive Science and little is known about the nature of reasoning with these images. How do viewers reason with a visual proof by induction? Do they consider the conclusions to be certain, as in mathematical induction, or only likely, as in standard inductive reasoning?

## Induction in Mathematics, Mathematical Induction, and Visual Proofs

The distinction between certain, necessary conclusions and probable or likely conclusions is of central concern in mathematics. Proofs - deductive arguments which provide certain conclusions - are exalted. The writing of proofs, however, comprises only a small part of mathematical practice, and it is widely acknowledged that inductive reasoning plays an important role in mathematics (see Polya, 1954 for an account of induction in mathematics). A commonly held view is that inductive reasoning is an essential part of mathematical discovery, while deduction is required for formal mathematical justification (i.e., proof).

Consider the expressions in Figure 1(a). One might notice a pattern in these examples, namely, that when one adds consecutive odd numbers starting at 1 , the resulting sum seems to be the square of the number of terms being added. We might guess that this pattern holds for other numbers; for example, we might predict that the sum of the first 8 odd numbers is 64 . However, while these six examples allowed us to discover a possible relationship, the examples themselves do not prove that the general theorem is true for all natural numbers. Without a formal proof, any conjecture we have is uncertain and remains open to the possibility of counterexamples. A formal proof of our theorem using mathematical induction is given in Figure 1(b).

Figure 1(c) shows a visual proof of the same theorem (from Brown, 1997). In the image, consecutive odd numbers of dots are arranged in layers, beginning with 1 in the lower left-hand corner. When the dots in the first $n$ layers are considered together the resulting array forms a square, and so the total number of dots in the array is given by $n^{2}$. While the image displays only the first six cases of the general theorem, a viewer might be inclined to guess that the pattern will continue to hold as more layers are added, and therefore be convinced that the general theorem is true. Indeed, images such as these have been described as "rapidly and deeply convincing" (Doyle et al., 2014).

| Theorem: The sum of the first $\boldsymbol{n}$ odd numbers is equal to $\boldsymbol{n}^{\mathbf{2}}$. |  |  |
| :---: | :---: | :---: |
| (a) Six cases | (b) Proof by mathematical induction Theorem: $1+3+\ldots+(2 n-1)=n^{2}$ | (c) Visual Proof |
| $1=1^{2}$ | Base case: $n=1 \rightarrow 1=1^{2}$ | 000000 |
| $1+3=4=2^{2}$ | Inductive step: Assume $1+3+\ldots+(2 k-1)=k^{2}$, |  |
| $1+3+5=9=3^{2}$ | for some fixed number $k$. Adding the next odd | 00000000 |
| $1+3+5+7=16=4^{2}$ | number $2 k+1$ to both sides of the equation, we | 00000000 |
| $1+3+5+7+9=25=5^{2}$ | have: $1+3+\ldots+(2 k-1)+(2 k+1)=k^{2}+(2 k+1)$ | $\begin{array}{llll} 000 & 0 & 0 \end{array}$ |
| $1+3+5+7+9+11=36=6^{2}$ | Re-writing the last odd term and factoring the right side gives us: | $\begin{array}{lll\|l\|l\|l} \hline 0 & 0 & 0 & 0 & 0 & 0 \\ \hline 0 & 0 & 0 & 0 & 0 & 0 \end{array}$ |

Figure 1: Varying forms of evidence for a general theorem. (a) Specific cases suggest, but do not prove, the general theorem. (b) Formal proof of the general theorem by mathematical induction. (c) Visual proof (from Brown, 1997).

It is unclear, however, the exact nature of the conclusions drawn from the visual proof. As many have pointed out, any image is necessarily finite and thus can only display particular cases of a general theorem (Doyle et al., 2014; Rips \& Asmuth, 2007). This would suggest that the image in Figure 1(c), like the cases presented in 1(a), would serve as the basis for a standard inductive generalization - the image might convince the viewer that the theorem likely holds for all natural numbers, but cannot provide certainty. On the other hand, the image contains structure that is not available in the same cases presented numerically, and which could be exploited in order to demonstrate that the property would necessarily continue to hold for values not depicted in the image. Such an argument would need to demonstrate that the square shape is preserved if and only if the next layer contains the next consecutive odd number of dots. For example, if we start with an $n \times n$ square, the $(n+$ $1)^{\text {st }}$ layer could be constructed by copying the $n^{\text {th }}$ layer and translating the copy up one unit and right one unit (Figure $2 \mathrm{a}, \mathrm{b})$. This results in two vacant positions that must be filled in order to maintain the square shape (Figure 2c, d). Thus, every layer must contain exactly two more dots than its predecessor. Since the difference between any two consecutive odd numbers is 2 , we can conclude that the new layer must contain the next consecutive odd number of dots.

Figure 2: Rigorous image-based argument for the general theorem

Though not a traditional deductive proof, it could be argued that an argument such as this does establish the truth of the general theorem for all natural numbers, and that this conclusion meets the level of certainty required for mathematical proof. It is unknown how accessible such arguments are to viewers, and, more generally, how closely the conclusions drawn from the visual proof resemble the conclusions drawn from a formal proof. In this study we seek to assess the extent to which a visual proof may serve a proof-like function. Specifically, we ask two key questions: (1) Given the visual proof, do viewers generalize the theorem to cases not depicted in the image? (2) If so, is that conclusion considered certain, as in mathematical induction, or only likely, as in standard inductive reasoning?

Finally, to properly address these questions we consider who is viewing the image and in what context the image is viewed. In this study we compare two groups of viewers, one drawn from the general population of university students and one drawn from a group that has received university-level training in formal proofs, including mathematical induction. Additionally, to address the key theoretical difference in mathematics between discovery (in which inductive reasoning is acceptable) and justification (in which it is not), we manipulate the context in which the image is viewed by varying the amount of information provided to the viewer.

## Method

## Participants

Two groups were drawn from distinct populations. The first group ( $n=25$ ) was recruited through the university subject pool. None of these participants had taken a university-level course on mathematical proofs, and so we refer to this group as "proof-untrained" (PU). The second group ( $n=24$ ) was recruited through the mathematics department and consisted of individuals who had received at least a B- in "Mathematical Reasoning", a university-level mathematics course on formal proof strategies including mathematical induction. We refer to this group as "proof-trained" (PT). PT participants had taken significantly more university-level math classes than had PU participants (mean PT $=6.67$,
mean $\mathrm{PU}=2.8, \mathrm{t}=6.58, \mathrm{df}=44.63, \mathrm{p}<0.001)$. No PU participants had taken the "Math Reasoning" course on proofs (but four of the 25 indicated familiarity with mathematical induction).

## Materials

Each participant received one of three tasks. All three tasks included the visual proof in Figure 1(c), which was designed to prove the target statement "The sum of the first $n$ odd numbers is equal to $n^{2 " \prime}$, but varied in the amount of information that was provided to the reader.
Condition A - Justification: The participant was given the full target statement and the visual proof. They were asked to explain how the picture shows that the statement is true.
Condition B - Supported Discovery: The participant was given the visual proof and a fill-in-the-blank version of the target statement ("The sum of the first $n$ odd numbers is equal to $\qquad$ ."). They were asked to fill in the blank and explain how they got their answer.
Condition C - Full Discovery: The participant was given the visual proof and told that a mathematician drew the picture while trying to prove a statement about the sum of odd numbers. They were asked to guess what the mathematician was trying to prove and explain their answer.

Additionally, participants completed a background questionnaire in which they provided the number and names of university math courses they had taken and their level of familiarity with mathematical induction.

## Procedure

Each participant received one of the three task sheets, and the researcher explained that their ultimate task was to create a short tutorial video in which they would explain their response as clearly as possible to potential third-party viewers. A camera was set up directly above the participant's workspace, recording their writing, speech, and manual gestures (Figure 3). Before filming their video each participant was given as much time as they needed to think and plan their response. During this time participants had access to pencils, highlighters, and blank paper, and were free to add any markings to the sheet that might be helpful in explaining their response. The participant indicated they

Figure 3: Screenshot from video footage of a participant's workspace
were ready to start their tutorial video by placing a sign under the camera, and then filmed their explanation. The planning and filming were entirely self-paced and occurred without the researcher present.

When the participant indicated that they had finished their tutorial video, the researcher returned to the room and conducted a semi-structured interview with the participant. To assess whether the participant had generalized the target statement to cases not depicted in the image, any participant who demonstrated understanding of the target statement was asked two questions: "Do you think the statement is true in all cases?" (Q1) and "What would be the sum of the first 8 odd numbers?" (Q2). If the participant indicated generalization to nearby cases (by answering "yes" and " 64 ", respectively), the researcher raised the possibility that large-magnitude counterexamples to the statement may exist and asked the participant what they thought about that suggestion. Any participant who resisted the suggestion of counterexamples was asked how they would argue against such a possibility. After the interview all participants completed the background questionnaire.

## Analysis

Two coders scored each video for six distinct outcomes. The participant's tutorial video received three scores:
(a) Mathematical Statement: Rated whether the participant demonstrated understanding of the target statement.
(b) Explanation Strategy: Rated whether the participant gave a case-based explanation (using the image to show particular cases of the statement), or a pattern-based explanation (describing a general pattern in the image).
(c) Relevant Features of Image: Reflected which features of the image the participant identified as relevant, including odd numbers in layers, square shape, possibility of pattern extension, and necessity of pattern extension.

An additional three scores were given based on the interview portion of the study.
(d) Generalization: Rated whether the participant demonstrated generalization of the target statement to nearby cases as assessed by questions Q1 and Q2.
(e) Resistance to Counterexamples: Rated the participant's resistance to the possibility of large-magnitude counterexamples, ranging from no resistance (0) to complete rejection (5).
(f) Image-Based Argument: Rated whether the participant provided a rigorous image-based argument comparable to the argument represented in Figure 2.

For nominal criteria (a)-(d) and (f), the two coders showed 96.2\% agreement (Cohen's Kappa=0.96). Criterion (e) was was scored on 1-5 scale and also showed high reliability between coders (Krippendorff's alpha $=0.894$ ).

## Results

The two groups differed with respect to the ability to demonstrate understanding of the target statement across conditions. While proof-trained (PT) participants systematically demonstrated such understanding, proof-
untrained (PU) participants' ability to do so varied significantly across conditions (Fisher Exact test, $p=0.012$; Figure 4). All PU participants showed understanding of the target statement when it was provided (Condition A), but only $6 / 8$ participants provided the target response of $n^{2}$ in Condition B, and $3 / 9$ participants generated the complete target statement in Condition C. PT participants, on the other hand, did not significantly vary in their likelihood to demonstrate understanding of the target statement across conditions (Fisher Exact test, $p=0.3$; Figure 4).

Figure 4: Proportion of participants who demonstrated understanding of target statement.

Of the 17 total PU participants across all conditions who demonstrated understanding of the target statement, 10 (59\%) used case-based explanations in their tutorial video (Figure 5); notably, none of these 10 participants referred to the square shape as a relevant feature of the image during their explanation. Explanation strategy varied significantly across conditions, with participants in Condition A showing a stronger preference for case-based strategies, while participants in Condition C were more likely to generate pattern-based explanations (Fisher Exact test, $p=0.026$ ) and more likely to mention the square shape ( $p=0.026$ ). As we found no other significant effects of task context, in the following analysis we group participants across all conditions who demonstrated understanding of the target statement, keeping PU and PT groups separate.

Figure 5: Explanation Strategy: PU participants were significantly more likely than PT participants to give casebased (rather than pattern-based) explanations.

Proof-Untrained (PU) Group In the interview, 16 of the 17 (94.1\%) PU participants who demonstrated understanding of the target statement indicated a willingness to generalize the statement to nearby cases (Figure 6a). Only 5 (31\%) of these participants indicated a high degree of
resistance to large-magnitude counterexamples (characterized by a resistance score of 4 or higher), and only one stated that counterexamples were impossible (Figure 6b). Notably, questionnaire responses revealed that three of the five PU participants who showed high resistance were familiar with mathematical induction. When asked for an argument against counterexamples, only two PU participants were able to generate a rigorous argument based on the image. PU participants had taken significantly fewer university-level math courses than had PT participants; however, number of math courses was not significantly correlated to any study outcomes for the PU group.

Proof-Trained (PT) Group Across all conditions there were 22 PT participants who demonstrated understanding of the target statement. These participants were significantly more likely than PU participants to provide pattern-based explanations (Fisher Exact test, $p=0.026$ ), with only $2 / 22$ (9\%) relying on case-based strategies (Figure 5). PT participants were significantly more likely than PU participants to mention the square shape as a relevant feature of the image ( $21 / 22$; Fisher Exact test $p<0.001$ ). In the interview, all 22 PT participants who demonstrated understanding of the target statement indicated a willingness to generalize the statement to nearby cases not depicted in the image. The likelihood to generalize did not differ between PT and PU participants (Figure 6a); however, PT individuals were significantly more likely to indicate a high degree of resistance to the suggestion of large-magnitude counterexamples (17/22; Fisher Exact test, p=0.008; Figure $6 b)$. When considering all participants who demonstrated understanding of the target statement, PT participants were significantly more likely to provide a rigorous image-based argument against counterexamples than PU participants (8/22; Fisher Exact test, p $=0.035$ ).

Figure 6: (a) Participants in both groups generalized the target statement to nearby cases. (b) However, PT participants showed significantly higher resistance to largemagnitude counterexamples than did PU participants.

## Discussion

The present study explored the conditions in which a visual proof by induction may serve a proof-like function, characterized by generalization to all natural numbers and a belief that this conclusion is necessarily true. Our findings reveal significantly different outcomes for the proof-trained and proof-untrained participants. Specifically, while both groups demonstrated a willingness to generalize to nearby cases, the PU participants showed relatively low resistance to the suggestion that large-magnitude counterexamples may exist. This suggests that for these viewers the visual proof serves as the basis for a standard inductive generalization, and does not provide certainty. Further evidence for this analysis comes from the observation that PU participants were significantly more likely to provide case-based explanations, using the image to demonstrate one or more particular cases of the general theorem. PT participants, on the other hand, showed higher resistance to counterexamples and were more likely than PU participants to provide a rigorous argument using the image. Thus, it seems that the image can serve a proof-like function for viewers who have been trained in formal proof methods. The significant differences between the PT and PU groups contradict claims that visual proofs by induction are equally convincing to all viewers regardless of their knowledge of mathematical induction (Brown, 2010), or that interpreting the image as a proof requires only "basic secondary school knowledge of mathematics" (Jamnik, 2001).

We were surprised to find that the PU participants highly educated adults enrolled at a prestigious university often overlooked key features of the visual proof. Less than $60 \%$ of the PU participants who demonstrated understanding of the target statement mentioned the square shape as a relevant feature of the image. Furthermore, many participants who re-drew the image during their explanation did so in a way that violated the row-column structure of the square array (Figure 7), indicating that they were truly unaware of its importance. However, failure to notice the relevance of the square shape does not explain the PU group's low resistance to counterexamples, as mentioning the square shape was not significantly related to high resistance (Fisher Exact test, $\mathrm{p}=0.59$ ) within this group.

Figure 7: Work of PU participants who re-drew the image in a way that violated the row-column structure and square shape of the array

There were 5 PU participants who expressed a high degree of resistance to the suggestion of large-magnitude counterexamples, two of whom were unfamiliar with mathematical induction. We cannot conclude, however, that the image was serving a proof-like function for these viewers. Prior research has shown that adults do not reliably distinguish between inductive and deductive mathematical arguments and often accept case-based arguments as valid proofs of statements about infinite sets (Eliaser, 2000; Martin \& Harel, 1989). Thus, even if the image functions as a basis for a standard inductive generalization, we would nonetheless expect to see a group of participants who find it highly convincing.

PT participants were more likely than PU participants to show high resistance to counterexamples, and subsequently more likely to provide a rigorous image-based argument for the general theorem. What accounts for these differences? One possibility is that PT participants had been exposed to significantly more university-level mathematics than PU participants. However, the number of university math classes taken prior to participation in the study was not related to any outcome for either group. This suggests that the differences between the two groups cannot be explained simply based on differing amounts of exposure to general mathematics. Instead, it seems that training in proof-writing - a specific and highly technical mathematical practice may make viewers more likely to draw certain conclusions from the image.

Based on our data, exposure to proof-writing could make certain conclusions more likely in at least three ways (not mutually exclusive). First, it could be that some aspect of the task reminds PT participants of the specific proofmethod of mathematical induction (indeed, $75 \%$ of PT participants mentioned mathematical induction at least once during their video and/or interview). These viewers might then recognize that they could use mathematical induction to prove the target statement, and perhaps even complete the proof (as did $25 \%$ of our PT participants). Thus, knowledge of the formal proof could provide an alternate means of acquiring certainty about the conclusion; once achieving this certainty, participants may be more likely to attempt to generate an alternate argument based on the image. However, it cannot be the case that knowledge of mathematical induction is a necessary condition for such an argument, as we observed one participant who was not familiar with mathematical induction produce a rigorous image-based justification of the general theorem.

Second, in addition to gaining familiarity with mathematical induction, training in proof-writing would also expose individuals to a set of general mathematical norms which may lead these participants to demonstrate a higher degree of certainty. All participants who demonstrated understanding of the target statement were asked if they believed the statement to be "true in all cases"; however, the two groups likely interpreted this question differently. For PT participants, "all" (when used in a mathematical context) is a technical term, which by
definition implies the impossibility of counterexamples. PU participants may have been operating with an everyday use of "all", in which the term is considered synonymous to "generally" or "usually" (e.g., "All Californians love the beach."). In this light, the two groups' differing responses to the suggestion of counterexamples may be revealing of their different conceptualizations of the term "all".

Finally, in the practice of writing proofs one learns standard ways of representing general mathematical objects, and these representations may be useful in interpreting visual proofs. We observed that PT participants often invoked the fact that odd numbers are of the form $(2 n+1)$ to explain how they knew that the layers (symmetric legs extending from a single corner dot) would always contain an odd number of dots. Fewer PU participants offered this argument, perhaps because they were not familiar with algebraic representations of parity. Future studies are necessary to determine whether knowledge of algebraic representations of parity allow viewers to exploit structure available in an image.

We also explored how conclusions drawn from the image differed between contexts of justification (Condition A) and discovery (Conditions B/C). We observed only three effects of task context. First, PU participants' ability to demonstrate understanding of the target statement varied significantly between conditions. Specifically, PU participants - while perfectly capable of understanding the target statement when it was provided - were highly unlikely to "discover" the full target statement based only on the image (with only $25 \%$ able to do so in Condition C). These results suggest that, even for most highly-educated viewers, the image must be accompanied by the statement it is intended to prove (or at least a substantial hint, as in Condition B). Next, we observed that PU participants in contexts of full discovery (Condition C) who generated the target statement were more likely to provide pattern-based justifications and more likely to mention the square shape than PU participants who were given the full target statement. This is not surprising, since the target statement was unknown to these participants at the outset of the task and was only discovered if the participant noticed a pattern in the image.

We find it interesting that these three results were the only effects of task context for either group. All participants who demonstrated understanding of the target statement were likely to generalize it to nearby cases, regardless of the justification/discovery context in which they had seen the visual proof. Subsequent resistance to large-magnitude counterexamples - relatively low for PU participants, and high for PT participants - did not vary significantly between task contexts. This suggests that certainty of the conclusion has more to do with the viewer's exposure to mathematical proof-writing than with the justification/discovery context in which the image is viewed. The lack of any effect of task context for PT participants suggests that the sharp distinction between justification and discovery, of such theoretical importance in mathematics, is less prevalent in advanced mathematical practice.

## Conclusion

In this study we investigated the reasoning underlying a visual proof by induction and the nature of the conclusions drawn from the image. A visual proof by induction displays a particular set of cases of a general theorem, yet it also contains structure that could be used to construct a rigorous argument that the theorem is necessarily true for all natural numbers. We found that, while most viewers are willing to generalize the theorem to nearby cases not displayed in the image, viewers who have been exposed to formal proof methods (including mathematical induction) show significantly higher resistance to the suggestion that largemagnitude counterexamples to the theorem are possible, and are significantly more likely to provide a rigorous imagebased argument against counterexamples. For participants without proof-training, conclusions drawn from a visual proof resemble a standard inductive generalization and do not display the level of certainty associated with mathematical proof. These results are consistent between contexts of justification and discovery, indicating that the certainty of conclusions drawn from a visual proof by induction are primarily dependent on the viewer's exposure to proof-writing, rather than the viewing context.

# Interpreting Asymmetries in Speech Perception with Bayesian Inference 

Jie Ren (Jie_Ren@Brown.Edu)<br>Department of Psychiatry and Human Behavior, Brown University, 1011 Veteran Memorial Pkwy, Riverside, RI 02915 USA<br>Joseph L. Austerweil (austerweil@wisc.edu)<br>Department of Psychology, University of Wisconsin - Madison, 1202 W. Johnson Street Madison, WI 53706 USA

#### Abstract

This paper proposes a Bayesian account of asymmetries found in speech perception: In many languages, listeners show greater sensitivity if a non-coronal sound $(/ \mathrm{b} /, / \mathrm{p} / \mathrm{l} / \mathrm{g} /$, $/ \mathrm{k} /$ ) is changed to coronal sounds ( $/ \mathrm{d} /, / \mathrm{t} /$ ) than vice versa. The currently predominant explanation for these asymmetries is that they reflect innate constraints from Universal Grammar. Alternatively, we propose that the asymmetries could simply arise from optimal inference given the statistical properties of different speech categories of the listener's native language. In the framework of Bayesian inference, we examined two statistical parameters of coronal and non-coronal sounds: frequencies of occurrence and variance in articulation. In the languages in which perceptual asymmetries have been found, coronal sounds are either more frequent or more variable than non-coronal sounds. Given such differences, an ideal observer is more likely to perceive a non-coronal speech signal as a coronal segment than vice versa. Thus, the perceptual asymmetries can be explained as a natural consequence of probabilistic inference. The coronal/non-coronal asymmetry is similar to asymmetries observed in many other cognitive domains. Thus, we argue that it is more parsimonious to explain this asymmetry as one of many similar asymmetries found in cognitive processing, rather than a linguisticspecific, innate constraint.

Keywords: speech perceptual asymmetry; Bayesian inference; natural statistics; category variability; nature vs. nurture; domain-general vs. domain-specific

## Introduction

Listeners from a variety of language backgrounds have shown asymmetric sensitivity to different directions of sound changes in speech perception. We focus on one particular asymmetry: consonants with a coronal place of articulation (/d/, /t/, /n/, /1/) are more tolerant to changes or mispronunciations than consonants with non-coronal places of articulation ( $/ \mathrm{g} /, / \mathrm{k} / \mathrm{/} / \mathrm{b} / \mathrm{l} / \mathrm{p} /$ ). For example, the German word for "railway", bahn primed the word for "train" when mispronounced as bahm. However, the word for "tree", baum, did not prime the word for "bush" when mispronounced as baun (Lahiri \& van Coillie, 1999). This indicates that listeners can accept a labial sound as the correct form of a coronal sound but not vice versa. ERP findings corroborate this phenomenon: At temporally early stages of speech perception, German-speaking adults displayed asymmetric discrimination for mispronunciations of familiar words with coronal vs. non-coronal onsets (Friedrich, Lahiri, \& Eulitz, 2008) and internal consonants
(Friedrich, Eulitz, \& Lahiri, 2006; Cornell, Lahiri \& Eulitz, 2013). Similar effects have also been observed with English-speaking (Roberts, Wetterlin \& Lahiri, 2013) and Bengali-speaking adults (Lahiri \& Marslen-Wilson, 1991).

To explain this asymmetric bias in speech perception, the predominant hypotheses have been derived from phonological theories (Kiparsky, 1982) in the framework of Universal Grammar (UG). In particular, the Featurally Underspecified Lexicon (FUL) model (Lahiri \& MarslenWilson, 1991; Lahiri \& Reetz, 2002) suggested that the place of articulation for coronal consonants (/d/ in $\underline{d u c k}$ ) is not stored (underspecified) in phonological representations. Consequently, mispronunciations in the onset of $\underline{d} u c k$, such as $\boldsymbol{g} u c k$, are still compatible with the representation of $d u c k$, and such mispronunciations should have minimal effects on the lexical activation of the word duck. By contrast, the place of articulation for a non-coronal consonant is fully stored (specified) in the phonological representation (the place of articulation of $/ \mathrm{g} /$ in goose is stored as [+velar]), so mispronunciations of the onset of goose, such as doose, will be incompatible with the representation of goose and thus will disrupt lexical activation of the word goose.

Studies with infants and toddlers also support predictions of the FUL model. 6-month-old Dutch-learning infants were habituated to repeated taan or paan tokens and then tested on their ability to discriminate trials in which the stimulus repeated versus trials in which the two stimuli alternated. Whereas infants habituated to paan discriminated the two types of trials, infants habituated to taan did not (Dijkstra \& Fikkert, 2011). The findings were interpreted as support for the FUL model: When the standard of comparison was taan, the place of articulation of the onset /t/ was not specified, so both $\underline{t} a a n$ and paan were compatible with the standard. But when the standard of comparison was paan, place of articulation of the onset / p / was specified, so only paan was compatible with the standard, and paan and taan were discriminable. 4- and 6-month-old Dutch- and Japaneselearning infants were also tested using the same procedure on their discrimination of labial (omba) and coronal (onta) sounds (Tsuji, Mazuka, Christia, \& Fikkert, 2015). Infants habituated to the labial sound omba discriminated the two types of trials, but infants habituated to the coronal sound onta did not, regardless of their language background.

Linguistic hypotheses, such as underspecification, provide one source of explanations for the observed asymmetry in speech perception. Consistent with the FUL model, Fennel
(2007) showed that infants detected a labial-to-coronal switch but failed to detect a coronal-to-labial switch. However, inconsistent with this hypothesis, a follow-up study (Fennell, van der Feest, \& Spring, 2010) showed that 14-month-olds were better able to detect a coronal-to-velar switch than a velar-to-coronal switch. To explain such discrepancy, they analyzed the onset formant frequencies of all the $/ \mathrm{b} /$, $/ \mathrm{d} /$ and $/ \mathrm{g} /$ tokens in their experimental stimuli, and discovered that $/ \mathrm{b} /</ \mathrm{d} /</ \mathrm{g} /$ in acoustic variability. Thus, the authors concluded that the asymmetries they observed might be better explained by acoustic variability than phonological specification.

We examine the same asymmetries in speech perception in the framework of Bayesian inference: Asymmetric perception of coronal and non-coronal places of articulation may arise from differences in the statistical properties of the coronal category and the non-coronal category in competition (e.g. within word minimal pairs). As presented later, coronal consonants as a category are more frequent and/or variable than non-coronal consonants in languages where asymmetric perceptions have been found. These statistical properties yield an asymmetric posterior distribution: Given a speech signal equidistant from a prototypical coronal and noncoronal articulation, the signal is more likely to be a coronal consonant.

## The Model

## Theoretical Overview

Following the tradition of categorical perception of speech sounds by Liberman et. al. (1957), Clayard et. al. (2008) and Feldman, Griffiths, and Morgan (2009), we interpret the asymmetry as the result of statistical inference of speech categories from a noisy speech signal. Listeners utilize available information from a variety of sources to achieve such a goal, including their prior knowledge of native speech categories and the acoustic properties of the speech signal.

A speech category is defined in the model as a distribution over acoustic dimensions. According to the model, when speakers articulate a sound, they first choose a speech category and then articulate a sound exemplar from that category. Each sound exemplar of the speech category varies from one another due to many factors, such as coarticulation, affect, focus and grammatical intonation. Although speaker's articulation over acoustic dimensions is multidimensional, for mathematical simplicity we assume articulations of a speech category can be reduced to a Gaussian distribution over a single acoustic dimension. Thus, the inventory of native speech categories is represented as a set of Gaussian distributions in the model. Different speech categories differ in the location of their means and in how much their articulation varies over the acoustic dimension (variance). In addition, categories may differ in frequency of occurrence with some categories used more frequently than others. The frequency of occurrence of each category is represented by its prior probability.

Listeners assume that the perceived signal was generated by a speech category that is masked by noise, including environmental noise and perceptual errors. The listeners' task is to recover the speech category that is most likely to have produced the speech signal. If there are two categories that could have generated the speech signal, listeners should take into account of both categories by weighing the statistical properties of each category. Suppose that in a hypothetical language, coronal and non-coronal categories have equal variance and equal frequency of occurrence. Then each of the two categories has an equal posterior probability to have generated a speech signal equidistant from the mean of the coronal and non-coronal distributions. However, in real languages, the coronal category is often higher in variances and/or frequencies of occurrence (the tip and blade of the tongue are more flexible and more variable). An ideal observer should take these factors into account, which may result in the posterior probability of the equidistant speech signal to be larger for the coronal than the non-coronal category.

## Mathematical Formulation

Here we formulate a Bayesian model of speech perception. Although we apply the model to the asymmetric perception of coronal and non-coronal consonants, the model may apply to any domain where a person observes a noisy signal from categories, with each category's exemplars being approximately Gaussian distributed ${ }^{1}$.

We consider speech perception as probabilistic inference. Listeners infer the category membership $C_{i}$ of a noisy signal $S$, as denoted by the conditional probability $p(S$ $\left.\mid C_{i}\right)$. We denote $i=1$ for coronal membership and $i=2$ for non-coronal membership. The posterior probability $p\left(C_{1} \mid S\right)$ that an observed noisy signal $S$ is a coronal sound can be obtained by Bayes' Rule:

$$
\begin{equation*}
P\left(C_{1} \mid S\right)=\frac{p\left(S \mid C_{1}\right) P\left(C_{1}\right)}{p\left(S \mid C_{1}\right) P\left(C_{1}\right)+p\left(S \mid C_{2}\right) P\left(C_{2}\right)} \tag{1}
\end{equation*}
$$

$P\left(C_{1}\right)$ in Equation 1 is the prior probability of the coronal category and $p\left(S \mid C_{I}\right)$ is the likelihood of observing stimulus $S$ given it was generated by a coronal category.

Now we derive a closed form solution to the posterior probability that a signal $S$ is coronal, $P\left(C_{I} \mid S\right)$. Suppose that the speaker articulates an exemplar $E$ of the coronal category $C_{l}$ and $E$ is Gaussian distributed with mean $\mu_{c 1}$, the prototype of the coronal category $C_{l}$. Exemplars within a category vary with variance $\sigma_{c l}{ }^{2}$. Therefore,

$$
E \mid C=C_{l} \sim N\left(\mu_{c 1}, \sigma_{c l}^{2}\right)
$$

The speaker's articulation, the speech signal passing through the environment, and the perceptual system of the listener all add noise to the exemplar. These sources of noise

[^183]combined into $\sigma_{S}{ }^{2}$. Therefore, the conditional distribution of $S \mid E$ is
$$
S \mid E \sim N\left(E, \sigma_{S}^{2}\right)
$$
where $\sigma_{S}{ }^{2}$ represents the random noise that is not due to within-category variability ${\sigma_{c l}}^{2}$. Due to conjugacy, $E$ can be marginalized out to form the likelihood $p\left(\mathrm{~S} \mid C_{1}\right)$, which is Gaussian distributed:
\[

$$
\begin{equation*}
S \mid C_{l} \sim N\left(\mu_{c 1}, \sigma_{c l}{ }^{2}+\sigma_{S}^{2}\right) \tag{2}
\end{equation*}
$$

\]

The likelihood's variance is the sum of two components: the category variance ${\sigma_{c l}}^{2}$, and random, environmental, and perceptual noise $\sigma_{s}{ }^{2}$. Plugging in the parameter values into a Normal distribution, Equation 2 can be written as:

$$
\begin{equation*}
p\left(S \mid C_{1}\right)=\frac{1}{2 \pi \sqrt{\sigma_{c 1}^{2}+\sigma_{S}^{2}}} \exp \left\{-\frac{\left(S-\mu_{c 1}\right)^{2}}{2\left(\sigma_{c 1}^{2}+\sigma_{S}^{2}\right)}\right\} \tag{3}
\end{equation*}
$$

Following the same logic, the likelihood of the non-coronal category $p\left(S \mid C_{2}\right)$ is

$$
\begin{equation*}
p\left(S \mid C_{2}\right)=\frac{1}{2 \pi \sqrt{\sigma_{c 2}^{2}+\sigma_{S}^{2}}} \exp \left\{-\frac{\left(S-\mu_{c 2}\right)^{2}}{2\left(\sigma_{c 2}^{2}+\sigma_{S}^{2}\right)}\right\} \tag{4}
\end{equation*}
$$

Plugging Equations 3 and 4 into Bayes Rule (Equation 1), we can rewrite the posterior probability of the coronal category given the perceived speech signal $S$ as

$$
\begin{equation*}
P\left(C_{1} \mid S\right)=\frac{1}{1+\beta_{1} \exp \left\{\beta_{2} S^{2}+\beta_{3} S+\theta\right\} * \frac{P\left(C_{2}\right)}{P\left(C_{1}\right)}} \tag{5}
\end{equation*}
$$

where
$\beta_{1}=\frac{\sqrt{\sigma_{c 1}^{2}+\sigma_{S}^{2}}}{\sqrt{\sigma_{c 2}^{2}+\sigma_{S}^{2}}}, \quad \beta_{2}=\frac{\left(\sigma_{c 2}^{2}-\sigma_{c 1}^{2}\right)}{2\left(\sigma_{c 2}^{2}+\sigma_{S}^{2}\right) *\left(\sigma_{c 1}^{2}+\sigma_{S}^{2}\right)}$
$\beta_{3}=\frac{-2\left(\mu_{c 1}\left(\sigma_{c 2}^{2}+\sigma_{S}^{2}\right)-\mu_{c 2}\left(\sigma_{c 1}^{2}+\sigma_{S}^{2}\right)\right)}{2\left(\sigma_{c 2}^{2}+\sigma_{S}^{2}\right) *\left(\sigma_{c 1}^{2}+\sigma_{S}^{2}\right)}$
The closed form solution for the posterior is given by Equation 5. We explore how the relative differences in variability and frequency between coronals and noncoronals affect the posterior probability of coronals $P\left(C_{1} \mid S\right)$. Then, we analyze the natural statistics of coronals and non-coronals to determine whether perceptual asymmetries would arise from them in an ideal observer.

## Quantitative Evaluation

Suppose that in a hypothetical language, the coronal category and the non-coronal category are equally frequent - have equal priors, $P\left(C_{1}\right)=P\left(C_{2}\right)$. Also suppose that the categories are equally variable, as encoded by $\sigma_{c l}{ }^{2}=\sigma_{c 2}{ }^{2}$. In these circumstances, Figure 1 depicts the posterior probability for a noisy speech signal to be perceived as a coronal sound, $P\left(C_{l} \mid \mathrm{S}\right)$.

Given equal variance and equal frequency of occurrence, the category boundary divides the perceptual space into two equal parts. This indicates that a noisy signal equidistant
from the category prototypes has an equal probability of being perceived as a coronal or a non-coronal. We now examine how heterogeneity of category variances (i.e. if $\sigma_{c l}{ }^{2}$ $\neq \sigma_{c 2}{ }^{2}$ ) and unequal frequency (i.e., if $P\left(C_{1}\right) \neq P\left(C_{2}\right)$ ) affect the posterior probability of the coronal category $P\left(C_{I} \mid S\right)$.

Figure 1: Posterior Probability (category boundary) of the coronal category given equal variance and equal frequency

Effect of Category Variance In many languages where perceptual asymmetries are found, exemplars of the coronal category are more variable than exemplars of the noncoronal category. For example, using a modified Levenshtein distance metric, Cohen-Priva (2012) aligned the underlying (dictionary) forms and phonetic realizations in the Buckeye Natural Speech Corpus (Pitt, Johnson, Raymond, Hume \& Fosler-Lussier, 2007). He created an articulatory confusion matrix for English segments in the corpus. Of the 43,915 coronal stop tokens, 21,576 (49\%) were pronounced either as allophonic variants or as some other phonemes, whereas of the 64,288 noncoronal stop tokens, only 2,997 ( $5 \%$ ) were pronounced as allophonic variants or as an alternative phoneme. Such analyses indicate that coronal stops are about 10 times more variable than noncoronal stops. Moreover, coronals (9\% of all coronal segments; $20 \%$ of coronal stops were deleted) were also more likely to be deleted than noncoronals ( $5 \%$ of all noncoronal segments, $4 \%$ of noncoronal stops were deleted).

The differences in natural language statistics of the within-category variances between coronal and non-coronal categories in the Buckeye corpus provide the following constraint: $\sigma_{c l}{ }^{2}>\sigma_{c 2}{ }^{2}$. Suppose that $\sigma_{c l}{ }^{2}=5 \sigma_{c 2}{ }^{2}$ (approximately the difference in the segment deletion rates for the English data in the Buckeye corpus), the posterior probability for a noisy speech signal to be perceived as a coronal sound is displayed in Figure 2 (with the case where the within-category variances are equal for reference).

As the red dashed curve shows in Figure 2, the category boundary has shifted towards the non-coronal category, leaving a larger posterior probability for a noisy signal equidistant between the categories to be perceived as a coronal sound. Suppose that the posterior probability for the speech signal [g] to be perceived as a coronal sound /d/ is 0.1 given equal variance (blue curve). The shift of category boundary (dashed red line) leads to an increase in the posterior probability for [g] to be perceived as /d/ (to a value around 0.2 ). Thus, due to the higher variance of the coronal
category, an ideal listener is more likely to perceive $/ \mathrm{g} /$ as an exemplar of the /d/ category. Now we examine the reversed direction, i.e. a coronal ([d]) signal is changed to a noncoronal sound (/g/) given unequal variance.

Figure 2: Posterior probability (category boundary) of the coronal category as a result of unequal variance.

Figure 3: Posterior probability (category boundary) of the non-coronal category as a result of unequal variance.

Figure 3 shows the posterior probability for a speech signal to be perceived as non-coronal. The blue curve in Figure 3 depicts the posterior probability given equal within-category variances. The red dashed curve shows the posterior probability given that the coronal category has larger variance. As the red dashed curve in Figure 3 shows, the category boundary has shifted towards the non-coronal category, producing a smaller posterior probability for a noisy signal to be perceived as a non-coronal sound. Suppose that the posterior probability for the speech signal [d] to be perceived as a non-coronal sound /g/ is 0.1 given equal within-category variances (blue curve). The shift of category boundary (red dashed curve) leads to a decrease in the posterior probability for [d] to be perceived as $/ \mathrm{g} /$ (to a value of approximately 0 ).

To summarize Figures 2 and 3, increasing the variance of the coronal category causes an ideal listener to be more likely to perceive a non-coronal signal ( $[\mathrm{g}]$ ) as an exemplar of the coronal category ( $/ \mathrm{d} /$ ), and less likely to perceive a coronal signal ([d]) as an exemplar of the non-coronal category (/g/). [g] can be a /d/but [d] cannot be a $/ \mathrm{g} /$.

Effect of Frequency of Occurrence Coronals also occur more often in natural speech than non-coronals. Table 1 (adapted from Ren, Cohen-Priva \& Morgan, under review) shows the frequencies of occurrence of the coronal category in three languages from typologically distinctive families.

Coronal segments in these languages are at least twice as frequent as either labial or velar segments (Japanese velar stops are exceptional and we will discuss this case later).

Frequency is represented by prior probabilities in the model. $P\left(C_{1}\right)$ and $P\left(C_{2}\right)$ are the prior probabilities of the coronal category and the non-coronal category, respectively. Suppose that $P\left(C_{1}\right)=2 P\left(C_{2}\right)$ (approximately the relative frequency in Table 1).

Table 1: Frequencies of segments in CALLHOME transcripts by place of articulation

|  | Consonant |  | Labial | Coronal | Velar |
| :---: | :---: | :---: | :---: | :---: | :---: |
| Language | Segments |  |  |  |  |
| Arabic | All |  | 91,409 | 222,774 | 94,624 |
|  | Stops |  | 25,592 | 54,279 | 38,544 |
| Japanese | All |  | 57,513 | 236,813 | 99,760 |
|  | Stops |  | 15,854 | 62,241 | 79,117 |
| Spanish | All |  | 101,717 | 320,167 | 53,483 |
|  | Stops | 44,366 | 62,961 | 43,005 |  |

Figures 4 and 5 show the posterior probability of the coronal category $P\left(C_{l} \mid S\right)$ and the non-coronal category $P\left(C_{2} \mid S\right)$, respectively. The category boundary (green dashed curve) has shifted towards the non-coronal category due to the larger prior probability of the coronal category. For comparison, the posterior probability given equal prior probabilities of coronals and non-coronals is plotted as the blue curve. This results in a larger posterior probability for a noisy non-coronal signal ([g]) to be perceived as a coronal sound (/d/) (Figure 4) and a smaller posterior probability for a noisy coronal signal ([d]) to be perceived as a non-coronal sound (/g/) (Figure 5).

Figure 4: Posterior probability (category boundary) of the coronal category as a result of unequal frequency

Figure 5: Posterior probability (category boundary) of the non-coronal category as a result of unequal frequency

Thus, similar to the effect of variance, larger frequency of occurrence of the coronal category also causes an ideal listener to be more likely to accept that the noisy signal [g] is an exemplar of the /d/ category but not vice versa, predicting the same pattern of asymmetry.

Japanese velar sounds provides an interesting test for an ideal listener model. As Table 1 shows, velar stops (/k/ and $/ \mathrm{k}^{\mathrm{y}} /$ ) occur more often than coronal stops (/t/) in Japanese. Our model predicts that assuming equal variance, the pattern of asymmetries should be reversed for Japanese listenersthey should be less sensitive to sound changes from noncoronal to coronal than vice versa. Japanese studies (see Tsuji et. al, 2015) so far have only tested infant listeners with labial (omba) and coronal (onta) but not velar (/k/ and $/ \mathrm{k}^{\mathrm{y}} /$ ) phonemes. Future experimental studies should examine this prediction with these velar and coronal phonemes.

Effect of Variance and Frequency In many languages both the prior distribution and the variance of the coronal category are larger than those of the non-coronal category. Here we examine how prior and variance interact.

Figure 6: Posterior probabilities of the coronal category as a result of unequal frequency and/or unequal variance

Figure 7: Posterior probabilities of the non-coronal category as a result of unequal frequency and/or unequal variance

Figure 6 shows the posterior probabilities of acoustic signals to be perceived as a coronal sound and Figure 7 shows the posterior probabilities of acoustic signals to be perceived as a non-coronal sound with differing assumptions regarding the relative frequency and variance of coronal and non-coronal sounds. The grey line shows category boundary shift as the result of both the larger prior and variance of the coronal category. As shown in both figures, the pattern of asymmetry remains the same, but there is an even larger posterior probability for a noncoronal signal to be perceived as a coronal (Figure 6), and
an even smaller posterior probability obtained for a noncoronal signal to be perceived as a coronal sound (Figure 7). Thus, with larger variance and larger frequency of occurrence, an ideal listener is even more likely to perceive a non-coronal signal ( $[\mathrm{g}]$ ) as a coronal sound (/d/), but even less likely to perceive a coronal signal ([d]) as a non-coronal sound (/g/).

## General Discussion

We presented an alternative account for the asymmetry in perceiving coronal and non-coronal consonants in speech processing: They arise due to Bayesian inference given the natural statistics of coronals and non-coronals. Listeners make use of their represented category frequency and variance to make inference about the category membership of a perceived signal. Asymmetry occurs when the two speech categories in competition (e.g. within a word minimal pair) are not equal in variance and/or frequency of occurrence.

Our approach diverges from the currently predominant approach in linguistics, which explains the asymmetric perception as due to underspecification of the coronal place of articulation. This theory relies on the special phonological status of coronal sounds only. Conversely, our approach accounts for the asymmetry as due to the relative statistical properties of different speech categories. The underspecification hypothesis is a language-specific, innate constraint, whereas our account is experience- (learning-) based and domain-general. For example, Quinn, Eimas \& Rosencrantz (1993) found that 4-month-olds habituated to pictures of cat faces could easily detect a change to a picture of a dog face. However, infants habituated to dog faces failed to detect a change to a cat face. A series of follow-up studies investigating this asymmetry confirmed that dog stimuli are more variable in appearance and that when variability was equated across categories the asymmetry disappeared (Eimas, Quinn \& Cowan, 1994; Mareschal, French \& Quinn, 2000). In music perception, Delbé, Bigand \& French (2006) examined effects of variability by training non-musician adults with two distributions of pitch sequences differing in variability and then testing them on sensitivities to the two directions of changes. Results indicated that changes from the less variable category to the more variable category are more detectable than vice versa.

Our account derives predictions to test in future work. First, category frequencies and within-category variances are learned from early language exposure. In languages where non-coronals are more frequent and/or vary more within-category, the model predicts that the asymmetry should be reversed. Second, at any developmental stage when listeners have stable representations of the corresponding frequency of occurrence and variance of two competing categories, perceptual asymmetries may occur in speech processing. Third, frequency and variance should have independent effects on speech processing. Further, for mathematical simplicity we assumed that a speech category is a Gaussian distribution over a single acoustic dimension.

Thus, the model does not differentiate between different sources/dimensions of variability (e.g., contextual effect, Ganong, 1980). Assuming we can control these factors experimentally and test the posterior probability of coronal and non-coronals in a fine-grained manner, the model makes quantitative predictions as to the precise form of the asymmetry. None of these predictions arises from UG but from the statistics of speech input exposure.

It is also worth noting that not all asymmetries in speech or other cognitive domains are caused by category natural statistics. Findings on vowel (Polka \& Bohn, 2003) and face (Corneille, Goldstone, Queller \& Potter, 2006) perception, for example, have suggested that similar asymmetric patterns could also be due to stimulus saliency and experimental training. Future studies may examine how these factors interact with frequency of occurrence and variances in category perception.

In conclusion, we have provided a novel explanation for the asymmetry between coronal and non-coronal sounds in speech perception. Whereas phonological specification as a hypothesis could be useful for linguistic purposes, it is not necessary to account for asymmetries in speech perception.

#### Abstract

Natural language dialogue between multiple participants requires conversational grounding, a process whereby interlocutors achieve a shared understanding. However, the mechanisms involved in the grounding process are under dispute. Two prominent models of dialogue between multiple participants are: interactive alignment, a simpler model that relies on automatic priming processes within individuals, and interpersonal synergy, a more complicated model emphasizing coordinated interaction across participants. Using recurrence analysis methods, Fusaroli and Tylén (2016) simultaneously evaluated both models and showed that alignment is an insufficient explanation for grounding or for the teams' task performance. However, their task and resulting dialogues lack the typical complexity of conversations or teamwork. Furthermore, the interpersonal synergy model was not clearly differentiated from other coordination-focused models of grounding with explicit foundations in strategy and intentionality (i.e., audience design, joint activity, perspective taking). Here we test recurrence-based models in a collaborative task that stressed the grounding process. Results support a coordination model of dialogue over the alignment model as a predictor of performance. Content-based mediation analyses showed that the coordination recurrence model includes critical aspects of strategic design and is not purely interpersonal synergy.

Keywords: Communication; Dialogue; Conversational Grounding; Multi-person Cognitive Models

## Introduction

The grounding process is a key focus of human dialogue research (Clark \& Wilkes-Gibbs, 1986; Clark \& Brennan, 1991; Branigan, Pickering, \& Cleland, 2000; Pickering \& Garrod, 2004). Conversational grounding is the process whereby interlocutors determine that they have understood one another, and results in additions to shared knowledge and understanding. Grounding underlies successful collaboration by developing a shared context, supporting immediate feedback of actions, and allowing for incremental progress in conveying intent (Brennan, 1998). Grounding processes influence communication effectiveness and resulting performance metrics such as laboratory task completion time (Clark \& Wilkes-Gibbs, 1986; Clark \& Krych, 2004; Reitter \& Moore, 2014), due in part to the requirements for shared understanding in collaborative tasks.

The proposed models of dialogue use multiple conversational participants as the unit of analysis, but suggest differ-
ent mechanisms for grounding processes (Horton \& Gerrig, 2005; Louwerse, Dale, Bard, \& Jeuniax, 2012; Schober \& Brennan, 2003). One prominent model is interactive alignment (Pickering \& Garrod, 2004). Alignment (also entrainment, convergence or imitation) refers to the increasing similarity of the interlocutors through adoption of each other's phonetic, prosodic, lexical, or syntactic content (Branigan et al., 2000). Alignment credits this to priming, an automatic, covert mechanism by which recent experiences influence the likelihood of future contributions. Alignment at lower linguistic levels presumably propagates to the semantic level and the situation model of the interlocutors, which forms the basis of a shared understanding of each other and of the world. Thus alignment provides an appealing, conceptually straightforward explanation of grounding phenomena.

Some researchers question the sufficiency of alignment to explain common ground and grounding of new material. The prominent alternative models of human grounding processes emphasize coordination and complementarity such as adjacency pairs in the interaction, rather than similarity. Coordination models separate into two categories: strategic design and interpersonal synergy. In strategic design, speakers appear to design utterances in light of their audience's knowledge. The knowledge may concern the audience's culture, group membership, spatial perspective, or previous conversational interactions (Clark \& Marshall, 1981; Schober, 1993). Strategic design is marked by intentionality-goaldirected conversational behavior that seeks and displays evidence of understanding. These goals invoke an additional layer of exchange concerning the collaborative management of the conversation, called Track 2 dialogue (Clark, 1996). Track 2 dialogue includes: acknowledgements of understanding, displays of non-understanding, and requests for clarification. Interpersonal synergy is a recent and relatively less examined theory. The coordination from interpersonal synergy either does not require intentionality (Fusaroli, RaczaszekLeonardi, \& Tylén, 2014), or redefines it (see also Gallagher \& Miyahara, 2012). Interlocutor coordination emerges from a complex dynamical system achieving stability in a specific context, and becomes cemented in interaction routines. The
introduction of new interlocutors into established interaction routines disrupts communication (Fusaroli et al., 2014).

## Quantification of Recurrence

Separate bodies of research have investigated interactive alignment and coordination models, but to the authors' knowledge only one study has attempted to examine the two theories with competing models for the same performance data (Fusaroli \& Tylén, 2016). Recent advancements in the analysis of dyadic dialogue utilize the non-linear analysis methods of recurrence quantification analysis (RQA) and cross recurrence quantification analysis (CRQA). RQA and CRQA originated from the study of dynamic systems and were developed to examine recurrence in chaotic systems, i.e., repetition of states in time series data. RQA seeks recurrence within one time series (analogous to autocorrelation) and CRQA seeks recurrence between two time series (analogous to cross-correlation). These methods reveal and quantify order and organization that is not readily apparent. Originally built for continuous data, these methods have been adapted for categorical data and used in the analysis of lexical content (e.g., Orsucci et al., 2013) and syntax (e.g., Dale \& Spivey, 2006).

## Grounding Process Models

Fusaroli and Tylén (2016) created models for alignment and coordination using recurrence analyses, and discriminated between these models by their relationship to task performance. They argued that the coordination recurrence model specifically represented interpersonal synergy, though strategic design is an unexamined alternative. Their approach is illustrated in Figure 1. The same time series contents appear in each panel but different outlined patterns reflect the different recurrence sensitivities. The alignment model detects patterns transferred from one speaker to the other, such as 'XYY' from speaker A to speaker B (though not illustrated, patterns that go from B to A will also be detected). The coordination model detects speaker-independent patterns, including patterns across speakers such as adjacency pairs. For instance, the pattern 'YXZXY' occurs between A and B and later B and A. In the self-consistency baseline model, recurrence of patterns within A and within B were tested separately selecting for analysis whoever had the higher recurrence rate.

The dialogue in Fusaroli and Tylén (2016) resulted from two participants performing a visual detection task. Each participant made an independent judgment of whether the target signal appeared in the first interval or the second interval of the stimulus. Dialogue only occurred when their judgment disagreed-they discussed the stimulus and came to a collaborative judgment. Collaborative benefit was computed as the ratio between joint performance and the highest individual's performance, where ratio values greater than 1 indicated a benefit from the joint decision. Recurrence values for lexical choice, pauses, and prosody were calculated according to each theory and then used as predictors in separate regression
models with collaborative benefit as the outcome, thereby relating each grounding model to task performance.

Both the alignment and coordination models were related to task performance, but coordination was a better predictor of performance for the lexical level and the speech/pause level. The two models were similar for the prosodic level.

This quantitative approach provides a promising beginning to the direct comparison between grounding models. However, the task and dialogue content was very limited. The task used simple visual psychophysics stimuli and required a simple choice between two intervals. The vocabulary and conceptualizations that appeared in the dialogues, though not reported, were most likely very limited. The importance of these results for more complex dialogues in a more complicated task setting was not established. In addition, the analysis failed to differentiate between interpersonal synergy and strategic design. Although similar in their emphasis on coordination, these models maintain important distinctions regarding the characterization of cognitive mechanisms. Intentionality (and goal-directed behavior) is one way to differentiate between the two models but their correspondence to the coordination recurrence model is not intuitive. Additional analyses must distinguish between synergy on the one hand and design and intentionality on the other.

## Current Study

The current study examined a team task that stressed the grounding process and applied the RQA and CRQA models for coordination and alignment on two lexical levels: the morpheme level used in Fusaroli and Tylén (2016) and the word level. As discussed below, word-level analysis facilitated an additional mediation analysis of recurrence model results. The task and resulting team dialogue resulted in rich, long dialogue with numerous and diverse content to stress grounding processes. Consistent with Fusaroli and Tylén, we hypothesized that the recurrence metrics calculated based on the coordination model would have a stronger relationship to performance than the alignment model. In addition, we sought to investigate what the coordination recurrence model is measuring, and its relationship to the strategic design model of grounding. We created a lexicon of Track 2 dialogue (described below) and tested if the coordination model statistically mediates the relationship between Track 2 dialogue and performance. Mediation can identify a process that underlies an observed relationship (Baron \& Kenny, 1986). We used mediation to see if the variance in performance explained by Track 2 dialogue is reduced by the coordination model. Such mediation demonstrates that the recurrence model for coordination captures aspects of strategic design in addition to, or possibly instead of, interpersonal synergy.

## Methods

## Uncertainty Elicitation Task Corpus

We used materials from the Uncertainty Elicitation Task corpus (Romigh, Rothwell, Greenwell, \& Newman, 2016).

Figure 1: Illustration of the recurrence tests for alignment, coordination, and baseline (adapted from Fusaroli \& Tylén, 2016). Alignment models were sensitive to patterns transferred between speakers. Coordination models were sensitive to patterns independent of speaker, which included patterns across speakers as illustrated here. Baseline models were sensitive to patterns within one speaker (i.e., self-consistency). (Figure used with permission from John Wiley and Sons).

Like Fusaroli and Tylén (2016), this was a symmetric dialogue task-no one speaker had the answer, so the conversational dynamics were flexible and negotiable. Partners had many unlabeled pictures of various real world scenes from both an overhead perspective and street-level perspectives, that they had to match with each other. This led to conceptually complex and diverse dialogues. Partners discussed: house features (e.g., siding, roof, windows, garage, porch, columns, 1 or 2-story), lot features (e.g., trees, yard, fence, driveway, garden, sidewalk, corner lot, playground, pool), street/neighborhood features (e.g., presence of stopsign, power lines, presence of alleyways, nearby parks), and car features (e.g., number of cars, type of vehicle: truck/van/sedan, color).

On each trial, two people sat in separate rooms and worked together to locate street-level pictures of different houses on an overhead map (Figure 2). Street-level images and satellite images were obtained from Google Maps with labels (e.g., street names) removed. The overhead map was the same for both participants and had 12 numbered buildings (1-12). The participants each had street-level pictures of 6 of those buildings on the right hand side of their screens. The participants were given street-level images from different points of view and they had to determine that they were discussing the same building. Their task was to relate the street-level views to the overhead map by labeling the street-level with a number $1-12$, and the trial ended when all street-level images had correct number labels. ${ }^{1}$ As accuracy was held constant, completion time was the performance metric (shorter times indicated better performance). Performance in the task was expected to be related to conversational grounding because participants needed to communicate effectively-make definite references to unlabeled street-level views of houses, share the information from their unique street-level views, and discuss the similarity between street-level and overhead imagery. Five teams of 2 people and each team completed 8 trials for a total of 40 trials. ${ }^{2}$

[^184]

Figure 2: Screen shot from the Uncertainty Elicitation Task. Building numbers appear on the overhead map and participants labeled street-level images using the drop-down boxes centered on each row of images.

## Recurrence Analyses

Our analysis examines recurrence at two lexical levels (the word level and the morpheme level) in search of the model that best predicts task-specific performance.

Prior to calculating the recurrence plot, RQA and CRQA require a number of parameters. We used values keeping with Fusaroli and Tylén (2016) and other categorical analyses of transcript data (Orsucci et al., 2013). The radius value was set to 0 , meaning only an exact match would be counted as a recurrence, which is appropriate for nominal data. For example, for the word-level analysis each word was given an arbitrary unique numerical identifier. The threshold for a line (i.e., recurrence patterns that are parallel to the positive diagonal) was set at 2 . Time delay was set to 1 . The word-level analysis used single words as the unit of analysis, which was specified by an embed value of 1 . The morpheme level ${ }^{3}$ used a 3-letter unit of analysis (i.e., a letter trigram), which was specified by an embed value of 3 .

[^185]The three models in Figure 1 were tested. The alignment model was represented by CRQA of a time series of Speaker A with a time series of Speaker B. To preserve the time sequence and phase information of the entire dialogue, added codes in each time series replaced the other speaker's contributions. The coordination model was represented by RQA of the time series for the entire block (Speakers A \& B). A baseline self-consistency model was represented by performing RQA of each speaker's time series with his/herself and using the recurrence plot with the highest recurrence rate.

The three separate recurrence models output separate recurrence metrics for different regression models, in order to assess the relationship of each recurrence model to task performance. This analysis process differs from a typical regression procedure where predictors are added or removed from a single regression model. Here, three different regression models with the same four predictors were based on different recurrence calculations. Individual recurrence metrics of recurrence rate, determinism, average line length, and line entropy were calculated for each of the three models (i.e., alignment, coordination, baseline), for each trial in the Uncertainty Elicitation Task corpus. The recurrence metrics quantify how much recurrence occurs (Recurrence Rate, $R R$ ), the proportion of recurrence that appears in longer sequences (Determinism, DET), the average length of recurrence sequences (Line Length, L), and the variety in recurrence lengths (Line Entropy, ENT). Recurrence metrics then functioned as predictors for a linear regression model of the performance scores (i.e., completion times) for each trial. Linear models were evaluated using $A d j R^{2}$ values. These models follow the analysis procedures from Fusaroli and Tylén (2016) assuming data from a between-subjects design. Subsequent tests address the repeated measures (i.e., within team) nature of our data. Analyses were performed in R, using the crqa package (Coco \& Dale, 2014).

We also created a lexicon (i.e., word list) for Track 2 dialogue using the Linguistic Inquiry and Word Count 2015 (LIWC) text analysis program (Pennebaker, Boyd, Jordan, \& Blackburn, 2015). Our analysis relied on two separate lexicons that may capture Track 2 issues of dialogue management: Assent (e.g., agree, OK, yes) and Certainty (e.g., indeed, always, never). We reasoned that Assent may capture an addressee's acceptance of a speaker's installment and Certainty may capture confusion regarding an installment. We tested how well the LIWC categories accounted for performance by using the LIWC counts (frequencies of words in the Assent and Certainty lists) for each trial as predictors of performance. We then tested if the parameters from the coordination recurrence model statistically mediated the relationship between the LIWC categories and performance, following the 'Causal Steps' procedure (Baron \& Kenny, 1986). This involved three "Steps" where the LIWC categories were treated as independent variables (IVs) and the recurrence parameters were treated as mediators (Ms): 1) the IVs and performance, 2) the IVs and the Ms, and 3) the (IVs +Ms ) and
performance. Multiple linear regression was used for Steps 1 and 3 while MANOVA was used for Step 2 in order to test for a relationship between multiple LIWC categories and multiple recurrence-parameter mediators.

## Results

First we show that the observed recurrence was not due to chance. Next we show that the coordination model has stronger relationships to task performance than the alignment model for both the word-level and the morpheme-level analyses. Moreover, the coordination model accounts for variance in performance after controlling for team differences whereas the alignment model does not. Mediation analysis shows that the coordination model reflects aspects of Track 2 dialogue.

## Chance Analysis

The structure of recurrence represented by these metrics was not due to chance. We compared the outputs of the recurrence analyses of the data to outputs using a shuffled time series (i.e., randomly ordering the words in the time series).

Paired $t$-tests indicated that recurrence structure is significantly different from shuffled controls for all models for all values (all $=p<.0001$ ), except for word-level recurrence rate. For the word-level test, the recurrence rates are exactly the same because shuffling does not add or remove words.

## Word-Level Analyses

The linear regression models for word-level analyses are shown on the left side of Table 1. The coordination model accounted for more of the variance in completion times (AdjR ${ }^{2}$ $=0.66)$ than the alignment model and the baseline model $\left(\operatorname{Adj} R^{2}=0.14 \& 0.51\right.$, respectively $)$. The baseline model accounted for more variance than the alignment model.

## Morpheme-Level Analyses

The linear regression models for morpheme-level analyses are shown on the right side of Table 1. The pattern of results was the same as the word level. The coordination model accounted for more of the variance in performance $\left(\operatorname{Adj} R^{2}=\right.$ 0.76 ) than the alignment model or the baseline model ( $\operatorname{Adj} R^{2}$ $=0.32 \& 0.64$, respectively). The baseline model accounted for more variance than the alignment model as well.

## Controlling for Team Differences

Space precludes a complete presentation, but controlling for team differences was necessary for the within-subjects design and Team ID was a significant predictor of performance ( $F(4$, $\left.35)=6.04, p<.001, \operatorname{Adj} R^{2}=0.34\right)$. Using statistical controls that removed the variance between teams, we tested if each recurrence model could explain the residual variance. The alignment model did not $\left(F(4,31)=0.53, p=.72, \Delta R^{2}\right.$ $=0.04)$ whereas the coordination model $\operatorname{did}(F(4,31)=8.21$, $p<.001, \Delta R^{2}=0.30$ ).

Table 1: Word-level analyses (left) and Morpheme-level analyses (right)—linear regression models for alignment, perspective taking, and baseline. Predictors were recurrence rate (RR), determinism (DET), average line length (L), and line entropy (ENTR). $\left({ }^{*} p<.05, * * p<.01, * * * p<.001\right.$ )

| Theory | Word-Level |  |  |  | Morpheme-Level |  |  |  |

## Mediation Analysis

Linear regression results for the LIWC categories Assent and Certainty appear at the top of Table 2. These categories significantly predicted task completion times $\left(A d j R^{2}=0.43\right)$. The coefficients for Assent and Certainty were both negative. More instances of these words resulted in faster completion times (i.e., better performance). Additional mediation tests used the word-level coordination model's recurrence parameters. The MANOVA in Step 2 showed that the LIWC lists were related to these recurrence parameters $(F(4,34)=6.62$, $p<0.001$, and $F(4,34)=9.70, p<0.001$, respectively). Step 3 showed that the recurrence parameters mediated the relationship between task completion times and LIWC categories (Table 2 bottom portion) by eliminating their significance.

Table 2: Mediation analysis for LIWC—See text for details. (*p<.05, **p<.01, ***p<.001)

| Step 1- LIWC's relation to performance |  |  |  |
| :---: | :---: | :---: | :---: |
| Assent*** | < . 001 | Certainty** | < . 01 |
| Step 2-LIWC's relation to Coordination |  |  |  |
| Assent*** | < . 001 | Certainty*** | < . 001 |
| Step 3-LIWC's \& Coordination's relation to performance |  |  |  |
| Assent | 0.30 | Certainty | 0.89 |
| $\mathrm{RR}_{S}{ }^{*}$ | <.05 | $\mathrm{L}_{S}{ }^{* *}$ | $<.01$ |
| $\mathrm{DET}_{S}$ | 0.32 | $\mathrm{ENTR}_{S}$ | 0.32 |

## Discussion

Findings clearly supported the coordination model over the alignment model for both levels of analysis. At the word level, coordination accounted for $52 \%$ more of the variance in task completion times than alignment, and $44 \%$ more at the morpheme level. Although the baseline model performed better than Fusaroli and Tylén (2016), the pattern of findings for
alignment and coordination was similar. Moreover, the relationships between coordination and performance found here were larger than those shown by Fusaroli and Tylén, despite the longer, more complex dialogues. While the coordination model accounted for performance above team differences, the alignment model did not.

Recent research agrees with these findings that communication processes are more complicated than priming-based alignment. Rather than repeating content, interlocutors' contributions provide new content that compliments past contributions (Tenbrink, Andonova, \& Coventry, 2008). Many studies of alignment do not include performance outcomes (e.g., Branigan et al., 2000) and therefore may not identify these insufficiencies. Alignment may still occur over longer time scales, which has been shown to predict task performance (Reitter \& Moore, 2014). The alignment recurrence model used here did not distinguish between short-term and long-term alignment, so it is possible that long-term alignment is responsible for the relationship between alignment and performance.

Beyond support for a general coordination model, the coordination recurrence model appears to contain aspects of strategic design. Indeed, Track 2 dialogue alone accounted for more variance in performance than alignment did at both the word level and morpheme level $\left(A d j R^{2}=0.43\right.$ vs. $0.14 \&$ 0.34 , respectively). Recent research supports the importance of design-utterances often reflect different perspectives and interlocutors appear to keep track of multiple perspectives at the same time (Brennan, Schuhmann, \& Batres, 2013).

## Conclusion

In this paper, we quantitatively modeled conversational grounding processes between two interlocutors. We tested two models for this process, alignment and coordination, in a complex collaborative grounding task. The results clearly discount an alignment model as a sufficient model of the conversational grounding process. Results also indicated that the coordination recurrence model is closely related to Track 2
dialogue and therefore strategic design models of the conversational grounding process must be considered. Our future research will examine whether strategic design accounts for these findings in addition to or to the exclusion of interpersonal synergy.

# Comprehenders Model the Nature of Noise in the Environment 

Rachel Ryskin<br>Massachusetts Institute of Technology<br>Richard Futrell<br>Massachusetts Institute of Technology, Cambridge, MA, USA<br>Edward Gibson<br>MIT

#### Abstract

Recent work suggests that language understanding is the result of rational inference over a noisy channel. Upon perceiving a sentence, listeners decode the speaker's intended sentence from the prior probability that a speaker would say that sentence and the probability that it would be corrupted to the perceived sentence by noise. Here we examine the listener's noise model. Readers were asked to correct sentences if they thought they contained an error. We manipulated context such that participants corrected exposure sentences containing either deletion, insertion, swap, mixed, or no errors (e.g., swap: A bystander was rescued by the fireman in the time of nick.). Test sentences were syntactically licensed but implausible (e.g., The bat swung the player). On test sentences, participants' corrections differed by exposure condition. This suggests participants track the type of errors that have a higher likelihood and make inferences about the intentions of the speaker accordingly.

# Is the strength of regularisation behaviour uniform across linguistic levels? 

Carmen Saldana (C.C.Saldana@sms.ed.ac.uk), Kenny Smith, Simon Kirby \& Jennifer Culbertson<br>Centre for Language Evolution, School of Philosophy, Psychology and Language Sciences, The University of Edinburgh, Dugald Stewart Building, 3 Charles Street, Edinburgh, EH8 9AD, UK

#### Abstract

Human languages contain very little unconditioned variation. In contexts where language learners are exposed to input that contains inconsistencies, they tend to regularise it, either by eliminating competing variants, or conditioning variant use on the context. In the present study we compare regularisation behaviour across linguistic levels, looking at how adult learners respond to variability in morphology and word order. Our results suggest similar strengths in regularisation between linguistic levels given input languages whose complexity is comparable.

Keywords: artificial language learning; statistical learning; regularisation; variation; complexity; morphology; word order

## Introduction

While languages exhibit variation at all linguistic levels, in the form of paraphrases, synonyms, allomorphs and allophones, that variation tends to be predictable: the choice of variant is (at least partially) conditioned by some aspect of the social or linguistic context. Occasionally, language learners are exposed to input that involves inconsistencies, for instance, when new variants are introduced into an established system, or when conventions are still not established, as in emerging languages (Senghas \& Coppola, 2001; Siegel, 2004). Learners under those circumstances tend to reduce or remove such inconsistencies, i.e. they regularise their input. This can be achieved either by removing competing variants, or conditioning variant choice on the context (Ferdinand, Kirby, \& Smith, 2017).

Regularisation has been documented extensively across linguistic levels (i.e. phonology, morphology, syntax and the lexicon) in natural language; e.g. in language acquisition, language change, and in emerging languages (Senghas \& Coppola, 2001; Siegel, 2004; van Trijp, 2013). Experimental studies involving artificial language learning and statistical learning techniques report regularisation behaviour during the learning and production of probabilistic unconditioned variation in different linguistic units, across different linguistic levels (Culbertson, Smolensky, \& Legendre, 2012; Fehér, Wonnacott, \& Smith, 2016; Hudson Kam \& Newport, 2005, 2009; Wonnacott \& Newport, 2005). Nevertheless, it still remains an open question whether regularisation behaviour applies with uniform strength across linguistic levels and to what extent level-specific biases interact with regularisation during language learning and use.

## Level-specific effects in regularisation behaviour

Research in second language acquisition and pidgin and creole studies has highlighted different developmental paths for morphology and syntax cross-linguistically (Good, 2015; Slabakova, 2013). Studies in pidginisation suggest that, in
periods when pidgins are highly inconsistent, linguistic levels might behave differently: morphologically complex traits such as inflectional morphology seem to be highly simplified whilst syntactic traits such as word order tend to reproduce the input complexity more closely (Good, 2015; Siegel, 2004). Good (2015) argues that this asymmetry is given by a break in transmission from source languages for morphological traits, which are only successfully transmitted if an entire contrasting paradigm is available to the learner, which is not the case in periods of linguistic instability. However, word order variation can be contrastive as well (e.g. S-Aux inversion to distinguish illocutionary forces). Alternatively, a more parsimonious hypothesis we could entertain is that a general tendency for pidgins to comprise highly simplified morphological traits and more conservative word order is rooted in the differing complexity of these traits in the source languages; Hudson Kam and Newport (2009) show that learners are more likely to regularise complex systems of variation.

Recent experimental studies have separately explored the effect of learning biases on typological asymmetries found in morphology and word order respectively. In morphology for example, St Clair, Monaghan, and Ramscar (2009) provide evidence of a preference for suffixing over prefixing, mirroring the cross-linguistic preference for suffixing. In word order, Culbertson et al. (2012) show that learners prefer consistent harmonic word order patterns (i.e. all modifiers either pre-nominal or post-nominal), also found more commonly in the world's languages. Moreover, Culbertson et al. (2012) show that this bias leads to different regularisation behaviour for different word order patterns. Nevertheless, no study has hitherto tried to systematically compare regularisation behaviour across linguistic levels. Uncovering differences in regularisation behaviour across linguistic levels could shed light on the intriguing asymmetry found in pidgin languages: morphological paradigms seem to be highly simplified whilst input complexity is more closely reproduced in word order.

In the present study we combine artificial language learning and statistical learning techniques to systematically compare the strength of regularisation of inflectional morphology and word order, controlling for asymmetries in the complexity and variability of the input languages.

## Experiment 1

We utilise the methodology developed in Culbertson et al. (2012); Hudson Kam and Newport (2005). Adult learners are exposed to a miniature artificial language featuring an inconsistent mixture of synonymous variants. We are interested in how learners restructure the probabilistic unconditioned variation in the input languages, and to what extent that
restructuring is comparable across linguistic levels (specifically, morphology and word order).

## Method

Participants Fifty-six native-English speakers (aged between 18 and 41, mean $=23.2$ ) were recruited from the University of Edinburgh's Careers Service database of vacancies. Each was compensated $£ 6$. Twenty-six participants were assigned to the Morphology condition, and 26 to the Word Order condition; the data from a further 4 participants (all in the morphology condition) were excluded as they either failed to learn the noun lexicon or failed to learn the associations between phrases and pictures.

Input languages We designed two novel languages which contained probabilistic unconditioned variation either in morphology or word order. Their respective probabilistic grammars are shown in Table 1. Both languages were used to describe simple pictures featuring one of two objects. Each object appeared either singly or in a pair; and could appear either in greyscale or coloured in blue. Descriptions were noun phrases composed of a Noun plus a Num(eral) and/or Adj(ective) modifier, which were presented orthographically and aurally to participants during the experiment.

All lexical items were 5 graphemes/phonemes long and had a neighbourhood density of 0 in the English lexicon. Nouns and modifiers differed in their syllabic structure; while all were bisyllabic, nouns (i.e. "mokte" and "jelpa") conformed to a CVC.CV pattern, and modifiers to CV.CCV (based on English phonotactics and the Maximal Onset Principle).
Procedure Participants worked through a six-stage training and testing regime.

Stage 1, noun familiarisation Participants were trained on the two bare nouns that corresponded to pictures of the two different objects in the artificial language. During this phase, participants underwent a block of training consisting of 6 exposure trials and 4 picture-selection comprehension trials (in that order) -each noun-picture pair appeared 5 times (order randomised). Common to all training blocks to follow, on each exposure trial participants were presented with a picture (in this block always of a single object in grey-scale) and a corresponding description in the language (in this block, a bare noun), displayed both visually and aurally. On comprehension trials, participants were asked to select a picture out of an array of four (in this stage, the two objects seen during training plus two distractors) that corresponded to the displayed description in the alien language, and received feedback on their accuracy.

Stage 2, one-modifier training In Stage 2 participants were trained on one-modifier NPs, i.e. a Noun plus either Num or Adj only. Pictures contained any of the two objects presented either in blue and singly (Adj only) or in greyscale and in pairs (Num only). For each picture, a variant was selected randomly from the grammar assigned to the participant. Both grammars contained majority variants with an

Table 1: Probabilistic input languages in the Morphology and Word order conditions. Languages contain probabilistic unconditioned variation in inflectional morphology or word order respectively. All morphological variation resides in the suffixation of the modifiers. All word order variants conform to constituent structure [Num [Adj N]]. There are three types of NPs: Num Only (single Num modifier) refer to objects in pairs and in grey-scale, Adj Only (single Adj modifier) refer to a single object coloured in blue, and two-Mod(ifier) NPs (with both Num and Adj modifiers) correspond to objects in pairs coloured in blue. Languages include two different nouns (each corresponding to a different object) and thus comprise a total of 16 NPs ( 8 per noun) that correspond to a total of 6 pictures (1 per NP type, 3 per object).

| NP TYPE | MORPHOLOGY CONDITION | WORD ORDER CONDITION |
| :---: | :---: | :---: |
| NUM Only | $0.6 \mathrm{NP} \rightarrow \mathbf{N}$ nefri | $0.6 \mathrm{NP} \rightarrow \mathbf{N}$ nefri |
|  | $0.4 N P \rightarrow$ N nezno | $0.4 N P \rightarrow$ nefri N |
| ADJ <br> OnLy | $0.6 \mathrm{NP} \rightarrow \mathbf{N}$ kogla | $0.6 N P \rightarrow \mathbf{N}$ kogla |
|  | $0.4 N P \rightarrow \mathrm{~N}$ kospu | $0.4 N P \rightarrow$ kogla N |
| Two MOD | $0.6 \mathrm{NP} \rightarrow \mathbf{N}$ kogla nefri | $0.6 \mathrm{NP} \rightarrow \mathbf{N}$ kogla nefri |
|  | $0.1 \overline{3} N P \rightarrow$ N kogla nezno | $0.1 \overline{3} N P \rightarrow$ nefri kogla N |
|  | $0.1 \overline{3} N P \rightarrow$ N kospu nefri | $0.1 \overline{3} N P \rightarrow$ nefri N kogla |
|  | $0.1 \overline{3} N P \rightarrow \mathrm{~N}$ kospu nezno | $0.1 \overline{3} N P \rightarrow$ kogla N nefri |

empirical probability of $P=0.6$, and minority variants with $P=0.4$, as shown in Table 1. This phase comprised 40 trials in total, divided in 2 blocks of 20 trials; each block consisted of 15 exposure trials followed by 5 picture-selection trials. Participants saw each of the four different one-modifier pictures 5 times per block (order randomised).

Stage 3, one-modifier testing Stage 3 of the experiment tested the participants' knowledge of the language. They saw the same pictures used in Stage 2 without accompanying text or audio and were asked to type in an appropiate description. They had to describe 20 pictures in total; each of the four different one-modifier pictures was presented 5 times in random order.

Stage 4, full training In Stage 4 participants were trained on a mix of one-modifier (a noun plus Adj or Num) and twomodifier NPs (a noun plus both Num and Adj). Two-modifier NPs were used to describe pairs of blue objects. For onemodifier phrases, variants were chosen in the same way as in Stage 2. For two-modifier phrases, variants were also selected randomly from the grammars assigned, with empirical probabilities of $P=0.6$ and $P=0.1 \overline{3}$ for the majority and the three minority variants respectively (see Table 1). This stage comprised 100 trials ( 20 Num Only, 20 Adj Only and 60 two-Mod), divided into 4 block of 25 ( 15 exposure train-
ing trials followed by 10 picture-selection trials). Participants saw each of the four one-modifier pictures 10 times, and each of the two two-modifier pictures 30 times.

Stage 5, full testing Stage 5 tested participants' knowledge of the whole language. They saw all pictures they had been trained on and were asked to type in appropriate descriptions. They had to describe 52 pictures in total: 10 Adj Only (5 per object), 10 Num Only ( 5 per object), 30 two-modifier ( 15 per object), and additionally, 2 pictures of bare objects by themselves and in grey-scale (1 per object).

## Results

Output variability Figure 1 shows the entropy of participants' production systems for both the Morphology and Word Order conditions. Analyses are run on Stage 5's testing exclusively, i.e. participants' final production sets. Words in the productions were corrected for typos (and only typos). Shannon entropy measures how variable participants' productions are; the higher the scores, the more variable and the lower the scores, the more regular. The Shannon entropy (H) of phrase use for participant is given by

$$
\begin{equation*}
H(X)=-\sum_{i=1}^{n} P\left(x_{i}\right) \log _{2} P\left(x_{i}\right) \tag{1}
\end{equation*}
$$

where the sum is over the different variants, and $P\left(x_{i}\right)$ is the empirical probability of variant $x_{i}$ in the set of a participant's productions, $X$. We treated the two nouns for the different objects as the same variant when we calculated the entropy of the phrase variants such that no variability is introduced by the correct use of the different nouns. Entropy lower- and upper- bounds will vary depending on the number of required and possible variants as well as on the number of production trials. The most regular expressive language contains only one-to-one picture-phrase mappings and therefore only three different variants, one Num Only (e.g. N nefri), one Adj Only (e.g. $N$ kogla) and one two-modifier (e.g. $N$ kogla nefri). The final production phase consisted of 50 trials (excluding the two bare noun trials), divided up into 20 one-modifier trials (half Num Only and half Adj Only) and 30 two-modifier trials: the entropy lower bound for the language overall is thus 1.37 bits, and 0 bits for each of the NP types.

Figure 1 shows the entropy scores for the set of all participants' productions (i.e. the overall language), as well as those for the production sets for specific NP types in isolation: onemodifier Num (Num Only), one-modifier Adj (Adj Only), and two-modifier (two-Mod) NPs. Entropy lower bounds and input entropies are represented as solid and dotted vertical lines respectively. A visual inspection of the Morphology and Word Order conditions in Figure 1 suggests that in many cases participants failed to reproduce the full variability of the input languages; entropy scores are generally lower.

We used the stats and lme4 packages developed in R (Bates, Mächler, Bolker, \& Walker, 2015; R Core Team, 2015) to run a linear mixed effects regression model (which we will call Model 1) to explore the effect of condition on

Table 2: Central tendencies of the proportion of majority input variants in production by condition and NP type. From left to right, the mean, median and mode(s).

|  | Proportion Majority Input Variant in Production |  |  |  |
| :--- | :--- | :--- | :--- | :--- |
|  |  | mean | median | mode $(s)$ |
| Morphology | Num Only | 0.704 | 0.8 | 0.919 |
|  | Adj Only | 0.669 | 0.7 | 0.916 |
|  | two-Mod | 0.609 | 0.65 | 0.843 |
| Word Order | Num Only | 0.580 | 0.65 | $0.094 \& 0.96$ |
|  | Adj Only | 0.585 | 0.7 | $0.104 \& 0.947$ |
|  | two-Mod | 0.442 | 0.33 | $0.089 \& 0.92$ |

regularisation behaviour (dependent variable: entropy). As fixed effects we entered Condition (two levels: Morphology as reference, and Word Order), NP Type (reverse Helmert coded with the 3 ordered levels: Num Only, Adj Only and two-Mod) and System (two levels: Input as reference, and Output). We also entered all interactions between fixed effects. As random effects, we included intercepts for Subject as well as by-Subject slopes for the effects of NP Type and System type. P-values were obtained through the lmerTest package (Kuznetsova, Bruun Brockhoff, \& Haubo Bojesen Christensen, 2015). Results show a significant effect of System ( $\beta=-0.346, S E=0.085, p<.001$ ), suggesting that participants did indeed regularise their input in their output productions. We also found a significant interaction between System and Condition ( $\beta=-0.284, S E=0.119, p=.021$ ), suggesting that participants regularised their input significantly more in the Word Order condition. Results show the expected effect of higher input entropies in two-Mod NPs ( $\beta=0.21, S E=0.024, p=<.001$ ), and no significant interactions between NP Type and System (largest: $\beta=0.027$, $S E=0.028, p=.324$ ) or between NP Type, System and Condition (largest: $\beta=-0.041, S E=0.039, p=.299$ ). These results suggest that participants regularised their input systems across conditions and NP types, and that participants in the Word Order condition regularised them more than those in the Morphology condition.
Variant production Table 2 provides the central tendencies for proportion use of the majority input variant for each NP type. We observe that all distributions in the Word Order condition are bimodal, with modes of the distributions of majority variant use at $P \leq 0.1$ and $P>0.9$ across NP types, suggesting two opposite trends amongst participants: one towards the over-production of the majority input word order variants and another, towards their under-production.

Participants under-producing the majority word order variant in one-modifier NPs are necessarily producing modifiers pre-nominally. Figure 2 shows the overall proportions of the variants produced for two-Mod NPs by all participants. The input proportions are represented by the yellow vertical lines. The word order produced the most is the majority input variant N Adj Num. Although the three remaining input variants (below the grey solid line division) were equally frequent in the input language, the Num Adj N word order is overall

Figure 1：Entropy scores of participants＇production systems．From top to bottom，scores for the Morphology（green）and Word Order（red）conditions in Experiment 1 and for the NoL1 Word Order condition（orange）in Experiment 2．From left to right， entropies of participants＇full production sets as well as entropies by NP type：one－modifier Num（Num Only），one－modifier Adj（Adj Only），and two－modifier（two－Mod）NPs．Input entropy scores are indicated by dashed vertical lines．Minimum entropy scores are indicated by solid vertical lines．Minimum entropy is always 0 for each NP type in isolation but 1.37 for the overall system as it necessitates a minimum of 3 variants，one per NP type．

Figure 2：Box plot displaying the output proportions of two－ modifier variants in the Word Order condition with individual participants＇data points overlaid．Seen（bottom）and unseen （top）variants during training are divided by a solid grey line． Vertical yellow lines indicate input proportions．
more frequently used（although only by a minority as indi－ cated by the median value 0 ）．Only $30 \%$ of participants pro－ duced systems with both harmonic variants（Num Adj N and N Adj Num）－and only $19 \%$ produced both variants more than once，suggesting that although both harmonic orders are preferred overall，they do not generally coexist within the pro－ ductions of a single participant．

We ran a logistic regression model，which we will call Model 2，to explore the average difference between the pro－ portions of Num Adj N variants in input and output linguistic systems．We entered System（two levels：Input as reference， and Output）as the only fixed effect．Random intercepts for Subject as well as by－Subject random slopes for the effect of System were also included．Results show that the Num Adj N variant is produced significantly less in output languages than in the input language（ $\beta=-7.641, S E=1.943, p<.001$ ）． Only a minority of participants overproduced this variant，the majority of participants were in fact under－producing it．On top of the observed preference for harmonic order，these re－ sults confirm a tendency to avoid systems with two opposite N－peripheral variants，i．e．N Adj Num and Num Adj N．

## Discussion of Experiment 1

Our results provide evidence that learners regularise proba－ bilistic unconditioned variation in both morphology and word order．Regularisation behaviour is in line with an overarching simplicity bias argued to be at play in language learning and use（Culbertson \＆Kirby，2016）．Though the input languages were similar in terms of overall system complexity，regulari－ sation behaviour was slightly stronger in the Word Order con－ dition than in the Morphology condition．A close analysis of the variant usage in the Word Order condition suggests that this difference is driven by a bias in favour of harmonic N Adj Num and Num Adj N variants but against their coexis－ tence within a system．This bias could be the result of L1 transfer；participants may have overproduced the Num Adj

Table 3: Probabilistic input language in the NoL1 Word order condition in contrast to the Word Order condition in Experiment 1. Changes in the variant set are indicated with boxes.

| NP TYPE | WORD ORDER | NOL1 WORD ORDER |
| :--- | :--- | :--- |
| NUM | $0.6 N P \rightarrow \mathbf{N}$ nefri | $0.6 N P \rightarrow \mathbf{N}$ nefri |
| ONLY | $0.4 N P \rightarrow$ nefri N | $0.4 N P \rightarrow$ nefri N |
|  |  |  |
| ADJ | $0.6 \mathrm{NP} \rightarrow \mathbf{N}$ kogla | $0.6 \mathrm{NP} \rightarrow \mathbf{N}$ kogla |
| ONLY | $0.4 N P \rightarrow$ kogla N | $0.4 N P \rightarrow$ kogla N |
|  |  |  |
|  | $0.6 N P \rightarrow \mathbf{N}$ kogla nefri | $0.6 N P \rightarrow \mathbf{N}$ kogla nefri |
| TWO | $0.1 \overline{3} N P \rightarrow$ nefri kogla N | $0.1 \overline{3} N P \rightarrow$ N nefri kogla |

|  | $0.1 \overline{3} N P \rightarrow$ kogla N nefri | $0.1 \overline{3} N P \rightarrow$ kogla N nefri |
|  |  |  |

N word order because it is the most common order in their L1 grammar. To minimise the possible effects of this levelspecific word order bias, Experiment 2 investigated learning in a second word order condition, removing the English-like two-modifier harmonic pattern from the input.

## Experiment 2

Experiment 2 follows the same design as the Word Order condition described in Experiment 1, with one difference: the set of two-modifier NP input variants. As illustrated in Table 3, we replaced the Num Adj N variant with the N Num Adj pattern, maintaining the number of harmonic word orders (two, i.e. N Adj Num and N Num Adj) but eliminating the L1 variant and the presence of opposite N-peripheral patterns. For ease of reference, we call Experiment 2 the NoL1 Word Order condition. We expect the change in the input language to mitigate the effect of L1 transfer and to increase the coexistence of both harmonic patterns.

Participants Twenty-eight native-English speakers (aged between 18 and 35 , mean $=24.8$ ) were recruited via the University of Edinburgh's Careers Service advertisement database. Participants received $£ 6$. Only the data from 26 participants were fit for analysis as two participants either failed to learn the noun lexicon or failed to learn the associations between phrases and pictures.

## Results

Entropy scores obtained in the NoL1 Word Order condition are shown in Figure 1 (coloured in orange). We ran a linear mixed effects model as in Experiment 1 to explore the effect of condition on regularisation behaviour (dependent variable: entropy), including the conditions in Experiment 1 plus NoL1 Word Order. The mixed-effects structure was the same as in the Model 1 but with reverse Helmert coding of Condi-

Figure 3: Box plot displaying the output proportions of twomodifier variants in the NoL1 Word Order condition with individual participants' data points overlaid. Divided by a solid grey line, seen (bottom) and unseen (top) variants during training. Vertical light brown lines indicate input proportions.
tion such that NoL1 Word Order was directly compared to the Morphology condition from Experiment 1, and the Word Order condition was compared to the average of the Morphology and NoL1 Word Order conditions. Results show a significant effect of System ( $\beta=-0.483, S E=0.051, p<.001$ ) and a significant interaction between Word Order and System ( $\beta=-0.073, S E=0.036, p=.046$ ), ratifying the results in Model 1. However, we did not find a significant interaction between NoL1 Word Order and System ( $\beta=-0.063, S E=$ $0.063, p=.317$ ), suggesting that participants in the Morphology and the NoL1 Word Order conditions regularised their input to similar degrees, and on average they regularised it less than participants in the Word Order condition in Experiment 1. As in Model 1, we did not find significant interactions between NP Type and System (largest: $\beta=0.016$, $S E=0.015, p=.288$ ) or between NP Type, System and Condition (largest: $\beta=-0.015, S E=0.011, p=.168$ ). These results suggest that participants regularised their input systems across conditions and NP types, and that whilst participants in the Word Order condition regularised more than those in the Morphology condition, participants in the Morphology and the NoL1 Word Order conditions regularised their input to similar degrees. Excluding the Num Adj N variant in the input language thus eliminated the difference between levels. In other words, participants do not regularise probabilistic unconditioned variation in word order more than in morphology.

Figure 3 shows the overall proportions of the variants produced for two-Mod NPs in the NoL1 Word Order condition. We observe that the most produced word order is the majority input variant N Adj Num, and that the harmonic N Num

Adj word order is overall more frequent than any other minority input variant. Unlike in the Word Order condition where systems with both Num Adj N and N Adj Num patterns were not common, $65 \%$ of participants produced systems with both N Adj Num and N Num Adj harmonic variants in the NoL1 Word Order condition. We ran a logistic regression model to test the difference between the proportions of N Num Adj variants in input and output linguistic systems across participants. We used the same mixed-effects structure as in Model 2. Results suggest that the proportion of N Num Adj variants in the output languages is not significantly different from the input proportion across participants ( $\beta=-0.594, S E=0.546, p=.277$ ).

## Discussion

Our experimental results reveal regularisation behaviour in the production of complex systems of variation in morphology and word order. They also suggest that regularisation behaviour is of similar strength between these linguistic levels given input languages with comparable initial complexities. In Experiment 1 we found higher levels of regularisation in word order than in morphology, apparently due to the specific properties of the set of variants in the input languages. When both harmonic pre-nominal and post-nominal two-modifier variants were included, the coexistence of both variants in a single production system was rare. Although a preference for harmonic order and consistent head position may have been at play, the interference of L1 transfer cannot be categorically rejected. Indeed previous research suggests that L2 learners tend to access their L1 knowledge if it matches the novel input (Weber, Christiansen, Petersson, Indefrey, \& Hagoort, 2016). In Experiment 2, we showed that eliminating opposite N -peripheral positions in the subset of two-modifier variants by replacing Num Adj N with N Num Adj eliminates the difference in regularisation between levels. Our results do not suggest general level-specific learning biases that could straightforwardly predict a typological asymmetry between the strength and speed of regularisation in morphology and word order hinted at in pidgin and creole studies (Good, 2015). Instead, they suggest that asymmetries in regularisation processes in language formation ought to be sought in asymmetries in the input complexity of traits across levels, also taking into account the overlap of features between contributing languages.

## Conclusion

Our results suggest similar strengths of regularisation between linguistic levels given input languages with comparable initial complexities. Nevertheless, preferences for certain patterns within a linguistic level might in fact vary the strength of regularisation behaviour within a given level.

# Converting Cascade-Correlation Neural Nets into Probabilistic Generative Models 

Ardavan S. Nobandegani ${ }^{1,3} \quad$ Thomas R. Shultz ${ }^{2,3}$<br>\{ardavan.salehinobandegani@ mail.mcgill.ca, thomas.shultz@mcgill.ca\}<br>${ }^{1}$ Department of Electrical and Computer Engineering, McGill University<br>${ }^{2}$ School of Computer Science, McGill University<br>${ }^{3}$ Department of Psychology, McGill University

#### Abstract

Humans are not only adept in recognizing what class an input instance belongs to (i.e., classification task), but perhaps more remarkably, they can imagine (i.e., generate) plausible instances of a desired class with ease, when prompted. Inspired by this, we propose a framework which allows transforming Cascade-Correlation Neural Networks (CCNNs) into probabilistic generative models, thereby enabling CCNNs to generate samples from a category of interest. CCNNs are a wellknown class of deterministic, discriminative NNs, which autonomously construct their topology, and have been successful in accounting for a variety of psychological phenomena. Our proposed framework is based on a Markov Chain Monte Carlo (MCMC) method, called the Metropolis-adjusted Langevin algorithm, which capitalizes on the gradient information of the target distribution to direct its explorations towards regions of high probability, thereby achieving good mixing properties. Through extensive simulations, we demonstrate the efficacy of our proposed framework. Importantly, our framework bridges computational, algorithmic, and implementational levels of analysis.

Keywords: Deterministic Discriminative Neural Networks; Probabilistic Generative Models; Markov Chain Monte Carlo

## 1 Introduction

A green-striped elephant! Probably no one has seen such a thing-no surprise. But what is a surprise is our ability to easily imagine one. Humans are not only adept in recognizing what class an input instance belongs to (i.e., classification task), but more remarkably, they can imagine (i.e., generate) plausible instances of a desired class, when prompted. In fact, humans can generate instances of a desired class, say, elephant, that they have never encountered before, like, a greenstriped elephant. ${ }^{1}$ In this sense, humans' generative capacity goes beyond merely retrieving from memory. In computational terms, the notion of generating examples from a desired class can be formalized in terms of sampling from some underlying probability distribution, and has been extensively studied in machine learning under the rubric of probabilistic generative models.

Cascade-Correlation Neural Networks (CCNNs) (Fahlman \& Lebiere, 1989) are a well-known class of discriminative (as opposed to generative) models that have been successful in simulating a variety of phenomena in the developmental literature, e.g., infant learning of word-stress patterns in artificial languages (Shultz \& Bale, 2006), syllable boundaries (Shultz \& Bale, 2006), visual concepts (Shultz, 2006),

[^186]and have also been successful in capturing important developmental regularities in a variety of tasks, e.g., the balancescale task (Shultz, Mareschal, \& Schmidt, 1994; Shultz \& Takane, 2007), transitivity (Shultz \& Vogel, 2004), conservation (Shultz, 1998), and seriation (Mareschal \& Shultz, 1999). Also, CCNNs exhibit several similarities with known brain functions: distributed representation, self-organization of network topology, layered hierarchical topologies, both cascaded and direct pathways, an S-shaped activation function, activation modulation via integration of neural inputs, longterm potentiation, growth at the newer end of the network via synaptogenesis or neurogenesis, pruning, and weight freezing (Westermann, Sirois, Shultz, \& Mareschal, 2006). Nonetheless, in virtue of being deterministic and discriminative, CCNNs have so far lacked the capacity to probabilistically generate examples from a category of interest.

In this work, we propose a framework which allows transforming CCNNs into probabilistic generative models, thereby enabling CCNNs to generate samples from a category. Our proposed framework is based on a Markov Chain Monte Carlo (MCMC) method, called the MetropolisAdjusted Langevin (MAL) algorithm, which employs the gradient of the target distribution to guide its explorations towards regions of high probability, thereby significantly reducing the undesirable random walk often observed at the beginning of an MCMC run (a.k.a. the burn-in period). MCMC methods are a family of algorithms for sampling from a desired probability distribution, and have been successful in simulating important aspects of a wide range of cognitive phenomena, e.g., temporal dynamics of multistable perception (Gershman, Vul, \& Tenenbaum, 2012; Moreno-Bote, Knill, \& Pouget, 2011), developmental changes in cognition (Bonawitz, Denison, Griffiths, \& Gopnik, 2014), category learning (Sanborn, Griffiths, \& Navarro, 2010), causal reasoning in children (Bonawitz, Denison, Gopnik, \& Griffiths, 2014), and accounting for many cognitive biases (Dasgupta, Schulz, \& Gershman, 2016).

Furthermore, work in theoretical neuroscience has shed light on possible mechanisms according to which MCMC methods could be realized in generic cortical circuits (Buesing, Bill, Nessler, \& Maass, 2011; Moreno-Bote et al., 2011; Pecevski, Buesing, \& Maass, 2011; Gershman \& Beck, 2016). In particular, Moreno-Bote et al. (2011) showed how an attractor neural network implementing MAL can account for multistable perception of drifting gratings, and Savin and Deneve (2014) showed how a network of leaky integrate-andfire neurons can implement MAL in a biologically-realistic
manner.

## 2 Cascade-Correlation Neural Networks

CCNNs are a special class of deterministic artificial neural networks, which construct their topology in an autonomous fashion-an appealing property simulating developmental phenomena (Westermann et al., 2006) and other cases where networks need to be constructed. CCNN training starts with a two-layer network (i.e., the input and the output layer) with no hidden units, and proceeds by recruiting hidden units one at a time, as needed. Each new hidden unit is trained to maximally correlate with residual error in the network built so far, and is recruited into a hidden layer of its own, giving rise to a deep network with as many hidden layers as the number of recruited hidden units. CCNNs use sum-of-squared error as an objective function, and typically use symmetric sigmoidal activation functions with range -0.5 to +0.5 for hidden and output units. ${ }^{2}$ Some variants have been proposed: Sibling-Descendant Cascade-Correlation (SDCC) (Baluja \& Fahlman, 1994) and Knowledge-Based Cascade-Correlation (KBCC) (Shultz \& Rivest, 2001). Although in this work we focus on standard CCNNs, our proposed framework can handle SDCC and KBCC as well.

## 3 The Metropolis-Adjusted Langevin Algorithm

MAL (Roberts \& Tweedie, 1996) is a special type of MCMC method, which employs the gradient of the target distribution to guide its explorations towards regions of high probability, thereby reducing the burn-in period. More specifically, MAL combines the two concepts of Langevin dynamics (a random walk guided by the gradient of the target distribution), and the Metropolis-Hastings algorithm (an accept/reject mechanism for generating a sequence of samples the distribution of which asymptotically converges to the target distribution).

We denote random variables with small bold-faced letters, random vectors by capital bold-faced letters, and their corresponding realizations by non-bold-faced letter. The MAL algorithm is outlined in Algorithm 1 wherein $\pi(\mathbf{X})$ denotes the target probability distribution, $\tau$ is a positive real-valued parameter specifying the time-step used in the Euler-Maruyama approximation of the underlying Langevin dynamics, $N$ denotes the number of samples generated by the MAL algorithm, $q$ denotes the proposal distribution (a.k.a. transition kernel), $\mathcal{N}(\mu, \Sigma)$ denotes the multivariate normal distribution with mean vector $\mu$ and covariance matrix $\Sigma$, and $\mathbb{I}$ denotes the identity matrix. The sequence of samples generated by the MAL algorithm, $\mathbf{X}^{(0)}, \mathbf{X}^{(1)}, \ldots$, is guaranteed to converge in distribution to $\pi(\mathbf{X})$ (Robert \& Casella, 2013). It is worth noting that work in theoretical neuroscience has shown that MAL, outlined in Algorithm 1, can be implemented in a

[^187]```
Algorithm 1 The Metropolis-Adjusted Langevin Algorithm
    Input: Target distribution \(\pi(\mathbf{X})\), parameter \(\tau \in \mathbb{R}_{+}\), num-
    ber of samples \(N\).
    Output: Samples \(\mathbf{X}^{(0)}, \ldots, \mathbf{X}^{(N-1)}\).
    Pick \(\mathbf{X}^{(0)}\) arbitrarily.
    for \(i=0, \ldots, N-1\) do
    Sample \(\mathbf{u} \sim\) Uniform[0,1]
    Sample \(\mathbf{X}^{*} \sim q\left(\mathbf{X}^{*} \mid \mathbf{X}^{(i)}\right)=\mathcal{N}\left(\mathbf{X}^{(i)}+\tau \nabla \log \pi\left(\mathbf{X}^{(i)}\right), 2 \tau \mathbb{I}\right)\)
        if \(\mathbf{u}<\min \left\{1, \frac{\pi\left(\mathbf{X}^{*}\right) q\left(\mathbf{X}^{(i)} \mid \mathbf{X}^{*}\right)}{\pi\left(\mathbf{X}^{(i)}\right) q\left(\mathbf{X}^{*} \mid \mathbf{X}^{(i)}\right)}\right\}\) then
                \(\mathbf{X}^{(i+1)} \leftarrow \mathbf{X}^{*}\)
        else
            \(\mathbf{X}^{(i+1)} \leftarrow \mathbf{X}^{(i)}\)
        end if
    end for
    return \(\mathbf{X}^{(0)}, \ldots, \mathbf{X}^{(N-1)}\)
```

neurally-plausible manner (Savin \& Deneve, 2014; MorenoBote et al., 2011). ${ }^{3}$ In the following section, we propose a target distribution $\pi(\mathbf{X})$, allowing CCNNs to generate samples from a category of interest.

## 4 The Proposed Framework

In what follows, we propose a framework which transforms CCNNs into probabilistic generative models, thereby enabling them to generate samples from a category of interest. The proposed framework is based on the MAL algorithm given in Sec. 3. Let $f\left(X ; W^{*}\right)$ denote the input-output mapping learned by a CCNN, and $W^{*}$ denote the set of weights for a CCNN after training. ${ }^{4}$ Upon termination of training, presented with input $X$, a CCNN outputs $f\left(X ; W^{*}\right)$. Note that, in case a CCNN possesses multiple output units, $f\left(X ; W^{*}\right)$ will be a vector rather than a scalar. To convert a CCNN into a probabilistic generative model, we use the MAL algorithm with its target distribution $\pi(\mathbf{X})$ being set as follows:

$$
\begin{align*}
\tilde{\pi}(\mathbf{X}) & \triangleq p\left(\mathbf{X} \mid \mathbf{Y}=L_{j}\right) \\
& =\frac{1}{Z} \exp \left(-\beta\left\|L_{j}-f\left(\mathbf{X} ; W^{*}\right)\right\|_{2}^{2}\right) \tag{1}
\end{align*}
$$

where $\|\cdot\|_{2}$ denotes the $l_{2}$-norm, $\beta \in \mathbb{R}_{+}$is a damping factor, $Z$ is the normalizing constant, and $L_{j}$ is a vector whose element corresponding to the desired class is +0.5 (i.e., its $j^{\text {th }}$ element) and the rest of its elements are -0.5 s . The intuition behind Eq. (1) can be articulated as follows: For an input instance $\mathbf{X}=X$ belonging to the desired class $j,{ }^{5}$ the output of

[^188]the network $f\left(X ; W^{*}\right)$ is expected to be close to $L_{j}$ in $l_{2}$-norm sense. In this light, Eq. (1) is adjusting the likelihood of input instance $X$ to be inversely proportional to the base- $e$ exponent of the said $l_{2}$ distance.

For a reader familiar with probabilistic graphical models, the expression in Eq. (1) looks similar to the expression for the joint probability distribution of Markov random fields and probabilistic energy-based models, e.g., Restricted Boltzman Machines and Deep Boltzman Machines. However, there is a crucial distinction: The normalizing constant $Z$, the computation of which is intractable in general, renders learning in those models computationally intractable. ${ }^{6}$ The appropriate way to interpret Eq. (1) is to see it as a Gibbs distribution for a non-probabilistic energy-based model whose energy is defined as the square of the prediction error (LeCun, Chopra, Hadsell, Ranzato, \& Huang, 2006). Section 1.3 of (LeCun et al., 2006) discusses the topic of Gibbs distribution for nonprobabilistic energy-based models in the context of discriminitive learning, computationally modeled by $p(\mathbf{Y} \mid \mathbf{X})$ (i.e., to predict a class given an input), and raises the same issue that we highlighted above regarding the intractability of computing the normalizing constant $Z$ in general. In sharp contrast to (LeCun et al., 2006), our framework is proposed for the purpose of generating examples from a desired class, as evidenced by Eq. (1) being defined in terms of $p(\mathbf{X} \mid \mathbf{Y})$. Also crucially, the intractability of computing $Z$ raises no issue for our proposed framework due to an intriguing property of the MAL algorithm according to which the normalizing constant $Z$ need not be computed at all. ${ }^{7}$

Due to Line 4 of Algorithm 1, MAL's proposal distribution $q$ requires the computation of $\nabla \log \tilde{\pi}\left(\mathbf{X}^{(i)}\right)$, which essentially involves computing $\nabla f\left(\mathbf{X}^{(i)} ; W^{*}\right)$ (note that the gradient is operating on $\mathbf{X}^{(i)}$, and $W^{*}$ is treated as a set of fixed parameters). The multi-layer structure of CCNN ensures that $\nabla f\left(\mathbf{X}^{(i)} ; W^{*}\right)$ can be efficiently computed using Backpropagation. Alternatively, in settings where CCNNs recruit a small number of input units (hence, the cardinality of $\mathbf{X}^{(i)}$ is small), $\nabla f\left(\mathbf{X}^{(i)} ; W^{*}\right)$ can be obtained by introducing negligible perturbation to a component of input signal $\mathbf{X}^{(i)}$, dividing the resulting change in the network's outputs by the introduced perturbation, and repeating this process for all components of input signal $\mathbf{X}^{(i)}$. It is worth noting that although the idea of computing gradients through introducing small perturbations would lead to a computationally inefficient approach for learning CCNNs, it leads to a computationally efficient approach for generation, as the number of input units are typically much fewer than the number of weights in CCNNs (and artificial neural networks in general). It is crucial to note that the normalizing constant $Z$ plays no role in the computation of $\nabla \log \tilde{\pi}\left(\mathbf{X}^{(i)}\right)$.

[^189]
## 5 Simulations

In this section we demonstrate the efficacy of our proposed framework through simulations. We particularly focus on learning which can be accomplished by two input and one output units. This permits visualization of the input-output space, which lies in $\mathbb{R}^{3}$. Note that our proposed framework can handle arbitrary number of input and output units; this restriction is solely for ease of visualization.

### 5.1 Continuous-XOR Problem

In this section, we show how our proposed framework allows a CCNN, trained on the continuous-XOR classification task, to generate examples from a category of interest. The output unit has a symmetric sigmoidal activation function with range -0.5 and +0.5 . The training set consists of 100 samples in the unit-square $[0,1]^{2}$, paired with their corresponding labels. More specifically, the training set is comprised of all the ordered-pairs starting from $(0.1,0.1)$ and going up to $(1,1)$ with equal steps of size 0.1 , paired with their corresponding labels (i.e., +0.5 for positive samples and -0.5 for negative samples); see Fig. 1(top-left). After training, a

Figure 1: A CCNN trained on the continuous-XOR classification task. Top-left: Training patterns. All the patterns in the gray quadrants are negative examples with label -0.5 , and all the patterns in the white quadrants are positive examples with label +0.5 . Red dotted lines depict the boundaries. Topright: The input-output mapping, $f\left(x_{1}, x_{2} ; W^{*}\right)$, learned by a CCNN, along with a colorbar. Bottom: The top-down view of the curve depicted in top-right, along with a colorbar.

CCNN with 6 hidden layers is obtained whose input-output mapping, $f\left(x_{1}, x_{2} ; W^{*}\right)$, is shown in Fig. 1 (top-right). ${ }^{8}$

[^190]

Figure 2: Generating example for the positive category, under various choices for MAL parameter $\tau$ and damping factor $\beta$. Contour-plot of the learned mapping, $f\left(x_{1}, x_{2} ; W^{*}\right)$, along with its corresponding colorbar is shown in each sub-figure. Generated samples are depicted by red dots. $N$ denotes the total number of samples generated by MAL, and $A R$ denotes the corresponding acceptance rate. (a) $\tau=5 \times 10^{-5}$ leads to a very slow exploration of the input space. (b) $\tau=5 \times 10^{-3}$ leads to an adequate exploration of the input space, however, $\beta=1$ is not penalizing undesirable input regions severely enough. (c) A desirable performance is achieved by $\tau=5 \times 10^{-3}$ and $\beta=10$.

Fig. 2 shows the efficacy of our proposed framework in enabling CCNNs to generate samples from a category of interest, under various choices for MAL parameter $\tau$ (see Algorithm 1) and damping factor $\beta$ (see Eq. (1)); generated samples are depicted by red dots. For the results shown in Fig. 2, the category of interest is the category of positive examples, i.e., the category of input patterns which, upon being presented to the (learned) network, would be classified as positive by the network. Because $\tau$ controls the amount of jump between consecutive proposals made by MAL, the following behavior is expected: For small $\tau$ (Fig. 2(a)) consecutive proposals are very close to one another, leading to a slow exploration of the input domain. As $\tau$ increases, bigger jumps are made by MAL (Fig. 2(b)). ${ }^{9}$ Parameter $\beta$ controls how severely deviations from the desired class label (here, +0.5 ) are penalized. The larger the parameter $\beta$, the more severely such deviations are penalized and the less likely MAL moves toward such regions of input space. Acceptance Rate (AR), defined as the number of accepted moves divided by the total number of suggested moves, is also presented for the results shown in Fig. 2. Fig. 2(c) shows that for $\tau=5 \times 10^{-3}$ and $\beta=10$, our proposed framework demonstrates desirable performance: virtually all of the generated samples fall within the desired input regions (i.e., the regions associated with hot colors, signaling the closeness of network's output to +0.5 in those regions; see Fig. 1(bottom)) and the desired regions are adequately explored (i.e., all hot-colored input regions being visited and almost evenly explored).

Fig. 2 depicts all the first $N=2000$ samples generated

[^191]by MAL, without excluding the so-called burn-in period. In that light, the result shown in Fig. 2(c) nicely demonstrates how MAL-by directing its suggestions toward the direction of gradient and therefore moving toward regions with high likelihood-could alleviate the need for discarding a (potentially large) number of samples generated at the beginning of an MCMC which are assumed to be unrepresentative of equilibrium state, a.k.a. the burn-in period. Fig. 3 shows the performance of our framework in enabling the learned CCNN to generate from the category of negative examples, with $\tau=5 \times 10^{-3}$ and $\beta=10$.

Figure 3: Generating example for the negative category, with $\tau=5 \times 10^{-3}, \beta=10$. Generated samples are shown by blue dots. Total number of samples generated is $N=2000$, with $A R=65.13 \%$.

### 5.2 Two-Spirals Problem

Next, we show how our proposed framework allows a CCNN, trained on the famously difficult two-spirals classification task (Fig. 4), to generate examples from a category of interest. The output unit has a symmetric sigmoidal activation
function with range -0.5 and +0.5 . The training set consists of 194 samples ( 97 samples per spiral), in the square $[-6.5,6.5]^{2}$, paired with their corresponding labels $(+0.5$ and -0.5 for positive and negative samples, respectively). The training patterns are shown in Fig. 4(top-left); cf. (Chalup \& Wiklendt, 2007) for details. After training, a CCNN with 14 hidden layers is obtained whose input-output mapping, $f\left(x_{1}, x_{2} ; W^{*}\right)$, is depicted in Fig. 4(top-right).

Figure 4: A CCNN trained on the two-spirals classification task. Top-left: Training patterns. Positive patterns (associated with label +0.5 ) are shown by hollow circles, and negative patterns (associated with label -0.5 ) by black circles. Positive spiral is depicted by a dashed line, and negative spiral by a dotted line. Top-right: The input-output mapping, $f\left(x_{1}, x_{2} ; W^{*}\right)$, learned by a CCNN, along with a colorbar. Bottom: The top-down view of the curve depicted in topright, along with a colorbar.

Fig. 5(top) and Fig. 5(bottom) show the efficacy of our proposed framework in enabling CCNNs to generate samples from the positive and negative categories, respectively. Although similar patterns of behavior observed in Sec. 5.1 due to increasing/decreasing $\beta$ and $\tau$ are observed here as well, due to the lack of space such results are omitted. The results in Fig. 5 depict all the first $N=15000$ samples generated by MAL, without excluding the burn-in period. In that light, these results again demonstrate the efficacy of MAL in alleviating the need for discarding a (potentially large) number samples generated at the beginning of an MCMC run.

Interestingly, our proposed framework also allows CCNNs to generate samples subject to some forms of constraints. For example, Fig. 6 demonstrates how our proposed framework enables a CCNN, trained on the continuous-XOR classification task (see Sec. 5.1), to generate examples from the positive category, under the following constraint: Generated

Figure 5: Generating example for the positive and negative categories, with $\beta=20$ and $\tau=0.7$. Contour-plot of the learned mapping, $f\left(x_{1}, x_{2} ; W^{*}\right)$, along with its corresponding colorbar is shown in each sub-figure. $N$ denotes the total number of samples generated by MAL, and $A R$ denotes the corresponding acceptance rate. Top: Generated example for the positive category, with $N=15000$ and $A R=40.69 \%$; generated samples are depicted by red dots. Bottom: Generated example for the negative category, with $N=15000$ and $A R=40.28 \%$; generated samples are depicted by blue dots.
samples must lie on the curve $x_{2}=0.25 \sin \left(8 \pi x_{1}\right)+0.5$. To generate samples from the positive category while satisfying this constraint, MAL adopts our proposed target distribution given in Eq. (1), and treats $x_{1}$ as an independent and $x_{2}$ as a dependent variable.

## 6 General Discussion

Although we discussed our proposed framework in the context of CCNNs, it can be straightforwardly extended to handle some other kinds of artificial neural networks, e.g. Multilayer Perceptron and Deep Convolutional Neural Networks. Furthermore, our proposed framework, together with recent work in theoretical neuroscience showing possible neurallyplausible implementations of MAL (Savin \& Deneve, 2014; Moreno-Bote et al., 2011), suggests an intriguing modular hypothesis according to which generation could result from two separate modules interacting with each other (in our case, a CCNN and a neural network implementing MAL). This

Figure 6: Generating examples for the positive category, under constraint $x_{2}=0.25 \sin \left(8 \pi x_{1}\right)+0.5$ (dash-dotted curve), with $N=5000$ and $A R=39.82 \%$. Contour-plot of the learned mapping, $f\left(x_{1}, x_{2} ; W^{*}\right)$, along with its corresponding colorbar is depicted. Generated samples are shown by red dots, which appear mainly as solid red curves due to high density.
hypothesis yields the following prediction: There should be some brain impairments which lead to a marked decline in a subject's performance in generative tasks (i.e., tasks involving imagery, or imaginative tasks in general) but leave the subject's learning abilities (nearly) intact. Studies on learning and imaginative abilities of hippocampal amnesic patients already provide some supporting evidence for this idea (Hassabis, Kumaran, Vann, \& Maguire, 2007; Spiers, Maguire, \& Burgess, 2001; Brooks \& Baddeley, 1976).

According to Line 4 of Algorithm 1, to generate the $i^{\text {th }}$ sample, MAL requires access to a fine-tuned, Gaussian noise with mean $\mathbf{X}^{(i)}+\tau \nabla \log \pi\left(\mathbf{X}^{(i)}\right)$ for its proposal distribution $q$. Recently Savin and Deneve (2014) showed how a network of leaky integrate-and-fire neurons can implement MAL in a neurally-plausible manner. However, as Gershman and Beck (2016) point out, Savin and Deneve leave unanswered what the source of that fine-tuned Gaussian noise could be. Our proposed framework may provide an explanation, not for the source of Gaussian noise, but for its fine-tuned mean value. According to our modular account, the main component of the mean value, which is $\nabla \log \pi\left(\mathbf{X}^{(i)}\right)$, may come from another module (in our case, a CCNN) which has learned some input-output mapping $f\left(X ; W^{*}\right)$, based on which the target distribution $\pi\left(\mathbf{X}^{(i)}\right)$ is defined (see Eq. (1)).

The idea of sample generation under constraints could be an interesting line of future work. Humans clearly have the capacity to engage in imaginative tasks under a variety of constraints, e.g., when given incomplete sentences or fragments of a picture people can generate possible completions (Sanborn \& Chater, 2016). Also, our proposed framework can be used to let a CCNN generate samples from a category of interest at any stage during CCNN construction. In that light, our proposed framework, along with a neurally-plausible implementation of MAL, gives rise to a self-organized generative model: a generative model possessing the self-constructive property of CCNNs. Such self-
organized generative models could provide a wealth of developmental hypotheses as to how the imaginative capacities of children change over development, and models with quantitative predictions to compare against. We see our work as a step towards such models. Last but not least, our framework strongly suggests that, contrary to conventional wisdom, the boundary between discriminative and generative models is blurry-perhaps they are just two sides of the same coin!

#### Abstract

Human behavior is frequently guided by social and moral norms; in fact, no societies, no social groups could exist without norms. However, there are few cognitive science approaches to this central phenomenon of norms. While there has been some progress in developing formal representations of norm systems (e.g., deontological approaches), we do not yet know basic properties of human norms: how they are represented, activated, and learned. Further, what computational models can capture these properties, and what algorithms could learn them? In this paper we describe initial experiments on human norm representations in which the context specificity of norms features prominently. We then provide a formal representation of norms using Dempster-Shafer Theory that allows a machine learning algorithm to learn norms under uncertainty from these human data, while preserving their context specificity.

Keywords: social cognition, moral psychology, computational modeling, machine learning

## Introduction and Motivation

Someone's cell phone begins to ring in the library. The person quickly answers it by whispering "hold on," then leaves the library and takes the call in a normal voice outside. The person understands that taking a phone call in the library is not socially acceptable, though briefly whispering is. Somehow, the situation activated a set of norms in this person's mind, including: "when someone calls you, you should answer the phone"; "when in a library, you must not talk on the phone"; "when in a library, you may briefly whisper."

Humans living in social communities function more effectively and peacefully when their actions are guided by a shared set of norms (Bicchieri, 2006; Ullmann-Margalit, 1977). The ability to represent and follow norms has many advantages: Norm-consistent actions increase multi-party coordination and cooperation and thus benefit the community as a whole. Norms also simplify people's action selection and standardize behaviors across time and generations. And norm-consistent actions are more predictable and understandable (Malle, Scheutz, \& Austerweil, 2017).

But how does the human mind represent norms, and how are they activated and learned? Surprisingly, there are few cognitive science approaches to the central phenomenon of norms. Logical and specifically deontological approaches have been proposed to formally represent a system of norms (Bringsjord, Arkoudas, \& Bello, 2006; Scheutz \& Malle, 2014; Pereira \& Saptawijaya, 2009; Beller, 2010). These are important starting points, but their formalizations do not necessarily correspond to how norms are represented in the human mind. By contrast, a cognitive science approach would aim at an account of how norms are cognitively represented, how they are activated in relevant situations, and how they are learned in the first place. Here we take a first step toward such an account, following a recent theoretical proposal (Malle et al., 2017). We introduce a basic formal representation of norms that allows us to examine the mentioned cognitive properties of norms (representation, activation, and learning), and we ask what computational models can capture these properties, and what algorithms could learn norms.

Our paper has three main parts. In the first, we present a novel belief-theoretic norm representation format that explicitly captures the context-specificity of norms and incorporates uncertainty associated with norm representations, using Dempster-Shafer Theory (Shafer, 1976). In the second part, we introduce experimental data on human norm representation and activation that underscore the context-specificity of norms and community members' strong but imperfect agreement (uncertainty) over norm applications. In the third part we use our formal norm representation to ask how such imperfect norms systems can be learned by a computational algorithm that honors several of the critical features of norms, including their context specificity and uncertainty.

## Part 1: A Representation Format for Norms

We begin by briefly outlining our norm representation format in first-order logic and provide some intuitions as to how context and uncertainty are accounted for in the format. The
purpose is to introduce some terminology and a minimal degree of formalism in the proposed approach, which will later be useful in developing an algorithm that can learn norms.

Consider a first-order alphabet $\mathcal{L}$, in which we have all the standard symbols (variables, predicates, functors) and logical connectives. In a deontic alphabet, we further include $\mathbb{O}, \mathbb{F}, \mathbb{P}$ that denote modal operators (generally, $\mathbb{D}$ ) for obligatory, forbidden and permissible, respectively. In this alphabet, we define a norm, as follows:

Definition 1 (Norm). A norm is an expression of the form:

$$
\mathcal{N}:=C_{1}, \ldots, C_{n} \Longrightarrow(\neg) \mathbb{D}\left(A_{1}, \ldots, A_{m}\right)
$$

where C represents context conditions and A represents actions or states. The norm expression states that when the contextual atoms $C_{i}$ are true then the Actions or States $A_{j}$ are either obligatory, forbidden or permissible, or their negation.

This type of norm definition follows an approach to normative reasoning and norm formalism that some of us have taken previously (Malle et al., 2017; Bringsjord et al., 2006; Scheutz \& Malle, 2014).

In this paper, we expand the above representation format by explicitly accounting for uncertainty of a norm as follows:
Definition 2 (Belief-Theoretic Norm). A belief-theoretic norm is an expression of the form:

$$
\mathcal{N}:=[\alpha, \beta]:: C_{1}, \ldots, C_{n} \Longrightarrow(\neg) \mathbb{D}\left(A_{1}, \ldots, A_{m}\right),
$$

where $[\alpha, \beta]$ represents a Dempster-Shafer uncertainty interval, with $0 \leq \alpha \leq \beta \leq 1$.

Example 1 Consider an example of an agent reasoning about actions it can perform or states it can enter in a library. We can represent this scenario as a Belief-Theoretic Norm System, $\mathcal{T}$, as follows:
$\mathcal{N}_{1}:=[0.9,1]::$ in $($ library,$X) \Longrightarrow$ (1) state $(X$, quiet $)$
$\mathcal{N}_{2}:=[0.8,0.95]::$ in $($ library,$X) \Longrightarrow \mathbb{P}$ action $(X$, reading $)$
$\mathcal{N}_{3}:=[0.9,1]::$ in $($ library,$X) \Longrightarrow \mathbb{F}$ action $(X$, yelling $)$
$\mathcal{N}_{4}:=[0,0.3]::$ in $($ library,$X) \Longrightarrow \mathbb{O}$ action $(X$, talking $)$
$\mathcal{N}_{5}:=[0.3,0.6]::$ in $($ library,$X) \Longrightarrow \mathbb{F} \operatorname{action}(X$, talking $)$
The norms in this example have intuitive semantics. They generally state that when agent $X$ is in the library (i.e., in $($ library,$X)$ ), then the norm is activated and the agent is obligated to enter a certain state (e.g., state $(X, q u i e t))$ or prohibited from performing a certain action (e.g., action( $X$, talking). The location of the center of the uncertainty interval generally suggests the degree of truth of the norm applying and the width of the interval generally suggests the level of support or evidence for that norm. So norms $\mathcal{N}_{1}, \mathcal{N}_{2}$, and $\mathcal{N}_{3}$ have tight uncertainty intervals close to 1 indicating a confident support for their truth. Norm $\mathcal{N}_{4}$ states that the action of "talking" is obligatory in libraries. Although the uncertainty interval for this norm is tight, the center is closer to zero indicating confident support for the falsity
of the norm. Finally, in rule $\mathcal{N}_{5}$ the question of whether talking is forbidden in a library may be more uncertain, generating a wider interval centered close to 0.5 , indicating support for both truth and falsity, but a general lack of confidence in the evidence. ${ }^{1}$

A belief-theoretic norm system of this form allows the separation of evidence from the norms themselves. The evidence may come in different forms across different modalities and from different sources. The norm system, however, displays the agent's current level of belief about a set of norms that are influenced by the evidence.

In any given situation, the agent may not be reasoning with every norm in a norm system. Instead, the agent may consider a subset of the system, perhaps including only norms that are applicable to the current situation. We capture this intuition in a norm frame, defined below.
Definition 3 (Norm Frame). A norm frame $\mathcal{N}_{k}^{\Theta}$ is a set of $k$ norms, $k>0$, in which every norm has the same set of context predicates and corresponds to the same deontic operator. Thus, in Example 1, norms $\mathcal{N}_{3}$ and $\mathfrak{N} 5$ would constitute a norm frame.

We define a norm frame in this way because it allows for cognitive modeling in a situated manner-that is, reasoning about behavior relevant to a specific situation. This contextspecificity provides a convenient constraint that can help simplify computation and better capture human norm representations, as introduced next.

## Part 2: Norm Representation and Activation in Human Data

We are currently engaged in an empirical research program that tests a number of novel hypotheses about the cognitive properties of norms (Malle et al., 2017). Here we summarize two experiments that illustrate some of these properties and provide the learning data for the norm learning algorithm we introduce in Part 3. In the first experiment, participants generated norms relevant to a variety of contexts; in the second experiment, participants detected norms relevant to those contexts.

## Methodology

In the generation experiment (Kenett, Allaham, Austerweil, \& Malle, 2016), participants ( $n=100$ recruited from Amazon Mechanical Turk, AMT) inspected four pictures, one at a time, that depicted an everyday scene (e.g., library, jogging path; see Figure 1 for examples). While inspecting each picture, they had 60 seconds to type as many actions as came to mind that one is "allowed" to perform in this scene

[^192](Permissions), or is "not allowed" to perform (Prohibitions), or is "supposed" to perform (Prescriptions). This betweensubjects manipulation of norm type was constant across pictures so that each participant answered the same question (e.g., "What are you permitted to do here?") for all four pictures they encountered.

Figure 1: Four sample scene pictures used to elicit norms
To increase generalizability at the stimulus level, the total number of scenes used in the experiment was in fact eight, four that previous participants had tended to describe as locations (e.g., library, cave), and four that they had tended to describe as activities (e.g., jogging outdoors, serving in a restaurant). Each participant was randomly assigned to receive either the "location" set or the "activity" set. Item set made no difference in the results.

The resulting verbal responses were lightly cleaned for spelling and grammatical errors and responses identical in meaning were assigned the same response code, using a conservative criterion so that variants such as "listening" and "listening to music" were counted as distinct. The resulting data structures were then analyzed for consensus (i.e., how many people generated a given response for a given scene) and context distinctiveness (i.e., whether a response generated for one scene was also generated in a different scene).

In the detection experiment, we presented participants ( $n$ $=360$ recruited from AMT) with the same pictures, four per participant. Along with each picture, we presented 14 actions (randomly ordered, one at a time) that a person might perform in this context. Any given participant's task was the same for each of their four pictures: to consider the particular scene and judge whether each of the 14 actions is either permitted, or prescribed, or prohibited. This norm type factor was again a between-subjects manipulation and hence constant across pictures. In addition, to increase generalizability, we used two different formulations for each norm type, summarized in Table 1. Formulation made no difference in the results.

The 14 actions assigned to a given scene under a given norm type (e.g., Library/permitted) consisted of seven "local" and seven "imported" actions. Local actions were the

Table 1: Eliciting Probes for Three Norm Types

| Norm Type | Probe formulations |
| :--- | :--- |
| Permission | Are you allowed to do this here? <br> Are you permitted to do this here? |
| Prohibition | Are you not allowed to do this here? <br> Are you forbidden to do this here? |
| Prescription | Are you supposed to do this here? <br> Should you do this here? |

seven most frequently generated actions for the given scene and norm type in the above generation experiment-for example, the seven actions most frequently mentioned to be permitted in the library. Imported actions were comprised of top-seven actions generated for other scenes (but under the same norm type). Thus, imported actions were still frequent responses to the same norm probe, but in different contexts. ${ }^{2}$ Table 2 provides an illustration of this selection process.

Table 2: Origin of Selected Actions for Library Scene

| Action | Origin |
| :--- | :--- |
| Local, permitted |  |
| reading | from top 7 of Library |
| studying | from top 7 of Library |
| sitting | from top 7 of Library |
| checking out a book | from top 7 of Library |
| learning | from top 7 of Library |
| being quiet | from top 7 of Library |
| using computers | from top 7 of Library |
| Imported, permitted |  |
| eating | from top 7 of Beach |
| walking | from top 7 of Cave |
| listening | from top 7 of Boardroom |
| filling boxes | from top 7 of Harvesting |
| washing hands | from top 7 of Public Bathroom |
| running | from top 7 of Jogging |
| talking | from top 7 of Restaurant |

## Experimental Results

We begin by highlighting three findings from the generation experiment. ${ }^{3}$ First, even though people were entirely unconstrained in their norm-guided actions, they showed a great deal of consensus on the most central norms for each scenario. Table 3 displays (in column Consensus) the seven most frequently mentioned permission norms in two representative scenarios, Library and Jogging, with consensus computed as the percentage of participants who mentioned the particular

[^193]action as permitted in the scenario. (The patterns are consistent across other scenarios.) Second, the most consensual norms are mentioned early on; in other words, what comes to mind first is likely to be a consensual norm. Table 3 shows (in column Position) the average rank position ( $1=$ first, $2=$ second, etc.) at which each action was generated, whereby the expected position under a random distribution would be 4.2 for Library and 4.6 for Jogging. Third, the norms generated for the eight scenarios showed remarkable context specificity. Not only do the two illustrated scenes have no norm in common among their top seven, but of the 56 permitted actions that were mentioned in the top- 7 in each of the 8 scenes, only 5 appeared in more than one scene.

Table 3: Permission Norms for Library and Jogging Scenes in the Norm Generation Experiment

| Library |  |  |
| :--- | :---: | :---: |
| Permitted Action | Consensus | Position |
| reading | $84 \%$ | 2.1 |
| studying | $68 \%$ | 1.8 |
| sitting | $47 \%$ | 3.1 |
| checking out books | $47 \%$ | 4.4 |
| using computers | $32 \%$ | 5.3 |
| learning | $32 \%$ | 6.0 |
| being quiet | $32 \%$ | 7.5 |
| Jogging |  |  |
| walking | $87 \%$ | 1.4 |
| running | $87 \%$ | 1.9 |
| jogging | $53 \%$ | 4.8 |
| talking | $53 \%$ | 5.1 |
| listening to music | $33 \%$ | 4.3 |
| biking | $27 \%$ | 4.7 |
| looking at birds | $27 \%$ | 6.2 |

Two main results stand out from the detection experiment. First, people showed very high consensus in affirming the permissibility of the seven local actions for their respective scenes. For both Library and Jogging, this rate was 99\%; and across all scenes, the number was $97.2 \%$. That is, even though some of these local actions were actively generated as "permissible" by only a third or half of previous participants (see Table 3), when directly confronted with these actions, people almost uniformly recognized their permissibility. (Moreover, this recognition was fast, taking only about 1100 ms on average.)

Second, participants clearly distinguished between the local and the imported actions, accepting the latter as permissible at a significantly lower rate. For Library, this rate was $43 \%$; for Jogging, it was $75 \%$; and across all scenes, it was $66.1 \%$ (all statistical comparisons to local actions $p<.001$, signal detection discrimination parameter $d^{\prime}=1.49$ ). That is, for a given context on average, $34 \%$ of presented actions were judged to be not permitted even though they were explicitly deemed permissible in other contexts.

These results suggest that norms can be activated by static
photographs, and people show high agreement in explicitly recounting these norms (generation experiment). In a more implicit setup (detection experiment), people are fast and almost unanimous in affirming the most important norms of a given context and differentiate them well from norms originating from a different context. Thus, both explicit and implicit judgments show substantial context sensitivity. If these are some of the properties of human social and moral norms, how can they possibly be learned, by humans and machines?

## Part 3: Learning Norms

## How Do People Learn Norms?

In learning social and moral norms, people deal with multiple different norm types (permissions, prescriptions, prohibitions), using many different learning mechanisms, and taking input from many different sources. Here we focus on the process of learning permission norms from simple observation, using responses from a sample of community members described earlier in the detection experiment. Our main goal is to put our proposed computational framework to a test. In the future we will develop further applications (e.g., learning of obligations or learning from instruction)

Consider a person who has never spent time in a library. Upon entering one for the first time, he observes several people reading, studying, and a few whispering. Some sit at computers, one is eating while sitting in an armchair, although there is a sign that says "No food or drink in the library." Our observer also sees several people at the check-out counter, subsequently exiting the library, where another sign says "Don't forget to check out." Briefly, a younger person runs alongside the stacks but then sits down next to an adult.

The number of people performing each behavior, their age, expertise, appearance, perhaps responses from others, and the meaning and force of various physical symbols will all contribute to the speed and confidence with which our protagonist learns the norms of a library. Below we offer a data representational format that incorporates these and other properties of the norm learning process, a format that can also accommodate partial information and unknown prior probability distributions and that can be extended to other learning mechanisms, such as verbal instruction or trial and error.

## Data Representation Format of Norm Learning

Consider a set $S=\left\{s_{1}, \ldots, s_{n}\right\}$ of $n$ evidence sources. For example, an evidence source $s_{i}$ could be a student in the library, the librarian, or a sign at the entrance. To simplify, we are interested in learning about a norm frame $\mathcal{N}_{k}^{\Theta}$ comprising $k$ norms (out of a larger possible set) that all share the same deontic type (here, permissions) and the same general context precondition (here, library).

Let an endorsement $e_{i, j}$ be the $i^{\text {th }}$ data source's endorsement of the $j^{\text {th }}$ norm, where $e \in\{0,1, \varepsilon\}$. The value $e_{i, j}$ is a form of truth assignment, indicating whether the source endorses the norm to be true (1), false (0) or unknown ( $\varepsilon$ ). For example, an observation that a student is reading can be in-
terpreted as showing that this student endorses the norm $\mathcal{N}_{2}$ to be true in this context, hence $e_{i, \mathscr{N}_{2}}=1$. The set $\Phi_{s_{i}}$ represents a given source's finite set of endorsements within a given norm frame, such that $\left|\Phi_{s_{i}}\right|=k$.

Informally, for a set of norms in a given context and for a particular source, we can learn about that source's endorsement of each norm; if we also assign a weight (e.g., reliability, expertise) to the source, we form a data instance. Multiple data instances (i.e., evidence from multiple sources) form a data set. More formally:

Definition 4 (Data Instance). $A$ data instance $d=$ $\left(\mathcal{N}_{k}^{\Theta}, s_{i}, \Phi_{s_{i}}, m_{s_{i}}\right)$ is a tuple comprising a norm frame $\mathcal{N}_{k}^{\Theta}$, a specific source $s_{i}$, a set of endorsements $\Phi_{s_{i}}$ provided by that source, and a mass assignment $m_{s_{i}}$ corresponding to the amount of consideration or reliability placed on source $s_{i}$.
Definition 5 (Dataset). A dataset $\mathcal{D}$ is a finite set of $n$ data instances $\left\{d_{1}, \ldots, d_{n}\right\}$.

Some of the desirable properties of the proposed data representation format are that we can accommodate various types of sources (e.g., behavior, verbal responses, signs and symbols), differential source reliability (mass), order effects (updates can be tuned, if necessary, to the order of received data), missing and imprecise information (we use $\varepsilon$ to represent ignorance), lacking prior probability distributions (we do not require any priors), and varying norm dependencies (e.g., we can capture a correlation between the prohibition to yell and the prohibition to talk).

## Algorithmic Learning of Experimental Data

We can now apply this representation format to the detection data we introduced earlier. The detection experiment featured, for each scene, a norm frame $\mathcal{N}_{k}^{\Theta}$ with $k=14$ potentially permissible actions, where half of the potential actions had been specifically identified as permitted in this scene and the other half as permitted in other scenes (see Table 2). Each participant, $s_{i}$, indicated whether each of 14 actions was in fact allowed in this scene, providing responses of yes (1) or no (0) or no response ( $\varepsilon$ ), thus forming a set of endorsements $\Phi_{s_{i}}$, with $|\Phi|=14$. In this particular case we treat all sources as equally reliable, hence carrying identical $m_{s_{i}}$ weights.

With these representations in hand we can formally define the norm learning problem within our framework and set the stage for an algorithm to analyze evidence and derive a norm structure for a given context in a given community. We remind the reader that, according to Definition 2, any norm (e.g., with respect to reading in a library) has an uncertainty interval $\left[\alpha_{1}, \beta_{1}\right]$ associated with it, which reflects the quality and consistency of the evidence for a given norm to hold. The learning problem thus becomes a parameter learning problem for discovering the values of the uncertainty interval for each norm in a norm frame:

Definition 6 (Norm Learning Problem). For a norm frame $\mathcal{N}_{k}^{\Theta}$ and dataset $\mathcal{D}$, compute the parameters $\alpha_{1}, \ldots, \alpha_{k}, \beta_{1}, \ldots, \beta_{k}$ of that norm frame.

As noted earlier, each data instance $d$ represents a potential arrangement of true and false values for each of the norms in a frame. Setting aside the possibility that $e_{i, j}=\varepsilon$, each data instance thus provides a $k$-length string of 1 s and 0 s (a given participant's response string in the detection experiment). This string is a sample of the normative endorsements in the given community. The norm learning algorithm represents each string as a hypothesis in a set of hypotheses (termed Frame of Discernment in Dempster-Shafer theory) and assigns uncertainty parameters to each norm, updating those values as it considers each new data instance. Algorithm 1, displayed below, achieves this form of norm learning from a human dataset.

```
Algorithm 1 getParameters \(\left(\mathcal{D}, \mathcal{N}_{k}^{\Theta}\right)\)
    \(\mathcal{D}=\left\{d_{1}, \ldots, d_{n}\right\}\) : Dataset containing \(n\) data instances for a
    norm frame
    \(\mathcal{N}_{k}^{\Theta}\) : An unspecified norm frame containing \(k\) norms \(\mathcal{N}\)
    Initialize DS Frame \(\Theta=\left\{\theta_{1}, \ldots, \theta_{2^{k}}\right\}\)
    \(m(\Theta)=1\)
    for all \(d \in \mathcal{D}\) do
        for all \(\mathcal{N} \in \mathcal{N}_{k}^{\Theta}\) do
            Set learning parameters \(p_{1}\) and \(p_{2}\)
            \(\operatorname{Bel}(\mathcal{N} \mid d)=\frac{\operatorname{Bel}(\mathcal{N} \cap d)}{\operatorname{Bel}(\mathcal{N} \cap d)+P l(d \backslash \mathcal{N})}\)
            \(P l(\mathcal{N} \mid d)=\frac{P l(\mathcal{N} \cap d)}{P l(\mathcal{N} \cap d)+\operatorname{Bel}(d \backslash \mathcal{N})}\)
            \(\operatorname{Bel}(\mathcal{N})_{\text {new }}=p_{1} \cdot \operatorname{Bel}(\mathcal{N})_{\text {prev }}+p_{2} \cdot \operatorname{Bel}(\mathcal{N} \mid d)\)
            \(P l(\mathcal{N})_{\text {new }}=p_{1} \cdot P l(\mathcal{N})_{\text {prev }}+p_{2} \cdot \operatorname{Pl}(\mathcal{N} \mid d)\)
        end for
        Set frame \(\Theta\) with \(\operatorname{Bel}(\mathcal{N})_{\text {new }}\) and \(\operatorname{Pl}(\mathcal{N})_{\text {new }}\)
    end for
    for all \(\mathcal{N} \in \mathcal{N}_{k}^{\Theta}\) do
        \(\alpha_{\mathcal{X}} \leftarrow \operatorname{Bel}(\mathcal{N})\)
        \(\beta_{\mathcal{N}} \leftarrow P l(\mathcal{N})\)
    end for
    return \(\alpha_{1}, \ldots, \alpha_{k}, \beta_{1}, \ldots, \beta_{k}\)
```

The algorithm iterates though each data instance in the data set (line 6) and, per instance, through each norm in the norm frame (line 7). For each iteration, we first set the hyperparameters $p_{1}$ and $p_{2}$ (line 8 ) that specify how much weight the algorithm will place on previous learned knowledge $\left(p_{1}\right)$ and on each new data instance ( $p_{2}$ ). These hyper-parameters are then used to compute a conditional belief and plausibility for a norm given that particular instance of data (lines 9,10 ). The conditional beliefs and probabilities then yield an updated belief and plausibility for each norm (lines 11, 12). Finally, the algorithm updates the uncertainty interval for each norm with the new belief and plausibility values.

The result is a set of belief-theoretic norms (norms accompanied with uncertainty intervals), where the width of the uncertainty interval indicates the amount of support for the norm (which may vary, for example, as a function of number of respondents in the human data sample) and the center position of the interval should correspond to the level of agreement in the human respondents' endorsement of the norm.

To put this algorithm to the test, we selected, from our detection experiment, a norm frame of 6 (out of 14) actions for
the context of Library and a frame of 6 (out of 14) actions for the context of Jogging Path. However, we wanted to capture the context specificity of norms and constructed the frames such that 4 actions (running, sitting, walking, and washing hands) were the same in each frame, albeit differentially endorsed in the two contexts (e.g., running was clearly not permissible in Library but very much permissible in Jogging). Thus, the algorithm had to track the norm value of a given action not in general, but conditional on the specific context. If the algorithm succeeds it should recognize which actions people consider permissible and which ones they consider impermissible, for each of the two contexts, and even for those actions that occur in both contexts.

Figure 2 illustrates this success. We display single runs of the algorithm across the dataset. In the single runs, the algorithm considers each data instance (each of 30 participants' judgments) in each context once (in a fixed order), leading to wide uncertainty intervals at first, but narrower ones as the number of data instances increases (up to the maximum of 30) . We also performed iterative runs (not shown), in which the algorithm considers the dataset multiple times, each time randomly selecting a possible order of instances, and converging on an optimal estimate of the norm endorsements in the given community. These estimates are highly comparable to the end points of single runs after 30 data instances.

Figure 2: Single run of learning across two contexts. The narrowing shaded regions indicate converging uncertainty intervals as new data instances are processed. Filled circles represent the descriptive statistics from the experimental data, indicating actual norm endorsement averages among participants-the proportion of participants who answered yes to the question: "Is this action allowed here?" The algorithm displays convergence towards the descriptive statistics (which it was not given), while maintaining a level of uncertainty reflecting the imperfect agreement within the data.

## Conclusion

In this paper we presented a formal representation of norms using first-order logic and Dempster-Shafer theory. The representation captures the context specificity of norms that our experimental data suggest are strongly present in humans. Using a data representation format that incorporates several properties of human norm representation and learning, we then developed a novel algorithm for automatically learning context-sensitive norms from the human data. Because the data format is highly generalizable, norms could be learned from different types of evidence sources in different contexts, and explicitly captures uncertainty due to variations in the source's reliability and the quality of the evidence. The proposed representation and learning techniques provide a promising platform for studying, computationally, a wide array of cognitive properties of norms.

# Attractor Dynamics in Delay Discounting: A Call for Complexity 

Martin Schoemann (martin.schoemann@tu-dresden.de)<br>Department of Psychology, Technische Universität Dresden, 01062 Dresden, Germany

#### Abstract

The outcomes of intertemporal choices indicate that people discount rewards by their delay. These outcomes are well described by discounting functions. However, to fully understand the decision process one needs models describing how the process of decision-making unfolds dynamically over time. Here, we validate a recently published attractor model that extends discounting functions through a description of the dynamics leading to a final choice outcome within and across trials. We focus on the decision dynamics across trials. We derive qualitative predictions for the inter-trial dynamics of sequences of decisions that are unique to this type of model. We test these predictions in a delay discounting game where we sequentially manipulated subjective values of options across all attribute dimensions. Results confirm the model's predictions. We discuss future challenges on integrating attractor models towards a general attractor model of delay discounting to enhance our understanding of the processes underlying delay discounting decisions.

Keywords: decision making; delay discounting; process dynamics, attractor dynamics; hysteresis; neural attractor model

## Introduction

Many everyday choices involve options that pose a conflict between immediate, but small gains, and delayed, but larger or more beneficial gains. This conflict occurs on many time scales. For example, you might wonder whether to enjoy spending your money now or saving it for a pension. Or you might be tempted to take the tasty pizza - which is immediately very tasty - instead of the light salad - which might be better for your cardiovascular system in the longterm. In such intertemporal choices (for a review, see Frederick, Loewenstein, \& O’Donoghue, 2002), humans discount the offered gain by the delay of delivery. This delay discounting is well described by utility discounting models which assume that the greater the delay in delivery of a reward, the more the utility of a reward is discounted. Hence, these discounting models represent the subjective value of a reward as a function of its delay (see Doyle, 2013 for an overview). While these mathematical models offer a good description of the average outcome of the decision process - the final choice - they mostly leave open how the exact decision process unfolds in time. Decoding this
process, though, is necessary in order to fully understand the way decisions are made. To fill this gap, recent developments aim to uncover the process dynamics leading to a final decision in delay discounting (Dai \& Busemeyer, 2014; Rodriguez, Turner, \& McClure, 2014; Scherbaum et al., 2016). Specifically, the attractor model approach (Figure 1) has recently been proved useful to uncover the process dynamics leading to a final choice outcome on different time scales, that is within and across sequential intertemporal choices (Scherbaum et al., 2016).

In this study, we will use the attractor model and the experimental paradigm as proposed by Scherbaum et al. (2016) to derive and validate qualitative predictions on the inter-trial dynamics of sequences of intertemporal decisions. More detailed, the attractor model of decision making in

Figure 1: Sketch of possible attractor layouts given different values of the control parameter c. This parameter depends on the relative difference in subjective value (attractiveness) of the options for a subject and hence configures the system for each potential combination of SS and LL: An increase in attractiveness for the LL option results in a negative control parameter which, in turn, increases the depth of the attractor representing the LL option (left panel). In contrast, an increase in attractiveness for the SS option results in a positive control parameter which, in turn, increases the depth for the attractor representing the SS option (right panel). Inherently, the control parameter $c$ is primarily dependent on the values and delays of the presented options, but also on a subject's tendency to discount. Within this potential landscape, the current system state (marked by a red dot) tends to move to the bottom of the potential wells and travels through all intermediate states on its way to a stable final choice.

Figure 2: Inter-trial dynamics in the attractor model. Choosing the LL option in a first trial leads to a bias in a second trial due to slow relaxation (e.g. inertia) of the system state during the inter trial interval (ITI, in this study 1.3 seconds).
delay discounting assumes that the depth of the attractors and hence the stability of its end-states is determined by a combination of each option's reward value and delay. By varying either both or one of those properties, the depth of the attractors can be manipulated. To that end, the depth of the attractors represents the relative attractiveness of each option, and that is, the respective subjective (discounted) value, within the attractor model (Figure 1). Hence, the difference in relative attractiveness between the two options determines the systems preference towards either option and is summarized by the control parameter, which we will call $c$. Figure 1 depicts three kinds of possible attractor layouts given three prototypical specifications of $c$. The attractors itself picture stable neural representations of the available options. So, the left and right panel of Figure 1 reflect almost exclusive activation of one option's representation, and hence illustrate configurations of the system with a preference towards one option $(c \neq 0)$. Accordingly, the special case where $\mathrm{c}=0$ (Figure 1 middle panel) reflects varying amounts of concurrent activation in which the system has not settled into a decision yet, and hence represents a decision in which both options receive an identical input and are thus equally attractive. In this special case scenario, a neutral starting state would keep the system indifferent until slight differences in input (or random noise) tips the system to one side or the other, resulting in a more or less arbitrary decision which was not driven by the systems preference. A major advantage of attractor models is that the decision is not only determined by the current attractor layout, which is in turn determined by the currently offered options, but also through the history of the system's previous decisions (Scherbaum, Dshemuchadse, \& Kalis, 2008; Townsend \& Busemeyer, 1989). This is due to the genuine assumption that the attractors are formed by the offered options and, hence, these attractors are not present between trials. The inertia of neural systems causes the system to temporally recline in the area where it ended up previously-in the vicinity of the vanished attractor representing the recent choice-and to relax only slowly to the neutral start state under no input. For example, if the
model chose one option in a first decision trial, it would remain in the vicinity of this option's attractor in the inter trial interval. In a second decision trial, it would hence start the decision with a bias to the previously chosen option, even if this trial comprises the other option being more attractive (see Figure 2).

Scherbaum et al. (2016) used this premise to predict and validate hysteresis effects (Tuller, Case, Ding, \& Kelso, 1994), which are also known as path-dependence, in intertemporal choice. Hysteresis or path-dependence occur, when the decision for one option biases the next decision in favor of the same option (see Figure 2). Hence, in a series of choices in which the initially unchosen option becomes increasingly more attractive (i.e. sequential manipulation of the difference in the relative attractiveness), people stick to the initially chosen option and switch to the now more attractive option much later than they would if their choices were unbiased. However, the sequential manipulation of the difference in the relative attractiveness was merely operationalized by variation of the delay, though the attractor model predicts the same hysteresis effects when the manipulation is realized through a variation of the reward value or even a combination of delay and value. We hence hypothesized that the emergence of hysteresis effects is independent from the attribute dimension which is used to sequentially manipulate the difference in the relative attractiveness between both options (intervals, value difference, or both together).

To provide an insight into hysteresis effects in delay discounting, we applied the same non-verbal delay discounting task as used in the original study. This task redresses the problem that in standard intertemporal choice tasks the sequential manipulation of reward values or delays is simply too obvious (Scherbaum et al., 2016; Scherbaum, Dshemuchadse, Leiberg, \& Goschke, 2013). In this task, subjects collect coins of different reward values with an avatar which they move on a checkered playing field by clicking with the computer mouse (Figure 3). The playing field stays constant across trials-except the options which change from trial to trial-and the avatar started each trial from the position of the previously chosen option. The goal is to collect as much reward as possible in the allotted amount of time. In each trial of the task, subjects have to choose between two reward options of different magnitude (small vs. large) at different distances (near vs. far fields). Therefore, this task translates delays into distances, which allows for a more implicit sequential manipulation of the relative attractiveness of options.

To implement the sequential manipulation of different attributes, we used this task in a modified, two-step procedure: In the first part, we measured the individual amount of discounting (the measurement block). Based on this amount of discounting, we created individually tailored sequences of decision to study hysteresis in the following part (the manipulation block). We expected the hysteresis effect to be present in all variants of sequential manipulations.

## Methods

## Subjects

43 students ( $65 \%$ female, mean age $=22.98$ years) of the Technische Universität Dresden took part in the experiment that lasted approximately 50 minutes. All subjects had normal or corrected to normal vision. Three out of 43 subjects were excluded from any subsequent analysis due to individual discounting behavior in the measurement block not allowing for a sufficient hysteresis manipulation in the manipulation block. Subjects gave informed consent to the study and received a $2.50 €$ show-up fee and the money they collected within the experiment $($ Mean $=3.17, \mathrm{SD}=0.39)$.

## Apparatus and Stimuli

The experiment was presented on a 17 -inch screen ( 1280 x 1024 pixels, 85 Hz ). As presentation software, we used Psychophysics Toolbox 3 (Brainard, 1997; Pelli, 1997) in Matlab 2010b (the Mathworks Inc.), running on a Windows XP SP2 personal computer. Responses were carried out by moving a high precision computer mouse (Logitech Laser Mouse USB).

Subjects moved an avatar on a playing field divided into $20 \times 20$ fields (Figure 3). To move the avatar, subjects clicked with the mouse in one of four horizontally or vertically adjacent movement fields, as signaled by a white border surrounding the fields. On each trial two reward options were presented as coins on fields marked with a red border: One reward was near but small, the other reward was far but large. The two options' positions were always chosen so that the first move into one direction decreased the distance to one option but increased the distance to the other option. This way, the first move of the avatar already represented a clear preliminary decision for one option and against the other option.

For both options, a number posed within each coin represented the reward value and the horizontal and vertical distance of the reward field to the field of the avatar represented the distance of the option. Reward values ranged from 1 to 99 credits and distances ranged from two to fifteen fields. For better comprehensiveness in the context of intertemporal choice, we maintain in the following the standard description of the time dimension using "soon",

Figure 3: Detail of the dynamic delay discounting paradigm.
"late", "delay", and "interval", although in our scenario time delay is represented by spatial distance. The relation between the two reward values can be characterized as the ratio of the higher and smaller reward value and will be denoted by "difference".

Above the avatar (Figure 3) subjects could see the remaining time within one block, as well as below the collected credits in Euro ( 1 credit $=1 / 10 €$ cent), but only in the very moment when either reward was collected.

## Procedure

Subjects' task was to collect as much reward as possible within the allotted time limit. In each trial, they had to choose between two reward options (one soon but small, $S S$, one late but large, $L L$; see design). They collected the selected reward by moving their avatar with the mouse across the playing field.

A trial started with an inter trial interval (ITI) of 1.3 seconds. Within this interval, the mouse cursor was locked in the center of the field containing the avatar. After the ITI, the two options were presented. As soon as the two options appeared, participants could click on the adjacent movement fields to move their avatar towards the chosen option (Figure 3). When the avatar reached one option, both options disappeared, the value of the selected option was added on the collected credits, and the next trial started.

The experiment consisted of four blocks, with one block lasting eight minutes. Between blocks, subjects were informed about the credits collected and were instructed to rest briefly before the self-paced start of the next block.

Before the start of the experimental blocks, subjects worked through a test block of two minutes to get used to the virtual environment, handling of the mouse, as well as the range of spatial distances and reward values.

## Design

The experiment consisted of four blocks with the first block (measurement block) being conceptually different from the three subsequent blocks as its aim was to measure the subjects' individual discounting behavior. In each of the three subsequent blocks (manipulation blocks) we realized a unique adaptive hysteresis manipulation constituting an interval block, a value block, and a combined block. Each subject's session started with the measurement block followed by the manipulation blocks. The sequential arrangement of the manipulation blocks was fully varied and balanced between subjects.

In the measurement block, reward values ranged from 11 to 99 and distances from three to 15 . That was given by orthogonally varying the intervals ( $1,4,8$, and 12 fields), the differences $(20,50,70,80,88,93,97$, and $99 \%)$, and the delay of the sooner option ( 2 and 3 fields). Additionally, the reward values of the late option were randomly chosen from a discrete uniform distribution between 55 and 99 credits. The combination of 8 differences, 2 distances of the SS options and 4 intervals between the SS and the LL option yielded a complete set of 64 trials. We generated 5 such
sets, with a randomized order of trials within each set. The measurement block's time limit ensured that subjects could work through the complete design matrix, that is one of those 5 sets, at least one time.

To realize the adaptive hysteresis manipulation, we calculated the subjects' individual discounting curve from which we adaptively derived trials compatible to the respective hysteresis manipulation (see Results). The structure of an adaptive hysteresis manipulation is to sequentially change subjects' preference from the SS towards the LL option, or vice versa. In our adaptive trial sequences, we aimed to change subjects' preference in 12 steps as indicated by the differences between the subjective value ratio (SS/LL) in the trials and the indifference points $(-0.3000,-0.2455,-0.1909,-0.1364,-0.0818,-0.0273$, $0.0273,0.0818,0.1364,0.1909,0.2455,0.3000)$, that is the manipulation points. ${ }^{1}$ It is imperative that a negative manipulation point indicates a preference for the LL option and a positive manipulation point a preference for the SS option. Furthermore, it applies that the higher the absolute manipulation point, the more distinct are the relative attractiveness of both options. Hence, a manipulation point of zero represents no preference, that is the indifference point. Please note that the interpretation of the manipulation point is analog to the interpretation of the control parameter.

We then applied this manipulation in three different subblocks. First, in the interval block we consecutively increased or decreased the delay of the LL option to the avatar while keeping all other factors constant within the sequence. For each sequence the delay of the sooner option and the reward value of the late option were randomly chosen from discrete uniform distributions between 2 and 3 fields, and 55 and 99 credits, respectively. The reward value of the sooner option was randomly drawn from the uniform distribution between subjects' two indifference points at the intervals 6 and 7. Furthermore, we varied the direction of these sequences (direction $=$ ascending or descending) and created eight sequences for each direction. This resulted in 16 possible sequences, and hence 192 trials.

Second, in the value block we consecutively increased or decreased the reward value of SS option while keeping all other factors constant within the sequence. Again, for each sequence, the delay of the sooner option and the reward value of the late option were randomly chosen. The delay of the LL option to the avatar was drawn randomly between all intervals at which subjects' indifference point was positioned in such a way that all 12 manipulation points were valid, that is, did not exceed 1 or fall below a value of 0 . For each trial within the sequence, the reward values of the SS option were then calculated. Again, we also varied the direction of these sequences and created eight sequences

[^194]

Figure 4: Subjects' indifference points in the measurement block, depicting the decrease in subjective value of the latelarge option as a function of intervals between the two options. Indifference points are the subjective value ratio (SS/LL) at which subjects chose indifferently between the two options, i.e., the probability of choosing LL over SS is $50 \%$. Note: Error bars indicate standard errors. The curve displays the fitted hyperbolic functions.
for each direction. This resulted in 16 possible sequences, and hence 192 trials.

Third, in the combined block we consolidated the former manipulations and varied both the delay of the LL option to the avatar and the reward value of the SS option in such a way that the manipulation points consecutively increased or decreased within the sequence. Again, for each sequence the delay of the sooner option and the reward value of the late option were randomly chosen. For each trial within the sequence, the delay of the LL option was randomly chosen from the set of intervals in which the respective manipulation point was valid. The reward values of the SS option were then calculated. Again, we also varied the direction of these sequences and created eight sequences for each direction. This resulted in 16 possible sequences, and hence 192 trials.

In sum, we applied a 2 (direction: ascending, descending) x 3 (manipulation type: interval, value, combined) full factorial within-subjects design.

## Results

On average, subjects completed 134 trials $(S D=23)$ in the measurement block. Hence, subjects ran through at least two out of five sets of 64 trials. The aim of the measurement block was to measure subjects' individual discounting behavior indicated by subjects' indifference points as depicted by Figure 4. As an estimate of the indifference point, the point of inflection of a logistic function was fitted to the individual choices as a function of increasing value

Figure 5: Average hysteresis plots between manipulation types. Plots depict subjects' mean response pattern over intervals (panel a) or manipulation points generated by variation of rewards only (panel b) and a combination of rewards and intervals (panel c). Note: Error bars indicate standard errors. The separate colors indicate whether mean responses were derived from ascending or descending sequences. The blue line represents descending sequences ( $\mathrm{LL} \rightarrow \mathrm{SS}$ ). The red line represents ascending sequences $(\mathrm{SS} \rightarrow \mathrm{LL})$.
differences was determined. ${ }^{2}$ To evaluate subjects' discounting behavior in one parameter, we extracted the $k$ parameter by fitting a hyperbolic function to each subject's indifference points over the different intervals. Data revealed an average $k$-parameter of the hyperbolic discounting curve with $M(S D)=0.23(0.19)$, bootstrapped $95 \% C I=[0.18,0.30]$, indicating a very strong discounting behavior. The hyperbolic model had a good fitting

[^195]performance over all subjects, indicated by a high average $R^{2}, M(S D)=.87(.10) .{ }^{3}$

In the manipulation blocks, subjects completed 387 trials ( $S D=67$ ) on average. Hence, on average, subjects ran through 32 hysteresis sequences ( $S D=6$ ), consisting 16 ascending $(S D=3)$ and 16 descending $(S D=3)$ sequences. The SS option was chosen in $48.37 \% ~(S D=22.19)$ of the trials, indicating only a slight decision bias which was not predicted by the model.

The core prediction of the model was that subjects show identical hysteresis effects irrespective of the specific hysteresis manipulation, that is, whether the sequential manipulation of the attractiveness of both options was realized through varying intervals, differences or a combination of both. Figure 5 depicts the hysteresis effect for each manipulation type. The plots indicate that the hysteresis effects are very similar between manipulation types, but show the qualitatively best pattern for the interval manipulation (Figure 5, panel a). In order to test model's predictions, we conducted a two-factorial Repeated Measures ANOVA (direction $x$ manipulation type) on subjects' mean choice. As expected, we solely found a main effect of direction $\left(F(1,39)=17.44, p<.001, \eta^{2}=0.31\right)$, indicating that hysteresis emerged irrespectively of manipulation types. Thus, neither the main effect of manipulation type $\left(F(2,78)=3.03, p=.054, \eta^{2}=0.07\right)$ nor the interaction $\left(F(2,78)=1.22, p=.302, \eta^{2}=0.03\right)$ were statistically significant. In order to focus the analysis on the hysteresis effect, that is, eliminating the variance of the absolute level of LL choices, we summarized hysteresis effects into one hysteresis parameter. The hysteresis parameter was given by calculating the differences between subjects' mean choice in ascending and descending hysteresis sequences for each manipulation type. An additional one-factorial Bayesian Repeated Measures ANOVA on the hysteresis parameter revealed that the data show substantial evidence in favor of the null hypothesis $\left(\mathrm{BF}_{01}=4.64\right)$ claiming that the hysteresis effect does not vary systematically between all three manipulation types. Therefore, we consider the predictions of the model as confirmed.

## Discussion

In this study, we tested predictions of the attractor model of delay discounting in a recent developed non-verbal delay discounting paradigm. Our results validated the model in such a way that its predictions concerning hysteresis effect in delay discounting were confirmed. Specifically, when sequentially varying the attractiveness of both options from a very strong preference towards the SS option to a very strong preference towards the LL option, and vice versa, hysteresis effects occur irrespectively of how the

[^196]attractiveness of any option is varied within the sequence. Therefore, the current study both replicated and added empirical evidence for the validity of the attractor model of delay discounting.

One might object that the predictions of the model were merely derived through a qualitative, argumentative manner. This is obviously true, but not a weakness of the current study. First, concerning the interval manipulation, it was already shown that the exact same predictions can be derived by means of computational simulation based on a competitive neural-network (Scherbaum et al., 2016), hence running a computational simulation with the same model would not provide any new information. Second, and this point is genuine, the model does not allow for reasonable separate simulations of all manipulation types. This is due to the fact that the model merely uses subjective values for each option. The emergence of those subjective values, however, is not covered within the model.

Leaving the emergence of subjective values open the model proves to be useful for predicting intra- and inter-trial dynamics in delay discounting, when a specific discounting function is already given, but it does not explain the emergence of discounting functions. This gap has also been argued for recently by others, reasoning that intertemporal choice consists of two processes (Rodriguez et al., 2014): First, the process of delay discounting, and second, the process of choice. This gap between the two processes could be closed by connectionist models, which have already been used to explain how different discounting functions emerge by linking discounting behavior with aspects of self-control (Scherbaum, Dshemuchadse, \& Goschke, 2012).

The two models provide insights into the dynamics of delay discounting and the dynamics of choice, respectively. Integrating these two models into one general connectionist model of delay discounting could provide insights into the interacting process dynamics of preference (delay discounting) and choice. Such an integration could therefore enhance our understanding of the processes underlying delay discounting decisions and, hence, complement our knowledge about decision outcomes.

#### Abstract

How do people explore in order to gain rewards in uncertain dynamical systems? Within a reinforcement learning paradigm, control normally involves trading off between exploration (i.e. trying out actions in order to gain more knowledge about the system) and exploitation (i.e. using current knowledge of the system to maximize reward). We study a novel control task in which participants must steer a boat on a grid, aiming to follow a path of high reward whilst learning how their actions affect the boat's position. We find that participants explore strategically yet conservatively, exploring more when mistakes are less costly and practicing actions that will be required later on.

Keywords: Reinforcement Learning, Strategic Exploration, Control, Exploration-Exploitation

## Introduction

Deciding how to act under uncertainty is a core problem for cognition. Cognitive agents must be able to navigate a world whose dynamics are initially unknown and generally uncertain, learning to generate rewards as they go along. In the context of reinforcement learning, we can think of control as a trade-off between exploration (i.e. trying out actions to gain more knowledge about the underlying system) and exploitation (i.e. using current knowledge of the system to maximize reward). However, whether and how human explorative control reflects future goals and current uncertainty is still unclear (Wilson, Geana, White, Ludvig, \& Cohen, 2014). Are human explorative actions strategic and goal-directed? Or are they rather passive, for instance involving a simple "exploration bonus" that treats uncertainty equally across all actions?

Traditionally, reinforcement learning models have addressed exploration rather implicitly, letting the agent learn about the underlying system en passant via outcomes produced while high rewards are chased (Rescorla, Wagner et al., 1972). Exploration, according to this definition, is what happens when an agent optimizes noisily. We will refer to this kind of exploration as passive exploration.

More recently, exploration has been incorporated into reinforcement learning models more explicitly via an exploration bonus (Schulz, Konstantinidis, \& Speekenbrink, 2016; Wu, Schulz, Speekenbrink, Nelson, \& Meder, 2017). An exploration bonus assigns additional utility to less explored actions and thereby assumes that the agent values uncertainty equally across all actions. Exploration, according to this definition, is what happens when expectations are inflated by their attached uncertainties. We will refer to this kind of exploration as $a g$ nostic exploration.

Another line of research tries to redefine exploration as goal-directed behavior (e.g., Thrun, 1992). The idea behind
this approach is that not all uncertainty should be treated equally but rather that exploration should be driven by both the current knowledge of the system and the agent's overall goal. Exploration, according to this definition, is a strategic action. We will refer to this kind of exploration as strategic exploration.

Many real-world control scenarios are non-episodic, such that there are no "second chances" and one may be unable to return to known states. In such situations, one must treat exploration strategically and with great caution to avoid accidents (Klenske \& Hennig, 2015). Imagine visiting a country with left-hand traffic from a country with right-hand traffic. Strategically exploring in order to learn how to drive on the left side could allow you to make your mistakes on the quiet roads first before hitting the highway. Moreover, as turning right will be more difficult than you are used to, practicing how to turn right is more important than practicing how to turn left and therefore should be exercised more frequently.

In machine learning, problems of planning under uncertainty have been approached via Bayesian reinforcement learning (BRL; Poupart, 2010), which assigns probabilistic beliefs over the dynamics of a system and the costs of states and actions in order to reason about potential changes to beliefs from future observations, and their influence on future decisions (Duff, 2002). BRL provides a useful framework for assessing strategic exploration behavior as we do here. More specifically, we will make use of the duality between reinforcement learning and control, that is tasks in which an agent has to keep a system at a certain state in order to generate rewards (Feldbaum, 1960; Klenske \& Hennig, 2015).

In what follows, we will assess how participants exert control within a novel control paradigm. Therein, strategic exploration allows them to produce greater long-term rewards formally, within a non-episodic, finite-horizon system with initially unknown dynamics. We will build on recent work by Klenske \& Hennig (2015) and assess behavior in two tasks: one in which, due to time-varying state costs, exploration can be delayed until it is more opportune; and one in which the learning agent can distinguish between more and less important exploration of directional actions. We first discuss in more detail the task and the three perspectives on exploration in control theory passive,agnostic and strategic exploration. We then assess qualitative predictions derived from these in two experiments. We find participants' behavior to be more in line with predictions derived by strategic exploration.

## Control task

In a simple computer game, participants have to navigate a boat as it crosses a sea towards regions in which they can earn a higher bonus. The boat moves incrementally from left to right and by changing its current angle of direction (see Figure 1), participants could attempt to steer the boat up or down, so as to remain in calm waters (blue) and avoid perilous rough seas (red). The overall goal of the game was to min-

Figure 1: Example path in Experiment 1, Free Late condition. Star $=$ starting position at $t=0$, circles $=$ subsequent positions. On each trial, the gray arrow shows contribution of underlying current and black arrow contribution of control angle. At $t=0$ the participant takes a control angle of 0 and drifts upward. On the 10 subsequent trials they attempt to counteract this upward drift by setting a negative angle. During the free exploration stage they use wider angles to explore the variation in the strength of the current at different $y$ positions. This allows them to discover that strength of the current is strongest in the center, approaching zero toward the top, constantly pulling the boat upwards.
imize the "cost" of the voyage while simultaneously learning both how to control their boat and about an underlying position-dependent "current" that drags the boat off course. In some periods, the area of low cost was very narrow, while in other periods, the area was very wide. Analogous to real sailing, participants had to learn to control the boat through experience, by trying different angles and observing the effect on the boat's position. This exploration is costly when the low-cost region is narrow, whilst exploration is almost "free" when the low-cost region is very wide.

Our control task is adapted from Klenske \& Hennig (2015). Therein, the boat is influenced by two factors, its current position $x_{1}$ and an underlying current $x_{2}$. This means that where the boat will end up on the next trial is influenced by the chosen angle, its current position, and the underlying current which is determined by an unknown nonlinear function. Within our experiments, the underlying current decreased from its full strength in the middle of the sea to zero at the upper and lower edges, and constantly pulled the boat upwards. For example, if participants entered the angle of 0 in the center of the sea, the boat would be pulled upwards
more than if they entered the same angle at another position further up. Formally, at each time $t$, the (vertical) position of the boat, $y_{t}$, depends on a two-dimensional latent state variable $x_{t}$ and independent random noise $\gamma_{t}$ as

$$
\begin{equation*}
y_{t}=\mathbf{C x}_{t}+\gamma_{t} \quad \gamma_{t} \sim \mathcal{N}\left(0, \sigma_{\gamma}\right) \tag{1}
\end{equation*}
$$

The latent state depends through a nonlinear function on the previous latent state, the controller input (i.e., the chosen angle) $u_{t}$, and additional noise $\xi_{t}$, as:

$$
\begin{equation*}
\mathrm{x}_{t+1}=\mathrm{A} \phi\left(\mathrm{x}_{t}\right)+\mathrm{B} u_{t}+\xi_{t} \quad \xi_{t} \sim \mathcal{N}\left(0, \Sigma_{\xi}\right) \tag{2}
\end{equation*}
$$

where

$$
\mathbf{A} \phi\left(\mathbf{x}_{t}\right)=\left[\begin{array}{cc}
1 & 0.4  \tag{3}\\
0 & 1
\end{array}\right]\left[\begin{array}{l}
x_{1, t} \\
x_{2, t}
\end{array}\right]+\left[\begin{array}{cc}
0 & 0 \\
\theta_{1} & \theta_{2}
\end{array}\right]\left[\begin{array}{c}
\frac{1}{1+e_{1, t}} \\
\frac{1}{1+e^{-x_{1, t}+5}}
\end{array}\right]
$$

$\theta=[0.8,0.4]^{\top}$, and $\mathbf{B}=[0,1]^{\top}$. The underlying drift is determined by the shifted sigmoid functions on the right-hand side of Equation 3. Given a finite-time horizon with terminal time $T$, the following quadratic cost function was used:

$$
\begin{equation*}
\mathcal{L}(\mathbf{x}, \mathbf{u})=\sum_{t=0}^{T}\left(\mathbf{x}_{t}-\mathbf{r}_{t}\right)^{\top} \mathbf{W}_{t}\left(\mathbf{x}_{t}-\mathbf{r}_{t}\right) \tag{4}
\end{equation*}
$$

where $\mathbf{r}=\left[\mathbf{r}_{0}, \ldots, \mathbf{r}_{T}\right]$ is the target trajectory and $\mathbf{W}_{t}$ the timevarying state cost. The goal of the controller is to find the action sequence $\mathbf{u}=\left[u_{0}, \ldots, u_{T}\right]$ that minimizes the expected cost (and thereby maximizes the expected reward) to the horizon $T$.

## Control strategies

Controlling a system as defined in Eqs. (1) - (3) is difficult, as the state dynamics are nonlinear with an unknown function $\phi$ and parameters $\mathbf{A}$ and $\mathbf{B}$. The controller then not only needs to control the states in accordance to the reference path $\mathbf{r}$, but also learn the parameters (and functions) in order to derive a good control strategy $\mathbf{u}$. Thus, the controller not only needs to control the states, but also control her knowledge about the model, hence the term dual control.

We will now provide a description of the three different forms of exploration mentioned earlier, and their qualitative predictions in the present control task. The predictions are shown graphically in Figure 2 for the variants of the task used in Experiment 1, which tests whether participants will postpone exploration until it is most opportune, and Experiment 2, which tests whether participants perform strategic (directional) exploration.

## Passive exploration by certainty equivalence

A certainty equivalence controller completely ignores uncertainty about the dynamics and derives a control strategy as if the current (mean) estimates of the system are accurate and knowledge about the system is perfect. Effectively, any learning about the system happens passively, as the control strategy does not focus on minimizing uncertainty. As no active

A

B

C

Figure 2: Control environments and qualitative model predictions for Experiment 1 and 2. The agent moves one step right each time point (trials are delimited by white vertical lines) and can control the angle upwards/downwards in which a boat is steering. The background color represent the cost function; the more red, the lower the score; dark blue areas mark free exploration trials. Qualitative model predictions taken from Klenske \& Hennig (2015) are represented by horizontal line called 'predictive regions'. Black lines represent the predictive region for passive exploration, white lines for agnostic exploration, and purple lines for strategic exploration. The more space between the horizontal lines at a trial, the wider the region and the higher the expected variance of the controller's actions.
A: Strategic exploration holds off exploration until it comes at lower cost (broader trust region during the dark blue patch) and consequently performs better than passive exploration later on (narrower trust region).
B: If free exploration phase is moved to the end, strategic exploration explores less overall and expedites exploration to earlier, more costly stages, thereby reducing performance early on in order to achieve the best performance later on.
C: Instead of agnostically exploring both directions in the same way, strategic exploration uses the free exploration phase to try to move in a trajectory which is rewarding in the future, thereby performing better later on.
exploration is encoded into this model, it might miss out on important information that could be beneficial to produce better rewards later on. This form of control predicts no exploration, even when exploration is 'free' and beneficial to future rewards.

## Agnostic exploration by exploration bonus

To promote exploration, a straightforward adaptation of the certainty equivalent controller is to introduce a Bayesian exploration bonus. Effectively, this means adapting the cost function so that the costs of actions which reduce uncertainty in the model of the control dynamics-as measured by the standard deviation of the posterior distribution over the parameters at each observation point-is temporarily reduced (cf. Srinivas, Krause, Kakade, \& Seeger, 2009). This model is still myopic as it only considers uncertainty at the current control step. Moreover, exploration is not strategic, as all uncertainty is treated equally and it does not take into account what knowledge might be most important later on. Under agnostic exploration, the expected behavior would be the attempt to identify all uncertain components, irrespective of their future usefulness.

## Strategic exploration as dual control

BRL involves reasoning about the effect of actions on future rewards and beliefs. Where an exploration bonus renders reducing uncertainty rewarding in itself, in BRL, reducing uncertainty is only attractive insofar as it is expected to result in an increase in future rewards. Optimal BRL requires determining the consequences of strengthening beliefs on future rewards, thereby finding the optimal balance between exploration and exploitation. Unfortunately, the optimal solution to the dual control problem of simultaneously controlling the
system as well as possible given current knowledge (exploitation) and learning about the system through experimentation in order to control it better later on (exploration), is known to be intractable.

Approximate dual control involves three conceptual steps which together yield what, from a contemporary perspective, amounts to an approximate solution to Bayesian RL: First, determine the optimal trajectory under the current mean model of the system (as in certainty equivalent control). Second, construct a local quadratic expansion around the nominal trajectory that approximates the effects of future observations. Third, within the current time step $t$, perform the prediction for an arbitrary control input $u_{t}$ and optimize $u_{t}$ numerically by repeated computation of steps 1 and 2 at varying $u_{k}$ to minimize the approximate cost (see Klenske \& Hennig, 2015, for implementation). Approximate dual control does not treat all exploration equally but rather explores strategically by, for example, holding off exploration until it is less costly or by exploring actions that will become important later on.

## Experiment 1: Holding off exploration

Our first experiment was designed to test passive exploration against both agnostic and strategic exploration by including a low-cost period which was either introduced relatively early ("Free Early" condition) or at the end of the task ("Free Late" condition). When a low-cost period is introduced early, controllers can make good use of it to explore and better their performance in later periods, while exploring in a low-cost period at the end of the task is not beneficial as there are no later rewards to reap.

Both conditions experienced an initial stage of medium state costs (see Figure 2). However, whereas for the Free

Early condition that stage is followed by a stage of free exploration (no costs of errors) which then leads to a stage of very high cost, the Free Late condition experiences the stage with high state costs first before then experiencing the stage with no costs (the two stages are swapped).

We expected participants to behave as strategic controllers and to initially hold off exploration in the Free Early condition until it comes at no cost in the low-cost period, allowing them to be prepared for the most difficult final stages. In contrast, participants in the Free Late condition were expected to explore more in the initial period, in order to be prepared for the second, most difficult stage. In addition, we expected participants in the Free Late condition to explore less in the low-cost period compared to those in the Free Early condition, as late exploration no longer brings benefits if the task is nearly over. Finally, we expected participants in the Free Early condition to generally perform better than participants in the Free Late group, as early exploration would enhance their knowledge of the system for the remainder of the task.

## Design

The manipulation involved changing the order of the reference trajectory (the state values that would produce the highest rewards) and state weightings.

In the Free Early-condition the reference trajectory and state weightings were:

$$
\begin{aligned}
\mathbf{r}_{1: 22} & =\left[\begin{array}{l}
0 \\
0
\end{array}\right] \quad \mathbf{r}_{23: 28}=\left[\begin{array}{l}
7 \\
0
\end{array}\right] \mathbf{r}_{29: 30}=\left[\begin{array}{l}
0 \\
0
\end{array}\right] \\
\mathbf{r}_{31: 36} & =\left[\begin{array}{c}
-7 \\
0
\end{array}\right] \mathbf{r}_{37: 40}=\left[\begin{array}{l}
0 \\
0
\end{array}\right]
\end{aligned}
$$

and

$$
\mathbf{W}_{1: 10}=\left[\begin{array}{ll}
1 & 0 \\
0 & 0
\end{array}\right] \quad \mathbf{W}_{11: 20}=\left[\begin{array}{ll}
0 & 0 \\
0 & 0
\end{array}\right] \quad \mathbf{W}_{21: 40}=\left[\begin{array}{cc}
10 & 0 \\
0 & 0
\end{array}\right]
$$

In the Free Late condition, these were:

$$
\begin{aligned}
& \mathbf{r}_{1: 12}=\left[\begin{array}{l}
0 \\
0

## Materials

Participants were told that they had to navigate a boat through the sea in a sailing competition. On every trial, their boat was at a current position $\left(y_{t}\right)$ and they had to determine an angle ( $u_{t}$, between $-180^{\circ}$ and $180^{\circ}$ ) in which they wanted to sail.

Additionally, they had different target areas $\left(r_{t}\right)$ on each trial marked by dark blue colors and how far they were off from the target area was penalized differently (based on $\mathbf{W}_{t}$ ). An example trial from the task (for the Free Early condition) is depicted in Figure 1.

The cost function was shown to participants through the color of each position in the sea. Participants could earn between 0 (positions with a red background) and 100 points (positions with a blue background) per trial.

## Participants

Sixty-one participants were recruited via Amazon Mechanical Turk and received $\$ 1$ and a bonus of up to $\$ 1$. Thirty-nine participants were male and the mean age was $31.3 \pm 8.4$.

## Results

The distribution of boat position, as well as average chosen angles, are depicted in Figure 3. We can see that, overall,

Figure 3: Boat positions by condition in Experiment 1. The heat map reflects number of participants who were at that position on a given trial. Error bars represent the standard error of the average position per trial. Arrows indicate the average chosen angle. Black dots mark the target trajectory and periods with different state weights are delimited by vertical lines.
participants managed to steer the boat reasonably well. A linear regression of condition, cost function weights (coded as dummy variables), and trial number onto participants' scores (see Table 1) showed that, unsurprisingly, cost function
weights had the largest effect on participants' scores. Moreover, performance increased significantly over trials. Importantly, condition affected overall performance, such that participants in the Free Early condition performed better than participants in the Free Late condition. This confirms the hypothesis that participants would benefit from early free exploration.

Table 1: Regression estimates for Experiment 1. $r^{2}=0.38$.

|  | Estimate | Std. Err. | t value | $\operatorname{Pr}(>\|\mathrm{t}\|)$ |
| ---: | ---: | ---: | ---: | ---: |
| Intercept | 99.9 | 2.76 | 36.2 | 0.000 |
| Condition | -3.04 | 1.07 | -2.84 | 0.004 |
| Med. cost: 1 | -15.7 | 2.13 | -7.39 | 0.000 |
| High cost: 10 | -47.3 | 1.30 | -36.3 | 0.000 |
| Trial | 0.18 | 0.07 | 2.61 | 0.009 |

Another hypothesis was that participants in the Free Early condition would explore more during the free exploration stage than participants in the Free Late condition. Confirming this hypothesis, the participant-wise variance of chosen angles during the free exploration stage was significantly larger for the Free Early condition than for the Free Late condition $(t(59)=2.62, p<0.01)$. As such, participants indeed seemed to strategically adapt their exploration behavior to the underlying cost function.

While we expected participants in the Free Late condition to explore more in the initial stage of medium difficulty than those in the Free Early condition, a similar test to the one above did not confirm this $(t(59)=0.63, p>0.5)$. As such, there is no clear evidence that participants in the Free Late condition used the medium difficulty period to explore in order to perform better in the high-difficulty period.

Overall, participants in Experiment 1 showed hallmarks of strategic exploration. However, they did not explore as vigorously as approximate dual control predicted, often only doing so during completely free exploration periods. As soon as exploration is somewhat costly, participants seem to shift focus back to normal (perhaps certainty-equivalence based) control, thereby more conservatively trading off between exploration and exploitation.

## Experiment 2: Directional exploration

The second experiment was designed to distinguish between agnostic and strategic exploration, involving the explicit exploration of directional actions. The design was again based on ideas put forward by Klenske \& Hennig (2015). In both conditions, a free exploration phase was followed by a high difficulty period, in which controllers either had to move the boat first up then down again (Up-Down condition) or first down and then up again (Down-Up condition).

If exploration is indeed strategic rather than agnostic and simply based on an exploration bonus, then participants in the Up-Down condition should focus exploration in the free exploration phase on first learning to travel precise increments
upwards and then precise increments downwards, whereas participants in the Down-Up condition should explore to do the opposite, as knowledge about these actions will be useful later on. Note that mimicking the later target trajectory during the free exploration phase is better then trying upwards and downwards movements at one position as the current, and with that the effect of a chosen angle on the position, varies nonlinearly depending on the boat's position.

## Design

The underlying dynamics were exactly the same as in Experiment 1 . The manipulation solely concerned the reference trajectory, which for the Up-Down condition was:

$$
\begin{aligned}
\mathbf{r}_{1: 23} & =\left[\begin{array}{l}
0 \\
0
\end{array}\right] \mathbf{r}_{24: 26}=\left[\begin{array}{l}
3 \\
0
\end{array}\right] \mathbf{r}_{27: 29}=\left[\begin{array}{l}
5 \\
0
\end{array}\right] \\
\mathbf{r}_{30: 32} & =\left[\begin{array}{l}
7 \\
0
\end{array}\right] \mathbf{r}_{33: 35}=\left[\begin{array}{l}
5 \\
0
\end{array}\right] \mathbf{r}_{36: 38}=\left[\begin{array}{l}
3 \\
0
\end{array}\right] \mathbf{r}_{39: 40}=\left[\begin{array}{l}
0 \\
0
\end{array}\right]
\end{aligned}
$$

And for the Down-Up condition, the reference trajectory was:

$$
\mathbf{r}=-\mathbf{r}
$$

The state weighting was the same for both groups:

$$
\mathbf{W}_{1: 2}=\left[\begin{array}{ll}
1 & 0 \\
0 & 0
\end{array}\right] \quad \mathbf{W}_{3: 21}=\left[\begin{array}{ll}
0 & 0 \\
0 & 0
\end{array}\right] \quad \mathbf{W}_{22: 40}=\left[\begin{array}{cc}
10 & 0 \\
0 & 0
\end{array}\right]
$$

## Materials

Participants were again told that they were taking part in a sailing contest. Participants in the Up-Down condition were then shown the control environment sketched out in Figure 2 (right panel), whereas participants in the Down-Up condition experienced the same control environment but flipped around the center horizontal axis.

## Participants

Forty-six participants were recruited via Amazon Mechanical Turk and received $\$ 1$ and a bonus of up to $\$ 1.16$ participants were female and the mean age was $34.32 \pm 11.17$.

## Results

Figure 4 shows participants' boat position by group. Again, participants seemed to be able to learn how to steer the boat towards its targets in both groups. As before, we performed a linear regression of the weights, trials and condition onto participants' score (see Table 2).

The weights had again the largest effect on participants' scores and participants' scores improved over time. There was no significant difference between the scores of the two conditions.

Strategic exploration is visible in the Up-Down condition as participants' mean position goes up and then down again, thereby showing clear signs of practicing the route to come. This can also be found by testing the difference between condition's average position during times of free exploration,

Figure 4: Boat positions by condition for Experiment 2. See legend of Figure 3 for further details.

Table 2: Regression estimates for Experiment 2. $r^{2}=0.45$.

|  | Estimate | Std. Err. | t -value | $\operatorname{Pr}(>\|\mathrm{t}\|)$ |
| ---: | ---: | ---: | ---: | ---: |
| Intercept | 97.8 | 2.72 | 35.9 | 0.000 |
| Condition | 0.23 | 1.75 | 0.13 | 0.89 |
| Med. cost: 1 | -11.3 | 1.69 | -6.56 | 0.000 |
| High cost: 10 | -26.6 | 1.37 | -19.4 | 0.000 |
| Trial | 0.16 | 0.06 | 2.41 | 0.01 |

which was significantly higher for the Up-Down condition $(t(44)=3.21, p<0.01)$. Strategic exploration was not as pronounced in the Down-Up condition, as the mean position seems closer to a straight line than the later target trajectory. Since the prevailing current would nudge any passive participants who aimed straight ahead upward, a bias toward the upper half is to be expected in both conditions. There is no evidence that participants in the Down-Up condition explored less, as there was no difference in the variance of chosen inputs during the free exploration phase between the conditions $(t(44)=-0.32, p>0.75)$. Participants in the Down-Up condition chose angles which were on average more downwards during the first 10 trials $(t(44)=-3.17, p<0.01)$. Thus, perhaps participants in the Down-Up condition also explored strategically, but were less able to steer the boat in a clear and consistent "practice run" of the desired future route.

## Discussion and Conclusion

Scenarios in which we have to explore to effectively exploit dynamical systems are ubiquitous in daily life. We introduced a novel control task and assessed to what extent people's exploration can be seen as a strategic, opportunistic, and goaldirected behavior.

We found that participants displayed hallmarks of strategic exploration, exploring differently depending on the cost function and, in some cases, practicing part trajectories which would become important later on. However, strategic exploration seemed more conservative than that of an idealized approximate dual control strategy. During periods of medium cost, participants seemed reluctant to explore in order to benefit their performance during a following high-cost period in Experiment 1. For controllers who learn and choose actions more noisily than statistical algorithms, perhaps the future benefits of this costly exploration did not outweigh the immediate costs. Participants also did not always play out strategies of future importance during free exploration trials as indicated by Experiment 2. As participants in the Up-Down condition could easily follow the underlying upward-current, participants in the Down-Up condition had to go against the current in order to explore strategically. Therefore, the difference in exploration behavior could imply that, for humans, serendipity still plays a part in discovery of effective exploration strategies.

As strategic exploration requires considerable planning, even when dual control is approximate, it is likely to require considerable mental effort. Future research could look into possible heuristics which approximate strategic exploration whilst further reducing computational costs.

# How Does Instance-Based Inference About Event Frequencies Develop? An Analysis with a Computational Process Model 

Christin Schulze (cschulze@mpib-berlin.mpg.de)<br>Thorsten Pachur (pachur@mpib-berlin.mpg.de)<br>Ralph Hertwig (hertwig@mpib-berlin.mpg.de)<br>Max Planck Institute for Human Development, Lentzeallee 94<br>Berlin, 14195 Germany

#### Abstract

To make inferences about the frequency of events in the world (e.g., the prevalence of diseases or the popularity of consumer products), people often exploit observations of relevant instances sampled from their personal social network. How does this ability to infer event frequencies by searching and relying on personal instance knowledge develop from childhood to adulthood? To address this question, we conducted a study in which children (age 8-11 years) and adults (age 19-34 years) judged the relative frequencies of first names in Germany. Based on the recalled instances of the names in participants' social networks, we modeled their frequency judgments and the underlying search process with a Bayesian hierarchical latent-mixture approach encompassing different computational models. We found developmental differences in the inference strategies that children and adults used. Whereas the judgments of most adults were best described by a noncompensatory strategy that assumes limited and sequentially ordered search (social-circle model), the judgments of most children were best described by a compensatory strategy that assumes exhaustive search and information aggregation (availability-by-recall). Our results highlight that already children use instance knowledge to infer event frequencies but they appear to search more exhaustively for instances than adults. One interpretation of these results is that the ability to conduct ordered and focused search is a central aspect in the development of noncompensatory instance-based inference.

Keywords: child development; sampling; probabilistic inference; heuristics; availability

## Introduction

The relative frequency of events in the world is an important ecological characteristic that impacts many actions and decisions. For instance, the relative frequency of other people's behaviors hints at social norms that should be followed; the number of people having bought different products may indicate differences in product quality that influence consumer choice; and the prevalence of diseases hints at health risks that may guide precautionary actions. Decision makers commonly do not have access to summary tables of these frequency statistics but need to infer them. An easily accessible but informative indicator for event frequencies in the population is their occurrence among the people one knows personally. That is, by searching for relevant instances in their personal social network people can collect a variety of information about the frequency of events in the world, and use this information to form
subjective frequency judgments. In this paper, we examine how this ability to search proximate social spaces to judge the relative frequency of events develops from childhood to adulthood.

Previous work has garnered much insight into how adults make instance-based inferences. Most prominently, according to Tversky and Kahneman's (1973) availability heuristic, adults judge the frequency of events by assessing the ease with which instances of the events can be brought to mind. More recent research has elaborated the specific mechanisms guiding this search in and retrieval from mnemonic sample spaces. For instance, it has been shown that adults often restrict search to directly experienced instances in their social circles and that these social circles are searched sequentially (e.g., Hertwig, Pachur, \& Kurzenhäuser, 2005; Pachur, Hertwig, \& Rieskamp, 2013).

Yet, currently only little is known about how search for information in proximate social spaces develops ontogenetically. Do already children exploit their social memories to draw inferences about the frequency of events in the world? And if so, how much do they sample, in which order do they consult social circles, and how do they integrate the information to draw inferences? Existing developmental work on judgment and decision making is consistent with opposing predictions. On the one hand, working memory limitations may confine young children to using information-frugal strategies because processing and integrating large amounts of evidence may be difficult (e.g., Bereby-Meyer, Assor, \& Katz, 2004). On the other hand, limitations in the ability to selectively focus attention on relevant information may lead young children to use more exhaustive but unsystematic search strategies (e.g., Davidson, 1991; Mata, von Helversen, \& Rieskamp, 2011).

To disentangle these opposing predictions, we first introduce the social-circle model, a cognitive process model that parameterizes key components of the inference process-including search order, evidence threshold, and response noise. Second, we take a Bayesian hierarchical mixture approach to modeling the inferences of children and adults in a task in which they made judgments about the relative frequency of common first names in Germany.

## The Social-Circle Model

To model people's inferences based on recalled instances, Pachur et al. (2013) proposed that people search
sequentially through the circles of their social networkdefined as self, family, friends, and acquaintances-and stop search as soon as the instance evidence in a circle allows them to make an inference. It is thus assumed that people's search for relevant instances is guided by the welldocumented hierarchical structure in the ordering of discrete social groups that make up a person's social network (e.g., Hill \& Dunbar, 2003; Milardo, 1992), which has also been shown to be important for search in social memory (e.g., Hills \& Pachur, 2012). Adults' frequency judgments have been found to be equally well described by a model that assumes such a noncompensatory strategy and by a more exhaustive, compensatory search strategy (Pachur et al., 2013). Here, we formalize and extend the assumptions in Pachur et al.'s (2013) analysis and propose a generalized social-circle model (SCM) that allows for variability in the order in which circles are inspected and for probabilistic aspects in the search, stopping, and decision stages of inference.

The SCM assumes that in order to judge which of two events, A or B , is more frequent in the population, decision makers search distinct social circles, defined as self, family, friends, and acquaintances. At each inspected circle $i$ the evidence, $e_{i}$, is represented as the difference in the number of instances recalled for each event, expressed as a proportion:

$$
\begin{equation*}
e_{i}=\frac{n_{i A}}{n_{i A}+n_{i B}}-\frac{n_{i B}}{n_{i A}+n_{i B}} \tag{1}
\end{equation*}
$$

## Search Rule

The order in which the circles are inspected is represented by circle-weight parameters, one for each circle ( $w_{i}$, constrained by $\sum w_{i}=1$; see Bergert \& Nosofsky, 2007), that can be estimated from the data. These weights represent the probability that a circle is inspected as

$$
\begin{equation*}
p\left(\text { inspect } \operatorname{circle}_{i}\right)=\frac{w_{i}}{\sum_{i}^{N} w} \tag{2}
\end{equation*}
$$

Once a circle has been inspected, it is not considered further (i.e., the denominator is calculated only over circles that have not yet been inspected). Note that search is thus assumed to be probabilistic. The probability of following a particular search order $p\left(\right.$ order $\left._{j}\right)$ is given by the product of the individual probabilities of circle inspection,

$$
\begin{equation*}
p\left(\text { order }_{j}\right)=\Pi_{j} p\left(\text { inspect circle } e_{i}\right) . \tag{3}
\end{equation*}
$$

## Stopping Rule

In the SCM it is assumed that the proportional evidence obtained from each circle is compared against a decision threshold, $d$. If the evidence from the recalled instances reaches or exceeds the threshold, a choice is made; if it is lower than the threshold, the next circle is inspected. The SCM implements a probabilistic version of this stopping rule by assuming normally distributed error for each circle, denoted as $\varepsilon_{i}$, generated from a normal distribution with mean zero and standard deviation $\sigma$. Specifically, it is
assumed that, if the evidence in a given circle (with added error) meets or exceeds $d$, then the decision maker selects option A (i.e., $\left|e_{i}+\varepsilon_{i}\right| \geq d$ ); if the evidence meets $-d$, then the decision maker selects option B (i.e., $\left|e_{i}+\varepsilon_{i}\right| \leq-d$ ). Thus, the probability of making a choice after inspection of circle $i$ is given by

$$
\begin{align*}
p_{i}(\text { choice }) & =p\left(\left|e_{i}+\varepsilon_{i}\right| \geq d_{i}\right) \\
& =p\left(e_{i}+\varepsilon_{i} \geq d_{i}\right)+p\left(e_{i}+\varepsilon_{i} \leq-d_{i}\right) \\
& =\Phi\left(\frac{e_{i}-d_{i}}{\sigma}\right)+\Phi\left(\frac{-e_{i}-d_{i}}{\sigma}\right) \tag{4}
\end{align*}
$$

where $\Phi(\cdot)$ is the standard normal cumulative distribution function.

## Decision Rule

The probability of selecting option A based on a particular order, $p_{j}(A \mid A B)$, follows from combining the choice probabilities resulting from circle inspection in that order (cf. Rieskamp, 2008). For example, for the order $j=1,2,3,4$ :

$$
\begin{align*}
& p_{j=1,2,3,4}(A \mid A B)=p_{1}(A \mid A B)+\left[1-p_{1}(\text { choice })\right] \times \\
& \quad p_{2}(A \mid A B)+\left[1-p_{1}(\text { choice })\right] \times\left[1-p_{2}(\text { choice })\right] \times \\
& \quad p_{3}(A \mid A B)+\left[1-p_{1}(\text { choice })\right] \times\left[1-p_{2}(\text { choice })\right] \times \\
&  \tag{5}\\
& {\left[1-p_{3}(\text { choice })\right] \times p_{4}(A \mid A B) .}
\end{align*}
$$

The total probability of selecting option A is defined as the sum of all $p_{j}(A \mid A B)$, each weighted by the probability of the decision maker following the order (see Equation 3):

$$
\begin{equation*}
p(A \mid A B)=\sum_{j=1}^{N!} p_{j}(A \mid A B) \times p\left(\text { order }_{j}\right) \tag{6}
\end{equation*}
$$

In sum, the SCM parameterizes three key components of instance-based inference: the decision maker's preferred search order (circle weight parameters, $w_{i}$ ), evidence threshold $(d)$, and response noise $(\sigma)$. Thus, depending on its parametrization, the model can capture various noncompensatory inference processes. In what follows, we apply the SCM to inference data from an experiment in which children and adults were asked to judge the relative frequency of common first names in Germany, and examine how well it accounts for participants' inferences compared to a compensatory strategy and a guessing strategy.

## Experiment

## Method

Participants Forty children (age 8-11 years; 18 female) and 40 adults (age 19-34 years; 19 female) who were recruited via the subject pool of the Max Planck Institute for Human Development participated in the experiment. The data of five additional children were excluded from the analysis because the children showed insufficient readingcomprehension (two children aged 7 years); did not recall any or only one instance for each name in the same social circle, yielding a guessing prediction for instance-based models on every trial (two children); or terminated the experiment prematurely (one child). Participants received a performance-based payment (earning 0.04 EUR for each
correct inference but losing the same amount for each incorrect inference; $1 \mathrm{EUR} \approx 1.12$ USD at the time of the experiment), and an additional flat fee of 10 EUR.

Materials Table 1 lists the 22 first names ( 11 female) that were used in the experiment. Because no census data about the frequency and distribution of first names in Germany was available, we approximated a frequency ranking by weighting popular baby names between 1911 and 2010 (Bielefeld, 2016) with each cohort's proportion in the population to date (Statistisches Bundesamt, 2014). ${ }^{1}$ We constructed a set of all possible 231 paired comparisons of the names, and informed participants that the accuracy of their inferences was judged on the basis of the available data. Participants were instructed to ignore the particular spelling of each name and to judge the relative frequency of names by taking possible variants of a name into account.

Procedure The experiment consisted of two tasks, an inference and a retrieval task, that were completed by all participants in this order. In the inference task, participants were asked to judge which of two first names is more frequent in Germany for each of the 231 name pairs. The pairs were presented sequentially on a computer screen in blocks of 23 pairs ( 24 pairs in the final block). The order in which name pairs were presented was randomized across participants; the order of names in each pair was predetermined so that correct and incorrect inferences (according to our statistics) were distributed equally across the two response alternatives. Each trial started with the display of a fixation cross at the center of the screen, followed by the presentation of two black silhouettes (either male or female) which were labeled with the respective names in the comparison (see Figure 1A). Participants made a selection by pressing one of two designated keys on the keyboard. After each choice, the selected name's silhouette was shown on a podium at the center of the screen to confirm the selection to the participant. There was no trial-by-trial feedback about the accuracy of decisions. Participants were encouraged to make as many correct judgments as possible. There was a self-paced pause after each block and participants completed two training trials with fictitious names before the start of the inference task. In the retrieval task, participants were asked to recall how

[^197]Table 1: The 22 first names used in the experiment, their approximated frequency rank in Germany, and the total number of instances children and adults recalled from their own social networks.

| Hannah | f | 21 | 42 | 44 |
| Gertrud | f | 22 | 6 | 9 |

many people with each of the 22 names shown in Table 1 they knew personally. For each name, participants counted each person among their family, friends, and acquaintances with that name by dragging and dropping pictorial representations of family members, friends, and acquaintances on a black silhouette labeled with the respective name (see Figure 1B). Following the retrieval of a person, participants were also asked to indicate their contact frequency with that person on a scale from one (less than once every six months) to five (multiple times per week). Additionally, participants could allocate a pictorial person labeled "self" to indicate the shown name was their own. Each recalled person was listed on the screen and counted toward an overall tally of persons with a particular name also shown on the screen. Before the start of the retrieval task, a training trial familiarized participants with the controls of this task. At the end of the experiment, participants were informed about their overall accuracy on the inference task and paid in cash by the experimenter.

Bayesian Hierarchical Mixture Modeling Based on the instances of names that each participant recalled from their social network in the retrieval task, we modeled each participant's decisions in the inference task with a Bayesian latent-mixture approach (see, e.g., Bartlema, Lee, Wetzels, \& Vanpaemel, 2014). Hierarchical mixture modeling allows

A

B

Figure 1: Illustration of the task screen and controls used during the inference task (A) and retrieval task (B).
us to simultaneously estimate discrete classes of participants who use categorically different inference strategies and to robustly model variation within each group of strategyusers, thus combining the advantages of pooling continuous individual differences hierarchically and assuming discrete differences among groups of individuals. We assumed three latent subgroups of participants, each using a different inference strategy: (a) the social-circle model, (b) availability-by-recall, which assumes a compensatory process (Hertwig et al., 2005; Pachur, Hertwig, \& Steinmann, 2012), and (c) a random guessing strategy.

According to availability-by-recall, all instances of an event are tallied across the entire social network and the option with the larger summed instance-evidence is chosen. For comparability, we applied the same response noise mechanism as for the SCM, which gives the probability of choosing option A as

$$
\begin{equation*}
p_{A b R}(A \mid A B)=\Phi\left(\frac{n_{A}-n_{B}}{\sigma}\right), \tag{7}
\end{equation*}
$$

where $n_{A}$ denotes the number of instances recalled for event A across all circles and $\sigma$ is a response noise parameter. For the guessing strategy, we assumed that participants randomly selected one of the two names in each pair with probability .50 . With this approach, we can estimate the proportion of participants using each strategy based on inference and recall data while taking into account the uncertainty surrounding such a classification. We modeled participants' inferences for all paired comparisons on which
a participant's instance knowledge allowed each strategy to make an unambiguous prediction. The two instance-based strategies did not make a prediction, if a participant recalled no or equal numbers of instances for both names in a comparison. The posterior distributions of model parameters were estimated via Gibbs sampling methods implemented in JAGS (Plummer, 2003). We used reasonably uninformative priors: For the $w_{i}$ and $d$ parameters of the SCM we assumed uniform priors on the group-level mean (beta distributions with shape parameters of 1 ) and gamma priors (with a shape parameter of 1.1051 and a scale parameter of 0.01051 ; see Bartlema et al., 2014) on the group-level precision. For the $\sigma$ parameters of the SCM and availability-by-recall we assumed uniform distributions constrained between 0.01-40 on the group-level mode and standard deviation. For the latent-mixture indicator variable we assumed a categorical prior that assigned equal weight to each strategy. ${ }^{2}$ To ensure efficient mixing, we used pseudo-priors that approximate the posterior density for the individual-level parameters. These pseudo-priors were obtained from an initial Bayesian hierarchical estimation procedure that was performed separately for each model (without a mixture component). In the model estimation, 16 chains each with 50,000 samples drawn from the posterior distributions were run after an initial burn-in period of 2000 samples. GelmanRubin statistics and visual inspections of the four chains indicated adequate chain convergence.

## Results

Behavioral Data We found differences between the age groups in inferential accuracy, $t(78)=5.17, p<.001$, $d=1.16, B F_{10}=8362$, and in reported instance knowledge, $t(60.00)=4.68, \quad p<.001, \quad d=1.05, \quad B F_{10}=1456$. On average, adults picked the more frequent first name more often than children ( $M=.64$ vs. $M=.57$ ) and recalled more people with any of the 22 first names in their social network ( $M=23.63$ vs. $M=14.28$; see also Table 1 ). One possible reason for children's lower inferential accuracy is that the instances they reported were less valid indicators of the actual frequency distribution of first names in the population (possibly because they recalled fewer instances overall). That is, for adults, there was a significant rank correlation between reported instances and actual frequency ranks, $r_{s}(20)=.524, p=.012, B F_{10}=4.99$. For children, however, no such correlation was found, $r_{s}(20)=.203, p=.364$, $B F_{10}=0.39 .{ }^{3}$

[^198]

Figure 2: Allocation of adult and children participants to three latent subgroups of strategy users.

Computational Modeling Figure 2 shows the membership probability of each adult (left panel) and each child (right panel) in each group of strategy-users, as derived from the posterior distribution of the latent-mixture variable. The figure shows that the judgments of most adults were best described by the SCM (55\% of adults compared to $38 \%$ of children). By contrast, the judgments of most children were best described by availability-by-recall ( $48 \%$ of children compared to $40 \%$ of adults). Only few participants were best described by the guessing strategy. Overall, there was greater uncertainty in the classification of children to latent groups than in the classification of adults. This was partly due to the lower number of instances children recalled resulting in poorer discriminability between the models.

Next, we compared children's and adults' search and decision processes by evaluating their group-level SCM parameter estimates. As shown in Figure 3, children and adults weighted the different circles in their social network similarly (although adults showed greater inter-individual variability in the weighting of different circles), applied similar decision thresholds, and did not differ on the response noise parameter (for all parameters, 95\% HDIs overlapped). Children's lower inferential accuracy was thus not due to a more error prone execution of an instance-based inference strategy. This also held for inferences described by availability-by-recall.

## Discussion

Our results suggest that already children systematically exploit their instance knowledge to make inferences about the frequency of events in the world. However, they do so differently than adults. Whereas the judgments of most adults were best described by a strategy that assumes limited information search, the judgments of most children were best accounted for by a strategy that assumes exhaustive search. This finding echoes previous research on multiattribute choice and cue-based inference which has found young children to use more exhaustive but unsystematic
search strategies (e.g., Davidson, 1991; Mata et al., 2011). A possible explanation for why children use more informationintensive strategies is that they have difficulties to selectively attend to relevant and diagnostic information (cf. Betsch, Lehmann, Lindow, Lang, \& Schoemann, 2016). In young children, this inability to effectively focus search may be driven by the required executive control functions being not yet fully developed (see Best \& Miller, 2010). In light of

Posterior Group-Level Parameter Estimates of the SCM

Figure 3: Posterior distributions of the group-level parameters of the SCM. Small circles and diamonds below the density plots show the posterior means for adults and children, respectively; lines show $95 \%$ HDIs.
children's more limited and less ecologically valid instance knowledge, their greater tendency to adopt exhaustive sampling strategies might represent an adaptive response to these limiting factors. However, it should also be noted that, due to children's lower instance knowledge, the discriminability between models was lower, which might have contributed to the more balanced strategy classification in children as well.

Our results extend previous research that has found children to use availability as a cue for judging the relative frequency of and their own memory for names (Davies \& White, 1994; Geurten, Willems, Germain, \& Meulemans, 2015). This prior work, however, did not use cognitive modeling to formalize and quantitatively analyze the development and use of instance-base inference strategies. By taking a formal computational modeling-based approach, our analysis enabled us to simultaneously detect developmental differences in the use of discrete strategies and parameterize the specific mechanisms underlying search for instances in memory. This approach highlighted that children search for instances more exhaustively but weight the subgroups in their social network similarly as do adults. The analysis also revealed substantial individual differences in the process of search for instances in memory among both age groups. In this respect, the social-circle model that we applied provides an advantage over previously proposed models of instance-based inference (e.g., Tversky \& Kahneman, 1973), which are silent regarding the specific mechanisms and order of instance sampling.

We conclude that the social-circle model provides an effective tool for capturing and illuminating individual and group differences in the cognitive processes that underlie instance-based inference. The insights gained with this model are consistent with the finding that search in social memory is guided by factors such as social proximity (Hills \& Pachur, 2012) and suggest that one important factor in the development of information-frugal strategies for judging frequencies is the ability to limit and selectively focus search on relevant instance knowledge.

# Prior Expectations in Linguistic Learning: A Stochastic Model of Individual Differences 

R. Alexander Schumacher<br>Northwestern University

Janet Pierrehumbert
University of Oxford

#### Abstract

When learners are exposed to inconsistent input, do they reproduce the probabilities in the input (probability matching), or produce some variants disproportionately often (regularization)? Laboratory results and computational models of artificial language learning both argue that the learning mechanism is basically probability matching, with regularization arising from additional factors. However, these models were fit to aggregated experimental data, which can exhibit probability matching even if all individuals regularize. To assess whether learning can be accurately characterized as basically probability matching or systematizing at the individual level, we ran a large-scale experiment. We found substantial individual variation. The structure of this variation is not predicted by recent beta-binomial models. We introduce a new model, the Double Scaling Sigmoid (DSS) model, fit its parameters on a by-participant basis, and show that it captures the patterns in the data. Prior expectations in the DSS are abstract, and do not entirely represent previous experience.

#### Abstract

Can grammatical gender influence how people conceptualize the referents of nouns? Using an implicit measure, we investigated whether such an effect could be found in a task where neither grammatical nor biological gender is highlighted. In the current study, conducted in English, speakers of French, German and Romanian with knowledge of English were asked to generate adjectives they associate with referents of nouns. Afterwards, the gender valence of the adjectives was measured. The results showed that participants generated more feminine adjectives for nouns with majority feminine translations compared to nouns with majority masculine translations. We found a stronger effect of grammatical gender for some semantic categories than for others. Significant effects of grammatical gender were present starting with the $2^{\text {nd }}$ adjective generated by participants (effects were stronger for adjectives generated $2^{\text {nd }}$ and $3^{\text {rd }}$ by participants, as opposed to the $1^{\text {st }}$ adjective).

Keywords: grammatical gender; conceptualization; categorization; semantic features; representation

## Introduction

Can the structure of the language you speak affect how you perceive and conceptualize the world around you? Although the question has a long history (see Koerner (1992) for an overview), the last two decades have seen an especially large increase in the amount of empirical work examining and testing the predictions that the different answers to it imply. This has lead to an accumulation of results showing that there are cases where differences in seemingly nonlinguistic aspects of cognition between speakers of different languages arise due to specific differences between the structures of those languages (see Wolff \& Holmes (2011) for a survey). Nonetheless, the jury is still out on a number of questions aiming to flesh out the details of how, when and why linguistic differences can lead to differences in the operation of cognitive processes.

One question that is not conclusively resolved is what types of effects language could have on cognition. Research supports, for example, the existence of effects of language that play a large role in the operation of some specific cognitive domains. Frank et al. (2012) shows that number words are a cognitive tool that, when suppressed, impairs Western college educated people's ability to encode exact numerical values. Thus number vocabulary plays an
important role in numerical cognition. Other work indicates that language also has some early effects on cognition. A body of research has shown that color vocabulary has an effect on categorical color perception (see Regier et al. (2010) for a review). There are also other types of effects and research indicates that cognitive differences between speakers of different languages arise due to the metaphors they use for talking about time, their frequency of use of a particular spatial frame of reference and knowledge of constructions for talking about mental states, among other differences (Wolff \& Holmes, 2011).

One unresolved issue is whether language could have broad or pervasive effects. Are effects of language only restricted to specific domains (e.g. specific color distinctions, numbers, orientation in space)? Or can differences in the structure of languages lead to broadly distributed effects across a wide range of contexts? For this question, it is worth examining grammatical features that apply to say all nouns (e.g., gender) or all verbs (e.g., tense). In this paper we consider the role of grammatical gender in shaping the way people think about things that are named by nouns - a very broad potential scope of influence.

## Grammatical Gender

Grammatical gender is a system of categorizing nouns into distinct classes, i.e. genders, which manifests itself via morphologically marking what gender the noun belongs to on some of the words that that noun is morphosyntactically related to (Corbett, 1991).

The forms that gender systems take vary. The ones that have garnered the interest in the research on the effects of language on cognition, however, usually share several properties. First, these systems have masculine and feminine genders, i.e. for nouns with human referents the assignment is fully semantic and dependent on biological sex, bar a small number of isolated exceptions in some languages. Second, the majority of nouns with non-human referents fall into the semantic residue, i.e. the category for which the assignment is based on the word's phonological or morphological, but not semantic properties. Third, a number of words in the semantic residue is assigned to either masculine or feminine gender. Languages with such systems provide the opportunity to ask: can the conceptualization of
a noun's referent accrue gendered properties because of the noun's grammatical gender assignment? If so, grammatical gender could exhibit a broad and pervasive effect on concept formation, since, by having a gender system, a language requires all nouns to be assigned to one of the gender categories. This could result in a broad range of concepts acquiring gendered properties that would be absent otherwise.

Why might we expect entities without biological sex to acquire stereotypically masculine or feminine properties as a result of being assigned to a grammatical gender category? As we mentioned, grammatical gender can be considered to be a system of noun categorization. Biological sex, in that case, is a highly diagnostic feature for determining the category assignment of nouns for humans. As the research on categorization indicates, diagnostic features better suited for differentiating between members and non-members of a category draw more attention to themselves (Tversky, 1977). In addition, category features could develop or become accentuated in response to the requirements that tasks involving categorization impose (Schyns \& Rodet, 1997; Medin et al., 1993). This could mean that nouns belonging to a grammatical gender strongly associated with humans of a particular sex might acquire gendered properties just by virtue of being in those genders. Intuitions of native speakers of languages with grammatical gender for why nouns get assigned to their respective genders in their language supports this view (Basetti, 2011).

## Prior Research and the Goals of the Current Study

A body of prior work supports the idea that grammatical gender influences conceptualization of objects and animals (Basetti \& Nicoladis, 2016). For example, Konishi (1993) asked native speakers of German and Spanish to rate nouns on a variety of semantic differential scales in their native language. The words were either feminine in German and masculine in Spanish or vice versa. Subjects tended to give higher ratings on scales associated with potency for words that were masculine in their native language. In another set of experiments by Sera et al. (1994), Spanish and English speaking adults and children were asked to either give human names or assign male or female voices to pictures of objects. The results showed that older Spanish speakers tended to assign names and voices in these tasks in a grammatical gender-congruent fashion, which was not the case for English speakers or Spanish preschoolers. Phillips and Boroditsky (2003) investigated the effects of grammatical gender by teaching native speakers of English ${ }^{1}$ an artificial language with grammatical gender and analyzed whether it influenced their performance on a similarityrating task. The results indicated that participants rated pictures of humans and objects as more similar when they were in the same grammatical gender.

However, other studies suggest that there are limitations

[^199]on when and how grammatical gender could have an effect on conceptualization. For example, Vigliocco et al. (2005) found an effect of animal name grammatical gender on similarity in a triad similarity judgment task when the stimuli were names of animals, but not when the stimuli were pictures of animals. Furthermore, the effect was not found for either names or pictures of artifacts. In another experiment, Kousta et al. (2008) asked participants to name pictures that appeared at a random location on the screen, and afterwards analyzed cases where participants' produced an incorrect word. The subjects were either Italian or English monolinguals, or Italian-English bilinguals. The monolinguals responded in their native language, whereas the bilinguals participated in the experiment in both Italian and English. The results showed that the grammatical gender of the Italian noun describing the picture tended to affect the responses of Italian monolinguals - they preserved the grammatical gender of the target word almost twice as often as English monolinguals. The responses of ItalianEnglish bilinguals followed a pattern similar to Italian monolingual pattern when they were tested in Italian. When they were tested in English, however, their pattern of errors was similar to the one exhibited by English monolinguals. Ramos and Roberson (2010) examined how speakers of Portuguese conceptualize inanimate objects in a series of experiments using different methodologies and compared their responses to the responses of an English-speaking group. The authors found that the grammatical gender of an object's name strongly influenced whether the Portuguese speakers assigned a male or a female voice to it, but had a smaller influence on the participant's responses in word similarity rating task, or in a triad similarity judgment task, especially when the stimuli were pictures, and not words.
These findings raise several issues. One alternative interpretation of the previously obtained effects is that they are by-products of task demands or of the particular stimuli that were used in the study. For example, when people are asked to give a name to an object, they might consciously or unconsciously understand that gendered information is important for this task. This seems especially likely when participants come from cultures where sets of male and female names have very little overlap, or when they are asked to give the name to something that can be very easily anthropomorphized, e.g. an animal. This then could lead to a pattern of responses that suggests an effect of grammatical gender on ingrained features of concepts, but that actually arose due to the demands of a particular context. Similar arguments could be made for other methodologies.

Another possibility is that some of the results arise because of the influence of information contained in the experimental stimuli. Given a set of words, the ones that are more similar phonologically or morphologically are more likely to prime each other (Kinoshita \& Lupker, 2004), and words in the semantic residue are assigned to a grammatical gender specifically based on their phonology or morphology. When a speaker of Spanish is participating in a semantic differential scale task and reads a masculine noun
ending in " 0 ", this weakly activates other words of similar morphology and phonology. That, supported by the experimental context, could lead to higher activation of frequently used words for human males and their properties. It, in turn, could lead to participants giving higher ratings to masculine words on scales associated with masculinity.

The experiment described below aims to address these issues. Three groups of non-native English speakers whose native languages have grammatical gender systems were asked to generate adjectives for English nouns. The adjectives were then scored on how feminine or masculine they were, and adjectives generated for nouns differing in grammatical gender between the languages were examined. This design addresses the issues discussed above in the following ways. The manipulation is implicit - there is no way for participants to guess that gender is of interest in the study - they are simply given a list of nouns and asked to generate adjectives that describe the referent. The adjectives are generated for English words, which eliminates the possibility of phonetic or morphological similarity between words driving the effect.

## Methods

## Participants

A total of 273 participants completed the study. Out of them, 99 were Romanian-English bilinguals ( 69 female; mean age $=24.03, \mathrm{SD}=6.83$; mean English proficiency $=$ $4.38 / 5, \mathrm{SD}=0.62$ ), 90 were German-English bilinguals ( 53 female; mean age $=24.37, \mathrm{SD}=5.91$; mean English proficiency $=4.08 / 5, \mathrm{SD}=0.80$ ) and 84 were FrenchEnglish bilinguals ( 51 female; mean age $=28.96$, $\mathrm{SD}=$ 11.52; mean English proficiency $=4.38 / 5, \mathrm{SD}=0.64$ ).

## Materials

A total of 225 nouns served as stimuli. Out of them, 200 were the most frequently used nouns in the English language based on the data from the Corpus of Contemporary American English (Davies, 2008). These words were used for several reasons. First, it decreases the possibility of an effect arising due to an unconscious experimenter bias in the choice of items. Second, these words are often encountered in written and spoken language, so their meaning is unlikely to be misunderstood by the participants. Lastly, the procedure allows for an easier selection of items in future experiments using a similar methodology, but examining speakers of languages other than the ones used in this experiment.

We were also interested in examining whether the semantic category of the noun modulates what adjectives are generated for it, as previous work in the field has shown that the semantic category of the noun affects participants' responses (e.g. Vigliocco et al., 2005). Because the list described above lacked nouns with animal referents, 25 such words were added to the stimuli.

## Procedure

All of the instructions in the experiment were given in English. At the very beginning participants were asked to verify their native language proficiency by translating an English sentence.

After this, the participants were informed that in the next part of the study they would see a list of nouns one by one, and that they would need to list the properties that they associate with their referents. For each noun the participants had to list three adjectives. Half of the participants were instructed to personify the nouns, i.e. imagine them as humans, and generate adjectives that would best suit those personifications, whereas the other half was not given personification instructions (and were instructed simply to produce adjectives). This was done in order to establish whether explicit invitations to personify (as when assigning names or voices) are necessary to induce effects of grammatical gender.

Next, the participants continued onto the adjective generation portion of the experiment. This part of the study consisted of 225 trials. During each trial the participants saw an English noun from the stimulus set and were asked to generate three adjectives for it. The participants were presented with all of the items shown in a random order.

After this, the participants were asked to translate all of the nouns they had encountered previously into their native language. At the end of the experiment, the participants filled in a questionnaire about their language background, education and residency.

## Post-Processing

Grammatical Gender of Translations Some of the nouns were translated by the participants in multiple ways. For example, German participants translated English "difference" both as "(der) Unterschied" (masculine) and "(die) Differenz" (feminine).

Due to this, we first established the grammatical gender for each of the translations generated by the participants. Afterwards, the number of translations belonging to each of the grammatical genders was calculated for each noun in each language. We call the most common grammatical gender among the noun's translations in a particular language its most common gender (MCG) in that language.

Noun Semantic Categories In order to analyze the effect of noun's semantic category, each noun was categorized as being either an abstract noun, a noun denoting an animal, a body part or a concrete object by two coders.

Noun Selection After the most common grammatical genders of the nouns were established, only the nouns that had most common masculine gender in one of the experimental languages, and feminine in one of the others were left for analysis, leaving a total of 68 nouns. In cases where the noun's MCG in the third language was neuter, only adjectives generated by participants speaking the other
two languages were analyzed. 39 denoted abstract concepts, 13 - animals, 4 - body parts and 12 - other concrete objects.

Adjective Gender Valence Our next task was to operationalize how masculine or feminine the generated adjectives were. The participants generated a total of 45972 adjective tokens for the nouns remaining in the sample. Out of them, 36426 were also generated for nouns for humans (i) whose referent was clearly biologically male or female (e.g. "man", "woman") or (ii) that differed in translation depending on the sex of the referent (e.g. English "friend" = French "ami" (masc) or "amie" (fem)). For each of those adjectives, we calculated its token frequency among adjectives generated for males (a total of 12564) and adjectives generated for females (a total of 3681 tokens). After that, we subtracted the frequency of each adjective among adjectives generated for biological females from its frequency among those generated for biological males. We consider this to reflect adjectives' relative gender valence: relatively more positive values indicate more masculine connotations, relatively more negative values indicate more feminine connotations.

## Results

The data were analyzed with linear mixed-effects models using the lme4 and multcomp packages for R (Bates et al., 2015; Hothorn et al., 2016). The most common gender (MCG) of the noun in the participant's native language, the noun's semantic category, personification condition, i.e. whether the participant was asked to personify the nouns, and the order of the adjective were modeled as fixed effects, whereas subject IDs and items were modeled as random effects.

As a manipulation check, we examined whether the biological gender of the referent for nouns denoting humans predicted what adjectives would be generated for it. As can be seen on figure 1 , nouns for males on average received more masculine adjectives $(M=0.001)$ compared to nouns for females ( $\mathrm{M}=-0.005$ ). We compared mixed-effect models with gender valence of the adjective as the dependent variable, random intercept for subject and bysubject random slope for MCG of the noun, and a random intercept for noun. The model with MCG of the noun fit the data significantly better ( $\chi 2=21.871, \mathrm{p}<0.001$ ).

Following that, we analyzed the data from nouns for nonhumans. Only comparisons between adjectives generated for nouns that had either masculine or feminine MCG are reported. Besides the specified fixed effects, all of the models below contain random intercept for subject and bysubject random slope for MCG, as well as random intercept for noun and by-noun random slope for personification.

Adjectives generated by the participants for nouns with majority masculine translations had higher gender valence ratings $(M=0.0007)$ than adjectives generated for nouns with majority feminine translations ( $\mathrm{M}=0.0002$ ), as figure 2 shows. To investigate whether the difference is significant, we compared mixed-effect models with
personification, noun's semantic category, order of the adjective, as well as all of their interactions as fixed effects. Comparison of the models with and without MCG as a fixed effect revealed that it significantly improves the fit of the model ( $\chi 2=14.988, \mathrm{p}<0.01$ ).

The effect, however, could potentially arise due only to the adjectives generated by participants who were asked to personify the noun's referent. To examine that possibility, we compared mixed-effect models with and without an interaction between personification and MCG. The models contained all other possible main effects and interactions between them. Model comparison revealed no significant differences between them $(\chi 2=2.3089, p=0.13)$.

Figure 1: Gender valence of adjectives for humans.

Figure 2: Gender valence of adjectives for non-humans.
Comparison of models with and without an interaction between noun category and MCG revealed a significant difference between them ( $\chi 2=9.1268, \mathrm{p}<0.05$ ). Further multiple comparisons analysis showed a significant difference of the gender valences of adjectives for animal nouns ( z -value $=3.713, \mathrm{p}<0.01$ ) and a marginally significant difference for abstract nouns ( z -value $=2.929, \mathrm{p}$ $=0.078$ ) in the expected gender-congruent directions, but no significant differences in gender valence for nouns for body parts or concrete objects (see fig. 3). We note however that the categories of body parts and concrete objects contained very low numbers of items (4 and 12 respectively). Further,
our design does not license us to generalize the results found for these specific items to their respective semantic categories as a whole.

Figure 3: Gender valence of adjectives belonging to different semantic categories.

Figure 4: Gender valence of first, second and third adjectives generated by participants for non-human nouns.

Last, we examined when the effects of grammatical gender emerge by looking separately at adjectives generated first, second, and third for each noun. Comparison of models with fixed effects of MCG, personification and noun category, as well as all of their interactions, but differing in having or not having a fixed effect of adjective order, revealed a highly significant difference in their fit ( $\chi 2=$ 23.465 , $\mathrm{p}<0.001$ ). Additionally, a comparison of models with and without an interaction between MCG and adjective order was conducted. The models included all other possible main effects and interactions between them. The comparison revealed that the model with the interaction fit the data significantly better $(\chi 2=10.413, \mathrm{p}<0.01)$. Multiple comparisons analysis showed that adjectives generated first did not differ significantly depending on the MCG of the noun they were generated for $(z$-value $=-0.163$, $\mathrm{p}=1.00$ ). However, the difference in average gender valence was significant for second (z-value $=3.643, \mathrm{p}<$ 0.01 ) and third ( z -value $=4.054, \mathrm{p}<0.001$ ) adjectives generated for nouns with different MCG.

## Discussion

What do the results tell us? We see that the grammatical
gender of a noun in a particular language influences what adjectives are generated for it: feminine nouns tend to elicit relatively more feminine adjectives compared to masculine nouns.

The effect appeared even though the task was conducted in English and did not invite participants to think about biological or grammatical gender. This removes two possibilities for why it arose. The first possibility that can be ruled out is that phonological or morphological properties of the nouns used in the experiment made the grammatical gender more salient to the participants, since English nouns do not contain in themselves any information related to grammatical gender. Thus operations situated solely at the lexical level of processing could not explain the effect. Second, gender was not highlighted in the experimental context for the participants who received no instructions to personify. Additionally, the selection procedure for the items minimized the possibility that the stimuli set would implicitly push the participants towards thinking about gender when participating in the experiment. This suggests that the results could be taken as evidence for the existence of effects of grammatical gender on how referents of nouns are conceptualized. The exact mechanism through which this effect takes place is a question for future work, but the current study provides some suggestions. Similarly to some prior work (e.g. Vigliocco et al., 2005) grammatical gender had the most effect on adjectives for nouns denoting animals. The interaction between the noun's semantic category and the gender of the noun found in the current study provides some support for the hypothesis that anthropomorphization of the noun referent is the mechanism through which the effect comes into being.

Cross-linguistically nouns often constitute the most frequently occurring word class in a language (Liang \& Liu, 2013), and they are also used in everyday language for reference to humans, animals, objects, relations, categories and other types of entities. Because of this, the effect we found could have a broad and pervasive influence, affecting a wide range of processes relying on how referents of nouns are conceptualized.

The data also indicate that the effect did not emerge solely due to an invitation to personify the nouns that half of the participants received. Both participants who received instructions to personify and those who did not, showed effects of grammatical gender. It appears that an explicit invitation to personify (as when assigning names or voices in prior studies) is not necessary to induce effects of grammatical gender.

Of course, it is possible that participants personified the nouns even without being given the instruction to do so. For those who did not receive this instruction, the experiment did not make any suggestions for the participants to anthropomorphize the nouns' referents. If participants did engage in such unprompted personification, it seems likely that the effect would be observed outside of the context of this experimental task as well.

Last, we found that significant grammatical-gender
effects emerged starting with the second adjective participants generated for a given noun. This suggests that gender information is quite central in people's mental representations. There was however, no significant effect observed at the very first adjective.

This has the possibility of explaining why some studies using tasks where participants need to respond rapidly fail to observe effects of grammatical gender (e.g. Vigliocco et al., 2005; Kousta et al., 2008). The effect of grammatical gender is small in comparison to some other effects, for example the effect of cultural associations (Beller et al., 2015). It has also been suggested that more abstract pictures induce more schematic ways of conceptualizing what they depict and that verbal description of the less abstract pictures induces a similar effect (Holmes \& Wolff, 2010). This allows one to hypothesize that the strength of the gender effect in combination with its temporal development could leave it unnoticeable in conditions where the participants need to respond rapidly and where other perceptual or conceptual features of the stimulus are highly activated due to task demands or stimuli properties.

## Conclusion

The results obtained in this study support the view that grammatical gender affects object conceptualization. The effect was obtained in absence of any phonological or morphological aspects of the word carrying information about grammatical gender. Additionally, the effect was obtained without participants being invited to think about gender by any experimental instructions or demands (and participants could not have guessed that gender was of interest in the study). Finally, effects of grammatical gender emerged starting with the second adjective participants generated for a given noun. This suggests that gender information is quite central in people's mental representations (but did not emerge on the very first adjective). Furthermore, it is possible that the effect is quite pervasive, as it has the potential to affect anything that could be named by a noun.

# Inferring Human Interaction from Motion Trajectories in Aerial Videos 

Tianmin Shu * Yujia Peng * Lifeng Fan Hongjing Lu Song-Chun Zhu<br>\{tianmin.shu, yjpeng, lfan\}@ucla.edu hongjing@ucla.edu sczhu@stat.ucla.edu Department of Psychology and Statistics, University of California, Los Angeles, USA

#### Abstract

People are adept at perceiving interactions from movements of simple shapes but the underlying mechanism remains unknown. Previous studies have often used object movements defined by experimenters. The present study used aerial videos recorded by drones in a real-life environment to generate decontextualized motion stimuli. Motion trajectories of displayed elements were the only visual input. We measured human judgments of interactiveness between two moving elements, and the dynamic change of such judgments over time. A hierarchical model was developed to account for human performance in this task, which represents interactivity using latent variables, and learns the distribution of critical movement features that signal potential interactivity. The model provides a good fit to human judgments and can also be generalized to the original Heider-Simmel animations (1944). The model can also synthesize decontextualized animations with controlled degree of interactiveness, providing a viable tool for studying animacy and social perception.

Keywords: social interaction; motion; decontextualized animation; hierarchical model; action understanding

## Introduction

People are adept at perceiving goal-directed action and inferring social interaction from movements of simple objects. In their pioneering work, Heider and Simmel (1944) presented video clips showing three simple geometrical shapes moving around, and asked human observers to describe what they saw. Almost all observers described the object movements in an anthropomorphic way, reporting a reliable impression of animacy and meaningful social interaction among the geometric shapes displayed in the decontextualized animation.

Later studies (Dittrich \& Lea, 1994; Scholl \& Tremoulet, 2000; Tremoulet \& Feldman, 2000, 2006; Gao, Newman, \& Scholl, 2009; Gao, McCarthy, \& Scholl, 2010) used more controlled stimuli and systematically examined what factors can impact the perception of goal-directed actions in a decontextualized animation. The results provided converging evidence that the perception of human-like interactions relies on some critical low-level motion cues, such as speed and motion direction. However, it remains unclear how the human visual system combines motion cues from different objects to infer interpersonal interactivity in the absence of any context cues.

To address this fundamental question, Baker, Saxe, and Tenenbaum (2009) developed a Bayesian model to reason about the intentions of an agent when moving in maze-like environments of the sort used by Heider and Simmel (1944). Other studies (Baker, Goodman, \& Tenenbaum, 2008; Ullman et al., 2009; Baker, 2012) developed similar models that could be generalized to situations with multiple agents and

(Right) A sample frame of an experimental trial. The two people being tracked in the aerial video are presented as two dots, one in red and one in green, in a black background. A video demonstration can be viewed on the project website: http: / / www. stat.ucla.edu/~tianmin.shu/HeiderSimmel/CogSci17
different contexts. These modeling studies illustrate the potential fruitfulness of using a Bayesian approach as a principled framework for modeling human interaction shown in decontextualized animations. However, these models have been limited to experimenter-defined movements, and by computational constraints imposed by the modelers for particular application domains.

The present study aims to generate Heider-Simmel-type decontextualized animations using real-life videos of visual scenes. As a naturalistic example, imagine that you are watching a surveillance video recorded by a drone from a bird's eye view, as shown in Fig. 1. In such aerial videos, changes in human body postures can barely be seen, and the primary visual cues are the noisy movement trajectories of each person in the scene. This situation is analogous to the experimental stimuli used in Heider and Simmel's studies, but the trajectories of each entity are directly based on real-life human movements.

In the present study, we first used real-life aerial videos to generate decontextualized animations and to assess how human judgments of interactivity emerge over time. We developed a hierarchical model to account for human performance. One advantage of using aerial videos to generate decontextualized animations is that the technique provides sufficient training stimuli to enable the learning of a hierarchical model with hidden layers, which could illuminate the representations of critical movement patterns that signal potential interactivity between agents. Furthermore, we assessed whether the learning component in the model can be generalized to the original animations by Heider and Simmel (1944).

## Computational Model

We designed a hierarchical model with three layers. As shown in Fig. 2, the first layer (the $X$ layer) estimates spatiotemporal motion patterns within a short period of time.

Figure 2: Illustration of the hierarchical generative model. The solid nodes are observations of motion trajectories of two agents, and the remaining nodes are latent variables constituting the symbolic representation of an interaction, i.e., the original trajectories are coded as a sequence of sub-interactions $S$ and interaction labels $Y$.

The second layer (the $S$ layer) captures the involvement of various motion fields at different stages of interactivity over a long period by temporally decomposing interactivity with latent sub-interactions. The last layer (the $Y$ layer) indicates the presence or absence of interactiveness between two agents.

The inputs to the model are motion trajectories of two agents, denoted as $\Gamma_{a}=\left\{\mathbf{x}_{a}^{t}\right\}_{t=0, \cdots, T}, a=1,2$. The position of agent $a(a=1,2)$ at time $t$ is $\mathbf{x}_{a}^{t}=(x, y)$. The total length of the trajectory is $T$. Using the input of motion trajectories, we can readily compute the velocity sequence of agent $a$ $(a=1,2)$, i.e., $V_{a}=\left\{\mathbf{v}_{a}^{t}\right\}_{t=1, \cdots, T}$, where $\mathbf{v}_{a}^{t}=\mathbf{x}_{a}^{t}-\mathbf{x}_{a}^{t-1}$.

To capture the interactivity between two agents based on the observed trajectories of movements, the model builds on two basic components. (1) Interactivity between two agents can be represented by a sequence of latent motion fields, each capturing the relative motion between the two agents who perform meaningful social interactions. (2) Latent motion fields can vary over time, capturing the behavioral change of the agents over a long period of time. The details for quantifying the two key components are presented in the next two subsections.

## Conditional Interactive Fields

As illustrated in Fig. 3, we use conditional interactive fields (CIFs) to model how an agent moves with respect to a reference agent. We randomly select an agent to be the reference agent, and then model the partner agent's movement by estimating a vector field of the relative motion conditioned on a specific distribution of the reference agent's motion.

To ensure that the fields are orientation invariant, we perform a coordinate transformation as Fig. 3 illustrates. At each time point $t$, the transformed position of the reference agent is always located at $(0,0)$, and its transformed velocity direction is always pointed to the norm of the upward vertical direction. Consequently, the position and velocity of the second agent after the transformation, i.e., $\tilde{\Gamma}=\left\{\tilde{\mathbf{x}}^{t}\right\}_{t=0, \cdots, T}$ and $\tilde{V}=\left\{\tilde{\mathbf{v}}^{t}\right\}_{t=1, \cdots, T}$, can be used to model the relative motion.

For a sub-interaction $s$ (interactivity in a relatively short time sharing consistent motion patterns, e.g., approaching, walking together, standing together), we define its CIF as a

Figure 3: Illustration of a conditional interactive field (CIF): after a coordinate transformation w.r.t. the reference agent, we model the expected relative motion pattern $\tilde{\mathbf{x}}^{t}$ and $\tilde{\mathbf{v}}^{t}$ conditioned on the reference agent's motion.

Figure 4: Temporal parsing by $S$ (middle). The top demonstrates the change of CIFs in sub-interactions as the interaction proceeds. The bottom indicates the change of interactive behaviors in terms of motion trajectories. The colored bars in the middle depict the types of the sub-interactions.
linear dynamic system:

$$
\begin{equation*}
\tilde{\mathbf{v}}^{t} \sim \mathcal{N}\left(A_{S} \tilde{\mathbf{x}}^{t}+B_{s}, \Sigma_{s}\right) \tag{1}
\end{equation*}
$$

where $A_{s}, B_{s}$, and $\Sigma_{s}=\operatorname{diag}\left(\sigma_{s 1}^{2}, \sigma_{s 2}^{2}\right)$ are the parameters of the Gaussian distribution to be learned for each subinteraction $s . \quad A_{s} \tilde{\mathbf{x}}^{t}+B_{s}$ can be interpreted as the expected motion at location $\tilde{\mathbf{x}}$ in the field.

## Temporal Parsing by Latent Sub-Interactions

We assume that a long interactive sequence can be decomposed into several distinct sub-interactions each with a different CIF. For example, when observing that two people walk towards each other, shake hands and walk together, we can decompose this interactive sequence into three subinteractions. We represent meaningful interactivity as a sequence of latent sub-interactions $S=\left\{s_{k}\right\}_{k=1, \ldots, K}$, where a latent sub-interaction determines the category of the CIF involved in a time interval $\mathcal{I}_{k}=\left\{t: t_{k}^{1} \leq t \leq t_{k}^{2}\right\}$, such that $s^{t}=s_{k}, \forall t \in \mathcal{T}_{k} . s_{k}$ is the sub-interaction label in the $k$-th interval representing the consistent interactivity of two agents in the interval. Fig. 4 illustrates the temporal parsing.

In each interval $k$, we define an interaction label $y_{k} \in\{0,1\}$ to indicate the absence or presence of interactivity between the two agents. The interaction labels also constitute a sequence $Y=\left\{y^{t}\right\}_{t=1, \cdots, T}$. We have $y^{t}=y_{k}, \forall t \in \mathcal{T}_{k}$, where $y_{k}$ is the interaction label in interval $\mathcal{T}_{k}$.

## Model Formulation

Given the input of motion trajectories $\Gamma$, the model infers the posterior distribution of the latent variables $S$ and $Y$,

$$
\begin{equation*}
p(S, Y \mid \Gamma) \propto \underbrace{P(\Gamma \mid S, Y)}_{\text {likelihood }} \cdot \underbrace{P(S \mid Y)}_{\text {sub int. prior }} \cdot \underbrace{P(Y)}_{\text {int. prior }} . \tag{2}
\end{equation*}
$$

The likelihood assesses how well the motion fields under corresponding CIFs of sub-interactions can account for relative motion observed in the video input, the spatial density of the relative position and the observed motion of the reference agent:

$$
\begin{equation*}
p(\Gamma \mid S, Y)=\prod_{k=1}^{K} \prod_{t \in \mathcal{T}_{k}} p\left(\tilde{\mathbf{v}}^{t}, \tilde{\mathbf{x}}^{t}, \mathbf{v}_{1}^{t} \mid s^{t}=s_{k}, y^{t}=y_{k}\right) \tag{3}
\end{equation*}
$$

where

$$
\begin{align*}
& p\left(\tilde{\mathbf{v}}^{t}, \tilde{\mathbf{x}}^{t}, \mathbf{v}_{1}^{t} \mid s^{t}=s_{k}, y^{t}=y_{k}\right)  \tag{4}\\
& =\underbrace{p\left(\tilde{\mathbf{v}}^{t} \mid \tilde{\mathbf{x}}^{t}, s_{k}, y_{k}\right)}_{\text {rel. motion }} \cdot \underbrace{p\left(\tilde{\mathbf{x}}^{t} \mid s_{k}, y_{k}\right)}_{\text {rel. spatial density }} \cdot \underbrace{p\left(\| \mathbf{v}_{1}^{t}| | s_{k}, y_{k}\right)}_{\text {ref. motion }} .
\end{align*}
$$

Note that $\mathbf{v}_{1}^{t}$ is the reference agent's velocity. When $y_{k}=1$, the first term is defined in equation (1), the second term is learned by Gaussian kernel density estimation, and the third term is defined as a Weibull distribution, which is suitable for learning a long-tail distribution of a non-negative variable. When $y_{k}=0$, the first term is defined as a Gaussian distribution $\mathcal{N}\left([0,0]^{\top}, \Sigma_{0}=\operatorname{diag}\left(\sigma_{0}^{2}, \sigma_{0}^{2}\right)\right)$, and the remaining two terms are uniform distributions in quantized spaces.

We model the prior term of sub-interactions $P(S \mid Y)$ using two independent components, i) the duration of each subinteraction, and ii) the transition probability between two consecutive sub-interactions, as follows:

$$
\begin{equation*}
p(S \mid Y)=\prod_{k=1}^{K} \underbrace{p\left(\left|\mathcal{T}_{k}\right| \mid s_{k}, y_{k}\right)}_{\text {duration }} \prod_{k=2}^{K} \underbrace{p\left(s_{k} \mid s_{k-1}, y_{k}\right)}_{\text {transition }} \tag{5}
\end{equation*}
$$

When $y_{k}=1$, the two terms follow a log-normal distribution and a multinomial distribution respectively; when $y_{k}=0$, uniform distributions are used for the two terms instead.

Finally, we use a Bernoulli distribution to model the prior term of interactions $P(Y)$,

$$
\begin{equation*}
p(Y)=\prod_{k=1}^{K} \prod_{t \in \mathcal{T}_{k}} p\left(y^{t}=y_{k}\right)=\prod_{k=1}^{K} \prod_{t \in \mathcal{T}_{k}} \rho^{y^{t}}(1-\rho)^{1-y^{t}} \tag{6}
\end{equation*}
$$

## Inference and Prediction

The model infers the current status of latent variables and produces an online prediction of future trajectories. Inference and prediction are performed for each time point from 1 to $T$ sequentially (rather than offline prediction, which gives the labels after watching the entire video).

We denote trajectories from 0 to $t$ as $\Gamma_{0: t}$, and the subinteractions from 1 to $t-1$ as $S_{1: t-1}$. Without loss of generality, we assume there are $K$ sub-interactions in $S_{1: t-1}$ with $\mathcal{T}_{K}$ being the last interval and $s^{t-1}=s_{K}$. We first infer $s^{t}$ under the assumption of interaction (i.e., $y^{t}=1$ ) by maximizing

$$
\begin{equation*}
p\left(s^{t} \mid \Gamma_{0: t}, S_{1: t-1}, y^{t}\right) \propto p\left(\tilde{\mathbf{v}}^{t}, \tilde{\mathbf{x}}^{t}, v_{1}^{t} \mid s^{t}\right) p\left(s^{t} \mid S_{1: t-1}, y^{t}\right) \tag{7}
\end{equation*}
$$

where,

$$
\begin{align*}
& p\left(s^{t} \mid S_{1: t-1}, y^{t}\right) \\
& =\left\{\begin{array}{ll}
p\left(\tau \geq\left|\mathcal{T}_{k}\right|+1 \mid s^{t}=s^{t-1}, y^{t}\right) & \text { if } s^{t}=s^{t-1} \\
p\left(\tau \geq 1 \mid s^{t}, y^{t}\right) p\left(s^{t} \mid s^{t-1}\right) & \text { otherwise }
\end{array} .\right. \tag{8}
\end{align*}
$$

Then the posterior probability of $y^{t}=1$ given $s^{t} \in \mathcal{S}$ is defined as

$$
\begin{equation*}
p\left(y^{t} \mid s^{t}, \Gamma_{0: t}, S_{1: t-1}\right) \propto p\left(s^{t} \mid \Gamma_{0: t}, S_{1: t-1}, y^{t}\right) p\left(y^{t}\right) \tag{9}
\end{equation*}
$$

This computation makes it possible to perform the following inferences and online prediction: i) we maximize (7) to obtain the optimal $s^{t}$; ii) we use (9) to compute the posterior probability of two agents being interactive at $t$ under the CIF of $s^{t}$ as an approximation of the judgment of interaction/noninteraction provided by human observers; iii) the model can synthesize new trajectories using the following computation,

$$
\begin{align*}
& s^{t+1} \sim p\left(s^{t+1} \mid S_{1: t}, y^{t+1}\right)  \tag{10}\\
\mathbf{x}_{1}^{t+1}, \mathbf{x}_{2}^{t+1} & \sim p\left(\mathbf{x}_{1}^{t+1}, \mathbf{x}_{2}^{t+1} \mid \mathbf{x}_{1}^{t}, \mathbf{x}_{2}^{t}, s^{t+1}, y^{t+1}\right)  \tag{11}\\
& =p\left(\tilde{\mathbf{v}}^{t+1}, \tilde{\mathbf{x}}^{t+1}, v_{1}^{t+1} \mid s^{t+1}, y^{t+1}\right)
\end{align*}
$$

where $\tilde{\mathbf{v}}^{t+1}, \tilde{\mathbf{x}}^{t+1}$, and $v_{1}^{t+1}$ are given by $\mathbf{x}_{1}^{t}, \mathbf{x}_{1}^{t+1}, \mathbf{x}_{2}^{t}$ and $\mathbf{x}_{2}^{t+1}$, and the last term is defined in (4). By setting $y^{t+1}=1$ or $y^{t+1}=0$ in (10) and (11).

## Learning

## Algorithm

To train the model, we used Gibbs sampling to find the $S$ that maximizes the joint probability $P(Y, S, \Gamma)$. The implementation details are summarized below:

- Step 0: To initialize $S$, we first construct a feature vector for each time $t$, i.e., $\left[\left\|v_{1}^{t}\right\|, \tilde{\mathbf{x}}^{t}, \tilde{\mathbf{v}}^{t}\right]^{\top}$. A K-means clustering is then conducted to obtain the initial $\left\{s^{t}\right\}$, which also gives us the sub-interaction parsing $S$ after merging the same consecutive $s^{t}$.
- Step 1: At each time point $t$ of every training video, we update its sub-interaction label $s^{t}$ by

$$
\begin{equation*}
s^{t} \sim p\left(\Gamma \mid S_{-t} \cup\left\{s^{t}\right\}, Y\right) p\left(S_{-t} \cup\left\{s^{t}\right\} \mid Y\right) \tag{12}
\end{equation*}
$$

where $S_{-t}$ is the sub-interaction temporal parsing excluding time $t$, and $S_{-t} \cup\left\{s^{t}\right\}$ is a new sub-interaction sequence after adding the sub-interaction at $t$. Note that $Y$ is always fixed in the procedure; thus we do not need $p(Y)$ term for sampling purpose.

- Step 2: If $S$ does not change anymore, go to next step; otherwise, repeat step 1.
- Step 3: Since we do not include the non-interactive videos in the training set, we selected 22 videos in the first human experiment (a mixture of interactive and non-interactive videos) as a validation set to estimate $\rho$ and $\sigma_{0}$ by maximizing the correlation between the model prediction of (9) and the average human responses in the validation set.

## Model Simulation Results

We tested the model using two sets of training data. The first dataset is a UCLA aerial event dataset collected by Shu et al. (2015), in which about 20 people performed some group activities in two scenes (a park or a parking lot), such as group touring, queuing in front of a vending machine or playing frisbee. People's trajectories and their activities are manually annotated. The dataset is available at http://www. stat.ucla .edu/~tianmin.shu/AerialVideo/AerialVideo.html

We selected training videos including interactivity from the database, so that the two agents always interact with each other in all training stimuli. Thus, for any training video, $y^{t}=1, \forall t=1, \cdots, T$. During the training phase, we excluded the examples used in human experiments. In total, there were 131 training instances.

In the implementation, we manually define the maximum number of sub-interaction categories to be 15 in our full model (i.e., $|S|=15$ ), which is over-complete for our training data according to learning (low frequency in the tail of Fig. 6). With simulated annealing (Kirkpatrick, Gelatt, \& Vecchi, 1983), Gibbs sampling converges within 20 sweeps (where a sweep is defined as all the latent sub-interaction labels have been updated once). The frequencies of the top 15 CIFs are highly unbalanced. In fact, the top 10 CIFs account for $83.8 \%$ of the sub-interactions in the training data. The first row of Fig. 5 provides a visualization of the top 5 CIFs.

The second dataset was created from the original HeiderSimmel animation (i.e., two triangles and one circle). We extracted the trajectories of the three shapes, and thus obtained 3 pairs of two-agent interactions. We truncated the movie into short clips (about 10 seconds) to generate a total of 27 videos. The same algorithm was used to train the model with 15 types of CIFs. The most frequent five CIFs are visualized in the second row of Fig. 5. Clearly, the richer behavior in the Heider-Simmel animation yielded a variety of CIFs with distinct patterns compared to the CIFs learned from aerial videos. The frequencies of CIFs are also more distributed in this dataset, as shown in Fig. 6.

We observed a few critical CIFs that signal common interactions from the two simulation results. For instance, in aerial videos, we observed i) approaching, e.g., CIF 1 and ii) walking in parallel, or following, e.g., the lower part of CIF 2; the Heider-Simmel animation revealed additional patterns such as i) orbiting, e.g., CIF 1, ii) walking-by, e.g., CIF 5, and iii) leaving, e.g., CIF 4.

## Experiment

## Stimuli

24 interactive stimuli were generated from different pairs of human interactions in aerial videos. We selected two people interacting with each other in each aerial video. We then generated the decontextualized animations by depicting the two people as dots with different colors. The dots' coordinates were first extracted from the aerial videos by human annotators. Note that the two dots were first re-centered to localize
the midpoint at the center of the screen in the first frame. The coordinates were temporally smoothed by averaging across the adjacent 5 frames.

24 non-interactive stimuli were generated by interchanging motion trajectories of two people selected from two irrelevant interactive videos (e.g., the motion of one dot in video 1 recombined with the motion of a dot in video 2). The starting distances between two dots in non-interactive stimuli were kept the same as in the corresponding interactive stimuli.

The duration of stimuli varied from 239 frames to 500 frames (mean frame $=404$ ), corresponding to 15.9 to 33.3 seconds, with a recording refresh rate of 15 frames per second. The diameters of dots were $1^{\circ}$ of visual angle. One dot was displayed in red ( $1.8 \mathrm{~cd} / \mathrm{m}^{2}$ ) and the other in green $\left(30 \mathrm{~cd} / \mathrm{m}^{2}\right)$ on a black background $\left(0 \mathrm{~cd} / \mathrm{m}^{2}\right)$. Among the 48 pairs of stimuli, four pairs of actions (two interactive and two non-interactive) were used as practice.

## Participants

33 participants (mean age $=20.4 ; 18$ female) were enrolled from the subject pool at the University of California, Los Angeles (UCLA) Department of Psychology. They were compensated with course credit. All participants had normal or corrected-to-normal vision.

## Procedures

Participants were seated 35 cm in front of a screen, which had a resolution of $1024 \times 768$ and a 60 Hz refresh rate. First, participants were given a cover story: "Imagine that you are working for a company to infer whether two people carry out a social interaction based on their body locations measured by GPS signals. Based on the GPS signal, we generated two dots to indicate the location of the two people being tracked." The task was to determine when the two dots were interacting with each other and when they were not. Participants were asked to make continuous responses across the entire duration of the stimuli. They were to press and hold the left-arrow or right-arrow button for interactive or non-interactive moments respectively, and to press and hold the down-arrow button if they were unsure. If no button was pressed for more than one second, participants received a 500 Hz beep as a warning.

Participants were presented with four trials of practice at the beginning of the session to familiarize them with the task. Next, 44 trials of test stimuli were presented. The order of trials was randomized for each participant. No feedback was presented on any of the trials. The experiment lasted for about 30 minutes in total.

## Results

Interactive, unsure and non-interactive responses were coded as $1,0.5$, and 0 , respectively. Frames with no responses were removed from the comparison. Human responses were shown in Fig. 8 (left). A paired-sample t-test revealed that the average ratings of non-interactive actions $(\mathrm{M}=0.34, \mathrm{SD}=0.13)$ were significantly lower than interactive actions $(M=0.75$,

Figure 5: Interactive fields of the top five frequent CIFs learned from aerial videos (top) and Heider-Simmel movie (bottom) respectively. In each field, the reference agent (red dot) is at the center of a field i.e., $(0,0)$, moving towards north; the arrows represent the mean relative motion at different locations and the intensities of the arrows indicate the relative spatial density which increases from light to dark.

Figure 6: The frequencies of learned CIFs with the training data generated from aerial videos (top) and the Heider-Simmel movie (bottom). The numbers on the x axis indicate the IDs of CIFs, ranked according to the occurrence frequency in the training data.

| Method | HMM | One-Interaction | Hierarchical Model |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: |
|  |  |  | $\|\mathcal{S}\|=5$ | $\|\mathcal{S}\|=10$ | $\|\mathcal{S}\|=15$ |
| $r$ | 0.739 | 0.855 | 0.882 | 0.911 | 0.921 |
| RMSE | 0.277 | 0.165 | 0.158 | 0.139 | 0.134 |

Table 1: The quantitative results of all methods in experiment 1 using aerial videos as training data.
$\mathrm{SD}=0.13), t(32)=13.29, p<0.001$. This finding indicates that human observers are able to discriminate interactivity based on decontextualized animations generated from the real-life aerial videos.

To compare the model predictions with human continuous judgments, we computed the average human ratings, and ran the model to simulate online predictions of sub-interaction and interaction labels on the testing videos (excluding the ones in the validation set). Specifically, we used (9) to compute the probability of two agents being interactive with each other at any time point $t$. The model simulation used the hyper-parameters $\rho=10^{-11}$ and $\sigma_{0}=1.26$.

Table 1 summarizes the Pearson correlation coefficient $r$ and root-mean-square error (RMSE) between the model predictions and the human ratings using aerial videos as training data. We compare our hierarchical model with two baseline models: i) Hidden Markov Model (HMM), where the latent variables $s^{t}$ and $y^{t}$ only depend on their preceding variables $s^{t-1}$ and $y^{t-1}$; ii) a model with only one type of subinteraction. Both models yielded poorer fits to human judgments (i.e., lower correlation and higher RMSE) than the hierarchical model. In addition, we changed the number of subinteraction categories to examine how sensitive our model is
to this parameter. The results clearly show that i) only using one type of sub-interaction provides reasonably good results, $r=.855$, and ii) by increasing the number of sub-interactions $|S|$, the fits to human ratings were further improved until reaching a plateau with a sufficiently large number of subinteractions.

Fig. 7 shows results for a few videos, with both model predictions and human ratings. The model predictions accounted for human ratings quite well in most cases. However, the model predictions were slightly higher than the average human ratings, which may be due to the lack of negative examples in the training phase. We also observed high standard deviations in human responses, indicating the large variability of the online prediction task for every single frame in a dynamic animation. In general, the difference between our model's predictions and human responses are seldom larger than one standard deviation of human responses.

We also tested the model trained from the Heider-Simmel movie on the same testing set (generated from the aerial videos), yielding a correlation of 0.640 and RMSE of 0.227 . The reduced fitting result indicates the discrepancy between two types of videos. The CIFs learned from one dataset may be limited in generalization to the other dataset.

One advantage of developing a generative model is that it enables the synthesis of new videos by (10) and (11), based on randomly sampled initial positions of the two agents ( $\mathbf{x}_{1}^{0}$, $\mathbf{x}_{2}^{0}$ ) and the first sub-interaction $s^{1}$. By setting the interaction labels to be 1 or 0 , the synthesized stimuli can be controlled to vary the degree of interactiveness. We ran a second experiment using model synthesized animations ( 10 interactive and 10 non-interactive clips). These synthesized videos were presented to human observers in random orders and the interactive ratings were recorded. The interactiveness between the two agents in the synthesized videos was judged accurately by human observers (mean rating of 0.85 for synthesized interactive clips, and 0.15 for non-interactive clips), suggesting that the model effectively captured the visual features that signal potential interactivity between agents.

Figure 7: Comparison of online predictions by our full model $(|\mathcal{S}|=15)$ (orange) and humans (blue) over time (in seconds) on testing videos. The shaded areas show the standard deviations of human responses at each moment.

Figure 8: Mean ratings of the interactive versus non-interactive actions in the experiment. Error bars indicate $+/-1$ SEM.

## Conclusion

In this paper, we examined human perception of social interactions using decontextualized animations based on movement trajectories recorded in aerial videos of a real-life environment, as well as Heider-Simmel-type animations. The proposed hierarchical model built on two key components: conditional interactive fields of sub-interactions, and temporal parsing of interactivity. The model fit human judgments of interactiveness well, and suggests potential mechanisms underlying our understanding of meaningful human interactions. Human interactions can be decomposed into sub-interactions such as approaching, walking in parallel, or standing still in close proximity. Based on the transition probabilities and the duration of sub-components, humans are able to make inferences about how likely the two people are interacting.

The model could be extended to be applied to the field of behavioral recognition. While previous work has focused on actions of individuals based on detecting local spatialtemporal features embedded in videos (Dollár, Rabaud, Cottrell, \& Belongie, 2005), the current work can deal with multiagent interaction. Understanding of the relation between agents could facilitate the recognition of individual behaviors by putting single actions into meaningful social contexts. In addition, the current model is only based on visual motion cues. The model could be enhanced by incorporating a cognitive mechanism (e.g., a theory-of-mind framework) to enable explicit inference of intentions.

University Avenue/1126 E. 59th St. Chicago, IL 60637 USA

#### Abstract

Comparison supports the development of children's analogical reasoning. The evidence for this claim comes from laboratory studies. We describe spontaneous comparisons produced by 24 typically developing children from 26 to 58 months. Children tend to express similarity before expressing difference. They compare objects from the same category before objects from different categories, make global comparisons before specific comparisons, and specify perceptual features of similarity/difference before non-perceptual features. We then investigate how a theoretically interesting subset of children's comparisons - those expressing a specific feature of similarity or difference - relates to analogical reasoning as measured by verbal and non-verbal tests in 6th grade. The number of specific comparisons children produce before 58 months predicts their scores on both tests, controlling for vocabulary at 54 months. The results provide naturalistic support for experimental findings on comparison development, and demonstrate a strong relationship between children's early comparisons and their later analogical reasoning.

Keywords: comparison; similarity; language development; analogy

## Introduction

Comparison - the process of jointly examining two objects or events and assessing their similarities and differences - is crucial in the development of children's word learning, categorization, and analogical reasoning skills (Namy \& Gentner, 2002; Gentner \& Namy, 2006; Gentner, Anggoro, \& Klibanoff, 2011; Richland \& Simms, 2015). Comparison is an effective learning tool because it promotes structural alignment: the mapping of two representations in a way that enables the recognition of relational commonalities and alignable differences. A large body of experimental work shows that inviting children to compare exemplars helps them to move beyond overall or global similarity to more specific kinds of similarity, including similarity based on relational commonalities, as in analogical reasoning (Loewenstein \& Gentner, 2001; Christie \& Gentner, 2014; Gentner et al.,
2016). However, to get a full picture of the role of comparison in the development of children's analogical reasoning skills, it is important to relate this experimental work to children's spontaneous behavior in a naturalistic environment. Previous work has shown that children spontaneously produce comparative utterances from early in their language development: for example, children spontaneously generate metaphors from the age of around 2 (Winner, 1979) and are able to explain them in terms of similarity (Billow, 1981). However, the nature of the comparisons children produce is not static over time, but follows a developmental trajectory. Özçalışkan, Goldin-Meadow, Gentner, and Mylander (2009) found that while children's earliest comparisons tended to be between objects that were similar to each other in many features, the acquisition of the word 'like' was associated with an increase in the number of comparisons between objects that only shared a single feature. These specific comparisons are argued to be a more sophisticated stage in the development of children's understanding of similarity than are global comparisons (Smith, 1989; Gentner \& Rattermann, 1991). As such, the prevalence of specific comparisons in children's early speech could potentially be an index of their later analogical reasoning skill.

The current work has two aims: 1) a descriptive aim, to characterize common patterns in the development of children's spontaneous comparisons produced in naturalistic contexts in the home; 2) an inferential aim, to test the hypothesis that variation in children's production of specific, singlefeature comparisons predicts variation in their scores on tests of analogical ability given much later, in 6th grade.

## Methods

## Participants

24 children and their primary caregivers were drawn from a larger sample of 64 families who participated in a longitudi-
nal study of language development (the same sample drawn on by Özçalışkan et al., 2009). Families were recruited via direct mailings to targeted zip codes and an advertisement in a free monthly parenting magazine. Parents who responded were interviewed regarding background characteristics, and the final sample was selected to be representative of the greater Chicago area in terms of race, ethnicity and income. The sub-sample of 24 families in the current study was selected randomly, within the constraints of preserving the demographic spread of the original sample. Of the 24 children, 11 were male and 13 female; 18 were white (of whom 3 were Hispanic), 3 were Black or African-American, and 3 were of two or more races. The distribution of socio-economic status across the 24 families was similar to that of the original sample, ranging from families with an income of under $\$ 15,000$ where the primary caregiver had some high school education, to families with an income of over $\$ 100,000$ where the primary caregiver had an advanced degree.

## Procedure

Parents and children were visited in their homes and videotaped engaging in their normal daily activities for 90 minutes. Home visits began when the children were 14 months old and continued at 4-month intervals, ending when the children were 58 months old ( 12 sessions in total). ${ }^{1}$ All child speech, and all parent speech directed to the child, was transcribed. Transcription reliability was established by having a second individual transcribe $20 \%$ of each transcriber's tapes. Reliability was at or above $95 \%$.

## Coding

Comparisons were coded from the transcripts of child speech during the 12 sessions. The criterion for a comparison was that the child expressed a similarity or difference between an identifiable source and target. Sources and targets could be objects or events. In cases where the source and target of the comparison were unclear from the transcript alone, the original video was consulted. For each identified comparison, we coded the following:
Word. The word that made the utterance a comparison; e.g. 'I'm a funny one like you' would be coded as 'like'.
Word category. Comparative words were classified into six categories: like (the words 'like' and 'alike'), same/different (the words 'same' and 'different'), comparative/superlative (any comparative or superlative adjective, e.g., 'bigger', 'best'), too (used either in contexts like 'too big' or contexts like 'I'm dancing too'), match (e.g., 'these match each other'), and other.
Object or event. Comparisons were coded for whether the Source and Target were objects (e.g., 'this [rug] look like a skirt') or events (e.g., 'I win too').

[^201]Expressing similarity or difference. Comparisons were coded for whether they expressed similarity (e.g. 'go like a elephant') or difference (e.g. 'I'm bigger than everybody!').
Global or specific comparison. Comparisons were coded for whether they expressed global similarity/difference (e.g., for Objects, 'I have toys just like yours'; for Events, 'they both win'), or specific similarity/difference (e.g., for Objects, 'red like the ladybug'; for Events, 'I go a lot faster than when I was three'). Comparisons could be specific even if the objects compared were overall similar, e.g., 'this [tree] is the tallest [tree]'. We expect global comparisons to appear earlier than specific comparisons (Smith, 1989; Gentner \& Rattermann, 1991).

Feature specified. Where a feature of similarity or difference was specified, this feature was coded. Features were classified into 6 categories: Spatial (e.g., size, shape, distance, speed), Sensory (e.g., color, weight, taste, smell), Evaluative (e.g., goodness, prettiness, badness), Emotion (e.g., being tired, mad, scared), Preference (e.g., liking one thing better than another thing), ${ }^{2}$ and Other. Features were also classified as Perceptual (based on a readily perceptible attribute, e.g. color, size) or Non-Perceptual (based on a more abstract, not directly perceptible feature, e.g., preference, goodness).
Within or between-category comparison. Comparisons were coded for whether the objects compared were from the same or different superordinate categories. Superordinate categories were taken from Özçalışkan et al. (2009), with three additions to accommodate new data (in italics): people, animals, body parts, vehicles, clothing, furniture, appliances, kitchen utensils, tools, musical instruments, food, plants, activity toys, places, decorations/crafts, words/letters, and shapes.

In the case of events, the objects of interest were those with corresponding roles in the two events. For example, if the parent said she was going to use some yellow paint, and the child said 'think I'll do yellow too', the objects in corresponding roles (parent/child, and yellow paint/yellow paint) are in the same superordinate categories (people and decorations/crafts, respectively). This would therefore be coded as a within-category comparison. If the child said 'I'm going to act like a bee', the objects in corresponding roles (child and bee) are in different superordinate categories (people and animals); this would therefore be coded as a between-category comparison. If children initially rely on overall similarity, then within-category comparisons should emerge earlier than between-category comparisons.

A total of 532 comparisons were codable under these guidelines.

## Later outcomes

The same children were followed longitudinally as part of an ongoing language development project. When the chil-

[^202]

## Age in months

Figure 1: Frequencies of word categories across sessions.
dren were in 6th grade (aged around 13 years), we administered two tests of analogical reasoning: the Verbal Analogies subtest of the Woodcock-Johnson Tests of Cognitive Abilities (Woodcock, McGrew, \& Mather, 2001), and a nonverbal test, Raven's Progressive Matrices (Raven, 1938). The Woodcock-Johnson Verbal Analogies is an orally administered test that consists of sets of paired items. The participant has to fill in the missing item by abstracting the relation that holds between the first pair. For example, the participant is given the prompt 'mother is to father, as sister is to...', and expected to fill in the missing term 'brother'. Raven's Progressive Matrices consists of a series of geometric analogy problems. The participant is presented with a matrix that has one entry missing and must select the correct entry from an array of $6-8$ choices. These two measures were taken as outcomes in our analyses.

## Results

## Onset and prevalence of comparisons

Children varied in the age at which they produced their first comparison. For the purpose of this analysis, age of onset was defined as children's age during the session where they produced at least one comparison and also produced at least one comparison during the immediately following session. Under this criterion, the earliest onset was at 26 months, and the latest was at 50 months. The average age of onset was 36 months, with a standard deviation of 6 months. Comparisons were relatively infrequent: they ranged from $0 \%$ to $2.2 \%$ of a child's utterances in a given session. However, the fact that we reliably find comparisons even in short 90-minute sessions suggest they are a robust feature of children's early talk.

Figure 2: Frequencies of comparisons expressing similarity and difference across sessions.

## Comparison words

The most commonly used comparison word was 'like', followed by 'too', 'bigger', 'same', and 'better'. Together, these words accounted for $73 \%$ of the comparisons the children expressed. Table 1 shows counts and percentages for the word categories detailed in the Methods.

Table 1: Word categories.

| Word category | Number of uses | Percent |
| :--- | :--- | :--- |
| like | 219 | $41 \%$ |
| comparative/superlative | 142 | $27 \%$ |
| too | 76 | $14 \%$ |
| same/different | 45 | $8 \%$ |
| other | 34 | $6 \%$ |
| match | 16 | $3 \%$ |

Figure 1 shows the frequencies of the 4 most prevalent word categories over sessions. 'Like' is the first word category to reliably emerge. While 'like' and comparatives/superlatives are overall more frequent, all word categories generally show an increase in use across sessions.

## Expressing similarity and difference

Figure 2 shows the trend over sessions for expressing similarity versus difference. Similarity comparisons were more numerous overall ( 346 to 186). The general trend was for similarity comparisons to emerge earlier than difference comparisons, and to remain more numerous until the final session. On a by-individual level, 20 out of 24 children produced a similarity comparison before they produced a difference comparison; 1 produced a difference comparison before produc-

Figure 3: Frequencies of global and specific comparisons across sessions.
ing a similarity comparison; and 3 produced examples of both simultaneously. This trend for similarities to precede differences was significant, $\chi^{2}=27.25, p<.001$.

## Objects and events

While object comparisons were more numerous in general (358 compared to 174 event comparisons), the overall trend was for object and event comparisons to emerge at around the same time. 11 out of 24 children produced an object comparison before they produced an event comparison; 8 produced an event comparison before they produced an object comparison; and 5 produced examples of both simultaneously. The trend in ordering was not significant, $\chi^{2}=2.25, p=.32$. Thus it appears that from comparison onset, children are capable of expressing comparisons between events as well as comparisons between objects.

## Global and specific comparisons

The numbers of global and specific comparisons were broadly equivalent: 249 global to 283 specific. Figure 3 shows the trend over sessions. Global comparisons appear to be more numerous than specific comparisons in the first two sessions; in subsequent sessions they are at equivalent levels, until the final two sessions when specific comparisons are higher. By individuals, as predicted, global comparisons tended to precede specific comparisons: 14 of 24 children produced a global comparison before they produced a specific comparison, while 5 produced a specific comparison before they produced a global comparison, and 5 produced both in the same session. While not as strong as the tendency for similarity to precede difference, this trend in ordering was significant, $\chi^{2}=6.75, p=.034$.

## Features specified

The most frequently specified features were spatial or sensory; together, these accounted for $70 \%$ of the specific comparisons the children expressed. Table 2 shows overall counts and percentages.

Table 2: Feature categories.

| Feature category | Number of uses | Percent |
| :--- | :--- | :--- |
| Spatial | 136 | $48 \%$ |
| Sensory | 62 | $22 \%$ |
| Evaluative | 49 | $17 \%$ |
| Other | 30 | $11 \%$ |
| Emotion | 4 | $1 \%$ |
| Preference | 3 | $1 \%$ |

More perceptual features (202) were specified than nonperceptual features (80). The overall trend was for perceptual features to be specified earlier: by individual, 16 children specified perceptual features before they specified nonperceptual features, 4 specified non-perceptual features before they specified perceptual features, and 4 did both in one session. The trend for perceptual features to be specified first was significant, $\chi^{2}=12, p=.002$.

## Within- and between-category comparisons

Comparisons between objects in the same superordinate category (or between events involving objects in the same superordinate categories) were more numerous than comparisons between different superordinate categories (421 compared to 133). As predicted, comparisons between objects in the same category generally tended to precede comparisons between objects in different categories. 14 of 24 children produced a within-category comparison before a between-category comparison. 5 produced a between-category comparison first, and 5 children did both in one session. This trend in ordering was significantly different from chance, $\chi^{2}=6.75, p=.034$.

## Comparison type interactions

We also examined interactions between comparison types.
Firstly, we asked whether the children's comparisons expressing similarity were more likely to specify a feature than their comparisons expressing difference, or vice versa. 118 (34\%) of similarity comparisons specified a feature of similarity, while 165 ( $89 \%$ ) of difference comparisons specified a feature of difference. Given their marginal totals, similarity comparisons were less likely than expected to specify features, and difference comparisons were more likely than expected to specify features. This difference was significant, $\chi^{2}=145.38, p<.001$.

We then asked whether comparisons involving objects in the same superordinate category were more likely to express similarity or difference, as opposed to comparisons involving objects in different superordinate categories. Comparisons of within-category objects, or events involving within-category

Figure 4: Scatterplot showing number of specific comparisons produced from 26-58 months (x axis) and score in Verbal Analogies test in 6th grade (y axis).
objects, were broadly as likely to express similarity as difference: $240(60 \%)$ of these expressed similarity. On the other hand, comparisons of between-category objects, or events involving between-category objects, were more likely to express similarity ( 105 , or $80 \%$ ) than difference. This trend was significant, $\chi^{2}=15.32, p<.001$.

## Relation to later outcomes

We then tested the hypothesis motivated in the Introduction, that the number of specific comparisons (expressing a single feature of similarity or difference) that children made during the 12 observational sessions would predict their performance on tests of analogical reasoning in 6th grade.

Our outcome measures were the two analogy tests described in the Methods: the Woodcock-Johnson Verbal Analogies test, and Raven's Progressive Matrices. Both a verbal and a non-verbal test were administered in order to address the potential confound of language skill, which could influence both children's comparison production and their verbal analogy test scores. To further account for language proficiency, we controlled for the child's score on the Peabody Picture Vocabulary Test (PPVT-III; Dunn \& Dunn, 1997) at 54 months (the penultimate session of the 12 during which comparisons were collected).

Figures 4 and 5 show scatterplots of the relationship between the number of specific comparisons the children produced during the pre-school observation sessions and their 6th grade scores on the Verbal Analogies and Raven's Progressive Matrices tests, respectively.

Table 3 shows the results of the statistical model predicting Verbal Analogies score from specific comparison count and

Figure 5: Scatterplot showing number of specific comparisons produced from 26-58 months (x axis) and score in Raven's Progressive Matrices test in 6th grade (y axis).

PPVT at 54 months. Specific comparisons remained a significant predictor after controlling for PPVT, although PPVT had a larger effect. The adjusted $R^{2}$ for the model was .64, indicating that these two variables together explain around two-thirds of the variance in Verbal Analogies score.

Table 3: Verbal Analogies model

| Predictor | Standardized $\beta$ | $t$ | $p$ |
| :--- | :--- | :--- | :--- |
| \# specific comparisons | 0.37 | 2.44 | .024 |
| PPVT at 54 months | 0.55 | 3.60 | .002 |

Table 4: Raven's Progressive Matrices model

| Predictor | Standardized $\beta$ | $t$ | $p$ |
| :--- | :--- | :--- | :--- |
| \# specific comparisons | 0.67 | 4.27 | $<.001$ |

Table 4 shows the results of the model predicting Raven's Progressive Matrices score from specific comparison count. In this case, a likelihood ratio test showed that adding PPVT did not improve the model, $F(1)=1.05, p=.318$. The adjusted $R^{2}$ for the model was .43 , indicating that specific comparison count alone explains around $40 \%$ of the variance in Raven's Progressive Matrices scores.

## Discussion

Children's earliest comparisons tend to express global similarity between objects or events within the same superordi-
nate category. Later in development, children begin to express difference, to specify features of comparison, and to compare objects and events from different superordinate categories. Turning to the content of these comparisons, children are particularly motivated to comment first on similarities and differences in perceptual features such as size, color, and speed, and later on evaluative features such as goodness, prettiness, and their opposites.

While children are more likely to express global similarity than specific similarity, most difference comparisons are specific rather than global. This finding suggests that children are less motivated to comment on overall dissimilarity than on overall similarity: differences are only interesting insofar as they are specific. We also find that comparisons involving objects in different superordinate categories tend to disproportionately express similarity, rather than difference, despite these objects being a priori less similar to each other. This seemingly counter-intuitive result backs up existing theory: more similar objects are more likely to have salient, alignable differences than objects which are dissimilar (Markman \& Gentner, 1993; Gelman, Raman, \& Gentner, 2009).

The relationship we find between children's early comparisons and their later analogical reasoning skill can potentially be interpreted in a number of ways. One possibility is that children who make more specific comparisons gain more practice in identifying dimensions of similarity or difference: thus, making these comparisons directly helps build their analogical skills in ways that persist through later development. Another possibility is that both our predictor variable (the prevalence of specific comparisons in the pre-school years) and our outcome variable (performance on verbal and nonverbal analogy tests in 6th grade) can be traced back to an underlying variable such as intelligence. The current work cannot tease these explanations apart. However, in future work, we aim to code the comparisons parents produce during the sessions before their children start producing comparisons themselves. It will then be possible to use causal modeling to investigate the extent to which parent comparison input predicts child comparison production, controlling for parent IQ. If parent comparison input influences child production of comparisons beyond a heritable IQ effect, this outcome could potentially open the door for interventions aimed at boosting children's comparison production in the home by providing them with particularly helpful kinds of input.

# Learning About Causal Systems Through Play 

Zi L. Sim* (zi@berkeley.edu)<br>Kuldeep K. Mahal* (kmahal@berkeley.edu)<br>Fei Xu (fei_xu@berkeley.edu)<br>Department of Psychology, University of California, Berkeley<br>Berkeley, CA 94720 USA

#### Abstract

It is commonly believed that children are able to learn through play. Recent studies have found that children are able to learn causal rules through free play (Sim \& Xu, in press). One such study found that children learned how to correctly activate machines, using either a block that was the same shape or the same color as the machine, when given five minutes to play with them. However, would children be able to learn a more complex causal rule through free play as well and would their performance be comparable to children who were didactically taught the same causal rule? In the current study, we show that children are able to learn more complex causal rules through free play. We also show that children perform significantly better when learning these rules through free play or by first engaging in free play and then observing, as opposed to solely through observation.

Keywords: free play; causal learning; generalization

## Introduction

It is widely accepted that play is important for young children. Most elementary schools have a designated play time, where children are free to play and socialize with their peers. Studies have shown that on average children spend 51 hours a week, or $30 \%$ of their week, engaging in free play (Hofferth \& Sandberg, 2001). Play is also commonly encouraged by parents and educators, and access to play has been recognized by the United Nations Convention on the Rights of the Child (UNCRC) as a fundamental human right (Davey \& Lundy, 2011). It is evident that children spend a lot of time playing and are encouraged to do so, but it remains unclear why this is the case. Why do children spend such a large portion of their time playing, and why do adults actively encourage play behavior?

One explanation is that play has the potential to result in better learning than direction instruction because play provides learners with the opportunity to choose what they want to do (Whitebread, Coltman, Jameson, \& Lander, 2009; Weisberg, Hirsh-Pasek, \& Golinkoff, 2013; Weisberg, HirshPasek, Golinkoff, \& McCandliss, 2014). By doing so, learners may better encode new information in their memory (Metcalfe \& Kornell, 2005); process the problem structure more deeply (Sobel \& Kushnir, 2006); they may pay more attention and are more motivated (Corno \& Mandinach, 1983); or they may be able to focus on acquiring data that can address gaps in their knowledge (Markant \& Gureckis, 2013). There is some empirical evidence that adults benefit from the opportunity to select the information that they want to learn. In fact, research has shown that adults learn better when they
engage in active hypothesis testing, where they are able to select the data they observe to test their hypotheses, as compared to those who engaged in reception learning, where they observed data generated by another adult (Castro et al., 2009; Markant \& Gureckis, 2014; Sobel \& Kushnir, 2006).

For example, in one study, adults were shown a spectrum of sixteen "alien eggs" on a computer that went from spiky to smooth. Students were told that spiky eggs most likely hatched into alien snakes while smooth eggs most likely hatched into alien birds. They were asked to determine the boundary between the two types of eggs, so they had to determine the point at which the eggs shifted from hatching one species to the other species. To do this, subjects either selected a sequence of eggs to see which animal hatched from them (active learning condition) or observed randomly selected eggs being hatched (random condition). The study found that participants in the active learning condition generally performed better than those in the random condition (Castro et. al, 2009), which suggests that adults experience benefits in learning when they play an active role in gathering information.

Within the developmental literature, several studies have established that children learn successfully when they have the opportunity to choose what they want to do as well. For example, researchers have found that children as young as five years were able to use self-generated evidence to learn about an ambiguous causal system (McCormack, Bramley, Frosch, Patrick, \& Lagnado, 2016; Schulz, Gopnik, \& Glymour, 2007). In another study, Sim and Xu (in press) found that three-year-olds were capable of forming higherorder generalizations about a causal system after a short play period. In this study, children were presented with a causal learning task in which blocks would activate machines either based on a shape-rule (a block that matched the machine in shape activated the machine), or a color-rule (a block that matched the machine in color activated the machine). Children were randomly assigned to a didactic condition, such that an experimenter showed the children how to activate the machines, or a free play condition, such that the children were given the opportunity to play freely with these machines and blocks. The children were then tested using a first-order and a second-order generalization task. In the firstorder generalization task, children were asked to activate a familiar machine, and in the second-order generalization task, children were asked to activate a novel machine. The study found that both groups performed at levels well above chance, and there was no significant difference between the accuracy between the two conditions ( $\mathrm{Sim} \& \mathrm{Xu}$, in press).

Similarly, Smith and Dutton (1979) compared the performance of children in a play condition to both a training condition, where children were taught to use the materials by an experimenter, as well as a control condition, where children were neither taught by an experimenter nor played with the materials. Although children in the play and training condition performed significantly better in a problem-solving task compared to the control condition, there was no significant difference between the play and training conditions.

Although all of these studies suggest that children are able to learn through free play, there is as yet little evidence that young children's learning and generalizations under free play conditions would actually differ from those in didactic conditions. Learning in the free play condition has repeatedly been found to be comparable to a didactic condition, but has not been found to be different from a didactic condition.

Are there conditions under which young children may benefit more from the free play that they engage in independently, as compared to a training that is directed by an adult? In the current study, we examined this question by presenting children with a causal learning task in which the generalization to be acquired was more complicated than that examined in Sim and Xu (in press). To do so, machines in our study were activated when either two blocks that were the same shape as the machine, or two blocks that were the same color as the machine, were placed on the machine. Prior research have indicated that young children can learn causal rules of a similar form: Walker and Gopnik (2014) showed that after a short demonstration by an experimenter, 18- to 24-month-olds were able to learn a "same" or "different" causal rule, i.e. that a machine was activated only by placing two identical blocks on the machine, or that a machine was activated only by placing two dissimilar blocks on the machine. Given that the rule used in the current study is of a more complex form - the two blocks had to match each other and the machine on a specific dimension (i.e., shape or color) - we chose to test 3- and 4-year-olds in the current study.

Children were randomly assigned to a free play condition, where they were presented with six machines (three categories of machines, with two identical machines within each category) and twelve blocks to play with for approximately 10 minutes, or the didactic condition, where they observed an experimenter activate each machine once. To further examine any potential benefits of play, children who did not activate the machines at least once in the free play condition were placed in a third condition, the free-playfirst condition, where they observed the experimenter showing them how to activate the machines after they played by themselves for approximately 10 minutes. Similar to the study by Sim and Xu (in press), the children's ability to learn the correct rule was measured using a first- and second-order generalization test, where they were asked to activate both a familiar and a novel machine respectively.

## Method

## Participants

Sixty-one three- to five-year-old English-speaking children ( 29 boys and 32 girls) with the mean age of 48.4 months (range $=36.3$ months to 59.1 months) were tested. All were recruited from Berkeley, California and its surrounding communities. Children were tested either in a small testing room at our lab or in a small quiet room in a preschool. Each child was randomly assigned to the didactic $(\mathrm{N}=24)$ or free play condition ( $\mathrm{N}=22$ ). Children assigned to the free play condition but did not activate the machines at least once during the free play phase were placed in the free play first condition ( $\mathrm{N}=15$ ). The mean ages in the didactic, free play, and free play first condition were 48.1 months, 49.7 months, and 47.1 months respectively. An additional 9 children were tested but were excluded due to parent interference $(\mathrm{N}=5)$ and experimenter error $(\mathrm{N}=4)$.

## Materials

Five different types of machines were constructed for this experiment. Each type of machine made a distinct sound when activated. This activation was completed using a foot pedal connected to a remote that activated a doorbell that was placed inside the machines. There were two blue rectangle machines, two red triangle machines, two green circle machines, and one orange L-shaped machine. In addition, there was a colorful felt-covered plus-shaped machine (demonstration machine) that looked considerably different from the other four types of machines. Each machine was approximately $20 \mathrm{~cm} \times 12 \mathrm{~cm} \times 10 \mathrm{~cm}$.

A variety of small blocks (approximately $7 \mathrm{~cm} \times 5 \mathrm{~cm} \times$ 1 cm ) were used to activate the machines. The activator blocks were of different shapes and colors. Some matched the machines in shape but not in color, or in color but not in shape, while other distractor blocks matched in neither shape nor color. In total, twenty-two blocks were used.

## Procedure

Each child was tested individually. For children tested in our lab, parents sat next to the child during the procedure and were asked not to interact with their child. For children tested at preschools, an observer watched the procedure through a one-way mirror.

Both the didactic and free play conditions consisted of three phases: a demonstration phase, a training/free play phase, and a testing phase. For half the children, each machine was activated by placing two blocks on the machine that matched the machine in shape (shape rule). For the other half, each machine was activated by placing two blocks on the machine that matched the machine in color (color rule).

Children in the free play condition who did not activate the machines at least once during the free play phase formed a separate group: the free-play-first condition. This condition consisted four phases: a demonstration phase, a free play phase, a training phase, and a testing phase. In other words, children who did not activate any machines during free play
were then trained by the experimenter using the procedure of the didactic condition. For four of these children, machines were activated by the shape rule, and for eleven children machines were activated by the color rule.
Training and Free Play Phase

First-Order Generalization Test

Figure 1: Schematic of materials and procedure.
Didactic Condition For the didactic condition, the children sat at a small table across from an experimenter. The demonstration phase began with the experimenter showing the child 12 blocks and pointing out that the blocks had different shapes and different colors. The blocks were then removed and the demonstration machine was placed on the table along with one block. The experimenter then showed the child how to make the machine go by placing the block on the machine and pressing down. After the machine made a sound, the experimenter noted that the blocks made the machine go and then allowed the child to try. Two new blocks were then placed in front of the child. The child activated the machine by pressing down with these two blocks and the experimenter stated that the blocks made the machine go. This was repeated next with three new blocks. The blocks and machine were then removed, ending the demonstration phase. The duration of this phase was around four minutes.

The experimenter then told the child that she had some new machines to show them. She also emphasized that these new machines were much pickier than the demonstration machine, so only some blocks would make them go.

The training phase that followed began with the experimenter presenting the first machine (e.g., blue
rectangle machine). The experimenter placed four activator blocks on the table next to the machine (e.g., the red, green, yellow, and purple rectangle blocks if the machine was activated by the shape rule; the blue triangle, blue circle, blue heart, and blue star blocks if the machine was activated by the color rule). The experimenter then stated, "Let me show you how to make this machine go," and placed two of the four activator blocks (e.g., purple rectangle block and yellow rectangle block, or blue circle block and blue star block) on the machine and pressed both blocks down, activating the machine. She then exclaimed, "The machine made a sound! It played music!" The experimenter then told the child that she had another machine that was identical to the one in front of them. This machine was placed on the table, and the other two activator blocks were now placed on the new machine, activating it. The machines and blocks were then removed and the process was repeated with the remaining two sets of machines. Once the child had seen all six machines activated one time each, the training phase was complete. The order of the presentation for the types of machines was counterbalanced. The duration of the training phase was approximately five minutes.

The testing phase consisted of both a first-order generalization test and a second-order generalization test. The order of the tests was counterbalanced. For the first-order test, the children were first presented with six separate blocks: two blocks that matched the machine in shape, two blocks that matched the machine in color, and two distractor blocks that did not match the machine in shape or color (see Figure 1). The experimenter presented the blue rectangle machine from the training phase, and said, "Remember this machine? Remember that I made this machine go just now? Can you show me how to make this machine go?" If the child placed the correct blocks on to the machine, the machine activated and the experimenter neutrally stated that the machine made a sound. If the child did not place the correct blocks, the machine did not activate and the experimenter neutrally stated that the machine did not make a sound. For the second-order generalization, the child was presented once more with six new blocks (see Figure 1). The child was then shown a novel machine (the orange L-shaped machine) and told that the machine "was a picky machine too". The experimenter then asked the child, "Can you show me how to make this machine go?" Once again, the experimenter neutrally stated that the machine made a sound if the child was correct, or did not make a sound if the child was incorrect.

Free Play Condition For the free play condition, the children sat on a blanket on the floor. The demonstration phase in the free play condition was identical to that in the didactic condition.

The free play phase began with the experimenter saying that she needed to check that all the machines worked (pilot testing suggested that this step was necessary in order to encourage children to keep playing even if they did not active any machines after a few attempts). The machines were taken behind a table and activated so that the child could hear them
activate by the sound they made, but could not see how they were activated. The experimenter then placed all six machines (two blue rectangle machines, two red triangle machines, and two green circle machines) in front of the child and noted that these machines were pickier and that only some blocks made them go. The twelve activator blocks shown in the demonstration phase were placed in front of the child as well. The experimenter then told the child, "I just remembered I have to do some work now, but while I work, you can play with these machines and these blocks." The children were given approximately ten minutes to play with the machines and blocks. If the child did not make any attempt to activate the machines for one minute, the experimenter prompted the child by saying, "Why don't you try to make the machines go?" After ten minutes, the blocks and machines were removed, ending the free play phase.

The testing phase was identical to that of the didactic condition.

Free-Play-First Condition For the free-play-first condition, the children sat on a blanket on the floor. The demonstration phase and free play phase were identical to that in the free play condition. Children were then moved to a table and the training phase was identical to the training phase in the didactic condition. The testing phase was identical to that of the didactic and free play conditions.

## Coding

For children exposed to the shape rule, selecting the two blocks that matched the machine in shape was scored as one point. On the other hand, for children exposed to the color rule, selecting the two blocks that matched the machine in color was scored as one point. Since each child completed two tests, the maximum score that a child could receive was two points.

## Results

We analyzed effects on children's responses with generalized linear mixed effects models in R, using an alpha level of 0.05 for all analyses. Children's responses were coded as a binary variable where correct responses were coded as 1 and incorrect responses were coded as 0 . In the model, subjects were specified as a random factor since this was a repeated measures task; each subject gave two responses. Although children in the didactic condition and the free play first condition all saw a total of six activations, the same cannot be said for children in the free play condition. In the free play condition, the total number of activations ( $M=17.6, S D=$ 12.6) each child saw as well as the amount of time that each child played for ( $M=7.91, S D=2.34$ ) varied. Although the didactic condition did not receive any negative evidence (i.e., observing unsuccessful activations), this was not the case for both the free play condition and the free-play-first condition. The amount of negative evidence generated by each child in the free play condition varied ( $\mathrm{M}=29.5, \mathrm{SD}=21.8$ ). Children in the free-play-first condition also generated a varied amount of negative evidence $(\mathrm{M}=28.1, \mathrm{SD}=16.1)$. Preliminary analysis showed no significant effect of age, sex, or
presentation order of the machines and testing phases. Additionally, there was no significant difference in the children's performance between first-order and second-order generalization tests in each of the three conditions.

Figure 2: Percent accuracy for the conditions. Dashed line represents a conservative calculation of chance. Error bars represent standard error.

There was, however, a statistically significant difference between the performance of children who were in the free play condition ( $M=0.4318, S D=0.4168$ ) and children who were in the didactic condition ( $M=0.10, S D=0.21$ ), as shown in Figure 2. More specifically, our analysis showed that the free play condition performed significantly better than the didactic condition ( $\beta=2.259, S E=0.787, p=0.004$ ). Analysis of the exponentiated coefficients revealed that being in the free play condition increased the children's odds of being correct by $856 \%$. The free-play-first condition ( $M=0.4333$, $S D=0.4169$ ) also performed significantly better than the didactic condition ( $\beta=2.267, S E=0.840, p=0.007$ ), and being in the free play first condition increased the children's odds of being correct by $865 \%$. However, there was no significant difference between the performance of children in the free-play-first condition and the free play condition. In addition, we analyzed whether the amount of negative evidence received was predictive of performance in the free play and free-play-first conditions. It was found that the amount of negative evidence did not have a significant effect on performance ( $\beta=-0.005, S E=0.018, p=0.787$ ), indicating that the extent to which children received negative evidence during play did not influence their performance during the generalization test trials.

The best fit model was also found by comparing various models that included potential predictors of performance such as condition, sex, age, rule, and amount of negative and positive feedback. Through model comparisons, it was found that the best fit model predicted accuracy from condition ( $\chi^{2}=$ 13.72, $d f=2, p=0.001$ ). This model outperformed all other models, including the null model.

A conservative value for chance was also calculated by considering all possible two block combinations that could be placed on the machine and then calculating the probability of
placing the correct blocks. This resulted in a value of 0.067 for chance performance. Children in the free play condition were significantly more likely to choose the correct blocks compared to chance, $t(43)=4.834, p=0.00002$, as were children in the free-play-first condition, $t(29)=3.985, p=$ 0.0004 . Children in the didactic condition, however, were not significantly more likely to choose the correct blocks over chance, $t(47)=0.842, p=0.404$.

## Discussion

In the current study, we demonstrate that 3- and 4-year-old children can successfully acquire fairly complex causal generalizations through free play. They independently generated evidence that allowed them to understand the causal system that they were presented with, and they formed higher-order generalizations at a level above chance. More strikingly, children's learning in the free play condition and the free-play-first condition was superior to that of children in the didactic condition. Just as in the study by Sim and Xu (in press), children were equally successful in learning firstorder and second-order generalizations during the course of free play, and there was no difference in their performance when it came to learning the shape or the color rule. It is interesting to note that there were more children in the free-play-first condition who had been exposed to the color rule rather than the shape rule, which may indicate the potential influence of a shape bias. However, we did not find an overall difference in performance between children who were exposed to the color rule vs. the shape rule.

We also sought to determine if there were scenarios in which children benefited more from learning through free play than through direction instruction by an experimenter. We found that children who engaged in free play performed significantly better at test than children in the didactic condition. Even children who were unable to activate the machines during play but who later observed an experimenter doing so performed significantly better than those assigned to the didactic condition, suggesting that the former group also benefited from engaging in free play. To the best of our knowledge, this study presents the first evidence that children can learn about a causal system more effectively through play than through training. So why was learning more effective under free play?

One possible reason for this difference between the two conditions is that children in the free play condition were able to engage actively with the materials, whereas children in the didactic condition played a passive role in learning about the machines, observing an experimenter activate them but never activating the machines themselves. Sobel and Sommerville (2010) found that four-year-old children learned a causal structure more accurately when they were given some time to engage with a causal system. Likewise, McCormack et al. (2016) showed that children who acted out interventions on a causal system following specific directions from an experimenter performed better than children who witnessed the same interventions but watched as the interventions were performed by an experimenter. Together, these studies
suggest that children may benefit more from intervening on a causal system, rather than observing an experimenter do so. This may explain why the free-play-first condition performed significantly better than the didactic condition, even though the children never successfully activated the machines while playing.

It is also possible that the children in the didactic condition struggled because they had different hypotheses about how the machines worked which were not contradicted by the evidence they witnessed (e.g., they may have thought that each of the two blocks would activate the machine by itself). Children in the free play condition and in the free-play-first condition, in contrast, had the opportunity to carefully test their own hypotheses, particularly through the generation of negative evidence. In other words, children in these conditions were able to see which combinations of blocks would make the machine go, as well as which combinations of blocks would not make the machine go. However, we did not find in our additional analyses that the amount of negative evidence that children generated was predictive of their performance at test, suggesting that there was something more to the evidence that the children saw during free play that assisted them in forming the correct generalizations. Further research is still necessary to understand the differences we found between the free play and didactic condition in our study. One worthwhile direction is to conduct an additional "yoked" didactic condition, where the experimenter presents children with evidence that was generated by children from the free play condition. This additional condition will clarify whether the differences found in the present study can be attributed solely to the difference in the quality of evidence between conditions.

We note that the current findings also appear to differ from those of other studies comparing the performance of children in free play and training/didactic conditions for other kinds of tasks. For example, Klahr and Nigam (2004) compared discovery learning, which they defined as learning that children engaged in by themselves without the assistance or feedback from a teacher, to direct instruction in third- and fourth-grade children for designing unconfounded experiments, which are experiments that clearly reveal the effect of a particular variable. The researchers found that children in the direct instruction condition performed significantly better than children in the discovery learning condition. However, in this particular study, children in the direct instruction condition were engaged in designing and manipulating variables during training as well, while children in the didactic condition in the current study engaged with the materials more passively, observing as an experimenter taught them how the machines worked. Another difference between the two studies is that in the study by Klahr and Nigam (2004), children in the discovery learning condition were given time to explore the ramp and marbles and design experiments, however they were not provided with any negative or positive feedback. In our study, on the other hand, children in the free play condition were provided with both negative and positive evidence, since the machine only made
a sound when activated correctly. Although the finding from Klahr and Nigam (2004) is sometimes used as evidence for the benefits of direct instruction for teaching children science, our study suggests that children have the potential to learn causal systems effectively through play when provided with useful feedback, even if the feedback does not come from an instructor.

Previous work has demonstrated that children attending child-centered preschools, where free play and child initiative are highly encouraged, were more motivated to learn, showed more pride in their accomplishments, and claimed to be less worried than children attending didactic, highly academic preschools (Stipek, Feiler, Daniels, \& Milburn, 1995). The current study extends these results by showing that children can learn effectively through free play, and under some conditions, learning within a free play context may be better than learning in a didactic context. However, it is important to note that free play is just one aspect of the child-centered instructional approach in preschools, and our results cannot speak directly to any potential learning differences between the two instructional approaches.

In summary, the present study provides evidence that young children can learn effectively through free play, and this learning might be better than the learning achieved through direct demonstration. Our results provide one source of empirical evidence on why play is important for children and why unstructured play should be incorporated into school curriculums. This study also suggests that there is merit to child-centered learning in preschools, as it appears that children are able to learn through play and that they are able to successfully engage in active learning.

## Acknowledgments

We thank the Berkeley Early Learning Lab (BELL) for their help in testing and recruitment, as well as the parents and children for their participation. Mahal and Sim are joint first authors.

#### Abstract

In this manuscript we study individual variation in the interpretation of conditionals by establishing individual profiles of the participants based on their behavioral responses and reflective attitudes. To investigate the participants’ reflective attitudes we introduce a new experimental paradigm called the Scorekeeping Task, and a Bayesian mixture model tailored to analyze the data. The goal is thereby to identify the participants who follow the Suppositional Theory of conditionals and Inferentialism and to investigate their performance on the uncertain and-to-if inference task.

Keywords: conditionals; individual variation; and-to-if; norms; the Equation; inferentialism

## Introduction

According to a popular theory in the psychology of reasonning (the Suppositional Theory, or 'ST'), the probability of an indicative conditional (e.g. 'If I forget to pay the rent, then my landlord will complaint') is evaluated by a mental algorithm known as the Ramsey test (Evans \& Over, 2004; Oaksford \& Chater, 2007; Baratgin, Over, and Politzer, 2013).

The Ramsey Test: to evaluate P (if A , then C ) the participants add the antecedent to their background beliefs, make minimal adjustments to secure consistency, and evaluate the probability of the consequent on the basis of this temporarily augmented set of beliefs.
Quantitatively, this introduces the following prediction, which is known as "the Equation":

$$
\mathrm{PRED}_{1}: \mathrm{P}(\text { if } \mathrm{A} \text {, then } \mathrm{C})=\mathrm{P}(\mathrm{C} \mid \mathrm{A})
$$

Given that $\mathrm{P}(\mathrm{C} \mid \mathrm{A}) \geq \mathrm{P}(\mathrm{A}, \mathrm{C})$ follows from the axioms of probability theory (an inequality referred to as probabilistic coherence; PCh ), ST also predicts that:
PRED $_{2}$ : $\mathrm{P}($ if A, then C$) \geq \mathrm{P}(\mathrm{A}, \mathrm{C})$

Accordingly, the participants are predicted to conform to the following inequality in the so-called uncertain and-to-if inference (UAI), where they are presented with 'A and C' as a premise and 'if A, then C' as a conclusion and asked to assign probabilities to each:
Pred $_{2 \mathrm{~A}}: \mathrm{P}($ Conclusion $) \geq \mathrm{P}($ Premise $)$
Cruz, Baratgin, Oaksford, and Over (2015) found that the participants conformed to $\mathrm{PRED}_{2 \mathrm{~A}}$ at above chance levels. This has been taken as indirect evidence in favor of ST.
There is presently a considerable interest in and-to-if inferences, because recently a theory known as 'inferentialism' made its appearance into the psychology of reasoning, which posits that indicate conditionals express inferential relations. In the truth-conditional version of inferentialism, it rejects the validity of the and-to-if inference ' $\mathrm{A} \wedge \mathrm{C} \vDash$ if A , then C' (Douven, 2015). Truth-conditional inferentialism rejects the validity of this argument scheme, because the indicative conditional is viewed as expressing a reason relation and the mere truth of A and C does not ensure that they are inferentially connected. Rejecting the validity of the and-to-inference is a distinguishing feature of this approach that separates it from other popular semantics of conditionals like Stalnaker's possible worlds semantics or the de Finetti truth table endorsed by proponents of ST.
In Skovgaard-Olsen, Singmann, and Klauer (2016a) a weaker probabilistic implementation of inferentialism was given in the form of the Default and Penalty Hypothesis (DP), which employs the following explication of the reason relation:
PO: A is positively relevant for C (and a reason for C ) iff $\mathrm{P}(\mathrm{C} \mid \mathrm{A})>\mathrm{P}(\mathrm{C} \mid \sim \mathrm{A})$
NE: A is negatively relevant for C (and a reason against C$)$ iff $\mathrm{P}(\mathrm{C} \mid \mathrm{A})<\mathrm{P}(\mathrm{C} \mid \sim \mathrm{A})$
IR: A is irrelevant for $C$ iff $\mathrm{P}(\mathrm{C} \mid \mathrm{A})=\mathrm{P}(\mathrm{C} \mid \sim \mathrm{A})$
DP posits that the participants have the goal of evaluating whether a sufficient reason relation obtains when evaluating

P(if A, then C). According to Spohn's (2012: ch. 6) explication of the reason relation given above, this requires at least two things: (a) assessing whether A is positively relevant for C , and (b) assessing the sufficiency of A as a reason for C by means of $\mathrm{P}(\mathrm{C} \mid \mathrm{A})$. DP moreover postulates that the participants follow the heuristic, when processing natural language conditionals, of making the default assumption that (a) is satisfied, which reduces their task of assessing P (if A , then C ) to assessing $\mathrm{P}(\mathrm{C} \mid \mathrm{A})$. However, once the participants are negatively surprised by a violation of this default assumption, such as when they are presented with stimulus materials implementing the NE or IR category, they apply a penalty to $\mathrm{P}($ if A , then C ) to express the conditional's failure to express that A is a reason for C. An example would be the conditional 'If Oxford is in England, then Napoleon is dead' which sounds defective to the extent that the antecedent is obviously irrelevant for the consequent.
In support of DP, it was found in Skovgaard-Olsen et al. (2016a) that $\mathrm{PRED}_{1}$ only holds when $A$ is positively relevant for C in virtue of raising its probability. When A is negatively relevant by lowering C's probability, and when A is irrelevant for C by leaving its probability unchanged, violations of PRED $_{1}$ occur. Consistent with these findings, it was found in Skovgaard-Olsen et al. (2016b) that the abovechance level of conformity to $\mathrm{PRED}_{2 A}$ reported in Cruz et al. (2015) only holds for PO. In NE and IR the participants are performing below chance levels. Further-more, this is a pattern that is not reflected in their conformity to the theorem $\mathrm{P}(\mathrm{C} \mid \mathrm{A}) \geq \mathrm{P}(\mathrm{A}, \mathrm{C})$ across relevance levels, in spite of the fact the participants are supposed to conform to P(if A, then C$)=\mathrm{P}(\mathrm{C} \mid \mathrm{A})$, according to ST .
It is presently unclear whether this finding of lack of conformity to $\mathrm{PRED}_{2 \mathrm{~A}}$ in the NE and IR conditions indicates that the participants are making a reasoning error (by following ST) or whether they are not making a reasoning error but simply basing their performance on a different interpretation of conditionals (by following DP). The goal of the present study is to address this question.
In the present experiment, we seek to establish individual profiles of the participants based on their behavioral responses and reflective attitudes. In order to study their reflective attitudes we implemented a novel experimental paradigm - the Scorekeeping Task - suggested in Skovgaard-Olsen (2015), as well as a Bayesian mixture model tailored to classify the data coming from it (both are discussed in detail below). Based on this novel task and the associated data-analytic method, we were able to investigate two key questions: First, whether participants classified as ST accord with ST's PRED $_{2 \text { A }}$ prediction for the UAI across a relevance manipulation. Second, whether participants classified as DP accord with DP's prediction that PRED $_{2 \mathrm{~A}}$ only holds in the PO condition. In the IR condition, DP participants are expected to apply a penalty to conditionals in the conclusion of the UAI, such that P(if A, then C) < $\mathrm{P}(\mathrm{C} \mid \mathrm{A})$ can occur, effectively dismissing $\mathrm{PRED}_{2 \mathrm{~A}}$.

## Experiment

## Method

## Participants

A total of 354 people from the USA, UK, Canada, and Australia completed the experiment, which was launched over the Internet (via Mechanical Turk) to obtain a large and demographically diverse sample. Participants were paid a small amount of money for their participation.
The following exclusion criteria were used: not having English as native language (6 participants), completing the experiment in less than 300 seconds (2 participants), failing to answer two simple SAT comprehension questions correctly in a warm-up phase (89 participants), and answerring 'not serious at all' to the question how serious they would take their participation at the beginning of the study (zero participants). Since some of these exclusion criteria were overlapping, the final sample consisted of 261 participants. Mean age was 36.53 years, ranging from 20 to $75,66 \%$ were female, $66 \%$ indicated that the highest level of education that they had completed was an undergraduate degree or higher.

## Design

The experiment implemented a within-subject design with two factors varied within participants: relevance (with two levels: PO, IR) and priors (with four levels: HH, HL, LH, LL, meaning, for example, that $\mathrm{P}(\mathrm{A})=$ low and $\mathrm{P}(\mathrm{C})=$ high for LH).

## Materials and Procedure

We used a slightly modified version of 12 of the scenarios presented in Skovgaard-Olsen et al. (2016b). For each scenario we had 8 conditions according to our design (i.e., 4 conditions for PO [i.e., HH, HL, LH, LL], 4 conditions for IR). Each participant worked on one randomly selected (without replacement) scenario for each of the 8 withinsubjects conditions such that each participant saw a different scenario for each condition. Following the recommendations of Reips (2002), to reduce dropout rates, we presented two SAT comprehension questions as an initial high hurdle in a warm-up phase (in addition to using them for excluding participants). The experiment was split into four phases and on average took ca. 23 minutes to complete. Here we focus on conveying the underlying conceptual ideas.

## Phase 1, Behavioral Responses

The first phase contained eight blocks, one for each withinsubjects condition. The order of the blocks was randomized anew for each participant and there were no breaks. Within each block, the participants were presented with four pages. On the first page, the participants were shown a scenario text like the following:
Scott was just out playing with his friends in the snow. He has now gone inside but is still freezing and takes a bath. As both he and his clothes are very dirty, he is likely to
make a mess in the process, which he knows his mother dislikes.

The idea was to use brief scenario texts concerning basic causal, functional, or behavioral information that uniformly activates stereotypical assumptions about the relevance and prior probabilities of the antecedent and the consequent of 8 conditionals that implement our experimental conditions for each scenario. So to introduce the 8 within-subjects conditions for the scenario above we, inter alia, exploited the fact that the participants would assume that Scott's turning on the warm water would raise the probability of Scott being warm soon ( PO ) and that Scott's friends being roughly the same age as Scott would be irrelevant for whether Scott will turn on the warm water (IR).
This scenario text was repeated on each of the following three pages, which measured $\mathrm{P}(\mathrm{A}$ and C$), \mathrm{P}(\mathrm{C} \mid \mathrm{A})$, and $\mathrm{P}($ if A , then C ) in random order. Throughout the experiment, the participants gave their probability assignments using sliders with values between 0 and $100 \%$. To measure $\mathrm{P}(\mathrm{C} \mid \mathrm{A})$, the participants might thus be presented with the following question in an IR condition:
Suppose Scott's friends are roughly the same age as Scott. Under this assumption, how probable is it that the following sentence is true on a scale from 0 to 100\%:
Scott will turn on the warm water.

## Phase 2, the Scorekeeping Task

In this phase the participants were first presented with a new IRHH item to be rated in the same way as the items in phase one. Then the participants were presented with the following instruction:
When given the task you just completed, John and Robert responded very differently to some of the scenarios as outlined below.
And it was explained that John and Robert responded in the following way to the "if-then sentence" and the "supposesentence" (where the "suppose-sentence" had been identified for the participants as the type of question quoted above for measuring $\mathrm{P}(\mathrm{C} \mid \mathrm{A})$ ):
John assigned 99\% to the suppose-sentence and 1\% to the if_then sentence.
Robert assigned $\mathbf{9 0 \%}$ to the suppose-sentence and $\mathbf{9 0 \%}$ to the if_then sentence.
Note that although John and Robert are fictive participants, these values were based on actual data provided by other participants in response to the IRHH item in previous experiments. In order to reduce the processing demands, these values were repeated on each of the following four pages along with the IRHH item, which John and Robert allegedly had responded to. The conditional took the following form, and it was evaluated in the context of a dating scenario describing Stephen's preparations for a date with Sara: 'If Stephen's neighbour prefers to put milk on his cornflakes, then Stephen will wear some of his best clothes on the date'.

As part of the scorekeeping task, the participants were instructed to apply a sanction to John or Robert's response based on its adequacy. Given their large divergence, the participants were instructed that at most one of John or Robert's responses could be approved as adequate.
Since the experiment was run on Mechanical Turk we exploited the fact that an ecologically valid sanction for the participants would be not to have a task (a "HIT") approved. Since the approval of HITs on Mechanical Turk determines whether the participants are paid for a completed task (and moreover counts towards their reputation on Mechanical Turk, which determines whether they can participate in future HITs) it is our experience that the participants care a lot about the approval of their HITs. We therefore expected that applying the sanction of not approving either John or Robert's HIT based on its adequacy would be a contextually salient sanction, which the participants would be highly motivated to reason with.
Next the participants were asked to state the reasons that they could think of which could be given for or against John and Robert's responses in an open entry question, which was included in the experiment for exploratory purposes.
On the two pages that followed, the participants were presented with John's criticism of Robert and Robert's criticism of John in random order. Robert made the following complaint about John's response:
Robert's no difference justification: "There is no difference between the two questions. So why do you give a lower probability to:
'IF Stephen's neighbour prefers to put milk on his cornflakes, THEN Stephen will wear some of his best clothes on the date'
than you gave to: 'Stephen will wear some of his best clothes on the date' under the assumption that 'Stephen's neighbour prefers to put milk on his cornflakes'?
This makes no sense!"
John in turn made the following complaint about Robert's response:
John's irrelevance justification: "Whether 'Stephen's neighbour prefers to put milk on his cornflakes' or not is irrelevant for whether 'Stephen will wear some of his best clothes on the date'.
So why do you give such a high probability to: 'IF Stephen's neighbour prefers to put milk on his cornflakes, THEN Stephen will wear some of his best clothes on the date'? This makes no sense!"
In each case, the participants were asked to indicate (yes/no) whether they agreed with the following statements:
John's irrelevance justification [/Robert's no difference justification] shows that Robert's [/John's] response is wrong.
Robert [/John] needs to come up with a very good response to John's [/Robert's] criticism, if his HIT is to be approved.
Finally, after having seen the justifications from both sides, the participants were asked which justification they found
most convincing by choosing between the following options, presented in random order:

## The two justifications are equally convincing John's irrelevance justification Robert's no difference justification

The participants then had to indicate who's HIT deserved to be approved based on their justifications by selecting one of the options below, presented in random order:
None of their HITs should be approved
Robert's HIT should be approved
John's HIT should be approved

## Phase 3, the Uncertain And-to-If Inference

This phase tested the participants' performance on the UAI under relevance manipulations. Phase 3 was used to measure whether the participants displayed a consistent behavior on the UAI with the interpretation of the conditional that they had been classified according based on their responses in phase 1 and phase 2.
Phase 3 contained 8 blocks implementing the same withinsubjects conditions as phase 1. For each participant, the same permutations of scenarios and within-subject conditions that had been randomly generated in phase 1 was displayed again in random order. First the participants were instructed that they would be presented with a scenario text as earlier and a short argument based on the scenario text. They were told that the premise and the conclusion of this argument could be uncertain and that it was their task to evaluate the probabilities of the premise and conclusion. Each block contained one page. On the top of the page the scenario text was placed as a reminder. Below the participants were instructed to read an argument containing the conjunction as a premise and the conditional as a conclusion, employing sentences that they assigned probabilities to in phase 1. Furthermore, the actual value of the probability that they had assigned to the premise in phase 1 was displayed to the participants in a salient blue color. We here illustrate it using the example from above from phase 1 of a POHH item:
Premise: Scott's turns on the warm water AND Scott will be warm soon.
Conclusion: IF Scott's turns on the warm water, THEN Scott will be warm soon.
You have estimated the probability of the premise as: $\mathbf{9 0 \%}$. Please rate the probability of the statement in the conclusion on a scale from 0 to $100 \%$.
In Phase 4, we tested the participants’ interpretation of the probabilities (Hertwig \& Gigerenzer, 1999). These results are beyond the scope of the present manuscript and therefore not reported here.

## Bayesian Mixture Modeling

In order to investigate the participants' interpretation of the conditional, the probability judgments they produced in Phase 1 were classified as coming from one of two latent classes using an indicator variable $w$. This classification was
achieved by means of a Bayesian Mixture model (for a similar approach, see Lee, 2016). In the PO condition, where both ST and DP make the same predictions (see the left panel of Figure 1), the mixture model assumed that responses from an individual $i$ were generated by ST/DP ( $w_{i}^{P O}=1$ ), or by an unclassifiable response-generation mechanism ( $w_{i}^{P O}=0$ ), for an item-pair $j$ :

$$
P(\text { if } A \text {, then } C)_{i, j}=\left\{\begin{array}{c}
\beta_{i, j}+\varepsilon_{i, j}, \quad w_{i}^{P O}=0 \\
P(C \mid A)_{i, j}+\varepsilon_{i, j}, \quad w_{i}^{P O}=1
\end{array}\right.
$$

where $0 \leq \beta_{i, j} \leq 100$.
When an individual follows ST/DP, the generated P (if A , then C ) are expected to follow $\mathrm{P}(\mathrm{C} \mid \mathrm{A})$ along with some truncated Gaussian noise term $\varepsilon_{i, j}$ with mean 0 and variance $\sigma^{2}$ (see the left panel of Figure 1). This noise captures the variability that is commonly observed in probability judgments across the [0\%, 100\%] interval (see Costello \& Watts, 2016). When an individual follows an unclassified pattern, their responses were captured by a saturated model, which established a $\beta$ parameter per data point (predicting the latter perfectly). 1

In the IR condition, the model only considered participants that were classified as ST/DP in the PO condition (i.e., the PO condition served as a filter for the IR condition). Here, both ST $\left(w_{i}^{I R}=0\right)$ and $\mathrm{DP}\left(w_{i}^{I R}=1\right)$ make distinct predictions:

$$
P(\text { if } A, \text { then } C)_{i, j}=\left\{\begin{array}{cc}
P(C \mid A)_{i, j}+\varepsilon_{i, j}, & w_{i}^{I R}=0 \\
\theta_{i} P(C \mid A)_{i, j}+\varepsilon_{i, j}, & w_{i}^{I R}=1
\end{array}\right.
$$

with $0 \leq \theta_{i} \leq 1$.
When individuals follow ST, the generated P (if A , then C) are again expected to follow $\mathrm{P}(\mathrm{C} \mid \mathrm{A})$. In contrast, when individuals follow DP, P (if A , then C ) follows a penalized version of $\mathrm{P}(\mathrm{C} \mid \mathrm{A})$ (with the penalty being determined by $\theta$ ).

Note that when $\theta=1$, the ST and DP models coincide, although the implied predictions are not really in accordance with the gist of DP. However, this point turns out not to be of practical import, because since ST is more parsimonious it will be preferred when $\theta=1$ (see Lee, 2016).

Figure 1. Predictions from both theoretical accounts (including some moderate degree of truncated noise).

[^203]

Figure 2. Individual associated to the different Phase 1 classifications, and their respective posterior individual-level classifications (note that in the IR condition, only participants classified as ST/DP in the PO condition were considered).

The key parameters of interest in this analysis are the posterior probabilities of $w_{\mathrm{i}}=1$ obtained in the PO and IR conditions. In the PO condition, when the mean of this posterior probability was estimated to be below or equal to .50, the individual was classified as following the saturated model. When the mean is estimated to be larger than .50 , the individual was classified as following ST/DP. In the IR condition, these same ranges of values led to the ST and DP classifications, respectively.

The individual classifications jointly obtained for PO and IR were used to characterize the conformity of individuals’ responses to theoretically-meaningful inequalities, namely UAI and PCh. For participant $i$, the probability that her response to a given item-pair $j$ conformed to a given inequality is given by $\Phi\left(\Delta_{i}+K_{i, j}\right)$, with $\Phi()$ being the probability function of the standard Normal distribution. Parameter $K_{\mathrm{i}, \mathrm{j}}$ is a correction term for participant $i$ and itempair $j$ such that $\Phi\left(K_{i, j}\right)$ corresponds to the probability that the responses to a given item-pair were inequality-conforming by chance alone (Singmann, Klauer, \& Over, 2014). Parameter $\Delta_{i}$ corresponds to that individual's displacement from chance (i.e., when $\Delta_{i}$ is positive, that individual produces inequality-conforming responses at an abovechance rate). Using a hierarchical framework, these individual parameters were assumed to come from a Normal group-level distribution, with mean $\mu_{\Delta}$ and standard deviation $\sigma_{\Delta}$. If individuals in general conform to the UAI or PCh, then their respective $\mu_{\Delta}$ should be consistently above 0 (i.e., the probability of $\mu_{\Delta}$ being below 0 should be very small). These parameters were estimated separately for individuals classified as ST and DP in the IR condition.

A very similar hierarchical approach was used to model the relative probability of an individual judging the nodifference justification (in line with ST) as most convincing after having seen both sides, as well as the relative probability attributing the HIT to such justification.

## Results

The posterior-parameter distributions of mixture model were estimated via Gibbs sampling using the generalpurpose software JAGS (Plummer, 2003). Chain convergence was confirmed via the R-hat statistic and visual inspection. The individual-level classifications shown in Figure 2 show that the probabilities generated by the majority (225 out of 261) of individuals in the PO condition were in line with ST/DP. In contrast, only a very small group of individuals were in line with ST in the IR condition (39 out of 225); most followed the predictions of DP. The individual data shown in Figure 1 shows that the data classified as ST/DP in the PO condition as well as ST and DP in the IR condition were in line with the model predictions. To address the worry that participants belonging to ST were misclassified as DP, we visually inspected the responses of every participant individually.
The classifications lead to clear differences in both UAI and PCh, as well as in the probability of judging the nodifference justification as most convincing. As shown in Table 1, for UAI the posterior $\mu_{\Delta}$ estimates in the IR condition for individuals classified as ST are systematically above 0 , but systematically below 0 for individuals classified as DP. In the case of PCh, the posterior $\mu_{\Delta}$ estimates were systematically above 0 , as expected. The latter result was less clear for ST, but this is expected given the small number of participants classified as being in line with ST.
Finally, the relative probabilities of judging the nodifference justification (consistent with ST) as most convincing and attributing the HIT were drastically different for individuals classified as following ST and DP. These posterior probabilities were considerably larger for ST (see Table 1). Note that these were conditional probabilities of finding the ST justification most convincing, and accepting the ST HIT, given the participants expressed preferences for either ST or DP in phase 2.

|  | ST Followers $(\mathrm{N}=39)$ | DP Followers $(\mathrm{N}=186)$ |
| :--- | :---: | :---: |
|  | $\mu_{\Delta}$ | $\mu_{\Delta}$ |
| UAI | $0.61[0.16,1.11](72 \%)$ | $-0.46[-0.65-0.28](47 \%)$ |
| PCh | $0.21[-0.07,0.51](68 \%)$ | $0.14[0.02,0.27](66 \%)$ |
| P(ST mc) | $.94[.78,1]$ | $.15[.09, .22]$ |
| P(ST HIT) | $.92[.77,1]$ | $.21[.15, .28]$ |

Table 1. Median group-level posterior parameter estimates (and their respective $95 \%$ credibility intervals) obtained in the IR condition. Percentages of responses conforming to UAI and PCh are given in parentheses. The estimates associated to $\mu_{\Delta}$ in the PO condition (where participants were classified as ST/DP) were 1.66 [1.14, 2.24] and 1.19 [ $0.82,1.61]$ for UAI and PCh, respectively. ' $\mathrm{P}(\mathrm{ST} \mathrm{mc})$ ' $=\mathrm{P}($ ST most convincing | ST or DP most convincing $)$. $' P(S T$ HIT $) '=P(S T$ receive HIT | ST or DP receive HIT).

## Discussion

In this paper we have presented a novel experimental design to study the reflective attitudes of the participants and an accompanying Bayesian mixture model to study individual variation. We have seen that it is possible to classify the participants according to whether they follow the Suppositional Theory of Conditionals or the Default and Penalty Hypothesis. We then used these classifications to study the participants' performance on the uncertain and-toif inference task to examine whether the participants consistently followed the assigned interpretation of the conditional in an inference task.
This experimental design gives us a very rich data set that we have not exhausted in this brief note. Nevertheless, the data we did analyze show a very clear pattern. In the PO condition of phase 1, $86 \%$ of the participants followed the Equation ( $\mathrm{PRED}_{1}$ ), whereas only 39 of these participants followed the Equation in the IR condition. The remaining 186 participants showed a clear tendency in the IR condition to assign lower probabilities than if they had treated the P (if A, then C) as a conditional probability. For the 39 ST participants from phase 1 there was a .94 probability that they find the ST character to be most convincing one, conditional on the fact that they had a preference. Of the 186 DP participants in phase 1, this conditional probability was .85 , this time in favor of the DP character.
Finally, the participants' performance on the uncertain and-to-if inference task in phase 3 indicated that the participants acted consistently with their assigned interpretation of the conditional. As a theorem of probability theory, the PCh inequality $(\mathrm{P}(\mathrm{C} \mid \mathrm{A}) \geq \mathrm{P}(\mathrm{A}, \mathrm{C})$ ) remains valid for both groups, so they should conform to it at above chance levels irrespectively of the relevance condition. In contrast, whether the participants should conform to the UAI inequality ( $\mathrm{P}($ Conclusion $) \geq \mathrm{P}($ Premise $)$ ) in the IR condition, depends on whether they interpret the conditional in the conclusion as a conditional probability.
In the PO condition both groups were above chance levels for conformity to both the UAI and PCh inequalities. For the ST participants, a tendency was found to continue to conform to the UAI and PCh inequalities in the IR condition at above chance levels. (However, the estimates were
connected with uncertainty given the modest size of the ST group.) In contrast, for the DP participants an interaction was revealed between relevance and type of inequality in that these participants continued to display conformity to PCh at above chance levels in the IR condition while ceasing to conform to the UAI inequality at above chance levels. The results thus indicate that it was possible to separate two individual profiles in the participants' interpretation of the conditional. For each profile, the participants were shown to behave consistently with their interpretation of the conditional in the uncertain and-to-if inference.
In Skovgaard-Olsen et al. (2016b), it was found that the above-chance level conformity to UAI, which Cruz et al. (2015) did not generalize to the IR condition. However, since these results were analyzed at the group level, it was hard to tell whether they indicated that the participants were incoherent or whether they followed DP instead. With the present results we have a first indicator that two groups can be identified at the individual level that consistently follow their assigned interpretation of the conditional in the uncertain and-to-if inference.

#### Abstract

Turn-taking in conversation is a cognitively demanding process that proceeds rapidly due to interlocutors utilizing a range of cues to aid prediction. In the present study we set out to test recent claims that content question words (also called wh-words) sound similar within languages as an adaptation to help listeners predict that a question is about to be asked. We test whether upcoming questions can be predicted based on the first phoneme of a turn and the prior context. We analyze the Switchboard corpus of English by means of a decision tree to test whether $/ \mathrm{w} /$ and $/ \mathrm{h} /$ are good statistical cues of upcoming questions in conversation. Based on the results, we perform a controlled experiment to test whether people really use these cues to recognize questions. In both studies we show that both the initial phoneme and the sequential context help predict questions. This contributes converging evidence that elements of languages adapt to pragmatic pressures applied during conversation.

Keywords: questions; wh-words; question words; turntaking; speech-act recognition; question prediction

## Introduction

People spend an average of 2-3 hours every day in conversation, producing around 1200 turns (Levinson, 2016). The structure of conversation, far from being chaotic, places specific constraints on speakers (Sacks, Schegloff \& Jefferson, 1974). Recently, it has been recognized that these constraints have implications for processing and therefore for the way languages evolve (see Levinson, 2016). In this paper we explore a phenomenon at the interface of conversation, processing and cultural evolution.
Conversation progresses through exchanging bursts of information - mostly through use of language - that are orchestrated in consecutive turns produced by the speakers (Sacks et al., 1974). The surprising aspect of turn-taking is that it is orchestrated in a remarkably tight manner. Speakers strive to minimize gaps and overlaps between turns (Sacks et al., 1974), with the average gap length being only 200 ms cross-culturally (Stivers et al., 2009; Kendrick \& Torreira, 2015; Levinson \& Torreira, 2015). Thus, while languages themselves differ, the pressure for rapid turntaking is the same.

The surprising fact that turns are produced in such a tight window of time becomes even more puzzling if we take into account that it takes a minimum of 600 ms to plan and begin uttering a single word (Schriefers, Meyer, Levelt, 1990;

Levelt, 1993). In this context, one has to ask a question how is it possible that the gap between turns is shorter than the planning of the response? The obvious answer is prediction (Sacks, Schegloff \& Jefferson, 1974; Levinson, 2013). Listeners project what the current speaker will say and when their turn will end (Holler and Kendrick, 2015; Bögels \& Torreira, 2015). Thus, the next speaker can start preparing their turn in advance so that it can be delivered on time.

Predicting the specific type of a speech act is extremely important as different speech acts have different social and cognitive pressures on speakers. For example, when we are greeted, the greeter expects a greeting in response. Or when we are asked a question, we are socially obliged to give an answer, and hesitations can lead to inferences about the intent of the responder (Kendrick \& Torreira, 2015). Thus, social constraints put pressure on cognition to respond rapidly in interactive conversation. We suggest that languages should evolve to provide listeners with early cues that facilitate this process. Perhaps the context in which this would be most evident is in recognizing questions, to which we now turn.

Answering questions is a complex process involving understanding the question, retrieving or calculating the relevant answer and planning the response. Previous research suggests that the planning of the response starts as soon as an answer can be retrieved (Bögels, Magyari \& Levinson, 2015; Bögels, Casillas, \& Levinson, 2016; Barthel, Meyer \& Levinson, 2017). However, even before planning their answers, speakers first have to recognize that they are being asked a question.

Gisladottir, Chwilla, \& Levinson (2015) show that people can recognize the type of a speech act at an early stage if the preceding turns sufficiently constrain the context. For example, if I have just produced an initiating turn (like a greeting or asking a question), my interlocutor is most likely to produce a responding action (like an answer), rather than ask a question of their own. Therefore, one early cue as to whether a question will appear is the prior context.

Beyond that, there are also early cues in the question itself, before the turn can be identified as a question syntactically or semantically. Levinson (2013) suggests that question recognition is possible due to front-loading of the cues at the beginning of a turn. For example, questions can
be recognized by early cues in intonation (Levinson, 2013), pitch (Sicoli et al. 2014) and eye-gaze (Rossano, Brown \& Levinson, 2009; Rossano, 2012). Moreover, shifting question words to the initial position of the utterance (e.g., wh-movement in English) appears to be one of the most evident examples of front-loading (Levinson, 2013). Even when wh-movement is not permitted in the formal grammar of many languages, it is often evident in colloquial interactions (e.g. in Japanese, Levinson, 2013). Surprisingly, though, there is no quantitative research investigating whether this feature actually helps in question recognition.

Slonimska \& Roberts (accepted) were the first to quantitatively assess whether question words, also called wh-words, are plausible candidates as a cue to content question recognition. They suggest that a systematic phonetic similarity between question words within a language could provide a cue for that. In other words, if question words tend to sound similar, it would be easier for the addressee to predict that a question is about to be asked, and they can prepare themselves accordingly. For example, in English many question words begin with /w/ (what, why, where, when), and in Latvian many begin with /k/ (kas, kad, kur, kurš, kas, kāpēc).

Even though there is some qualitative research arguing that there is no systematicity in question words (Cysouw, 2004), Slonimska \& Roberts (accepted) show that there is a statistical tendency for question words to sound similar within languages. When they analyzed 266 languages the authors found that there is a higher similarity between the first phoneme of question words (within languages) than would be expected by chance, than other sets of words and also when controlling for historical factors. Accordingly, Slonimska \& Roberts argue that this phenomenon constitutes a product of cultural evolution that is selected for due to its benefit in interaction - i.e., rapid question recognition. Their study, however, is based purely on observational data of word forms. This leaves several issues to be addressed before their claim can be supported. First, are phonological regularities in question words actually statistically good predictors of questions in conversation? Secondly, do people actually use these cues to recognize questions? Finally, what is the relationship between the use of these cues and the prior conversational context?

We address these issues by means of two studies. First, we explore a large corpus of natural conversations and subsequently use the insights from the corpus study to design an experiment in which we test the hypotheses in a controlled setting by using stimuli from the same corpus.

As such, the present project not only informs the theoretical field in regard to question recognition, but it also makes a case for a new approach to research - namely, by creating a synergy between ecologically valid corpus analysis and experimentally controlled quantitative insights into the phenomenon.

## Corpus study

## Method

To assess whether we can gain support for our hypotheses, we first carried out an exploratory corpus analysis of naturalistic data - i.e., spoken conversations. We addressed this by means of the method of binary decision trees, also known as recursive partitioning (Strobl, Malley, and Tutz, 2009). A binary decision tree represents the optimal series of yes-no questions that a rational agent would ask about predictor variables in order to estimate an outcome variable (see Roberts et al., 2015).

In the current study we are interested in whether the first phoneme of the turn (first predictor) and context of the previous turn (second predictor) would help in recognizing an incoming turn as a content question (outcome variable). Namely, we predicted that the data would be clustered in such way that specific first phoneme (/w/, /h/ versus other phonemes in English) of the current turn and specific type of previous turn (non-initiating turn versus initiating turn) would help identify whether the current turn was a question. Unlike regression frameworks, the predictor variables that a binary decision tree uses are not set by the researchers, but chosen by an algorithm in order to maximize performance and parsimony. It could pick any combination of phonemes as identifying factors if suggested by the data. Therefore, our prediction of the form of the tree is a strong one.

Materials and design. We used the Switchboard corpus (Calhoun et al., 2010) that consists of telephone conversations in American English. This corpus is transcribed and annotated in detail, including a division of utterances into sequential turns by Roberts et al. (2015). The data was prepared for the analysis in R and later analyzed by means of the package "party" (Hothorn, Hornik \& Zeileis, 2006).

Each observation consisted of a transition between two turns between speaker A and speaker B. We specified the outcome variable - question - according to whether B's turn (i.e., current turn) was a question (content/open question) or not, according to the dialogue act annotation. We used the last speech act of A's turn (i.e., previous turn) for the second predictor variable specifying whether this turn was initiating or non-initiating (see Roberts et al., 2015). For example, B's turn was "What kind do you like to watch" - this was a turn that was a question and that started with $/ \mathrm{w} /$. The turn that preceded this question (i.e., A's turn) was "and uh you know there so there only a few that i that i like to watch routinely" - this was a statement (i.e., non-initiating turn).

We excluded the following fillers from the B's turn: ahm, er, ah, hmm, oh, uh, aa, um, ow. Then, the first phoneme from B's turns was extracted to create the predictor variable phoneme. This variable consisted of 34 unique phonemes (coded according to the transcription convention of Switchboard). Finally, we excluded all turns for which B's turn was a backchannel, considering that backchannel serves a monitoring rather than an informing function.

The final data included 9185 turns in total out of which 226 turns were content or open questions. Out of all turns, 1456 were initiating and 7729 were non-initiating turns. 1562 current urns ( $17 \%$ ) started with $/ \mathrm{w} /$ or $/ \mathrm{h} /$.

For the analysis we had 2 predictor variables: context from the A's turn (initiating or non-initiating) and first phoneme of the B's turn (34 unique phonemes). The outcome variable was whether the current turn (i.e., B's turn) was a content/open question.

## Results

The decision tree divides the data at each node of the tree starting from the top of the figure. Leaves of the tree at the bottom of the figure show the proportion of turns that are questions (see Fig.1).

The decision tree splits the data first based on the first phoneme of the turn. The exact division of the phonemes is as follows: $/ \mathrm{w} /$ and $/ \mathrm{h} /$ versus all the other phonemes, with the proportion of questions being higher for turns starting with $/ \mathrm{w} /$ and $/ \mathrm{h} /$. Thus, the decision tree, which is blind to our predictions, splits the data exactly in line with our predictions.

Following the branch that clusters the data on the right (/w/, /h/), the data is further clustered according to the type of the previous turn. If the previous turn was an initiating turn the proportion of question turns is considerably lower than if previous turn was not an initiating turn. If the

Figure 1: The decision tree of question turns split according to the sequential type of the previous turn and the first phoneme of the current turn. Non-IN: non-initiating turn, IN: initiating turn, phoneme transcription conventions come from the Switchboard corpus.

previous turn is not initiating, the data is further split into whether the phoneme of the current turn is $/ \mathrm{h} /$ or $/ \mathrm{w} /$. Note that proportion of questions is higher in $/ \mathrm{h} /(22 \%)$ leaf than in $/ \mathrm{w} /(13 \%)$. This may be because "well ...", is often used as a filler at the beginning of a turn and thus decreases the overall proportion of questions in $/ \mathrm{w} /$ leaf. Moreover, there are more turns overall that start with $/ \mathrm{w} /$ than with $/ \mathrm{h} /$, therefore the proportion in /w/ leaf is also lower.
In regard to the data clusters on the left (turns starting with phonemes other than $/ \mathrm{w} /$ and $/ \mathrm{h} /$ ), it is evident that the proportion of question turns is extremely low in all leaves of the tree.

Overall, the analysis confirmed our initial hypotheses. Furthermore, based on the analysis we can also expect that the probability of a turn being a question will be additionally boosted if both cues are present - namely, if an incoming turn starts with $/ \mathrm{w} /$ or $/ \mathrm{h} /$ and the previous turn is non-initiating.

## Experimental study

The corpus study suggested that the prior context and the initial phoneme of a turn helps identify questions statistically. The experimental study tests whether real people actually make use of these cues.

## Method

Participants. For the experiment 25 participants ( 14 male, 11 female) were recruited. Participants' age ranged from 21 -70 years $(M=32, S D=11)$. All participants were native speakers of English but had various nationalities (e.g., American, British, Canadian, Australian, Indian, Latvian).

Materials and design. In this experiment participants listened to series of audio samples extracted from the Switchboard corpus. Each sample consisted of a context turn (initiating or non-initiating) produced by the first speaker and a response produced by the second speaker.

The context turn type could be either initiating (yes/no questions and wh-questions) or non-initiating (statements). The response turn type could be either content questions or non-questions. Each response turn was clipped to contain only the first phoneme, which could either be a wh phoneme (/w/ or $/ \mathrm{h} /$ ) or another phoneme. We therefore had the following fully crossed $2 \times 2 \times 2$ design: context type (initiating/non-initiating) x response type (content question/other) x response phoneme (wh/other). In addition, the response turn could be blank (no audio, with context being initiating or non-initiating). This resulted in 10 conditions.

Table 1: Example of a 10 conditions consisting of 2 types of context turn (initiating/non - initiating) and 5 types of response turn.

| Context turn |  | Response turn |  |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  |  | /w/ |  | Other |  | Blank <br> no 2nd <br> turn |
|  |  | /w/ ques. | /w/ not quest. | not/w/ quest. | not/w/ non-quest. |  |
| Not initial | I do enjoy playing | Wh [at is your ...] | $\boldsymbol{W}$ [ell I wish...] | D [o you have...] | $\boldsymbol{Q}$ [uite a while...] | - |
| Initial | And how did it go | $\boldsymbol{W h}$ [at is your...] | $\boldsymbol{W}$ [ell I wish...] | D [o you have...] | $\boldsymbol{Q}$ [uite a while...] | - |

Context type was manipulated to test the effect of context and response phoneme was manipulated to test the effect of the first phoneme. Response type was manipulated so that we could assess whether the other question cues (e.g., raised pitch at the beginning of the question word) contribute in question prediction. The blank turn was added to establish a baseline for predicting an upcoming question without an initial phoneme.

We used the software Praat (Boersma \& Weenink, 2014) to cut and concatenate each first turn with each second turn (e.g., (first turn: statement) + (second turn: /w/ from whquestion)). Subsequently, each turn pair was processed in the software Audacity (Mazzoni \& Dannenberg, 2000) by adjusting a gap between the turns, so that the gap between first and second turn was 250 ms .

We created 25 samples for each of the 10 conditions, resulting in 250 unique audio samples. These were split into 5 groups of 50 samples so that each context sample or response sample only appeared once inside each group.

Procedure. The experiment was presented via the online software Qualtrics (Snow \& Mann, 2010). In each trial, a participant clicked a button to listen to a sample through headphones. Then they were asked to determine whether the second person would ask a question or not by means of completing a sentence "The Second turn is $\qquad$ " on the screen by pressing one of two buttons: "not a question" or "a question". The experiment began with 2 practice trials ensuring that participants understood the task. Participants were assigned to an audio sample group and heard the samples from that group in a random order.

## Results

We excluded 1 participant from the analysis due to the fact that this participant took 3 times longer than other participants to complete the experiment ( 38 minutes compared to an average of 12 minutes).

A logistic mixed model was used to predict whether the participant thought the response turn was a question (binary decision, yes or no, using the R package lme4, Bates et al, 2015). The predictor variables were context (initiating/noninitiating) and phoneme (wh, other, none). These predictors were coded as fixed effects and compared to a baseline model which included fixed effect of trial, random effect of context sample and phoneme sample, random effect of
participant and random slopes for context and phoneme by participant.

There was a significant main effect of context $\left(\chi^{2}(1)=\right.$ $45.74, p<.001)$. Participants were more likely to rate the turn as a question when preceded by a non-initiating context than an initiating context (see Fig.2).

There was a significant main effect of phoneme $\left(\chi^{2}(2)=\right.$ $13.83, p<.001)$. Turns that started with wh phonemes were more likely to be rated as questions in comparison to turns starting with other phonemes or without the response from the second speaker. The model estimated that the probability of considering a turn a question was $90 \%$ for wh phonemes compared to $71 \%$ for other and $70 \%$ for none in noninitiating context. In initiating context this was $9 \%$ compared to $4 \%$ for other and $2 \%$ for none. There was no significant difference in question prediction between other phoneme and no response. Considering that there was only one variant of $/ \mathrm{h} /$ responses present in our stimuli, we ran analysis with these trials removed. There was no difference in the results with or without these trials.

Importantly, we also assessed whether participants could differentiate between the type of the response sample (a question or not) from which the phoneme was extracted. We found no effect of the response type $\left(\chi^{2}(1)=0.11, p=.75\right)$.

Figure 2: Raw proportions of participants answering that an incoming turn is a question based on the previous context and the first phoneme of the incoming turn.
Error bars indicate 95\% CI of observations grouped within participants.

## Context

Thus, participants answered comparably to the phoneme samples that actually were questions and samples that were not questions. Most importantly, there was no interaction between response phoneme and the type of the response $\left(\chi^{2}=0.008, p=0.93\right)$. Thus, participants treated wh phonemes from real questions comparably to wh phonemes from other speech acts. These results suggest that participants are responding to the phoneme, not any other acoustic cue in the sample.

There was no significant interaction between context and phoneme $\left(\chi^{2}(2)=1.34, p=.51\right)$, although the trend was in the predicted direction.

## Discussion and conclusions

In the present paper we set out to explore whether the first phoneme of a turn and the prior context can serve as a cue to question recognition. We found that both of these features contribute to this process. Although an effect of context was clearly expected, it was less certain whether there would be an effect of the first phoneme. This is the first experimental study supporting the claim of Slonimska \& Roberts (accepted) that the first phoneme of question words can be used to predict an upcoming question.

We approached this topic from two different but mutually enhancing perspectives. We first assessed the hypothesis by analyzing natural conversations. Thus, we could look for patterns in ecologically valid data. The fact that the decision tree generated the same predictions as our hypothesis served as a sound basis for an experimental testing. Indeed, the samples from the corpus were used as experimental materials and the design was partly informed by the interaction between the two factors that the corpus study suggested. The hypotheses were also confirmed in the experiment, but there were two minor differences. First, the initial phoneme had a stronger effect than context in corpus study and vice versa in the experiment. Secondly, the corpus study predicted an interaction between initial phoneme and context, which was not found in the experiment. This may be because the probability of occurrence of various combinations is different in the corpus compared to the experiment, the experiment did not have enough statistical power, or more generally there is a difference between cues that are present in the data and ones that are actually used by people.

Another obvious difference between the two studies is that the speakers in the corpus had more prior context information than participants in the experimental study. Future experimental studies could include more extensive contextual information for the participants to be able to make predictions about the incoming turn.

Furthermore, the experimental participants were only passive listeners of the audio samples and their responses were not on-line. Future studies could take advantage of new paradigms to make it possible to combine interactive conversation with the use of controlled audio samples (e.g. Bögels, Magyari \& Levinson, 2015).

Slonimska \& Roberts (accepted) argue that question words tend to sound similar at the beginning of the word within a language to trigger question recognition. This leads to a prediction that $/ \mathrm{w} /$ should be a better cue than $/ \mathrm{h} /$, considering that there are more question words starting with $/ \mathrm{w} /$ than $/ \mathrm{h} /$. We found support for this in the corpus study. However, there was only one instance of $/ \mathrm{h} /$ phoneme in the experimental samples. We ran analyses with /h/ samples excluded and found no difference in the results. Therefore, although $/ \mathrm{w} /$ appears to boost question recognition, generalization to wh phonemes in English may not be warranted. Future studies could consider the differences between hearing $/ \mathrm{w} /$ and $/ \mathrm{h} /$ at the beginning of a turn in regard to question recognition.

It could be argued that the effect sizes in either study are too small to cause an evolutionary change in the language. However, we point out that even a small pressure would exert itself many times even in one conversation, and across cultural evolutionary time, small changes can accumulate to cause substantial changes.

Importantly, we advocate the virtuous cycle of looking for the phenomena in natural data, testing it in a controlled way and referring back to the real world. It can raise new questions and, most importantly, research can proceed in a more valid way than by using a single approach. This is clearly evident in our study - two approaches used in our study revealed differences that are important to account for, and which a single approach would have missed.

The findings in this paper are limited to English language and future research should continue exploring this cue in other languages, as well as diachronically. Only in this way can we be certain that this is not a single-language phenomenon or based on some idiosyncrasy of English but is actually a universal tendency. However, the puzzle remains - why else would question words sound so similar within so many languages (given that Slonimska \& Roberts account for historical factors in their study and still find significant similarities)?

To summarize, by using different approaches in exploring the same topic we now have converging evidence for the question word similarity hypothesis: first, question words tend to sound similar within languages (Slonimska \& Roberts, accepted); also, this phonetic cue can help in predicting questions in real conversations as shown in the corpus analysis; and finally people actually use this cue to predict questions when presented in a semi-natural setting. Thus, we suggest that the tendency for question words to sound similar is not a random occurrence, but might have evolved under a selective pressure to act as one of the early cues for question recognition in interactive conversation.

#### Abstract

Humans make complex inferences on faces, ranging from objective properties (gender, ethnicity, expression, age, identity, etc) to subjective judgments (facial attractiveness, trustworthiness, sociability, friendliness, etc). While the objective aspects of face perception have been extensively studied, relatively fewer computational models have been developed for the social impressions of faces. Bridging this gap, we develop a method to predict human impressions of faces in 40 subjective social dimensions, using deep representations from state-of-the-art neural networks. We find that model performance grows as the human consensus on a face trait increases, and that model predictions outperform human groups in correlation with human averages. This illustrates the learnability of subjective social perception of faces, especially when there is high human consensus. Our system can be used to decide which photographs from a personal collection will make the best impression. The results are significant for the field of social robotics, demonstrating that robots can learn the subjective judgments defining the underlying fabric of human interaction. Keywords: social impression; deep learning; face perception

## Introduction

With the huge success of deep learning techniques, current state-of-the-art computer vision algorithms have approached or exceeded human ability in recognizing a face (Taigman, Yang, Ranzato, \& Wolf, 2014; Stewart, Andriluka, \& Ng, 2016) and identifying the objective properties of a face, such as age and gender estimation, (Guo, Fu, Dyer, \& Huang, 2008). However, humans not only read objective properties from a face, like expression, age, and identity, but also form subjective impressions of social aspects of a face (Todorov, Olivola, Dotsch, \& Mende-Siedlecki, 2015) at first sight, such as facial attractiveness (Thornhill \& Gangestad, 1999), friendliness, trustworthiness (Todorov, Baron, \& Oosterhof, 2008), sociability, dominance (Mignault \& Chaudhuri, 2003), and typicality. In spite of the subjective nature of social perceptions, there is often a consensus among human in how they perceive attractiveness, trustworthiness, and dominance

[^204]in faces (Falvello, Vinson, Ferrari, \& Todorov, 2015; Eisenthal, Dror, \& Ruppin, 2006). This indicates that faces contain high-level visual cues for social inferences, therefore making it possible to model the inference process computationally. Social judgments, as an important part of people's daily interactions, have a significant impact on social outcomes, ranging from electoral success to sentencing decisions (Oosterhof \& Todorov, 2008; Willis \& Todorov, 2006).

Are deep learning models, which are successful in various visual tasks, also capable of predicting subjective social impressions of faces? Even before the advent of deep learning, there have been models using traditional computer vision algorithms and simulated faces to model the perception of facial attractiveness (Thornhill \& Gangestad, 1999; Eisenthal et al., 2006; Kagian et al., 2008; Gray, Yu, Xu, \& Gong, 2010), trustworthiness (Falvello et al., 2015; Todorov, Baron, \& Oosterhof, 2008), sociability, aggressiveness (Mignault \& Chaudhuri, 2003), familiarity (Peskin \& Newell, 2004), and memorability (Bainbridge, Isola, \& Oliva, 2013; Khosla, Bainbridge, Torralba, \& Oliva, 2013). Recently, there has been work on modeling the "big five" personality traits perceived by humans when viewing another person in video clips (Escalera et al., 2016).

In this paper, we examine human social perceptions of faces in 40 dimensions extensively and systematically. We evaluate the human consistency and correlation in 40 social features ( 20 relevant pairs) that are typically studied by social psychologists (Todorov, Said, Engell, \& Oosterhof, 2008), and relevant to social interactions (Todorov et al., 2015; Oosterhof \& Todorov, 2008), and use state-of-the-art deep learning algorithms to model all 40 of them. Using the internal representations learned from the deep learning models, our model can successfully predict human social perception whenever human have a consensus. We further visualize the key features defining different social attributes to facilitate a understanding of what makes a face salient in a certain social dimension.

## Methods

## Dataset

To predict human social impressions of faces, we use a public dataset (Bainbridge et al., 2013) consisting of 2,222 face images and annotations for 40 social attributes. Each attribute is rated on a scale of $1-9$ by 15 subjects. We take the average rating from all raters as a collective estimation of human judgment for the social features of each face.

The 40 social attributes consist of 20 pairs of related traits: (attractive, unattractive), (happy, unhappy), (friendly, unfriendly), etc. Some of these traits are highly correlated and predictable from others, especially within the trait pairs. To understand the human-perceived correlations between these traits, we compute the Spearman's rank correlation between the average human ratings of every pair of social features and show their correlations in a heatmap (Figure 1(a)). We order traits in the map based on similarity and positive or negative connotation. From the figure, we see that negative social features such as untrustworthy, aggressive, cold, introverted, and irresponsible form a correlated block. Likewise, the most positive features such as attractive, sociable, caring, friendly, happy, intelligent, interesting, and confident are highly correlated with each other. Although we choose 20 pairs of opposite features, they are not completely complementary and redundant. Principal Component Analysis of the covariance matrix shows that it takes 24 principal components to cover $95 \%$ of the variance.

## Regression Model for Social Attributes

After averaging human ratings, each face receives a continuous score from 1 to 9 in all social dimensions. We model these social scores with a regression model. We propose a ridge regression model on either features from deep convolutional neural networks (CNN) or traditional face geometry based features, and present results from both feature sets. Such visual features are usually high-dimensional, so we first perform Principal Component Analysis (PCA) on the extracted features of the training set to reduce dimensionality. The PCA dimensionality is chosen by cross-validation on a validation set, separately for each trait. The PCA weights are saved and further used in fine-tuning our CNN-regression model.

## Regression on Geometric Features

Past studies have found that facial attractiveness can be inferred from the geometric ratios and configurations of a face (Eisenthal et al., 2006; Kagian et al., 2008). We suggest that other social attributes can also be inferred from geometric features. We compute 29 geometric features based on definitions described in (Ma, Correll, \& Wittenbrink, 2015), and further extract a 'smoothness' feature and 'skin color' feature according to the procedure in (Eisenthal et al., 2006; Kagian et al., 2008). The smoothness of a face was evaluated by applying a Canny edge detector to regions from the cheek and forehead areas (Eisenthal et al., 2006). The more edges detected, the less smooth the skin is. The regions we chose
to compute smoothness and skin color are highlighted in the right subplot of Figure 2. The skin color feature is extracted from the same region as smoothness, converted from RGB to HSV. However, regressing on these handcrafted features alone is not enough to capture the richness of geometric details in a face. We therefore use a computer vision library (dlib, $\mathrm{C}++$ ) to automatically label 68 face landmarks (see Figure 2) for each face, and then compute distances and slopes between any two landmarks. Combining 29 handcrafted geometric features, smoothness, color and the distance-slope features, we obtain 4592 features in total. Since the features are highly correlated, we apply PCA to reduce dimensionality. Again, the PCA dimensionality is chosen by cross-validating on the hold out set separately for each facial attribute. Then a ridge regression model is applied to predict social attribute ratings of a face. The hyper-parameter of ridge regression is selected by leave-one-out validation within the training set.

## Regression on CNN Features

Previous studies have shown that pretrained deep learning models can provide feature representations versatile for related tasks. We therefore extract image features from pretrained neural networks, choosing from six architectures with different original training goals: (1) VGG16, trained for object recognition (Simonyan \& Zisserman, 2014), (2) VGGFace, trained for face identification (Simonyan \& Zisserman, 2014), (3) AlexNet, trained for object classification (Krizhevsky, Sutskever, \& Hinton, 2012), (4) Inception from Google, trained for object recognition (Szegedy et al., 2015), (5) a shallow Siamese neural network that we train from scratch to cluster faces by identity, (6) a state of the art VGG-derived network (Face-LandmarkNN) trained for the face landmark localization task.

To find the best CNN features among the six networks, we first find the best-performing feature layers of each network in the ridge regression prediction task. Before the ridge regression, we perform PCA and pick the PCA dimensionality that gives best results on the validation set. Then, we compare the results among networks to select the best features overall.

## Results

After comparing all 6 networks, we find that the conv5_2 layer of VGG16 (trained for object classification) lead to the best results. This set of features significantly outperforms the three networks trained solely on faces, while also slightly outperforming AlexNet and Inception networks. These bestperforming CNN features also exceed the prediction correlation of the geometric features in most attributes. Figure 3 compares prediction performance of the CNN model and the geometric feature model.

We speculate that the poor performance from the face recognition networks can be attributed to their optimization for specific facial tasks. Learning face landmark configurations and differences between faces that define identity may not correlate well with the task at hand, which looks for commonalities behind certain social features beyond identity. The

Figure 1: Correlation heatmaps among social features. (a): human; (b): CNN-based model.

Figure 2: 68 face landmarks labeled by dlib software automatically. The gray regions are used for computing smoothness and skin color.
landmark networks should presumably give results similar to the geometric features, but did not learn features corresponding to all of the features we manually extracted.

We also try fine-tuning the best performing CNN model with back propagation but do not observe further improvement in performance. Hence our reported results are without fine-tuning.

To evaluate model performance, we did a random train/validation/test split 50 times, with a ratio of 64/16/20 respectively. The prediction performance of our model is evaluated using Pearson's correlation with the average human ratings on the test set. For each social attribute, we also compute human group consistency as an index of the strength of learning signal.

Among the social attributes, human subjects agree most about 'happy' and disagree most about 'unfamiliar.' For both regression models (CNN based regression and geometric fea-
ture based regression), model performance grows as the consensus on a social trait increases.

Since a change in expression would produce a change in landmark locations, it is not surprising that landmark-based geometric features achieve comparable or slightly higher correlation with the CNN model when predicting social attributes which are highly related to expressions (such as 'happy', 'unhappy', 'cold' and 'friendly' etc). For other social attributes, the CNN model performs better, by about 0.04 higher in correlation on average. This implies that CNN features encode much more information than landmark-based features. It is useful to visualize such features to understand what aspects make them powerful enough to predict social attributes.

## Evaluating Against Human Consensus

An important gauge of model success is quantitative comparison between the subjective social features predicted by our best performing model and those perceived by humans. We take our model predictions, compute the Spearman correlation between every pair of traits, and display them in a heatmap (see Figure 1 (b)). The resulting heatmap shares similar patterns with the figure generated from average human ratings (see the left panel in Figure 1). Pearson Correlation between the upper triangle of the two similarity matrices (human and model prediction) is 0.9836 . This suggests that our model successfully preserves human-perceived relationships between traits.

Since these social impressions are subjective ratings, it is informative to examine the extent with which people agree

Figure 3: Model comparison on 40 social features.
with each other on these judgments. To calculate human group consistency, we perform the following procedure 50 times for each attribute and then average the results: (1) For each face, we randomly split the 15 raters into two groups of 7 and 8. (Note: The raters assigned to each face are generally different sets). (2) We calculate the two groups' average ratings for each face, obtaining two vectors of length 2,222 (the number of faces in the dataset). (3) Finally, we calculate the Pearson correlation between the two vectors. We find that human agreements covary with model performance and observe an extremely high correlation, as illustrated in Figure 4.

Figure 4: Human within group consistency vs. model's correlation with human average. Pearson correlation $\rho=0.98$, $p<10^{-5}$

## Feature Visualization

Here, we visualize features from our model which are important for social perceptions. We choose facial attractiveness as
an example, but the same method can be applied to the other social features.

To identify visual features that ignite attractiveness perception, we find the top 9 units of highest influence on attractiveness at conv5_2 as follows. First, we compute a product of three terms: (1) A unit's activation from conv5_2, (2) that unit's weight to the following fc_PCA layer, (3) the fc_PCA unit's weight to the output unit. We then sort all conv5_2 units' average products of these three terms and identify the top 9 neurons that contribute to the output neuron for the corresponding social feature. Then we employ the method described in (Yosinski, Clune, Nguyen, Fuchs, \& Lipson, 2015; Zeiler \& Fergus, 2014) to find top-9 input images that cause high activations in each of the top-9 conv5_2 neurons. Also we use deconvolution to create an image of the features activating that unit for each face, with varying levels of success.

Figure 5 captures the features that are important for predicting the attractiveness of a face. The feature importance descends from left to right and top to bottom. The important features identified by our model are related to eyes, hair with bangs, high nose-bridges, high cheeks, dark eyebrows, strong commanding jawlines, chins, and red lips. Note that among the 9 cropped input image patches, not all the faces are perceived as attractive overall; despite having a feature that contributes to attractiveness. An attractive face needs to activate more than one of these features in order to be considered attractive. This observation agrees with our intuition that attractiveness is a holistic judgment, requiring a combination of multiple features.

It also seems that several attractiveness features include relationships between different facial features. For example, while the first feature in the upper left of the figure emphasizes the eye, it also includes the nose. This is also true of the upper right feature. Additionally, smiling is important in perceived attractiveness, as emphasized by the feature in the lower left of the figure.

Figure 5: Visualization of features in the pretrained-VGG16 regression network. For conv5_2 layer, we show the top 9 activations of the top 9 neurons that maximally activate the attractiveness neuron across the training data, projected down to pixel space using the deconvolutional network approach (Zeiler \& Fergus, 2014) and their corresponding cropped image patches. Best viewed in electronic form, and zoomed in.

## Conclusion

We have shown that a deep network can be used to predict human social perception of faces, achieving high correlation with the average human ratings. As far as we know, this is the widest exploration of social judgment predictions, showing human-like perceptions on 40 social dimensions. Reflecting previous work in recognizing facial expressions, where happiness is the easiest to recognize, our highest correlation is on the happy feature. However, previous work in this area tends to classify a face as happy or not, rather than the degree of rated happiness. By predicting this as a continuous value, rather than categorical data, the subjective nature of human judgment is modeled smoothly, along with the subjective face trait landscape.

We find that, for attributes which are recognized via facial actions, such as happy, unhappy, or aggressive (probably associated with anger) or lack of facial action, such as cold or unemotional, a simple regression model based on the placement of facial landmarks works well, although the deep network performs nearly as well.

Of greater significance is our model's correlations with human judgments for traits such as trustworthiness, responsibleness, confidence, and intelligence, which correspond to more static features of the face. In this area, the deep network, which responds to facial textures and shape, has superior performance. While these judgments do not correspond to the traditional notion of "ground truth", they are descriptions for which humans have a fair amount of agreement, suggesting
the presence of a signal to be recognized.
Furthermore, we have shown, yet again, that a machine can recognize attractiveness. For this dataset, our deep network correlates with average human ratings at 0.75 . This provides a new benchmark for this dataset. This is one of a few areas where the deep network significantly outperforms the geometric features, as skin texture is likely to matter.

Many of these features are redundant. For example, friendly and happy are highly correlated (see Figure 1, and the red block indexed by happy and friendly). Similarly, aggressive and mean are highly correlated, which presumably requires not smiling. Meanwhile, it is also noteworthy that some traits considered to be "opposite" in this list are not simply the inverse of one another. For example, there is a large difference in human agreements on "sociable" $(0.74)$ versus "introverted" $(0.50)$, suggesting they are not opposites.

We also examined some of the features from the deep network. It is notable that these are difficult to verbalize, which is quite different from geometric features.

These results are significant for the field of social robotics. While a robot should not purely judge a human on appearance, much of human interaction is dictated by the underlying fabric of social impressions. Thus, it is important for a robot to be aware of this subjective social fabric, opening the door to useful knowledge such as whether humans might judge a person to be trustworthy. These judgments may happen subconsciously for humans, while a robot can be more objective, predicting these judgments and objectively choosing when to
consider them in a decision. A robot need not treat an attractive or unattractive person differently for its own purposes, but this knowledge could affect how interactions are made for the sake of the human, knowing in advance how that person may feel that they fit into the social landscape.

Expansions on this work may include investigating the image properties that determine high level social features, beyond the attractiveness features we display in Figure 5. Additionally, social trait prediction may benefit from a single model with a shared representation, while this paper approaches each attribute as a separate regression task.

For future work, we aim to develop a generative model which can automatically modify a face's attributes (either objective or subjective) while preserving its realism and identity. Practically speaking, such a model could improve a face's perceived social features in positive ways (e.g. make a face look more sociable, trustworthy). More importantly, it would enable psychologists to quantify human biases during the formation of social impression in a precise and systematic manner. Psychologists could generate variants of a real face differing in age, gender, race, and explore how various factors separately and jointly affect the social impressions of faces.

# A Rational Approach to Stereotype Change 

Jake Spicer (J.Spicer@ warwick.ac.uk)<br>Department of Psychology, Humanities Building, University of Warwick, Coventry, UK

Adam Sanborn (A.N.Sanborn@warwick.ac.uk)<br>Department of Psychology, Humanities Building, University of Warwick, Coventry, UK

#### Abstract

Existing theories of stereotype change have often made use of categorisation principles in order to provide qualitative explanations for both the revision and maintenance of stereotypical beliefs. The present paper examines the quantitative methods underlying these explanations, contrasting both rational and heuristic models of stereotype change using participant data and model fits. In a comparison of three models each simulating existing descriptions of stereotype change, both empirical data and model fits suggest that stereotypes are updated using rational categorisation processes. This presents stereotype use as a more rational behaviour than may commonly be assumed, and provides new avenues of encouraging stereotype change according to rational principles.

Keywords: Stereotypes; Categorisation; Rational Behaviour

## Introduction

Stereotypes have often been found to be resistant to change, with beliefs and expectations regarding a group often persisting even when faced with directly contradictory information (Hilton \& von Hippel, 1996). This presents a problem when trying to combat stereotypes underlying prejudice or discrimination through out-group exposure as has often been suggested by theories such as the Contact Hypothesis (Allport, 1954), as there is no assurance that simply demonstrating the inaccuracy of these beliefs will be effective in encouraging revision. It is therefore necessary to examine the processes by which stereotypes are updated with experience, and, in cases of stereotype persistence, determine how counter-stereotypical information can be disregarded in order to develop better methods to encourage change.

Past research into this field has offered three possible processes of stereotype revision: book-keeping, in which the stereotype is slowly adjusted with each relevant observation; conversion, in which the stereotype can undergo sudden and drastic changes in response to particularly notable contradictory exemplars; and subtyping, in which counter-stereotypical evidence is isolated from the rest of the category in a distinct subgroup, ignored when making category judgements. This presents three potential explanations for stereotype persistence: stereotype-incongruent exemplars may be noted via book-keeping but remain out-weighed by prior stereotypical beliefs; these exemplars may not have been sufficiently significant to evoke change via conversion; or these exemplars may have been excluded entirely via subtyping.

This distinction was examined by Weber and Crocker (1983) by manipulating the presentation format of counterstereotypical evidence in summaries of lawyers: equal
amounts of stereotype-incongruent evidence were either concentrated into only a few exemplars, or dispersed across many exemplars. This generates three competing expectations between the three models: conversion suggests that these concentrated exemplars would act as extreme disconfirmers, encouraging significant revision to the stereotype. Conversely, subtyping would suggest that concentrating incongruent evidence should make it easier to isolate, thereby preserving existing stereotypical beliefs. Book-keeping, meanwhile, focuses only on the amount of data rather than the presentation format, and so suggests no difference between these conditions. Measures of the strength of stereotypical beliefs following exposure to these exemplars were found to be stronger in the concentrated condition, supporting the subtyping model, an effect that has since been replicated in a number of studies (Bott \& Murphy, 2007; Johnston \& Hewstone, 1992).

This depicts stereotype persistence as an issue of categorisation, occurring where counter-stereotypical group members are placed in a distinct subgroup rather than integrated into existing structures. The mechanisms underlying stereotype revision could then be well described by existing models of categorisation, particularly those which perform a similar process of partitioning a category into lower-order subgroups. One key example of such a model is the Rational Model of Categorisation (RMC) developed by Anderson (1991), which organises a category into 'clusters' of exemplars based on similarities in observed features. The organisation of these clusters then determines the impact of stored data on subsequent judgements, with larger clusters tending to have more influence on expectations of given traits appearing in the category.

The subtyping effect could therefore be seen as the result of standard categorisation processes creating partitions of the category based on observed data patterns which determine the impact of incongruent information on later judgements: isolating this information leads to subtyping, diminishing its impact, while integration of congruent and incongruent information leads to book-keeping, and so greater stereotype revision. If so, subtyping may not be the result of a bias towards ignoring counter-stereotypical data in order to preserve stereotypical beliefs, but a rational incorporation of all available data under certain data patterns which happens to mitigate the influence of stereotype-incongruent information. As such, subtyping could be considered a more rational process
than it may initially seem, and so could be fought using similarly rational mechanisms to encourage stereotype change.

The present study therefore presents a rational approach to stereotype use; in the following paper, we develop several candidate models to approximate the existing depictions of stereotype revision, contrast the predictions of these models with participant data to assess their accuracy, and use these findings to offer some insight into the process of stereotype change.

## Model Details

We began by developing an edited version of the RMC in order to examine the categorical explanation proposed for the subtyping effect. This made use of the standard version of the RMC using discrete exemplar dimensions as defined by Anderson (1991), chosen for its reasonable level of simplicity and ease of application to the design of Weber and Crocker (1983). The RMC assigns exemplars sequentially to a cluster based on similarities in observed features using a Bayesian model to approximate the ideal partition:

$$
\begin{equation*}
p(k \mid f)=\frac{p(k) p(f \mid k)}{\sum_{k} p(k) p(f \mid k)} \tag{1}
\end{equation*}
$$

where $k$ is the cluster and $f$ is the feature set of the exemplar under consideration. This posterior probability is calculated for all existing clusters as well as a new potential cluster, with the highest probability determining assignment. Following Anderson (1991), the prior probability was defined as:

$$
p(k)= \begin{cases}\frac{c n_{k}}{(1-c)+c n} & \text { if } k \text { is old }  \tag{2}\\ \frac{(1-c)}{(1-c)+c n} & \text { if } k \text { is new }\end{cases}
$$

where $n_{k}$ is the number of exemplars in cluster $k, n$ is the total number of members assigned to the partition, and $c$ is a coupling parameter describing the probability of two exemplars being grouped together independent of any observations.

The likelihood also followed the format of Anderson (1991):

$$
\begin{equation*}
p(f \mid k)=\prod_{i} p_{i}(j \mid k) \tag{3}
\end{equation*}
$$

where the exemplar's features are divided into dimensions $i$ holding values $j$. As stated above, the discrete form of this probability was used, in keeping with the exemplar structure used by Weber and Crocker (1983):

$$
\begin{equation*}
p_{i}(j \mid k)=\frac{n_{j}+\alpha_{j}}{n_{k}+\alpha_{0}} \tag{4}
\end{equation*}
$$

where $n_{j}$ is the number of exemplars in cluster $k$ showing trait value $j$ on dimension $i, n_{k}$ is the number of cluster members showing a value on that dimension and $\alpha_{j}$ is a parameter reflecting the prior expectation of the occurrence of that value, while $\alpha_{0}$ is the sum of these alpha values.

Once a partition has been generated, the model is then able to calculate a probability value measuring the likelihood of a
new group member exhibiting a congruent trait value on any dimension. This is done by taking an average of the rate of congruent traits in each cluster weighted by the probability of that cluster:

$$
\begin{equation*}
p(\text { con })=\sum_{k} p(k) p(\text { con } \mid k) \tag{5}
\end{equation*}
$$

where $p($ con $\mid k)$ follows the format of Equation 4, focussing on congruent trait values. This explains how isolating incongruent data in a distinct subtype mitigates its impact: smaller clusters provide less evidence to outweigh prior expectations, here represented by the $\alpha$ parameter. As such, there is less confidence that future members of the incongruent cluster will demonstrate similar trait values, while the larger congruent cluster carries more certainty. To illustrate, consider a case in which 30 exemplars, 20 congruent and 10 incongruent, are either integrated or segregated. For the purposes of this illustration, $\alpha=1$ for both congruent and incongruent traits, and $c=1$, meaning no new cluster is considered:

As this shows, stereotype-congruency is estimated to be more probable in the segregated case because the $\alpha$ values are more impactful in the smaller cluster, offsetting the actual ratio of traits to a greater degree.

## Stereotypes as Prior Clusters

As the category in question is a familiar social group with which participants are likely to have previous experience, the model included a cluster of exemplars added to the partition before exposure to the main exemplar set in order to simulate this prior knowledge. This also provided a more valid depiction of the origins of the group stereotype by making the members of this prior cluster stereotype-congruent, as well as allowing for potential interactions between prior knowledge and new information, as have been observed in other categorical modelling studies (Heit, Briggs, \& Bott, 2004). Exemplars in the prior cluster therefore displayed stereotypecongruent values on all stereotypical dimensions, as well as group membership on a separate dimension, while the number of cluster members was added as an additional model parameter.

## Alternative Models

While the above demonstration does show that the RMC is able to predict a subtyping effect, in order to determine whether this is truly the result of a rational process, the RMC
must be compared with a more heuristic depiction of the subtyping mechanism. A second model was therefore developed in which the segregated incongruent data is ignored rather than simply mitigated, essentially redrawing category boundaries to exclude counter-stereotypical information. This was achieved by restricting the clusters considered when making probability estimates to only the cluster with the highest posterior probability. This restriction was based on the findings of Murphy and Ross (1994), which suggested that participants often only considered the most likely cluster when making probability estimates rather than all generated clusters. This creates an additional candidate model for assessment, labelled the Restricted Rational Model of Categorisation (RRMC).

In addition, as a counterpoint to this 'extreme subtyping' model, a third model was developed in which book-keeping was enforced; this was achieved by limiting the RMC to using only a single cluster by fixing the $c$ parameter at 1 , forcing all exemplars to be grouped together despite any differences in features. This 'Single Cluster Model' (SCM) therefore removes the possibility of segregating incongruent data, eliminating any influence of data format and focussing entirely on the ratio of traits in the partition.

These three models therefore present three different mechanisms of stereotype revision: while both the RMC and RRMC use a partition that flexibly adapts to observed data patterns, the RRMC subsequently simplifies this partition by focussing on only one cluster, heightening any effects this representation may have generated, while the RMC remains more moderate. Conversely, the SCM focuses on trait ratios rather than data pattern, thereby dismissing any effects that may be predicted by the other candidate models.

There is, however, a key distinction between these rational and heuristic models which can be used to determine their validity: in the RMC, the subtyping effect is dependent on the smaller size of the subtype cluster, meaning that increasing the size of the subtype by adding more incongruent members should reduce and ultimately eliminate this effect. In contrast, the RRMC will continue to ignore the subtype regardless of its size unless the subtype becomes so large that it is selected as the most likely cluster, at which point estimates will change drastically to reflect the subtype's much lower rate of congruency. This could essentially reverse the subtyping effect at higher volumes of incongruent evidence, focussing on counter-stereotypical rather than stereotypical clusters, and so bearing a closer resemblance to the conversion-effect described above. The SCM, meanwhile, is unable to exclude incongruent data at all, and therefore predicts no subtyping effect at any volume of incongruent information.

The accuracy of these models can therefore be contrasted according to the change in the subtyping effect with further exposure to stereotype-incongruent evidence: the RMC predicts a reduction in subtyping at higher volumes of counterstereotypical data; the RRMC predicts a stable subtyping effect until a sudden reversal; and the SCM predicts no sub-
typing effect at any point. The following experiment therefore set out to compare these model predictions by extending the concentration design of Weber and Crocker (1983) across a higher total volume of evidence and taking measures of stereotypical beliefs throughout exposure. This also provided direct behavioural data for use in assessing the fit of the candidate models for a more complete test of these predictions.

## Experimental Data

## Method

Participants One-hundred-and-sixteen participants were selected from a University of Warwick undergraduate psychology class as part of a course requirement. The sample included 102 females and 14 males, while age ranged between 18 and 27 years, with a mean of 19 .

Design and Materials The experiment followed the concentration design of Weber and Crocker (1983) with an additional within-subjects manipulation of data volume: measures of stereotypical beliefs were taken at fixed intervals during the observation of a set of exemplar descriptions where stereotype-incongruent information was either concentrated in a subset of exemplars or dispersed across all exemplars. Two exemplar sets were therefore created for use in the experiment, each containing 90 total exemplars displaying four trait dimensions: the first dimension described the occupational label, and so was identical for all exemplars, while the remaining three dimensions described personality traits with three possible values (stereotype-congruent, stereotypeincongruent or neutral). In both sets, two-thirds of the 270 total traits were incongruent, one-sixth were congruent and one-sixth were neutral; incongruent traits made up the majority in order to allow for a potential incongruent cluster to be larger than any other in the category. In the concentrated exemplar set, these incongruent traits were concentrated such that 60 exemplars each displayed incongruent traits on all three personality dimensions, with the congruent and neutral traits being distributed equally between the remaining exemplars. In the dispersed exemplar set, all traits were distributed as equally as possible.

As in Weber and Crocker (1983), exemplars were said to come from the category of lawyers; exemplars were therefore transformed into member summaries for use in the experiment by assigning each value on the three personality dimensions a unique trait label. Sixteen total labels were used: 5 congruent (Intelligent, Industrious, Neat, Out-going and Well-dressed), 5 incongruent (Incompetent, Lazy, Messy, Shy and Slovenly) and 6 neutral (Warm, Religious, Jovial, Obnoxious, Reserved and Meditative). These labels were taken from Weber and Crocker (1983), being based on pilot tests determining stereotypical and counter-stereotypical traits for the target category of lawyers. Three labels of each trait type were randomly selected at the start of each run of the experiment for use in exemplar summaries. Summaries were also assigned randomly selected names to assist in individuation.

Procedure Upon arriving at the lab, participants were first randomly assigned to one of the two concentration conditions, determining which set of exemplars would be viewed; this was balanced to provide equal numbers, meaning 58 participants were allocated to each condition. Participants were told the experiment tested how perceptions of a group changed with experience, involving both viewing summaries of group members and answering questions about the traits of the group in general.

The experiment began by asking participants to estimate the likelihood of certain traits appearing in the category of lawyers according to the number of members in a sample of 100 lawyers displaying that trait. Estimates were requested for all 16 possible personality traits, though only 9 were used in the subsequent member summaries. This first question block therefore provided a measure of baseline beliefs before any experimental exemplars were viewed.
After providing estimates for all traits, participants began a presentation block in which member summaries were shown on screen for the participants to examine. In order to maintain attention on this information, participants were asked to rate the pleasantness of each group member on a scale of 1-10, though this measure was not used during analysis.

At set intervals of presentation, the test block was repeated, and participants were again asked to estimate the likelihood of each of the 16 traits appearing in the category to measure any changes in expectation. This occurred after viewing 6, $18,36,60$ and 90 total exemplars, with the ratio of traits within each interval being consistent with that of the complete exemplar set. At the start of each test block, participants were informed that though some of the questions had been asked before, they should answer based on how they felt at that point in time.

After viewing all 90 lawyer summaries and completing the final test block, the experiment ended, and participants were debriefed as to the aims and expectations of the study.

## Results

## Data Analysis

The results of the experiment were analysed using a mixed linear regression model including the factors of evidence volume, concentration condition and trait type. As the first test block was intended to provide a baseline, being unaffected by either volume or concentration, ratings from this round were not included in the regression model. This was confirmed using independent $t$-tests, finding no significant difference between conditions in either congruent ratings $(\mathrm{t}(114)=.190$, p $=.850)$ or incongruent ratings $(\mathrm{t}(114)=.296, \mathrm{p}=.768)$ in the first test block.

The regression model showed significant effects for volume in both congruent $(\beta=-2.23, \mathrm{t}(5086)=6.41, \mathrm{p}<.001)$ and incongruent ratings $(\beta=6.49, \mathrm{t}(5086)=15.6, \mathrm{p}<.001)$, with congruent ratings decreasing and incongruent ratings increasing over the task. Similarly, condition is shown to be a significant predictor for both congruent ( $\beta=-6.36, \mathrm{t}(114)$
$=2.50, \mathrm{p}=.014$ ) and incongruent ratings ( $\beta=12.6$, $\mathrm{t}(114)$ $=3.19, \mathrm{p}=.001$ ), with congruent ratings being higher and incongruent ratings lower in the concentrated condition. Finally, the interaction between concentration and volume was found to significantly differ between congruent and incongruent ratings ( $\beta=-2.21, \mathrm{t}(5086)=3.76, \mathrm{p}<.001$ ), potentially indicating differences in the level of the subtyping effect over the task.

This was investigated further using two additional mixed linear regression models for each trait type, both including the factors of condition and evidence volume. Coefficient estimates from the congruent ratings model suggested evidence volume to be a significant predictor $(\beta=-3.11, \mathrm{t}(1620)=6.63$, $\mathrm{p}<.001$ ), but concentration condition to be non-significant ( $\beta=-3.63, \mathrm{t}(114)=1.24, \mathrm{p}=.218$ ), with no significant interaction between these factors $(\beta=.58, \mathrm{t}(1620)=.88, \mathrm{p}=$ .379). Conversely, the incongruent ratings model suggested a significant effect of volume $(\beta=4.48, \mathrm{t}(1620)=7.79, \mathrm{p}<$ $.001)$ and condition $(\beta=7.40, \mathrm{t}(114)=2.40, \mathrm{p}=.018)$, with a near-significant interaction $(\beta=-1.52, \mathrm{t}(1620)=1.87, \mathrm{p}=$ .062 ). The findings of the general model are therefore most evident in the incongruent ratings when the two trait types are separated, while congruent ratings do not display such strong effects.

## Model Comparison

Participant data was compared with model predictions made by the three candidate models to determine which provided the most accurate depiction of behaviour in the task. This used a grid search function across the three parameters, with the considered values being: for $c, 0.01$ to 0.99 in steps of 0.01 ; for $\alpha, 0.1,0.2,0.3,0.5,1,2,3,5,10,15,20,25$ and 30 ; and for membership frequency of the prior cluster, 0 to 50 in steps of 1 . The models were run through the same exemplar sets given to participants at each combination of parameter

Figure 1: Trait ratings for both trait types in both concentration conditions across the 6 test blocks. Error bars show 95\% CI.
values to generate estimates of the probability of both congruency and incongruency in new category members at each of the six exemplar intervals. These values were then used to calculate model likelihoods assuming identical parameter values for all participants in order to allow the model to fit both conditions simultaneously. Likelihoods were calculated in each of the six test blocks according to the product of the probability of all participant ratings for that trait type in that test block; these probabilities were defined according to a normal distribution using the model probability estimate as a mean and variance fit to maximise the final product. These values were then transformed into log likelihoods before being summed across test blocks and concentration conditions to create a single model log likelihood for all participants at that set of parameter values. Maximum log likelihoods from each model were then used to calculate BIC values for comparison. The RMC was found to have the lowest BIC score (11926, $\alpha=0.5, \mathrm{c}=0.01$, prior membership $=21$ ), indicating this model had a better fit to the experimental data than either the RRMC (11937, $\alpha=10, \mathrm{c}=0.09$, prior membership $=50$ ) or the $\operatorname{SCM}(11929, \alpha=10$, prior membership $=50)$.

Interestingly, when the predictions for this best fit for the RMC are examined, probability estimates for both measures are in fact identical between conditions; this is because all experimental exemplars were assigned to separate, singlemember clusters despite any similarities in features, mitigating all exemplars equally in both sets. This suggests that the differences observed in participant ratings between concentration conditions were sufficiently small such that the data could be best fit by identical behaviour in both conditions. As previously described, this is in fact a tenet of the SCM, which ignores the concentration of data via full integration of all exemplars; however, the SCM shows a steeper curve in both measures compared to the RMC, therefore predicting greater stereotype revision. As such, the scattering behaviour of the RMC better corresponds with the greater degree of maintenance observed in the data.

It is also notable that the best fit of the RRMC matches that of the SCM, as the maximum likelihood of the RRMC was found when all exemplars were grouped in a single cluster.

Figure 2: Trait probability estimates from the best fits of the three candidate models. Due to equality in estimates between conditions for all models, only one line is used for each measure.

As such, the RRMC also predicts greater revision than was observed in the experiment; however, because the SCM does not use a coupling parameter, the SCM holds a lower BIC value than the RRMC despite equal log likelihoods. It should be noted however that this comparison reveals only the best fit of the three candidate models rather than an absolute description of behaviour in the task; more complex models may therefore be needed to reflect the subtle differences observed in the participant data.

## Discussion

The results of the experiment provide three key findings: firstly, ratings of trait likelihood for both congruent and incongruent traits became less stereotypical over the course of the experiment, indicating that higher volumes of incongruent evidence were effective in evoking greater revision of stereotypical beliefs. Secondly, ratings were more stereotypical in the concentrated condition compared to the dispersed condition, as would be expected by subtyping. Thirdly, this concentration effect differed somewhat in size across the task, showing smaller differences between groups at higher volumes of evidence. When the trait types are separated, these findings are seen to be stronger in the incongruent ratings, while congruent ratings did not demonstrate the condition or interaction effects.

In general, these results appear to partially correspond with previous depictions of the subtyping effect: beliefs are more stereotypical where incongruent information is more easily segregated from existing category structures, whereas data patterns aiding integration demonstrate greater stereotype revision. This also matches with the categorical explanations for subtyping offered by both the RMC and RRMC, as both suggest that category partitions which place incongruent data in a separate cluster diminish the impact of this data on subsequent probability estimates, thereby leading to more stereotypical expectations.
There is, however, an additional aspect to the subtyping effect observed in this task which distinguishes between these models: the interaction between volume and concentration, while not quite reaching a significant effect in the separated regression models, does suggest that the subtyping effect did not remain entirely consistent across the task, but in fact dropped off in later test blocks, with incongruent trait ratings in particular appearing to converge between the two conditions. This finding corresponds with the predictions of the RMC made in the introduction to this study: because the subtyping effect in the RMC is the result of greater uncertainty in the data pattern of the subtype cluster due to its smaller size, increasing the size of this cluster attenuates the subtyping effect by providing more confidence in this pattern. This is in contrast to the RRMC's hypothesised cross-over from subtyping to conversion at higher volumes of incongruent evidence where the subtype becomes the most likely cluster due to its size, an effect which was not observed in the data.
The RMC therefore appears to provide the most accurate
theoretical account of the observed results, suggesting participants were most likely using a rational categorisation process to guide their judgements in this task. This suggestion is further supported by the RMC having the best fit to the behavioural data in the above model comparison, though it is notable that this best fit did not accurately capture the observed differences between concentration conditions. Even so, the RMC does still provide a better fit to the experimental results than either the RRMC or SCM, potentially suggesting the present findings are more likely to be due to standard rational processes than these more extreme depictions.

## Implications

The present study therefore provides evidence from both behavioural data and model fits that the maintenance of stereotypical beliefs generated by subtyping does appear to be the result of a rational incorporation of all available data rather than a heuristic strategy of stereotype preservation: isolating incongruent data in a distinct subtype does not completely exclude this information from consideration during category judgements, but instead mediates its impact according to the size of the subtype.

As such, the subtyping effect could be considered to be a normal aspect of standard categorisation processes operating on social groups, occurring where a particular data pattern inadvertently diminishes the impact of counter-stereotypical data. If so, stereotype change could be encouraged by using similarly rational techniques to circumvent subtyping, primarily by aiding the integration of incongruent data into preexisting clusters. More broadly, this finding provides a basis for a rational system underlying stereotyping, allowing for the generation of further predictions regarding stereotype use based on the principles of such rational models to be tested in future studies; such tests would be valuable in further developing the current model to provide a more complete depiction of rational stereotype use.

The current data also demonstrates that stereotype change can be drawn from even slight encounters with incongruent evidence in sufficient volume, with the effects observed in the experiment being based solely on the observation of member summaries rather than any significant interaction with actual counter-stereotypical group members. This is in contrast to past theories such as the Contact Hypothesis which often require intensive, long-term interaction with out-group members to generate a reduction in stereotypical beliefs (Allport, 1954). This is not to say that prior expectations have been completely overcome: revision still does not reach the level suggested by conversion (or indeed the actual ratio of evidence in the experimental data sets); even so, this does still provide limited evidence that stereotype maintenance can be counteracted through increased exposure to incongruent data.

The current design may therefore present a more economic path to combating prejudice, requiring less time and effort than some existing methodologies. What is more, the effects observed in this study could in fact be greater at more significant forms of encounter, potentially counteracting subtyping
at even lower volumes of incongruent data. It is not clear how the significance of an encounter should be represented within the current version of the model, but one basic option would be to represent a significant encounter as multiple observations in the partition, essentially viewing that individual as providing more data than a single exemplar. This suggestion should, however, be pilot tested to determine the validity of this representation before being incorporated into the model.

## Conclusion

The present study provides the starting point for a rational approach to stereotype use, providing both theoretical and empirical evidence that a rational model of stereotype change, while not universally accurate, does provide a reasonable account of behaviour both in this experiment and previous studies into stereotype maintenance. We therefore hope that this study can act as a foundation for continued work in this field, allowing subsequent research to further refine the presented models to provide a more accurate depiction of behaviour. This will serve to provide greater clarity regarding the operations underlying stereotype maintenance, and so aid in finding more potential methods for encouraging stereotype change.

# Population size, learning, and innovation determine linguistic complexity 

Matthew Spike (matthew.spike@anu.edu.au)<br>Centre of Excellence for the Dynamics of Language<br>Coombs Building, The Australian National University, ACT 2601, Australia

#### Abstract

There are a number of claims regarding why linguistic complexity varies, for example: i) different types of societal structure (e.g. Wray \& Grace, 2007), ii) population size (e.g. Lupyan \& Dale, 2010), and iii) the proportion of child vs. adult learners (e.g. Trudgill, 2011). This simple model of interacting agents, capable of learning and innovation, partially supports all these accounts. However, several subtle points arise. Firstly, differences in the capacity or opportunity to learn determine how much complexity can remain stable. Secondly, small populations are susceptible to large amounts of drift and subsequent loss, unless innovation is frequent. Conversely, large populations remain resilient to change unless there is too much innovation, which leads to a collapse in complexity. Next, if adult learners are prevalent, we can instead expect less sustained complexity in large populations. Finally, creolisation does not imply simplification in smaller populations.

Keywords: linguistic complexity; language variation; innovation; social networks; agent-based models; cultural evolution.

## Introduction

Languages vary in complexity. This was a controversial idea for much of the last century, but a growing body of empirical evidence has led to a new consensus in its favour (see Joseph \& Newmeyer, 2012). More intriguingly, the most complex languages in the world are often the ones with the least speakers, spoken by remote, inaccessible, and sometimes non-literate societies. The Archi language, for example, "spoken by a thousand people in one village 2,300 metres above sea level in the Caucasus" (Nichols, 2009, p.3), features verbs with around 1.5 million inflected forms. At the other end of the spectrum, some languages are notable for their apparent simplicity; often creoles (e.g. McWhorter, 2001), but not exclusively so (e.g. Gil, 2001).

There are several lines of thought regarding the origin of this variation in complexity. Trudgill (2011) proposes that when a language community includes a large proportion of adult second-language learners, it leads to a corresponding reduction in that language's complexity, but that, when 'left alone', languages tend towards greater complexity: i.e. there is a directionality to such language change. In a somewhat related idea, Wray \& Grace (2007) argue that esoteric societies (where intra-group communication dominates) lead to further complexification, while simplification occurs in exoteric societies (where people frequently interact with strangers). Nettle (2012) indicates a link between population size and grammatical complexity, citing empirical support from Lupyan \& Dale (2010), who found a (negative) correlation between population size and morphological complexity: similarly to Trudgill, they argue that complex features of language undergo negative selection in large populations with many second language learners, but further conjecture that the high morpho-
logical complexity found in languages spoken by small communities assists in child language acquisition. Finally, authors such as McWhorter (2001) point to the youthfulness of creole languages as the explanation for their simplicity: they haven't been around long enough to build up the diachronic "ornamentation" found in older, more complex languages.

These claims require empirical validation. However, it is notable that despite the increasing availability of crosslinguistic documentation (e.g. WALS, Dryer \& Haspelmath, 2013), no uncontroversial, universally applicable measure of linguistic complexity has arisen. Information-theoretic measures of complexity (e.g. Juola, 2008) can be hard to interpret (the various dimensions of complexity, such as the size of the lexicon and segmental inventory, and paradigmatic vs. syntagmatic complexity are conflated in such measures, and furthermore do not distinguish between descriptive complexity and structural complexity, see Crutchfield, 1994). The alternative would be to employ traditional linguistic analysis, but as pointed out by Nichols (2009, p.111), "measuring the total complexity of a language in cross-linguistically comparable and quantifiable terms would be a massive task and unreasonably costly in time and effort", and moreover any such result would be theory-dependent, and as such subject to accusations of false equivalence (e.g. Haspelmath, 2010) and subjectivity (e.g. Martin, 2011).

As an alternative to empirical analysis, formal tools would seem a good way of - at the very least - assessing the internal consistency of the claims in question. Indeed, two such models have been produced, the first by Lupyan \& Dale (2010) and the second by Reali et al. (2014). Lupyan \& Dale argue that population size correlates with the proportion of L2 learners, and their model suggests that it is this which reduces complexity; Reali et al. show a more direct effect of population size. The model presented here represents an attempt to synthesize and extend these results in a more general format. Results suggest that three factors determine the complexity of a language. Firstly, a population's effective size. Secondly, the amount of linguistic regularisation: this can be determined by a number of factors, including the number of learning experiences, the memory limitations of individual agents, and any cognitive bias for regularity. Finally, linguistic innovation is crucial, as the same amount of innovation can sometimes support greater complexity, while at other times leads to a collapse in complexity, depending on the size and nature of the population.

## Previous Models

Lupyan \& Dale (2010) present a mathematical model in their supplementary materials which is analysed in terms of the
evolutionary fitness of languages depending on the proportion of L1/L2 learners. They find that, under various assumptions, a high proportion of L2 learners implies that simple languages are maximally fit. However, neither interaction nor social structure are taken into consideration.

Reali et al. (2014) explicitly investigate population size in a model where agent interactions are governed by Gilbert random graphs. Agents produce token-like conventions which can be either easy or hard. Crucially, easy tokens can be reproduced by another agent after a single exposure, while hard tokens require two exposures. Finally, new conventions are occasionally produced according to a Chinese restaurant process, and agents have a hard limit on the number of tokens they can store, i.e. a limited memory. The finding is that, in smaller groups, significantly more hard tokens are able to establish themselves across the entire population than is the case with larger groups. Reali et al. suggest that language, and indeed all culture, might become preferentially simpler as societies increase in size and social connectivity.

These models support two of the hypotheses found in the literature: both the type of language learner (child or adult) and the population size are arguably factors behind the variation found in linguistic complexity. However, we are left with a number of questions: 1) Can we reconcile these two predictions; 2) How do we incorporate ideas such as that of Wray \& Grace (2007) about esoteric and exoteric cultures, and McWhorter (2001) regarding creoles; 3) How robust are the previous models across different parameter settings and instantiations? To investigate these questions, we need to systematically vary not just the population size, but also i) the type of social network, ii) the amount of linguistic regularisation, iii) the amount of linguistic innovation, iv) the initial state of the population, and $v$ ) whether intergenerational language acquisition is included or not. This is the target of the model presented here.

## Model description

Agents produce and store tokens representing conventions, but there is no distinction between different types of token, e.g. easy vs. hard. Instead, the complexity of a conventional system is assessed by counting the number of populationwide shared types. This casts the complexity of a given population's language in terms of the total amount of information required to acquire that shared system, abstracting away from the details of how that system is stored, used, or acquired. A complex language, then, is when all agents share a large number of conventional types, while a very simple language is when almost no conventional types are shared throughout the population. Note that this does not imply that individual agents do not store a large number of types, or even that many conventions are not shared by sub-populations. Another way this might be conceptualised in terms of Reali et al.'s 2014 model is that this model deals only in hard-to-learn conventions, while easily-learned conventions are simply assumed to be learnt independently, in a way which does not interfere
with hard ones.
Conventions $c_{j}$ are drawn from an infinite set $C=$ $\left\{c_{1}, \ldots, c_{n}, \ldots\right\}$. There is no distinction between different types of convention, for example easy or difficult, and all are equally weighted as $W_{c}=1$. There are $n$ agents $a_{i} \in$ $A=\left\{a_{1}, \ldots, a_{n}\right\}$, which are modelled as variants on Hoppe urns (Hoppe, 1984), after the models of innovative signalling found in Skyrms (2010, see p.124), and similar to the learning agents described by Reali et al. (2014). Depending on the starting condition, an agent is initially composed of $t$ convention tokens, where $t \geq 0$, and a single 'innovation token' with weight $W_{v} \geq 0$. The number of tokens of convention type $c_{j}$ possessed by agent $a_{i}$ is denoted $N_{i j}$.

The initial state of the population is either homogeneous, sampled, or heterogeneous. Homogeneous populations consist of agents with exactly the same 50 types of token. Sampled populations initiate by sampling from a set of 100 initial tokens, meaning that initially no type is likely to be found in every individual in larger populations. Finally, heterogeneous populations consist of agents with entirely different initial sets of tokens.

When an agent $a_{i}$ 'speaks', it selects a particular convention type $c_{j}$ with probability $P_{i j}$ given by:

$$
\begin{equation*}
P_{i j}=\frac{N_{i j}}{W_{v}+\sum_{k \in C} N_{i k}} \tag{1}
\end{equation*}
$$

Alternatively, the agent may produce an entirely new convention, with probability $P_{i v}=1-\sum_{k \in C} P_{i k}=\frac{W_{v}}{W_{v}+\sum_{k \in C} N_{i k}}$. If $x$ conventions have been created by the population to date, the new convention is denoted $c_{x+1}$.

An interaction between two agents is simple: one is denoted 'sender', and another 'receiver'. The speaker chooses a convention according to the distributions given above, and the receiver adds exactly one new token of that type. When the learning capacity is cast as a memory limit, each agent has a hard limit of $m$ tokens: if the number of stored tokens exceeds $m$, then one of the tokens is selected for deletion with a probability proportional to $N_{i j}$, but excluding the innovation token (which is never selected for deletion). Put another way, conventional types which are more strongly represented via their association with more memory tokens are correspondingly more likely to be selected for deletion, and vice versa.

Population structure is defined by the non-directed graph $G$. Three types of graph structure are investigated: 1) Fullyconnected graphs, in which every agent node connects with every other, 2) Erdős-Rényi random graphs $G(n, p)$, generated by assigning a probability $p=0.4$ that any agent node connects with another, and finally 3) Newman-Watts-Strogatz small-world graphs $G(n, k=2, p=0.4)$ : agents are first connected in a ring-structure, then to each neighbour two nodes away, and then to another randomly-selected node with probability $p$. Small-world networks capture the property of reallife social networks in that while any one person may not be connected to many others, the number of nodes which must be traversed between any two people is typically small, e.g.

Figure 1: Results are robust across many individual simulations. The complexity (number of population-wide shared tokens) over time as measured over 10 simulations of 1 million interactions each for different populations sizes (5, 25, and 100: line colours) and network structures (fully-connected, random and small-world: line dashes), with 'sampled' initial states, learning capacity of 100 , and an innovation rate of 0.1 . Error bars represent 1 standard deviation from the mean for individual simulations. Also note that network structure has no apparent long-term effect.
the concept of 'six degrees of separation'.
Interactions proceed by selecting, with uniform probability, an agent to be sender. The receiver is then chosen from the set of agents which connect to the sender, also with uniform probability. The agents interact, and the simulation continues by reiterating the process.

Population turnover, when instantiated, is 'gradual': it proceeds by choosing an agent at random and replacing them with a new agent, who then is exposed to a given number of tokens from connected agents, representing the number of learning experiences. In this way, fewer learning experiences are taken to represent more adult-like learners, and more experiences to be child-like.

As outlined before, the method of analysis is to count the number of population-wide shared types.

## Results

The parameters adjusted in relation to each other were i) population size: 5, 25 or 100 agents; ii) population structure: fully-connected vs. random vs. small-world; iii) population dynamic: static vs. gradual turnover; iv) initial composition: homogeneous vs. sampled vs. heterogeneous. v) learning capacity: 100, 500, or 1000 tokens; vi) innovation rate: $W_{V}=0.1,1,10$, or 100 . The main results are as follows:

## 1. Long-term complexity is robustly determined.

Figure 2: Both population size and learning capacity determine stability. The complexity (number of population-wide shared tokens) over time as measured over 10 simulations of 1 million interactions each for different population sizes (5, 25 and 100: line colours) and learning capacities (100, 500, and 1000: line dashes), with small-world networks, homogeneous initial conditions and an innovation rate of 0.1 . Note that a small learning capacity always leads to a collapse in complexity, while even a large learning capacity is unable to prevent drift and loss in small populations.

Although simulations were stochastic, results were robust as regards long-term complexity. That is to say, the type of population (as determined by the parameters above) reliably determines a stable level of complexity which is robust across i) individual simulations and ii) time: see Figure 1 . This level of complexity is determined by multiple factors (which are outlined shortly), but the existence of a 'steady state' (which may take some time to reach) is important. Differently understood, this means that (given our assumptions) complexity will not remain in constant flux unless some new factor comes into play, e.g. a change in population size.

## 2. Learning capacity and population size determine stability.

Across all conditions, the learning capacity of individual agents determines how complex the population-wide language can be. When memory or learning experiences are limited in number, the effect of linguistic drift increases: see Figure 2. This leads to certain variants being lost and a decrease in complexity. Population size plays a similar role, for as the number of individuals increases, the less of an effect drift can play. In essence, either the individual or the population must act as a 'reservoir' to avoid loss. In the case of individuals, this requires a large memory and/or many instances of learning; for populations, a

Figure 3: Innovation can maintain, increase or decrease complexity. The complexity (number of population-wide shared tokens) over time as measured over 10 simulations of 1 million interactions each for different population sizes (5,25 and 100: line colours) and innovation rates (1, 10 and 100: line dashes) with fully-connected networks, homogeneous initial state and an learning capacity of 1000 . Note that high levels of innovation lead to very high levels of complexity in small populations, but to a collapse in complexity in larger populations.
smaller learning capacity is required because individual tokens will likely be shared across many individuals and are thus robust to loss in any one individual. However, when learning is not sufficient, complexity will collapse even in large populations.
3. Innovation can maintain, increase, and decrease complexity depending on population size.
For smaller populations, only high rates of innovation can counteract linguistic drift. When they do, however, this can push levels of complexity much higher than would be possible for adult learners with similar learning capacities: see Figure 3. Low levels of innovation lead to catastrophic collapses in complexity for small populations, even when learning capacities are high. Contrasting with this, large populations - which easily maintain a given level of complexity - are overwhelmed by large amounts of innovation: in this case, too much innovation leads to less overall complexity.

## 4. Adult learners reduce complexity

When we include gradual population turnover, decreasing the number of learning exposure leads to decreased complexity: see Figure 4. The rate of innovation is less important, as we see different rates of innovation pattern together. However, learning capacity is more important than

Figure 4: Intergenerational learning and innovation in large populations. The complexity (number of population-wide shared tokens) over time as measured over 10 simulations of 5000 replacements with 1000 learning interactions each for populations of 100 agents with gradual turnover and different numbers of learning exposures ( 100,500 , and 1000: line colours) and rates of innovation ( 0.1 , and 1 : line dashes), with small-world networks and a heterogeneous initial state of 50 tokens. This shows that complexity is less stable in large populations of learners than is the case with interacting populations.
in static populations: when learning exposures are anything else than quite high, we can expect a decrease in complexity. As such, the maintenance of high levels of complexity requires child-like learners.

## 5. Creoles: complexity in small populations, simplicity in large populations

When a common language already exists, the level of complexity will either remain stable, or will be affected by the factors mentioned above: see Figure 5. On the other hand, when there is no common language, such as with the extreme state of interpersonal variation modelled by the 'heterogeneous' parameter, we see an interesting effect. When initial populations are large, these mixed societies never develop systems of any complexity. However, small groups with a similar composition lead to very high levels of complexity.

## 6. Social network structure has little effect:

Social network structure has a relatively small role to play in the development and maintenance of linguistic complexity. As long as networks have a small-world property, i.e. as long as the average path-length between any two people remains small (which is the case in all of the network types surveyed here), diffusion across the network is sufficiently

Figure 5: Creolisation does not necessarily imply simplicity. The complexity (number of population-wide shared tokens) over time as measured over 10 simulations of 1 million interactions each for different population sizes (5, 25, and 100: line colours) and innovation rates ( 0.1 and 1 : line dashes), with a heterogeneous initial state, small-world networks, and a learning capacity of 1000 tokens. When populations sizes are large, no complexity develops, but when population sizes are smaller then complexity is able to fixate.
large to ensure that the other results presented here remain valid.

## Analysis

Long-term complexity is reasonably deterministic given a set of assumptions about population size and structure, the rate of innovation and so on. All things remaining equal, then, population size and the nature of learning and innovation should have a predictable impact on linguistic complexity. On the other hand, it is worth noting that real-world populations are unlikely to remain static in regards to many of these assumptions: population sizes will rise and fall, societal pressures driving innovation will vary, and the nature of cultural integration between different social and linguistic groupings can drastically change over short periods of time. In the absence of more detailed case-specific analysis, however, these results should add weight to the theories discussed in the introduction.

Next, we can consider these findings in the light of wellestablished results from population genetics (e.g. the WrightFisher and Moran models of genetic drift) which show that i) small populations are highly susceptible to loss via drift while large populations are conservative, and that ii) fixation of new variants is much more likely in small populations than large ones. Taking these in turn:

1. The susceptibility of small populations to drift is in line
with the results which predict that maintaining high levels of complexity in small populations requires large amounts of innovation. Bromham et al. (2015), also citing the parallels between language change and evolutionary models, show that there is significantly more frequent word loss in smaller populations, so it seems reasonable to expect a similar process to occur at other levels of linguistic structure besides the lexicon. Perhaps a more pressing concern is that the model presented here is equivalent to a 'neutral model' of evolution. This runs against assumptions which are sometimes made in the literature regarding the directionality of linguistic complexification. Trudgill (2011) challenges previous assumptions that simplification is the natural direction of language change, arguing instead that when "left alone"(p.325), languages will gradually complexify, and that only external pressures such as a large proportion of second-language learners will lead to reduced complexity. This can be analysed in two ways: either that humans have something akin to a cognitive anti-regularisation bias which prevents drift-like processes from occurring, or that Trudgill simply perceives the natural state of linguistic development to take place in small groups with child learners. If the former, then recent work suggests that the opposite is the case: Ferdinand et al. (2013) identify a linguistic domain-specific bias in favour of regularisation. If the latter, then the model here corroborates with Trudgill's theories only if we can assume that the rate of innovation is very high.
2. Large populations are resistant to fixation or new variants, just as they are to the establishment of complexity. There are two factors behind this: firstly, when innovation rates are low, the probability of any new variant fixating within the population becomes very small. On the other hand, when there is too much innovation we see a collapse in overall complexity. This is in line with empirical results such as Lupyan \& Dale (2010), but the explanation differs. They argue that adult learners reduce complexity and child learners foster it: on the contrary, it appears that any more than an extremely sparse sampling by adult learners suffices to preserve population-wide complexity, due to the 'reservoir' like effect that large populations have. This, then, supports Trudgill (2011), but acts to constrain his theory: not just adult learners are necessary, but adult learners with extremely restricted exposure or learning capacities. The other condition in which we can expect adult learners to drive simplification is when they also contribute large amounts of innovation: this is an unexpected result, and is in need of empirical validation.

The results for large populations which tend towards either stability (when learning capacity is medium or high), or simplification (when learning capacity is very low), assume a static population where most change and innovation takes place in individual interactions. However, change and innovation also occur intergenerationally. Whether one or both of
these factors predominate had been a subject of perennial debate, but the results here make a solid prediction about what to expect if either is the case. That is, if interaction is at least one of the main factors, we should expect very little in the way of increasing complexification. If intergenerational change is the main factor, however, we should expect large populations of anything else than child learners to lead to dramatic simplification; if not, then we should expect simplification only when most learners have extremely sparse input. Whether this is or is not the case is a target for future empirical work.

Finally, the results indicate that creoles can attain complexity given reasonably small population sizes. In fact, this stands to reason given the previous results: given an initial pool of extremely wide variation, many variants are able to fixate in small populations, but very few to none in large populations. The take-home message from this is not that we should expect complexity in small mixed populations - as the assumptions made by this configuration of the model are particularly unlikely - but rather that we cannot assume that creolisation should automatically entail simplicity: we can expect it to appear under some circumstances.

## Conclusion

The relationship between linguistic complexity and social determinants is more nuanced than has been sometimes been assumed. At the very least, we need to consider not just the effective size of the population in question, but also give some thought to how learning proceeds - whether this is in terms of memory or learning exposures - and the nature of linguistic innovation. However, as previously observed, all of these factors can be difficult to accurately observe and/or measure, and undergo constant flux. In particular, linguistic innovation can be subject to a myriad of intrapersonal, interpersonal or larger cultural pressures and variations. Furthermore, the results presented here are from a highly idealised model of cultural learning and transmission: it may well be the case that including more detailed and realistic mechanisms, particularly as pertains to human language, will impact on some of the conclusions presented here. Even if this is the case, the model allows us to both draw several disparate theoretical claims together, while at the same time sharpening the predictions we can make regarding how social structure, population size, and the details of learning and innovation should impact linguistic complexity.

#### Abstract

Rational accounts of decision-making are incompatible with the prevalence and success of ubiquitous marketing strategies. In this paper, we demonstrate, using computational experiments, how an ideal Bayesian observer model of preference learning is compatible with the manipulation of purchasing decisions via a number of well-known marketing techniques. The ability of this model to predict the effects of both familiar and novel marketing interventions suggests it as a plausible candidate theory of consumer marketing. Simultaneously, by clarifying the logic underneath the interplay between environmental exposure and preference distortions seen in economic decisions, this model rationalizes the seemingly irrational susceptibility of consumers to marketing.

Keywords: decision-making; preference learning; advertrising; marketing; rational analysis

## Introduction

Marketing constitutes a genre of economic activity that is mysterious to existing formal accounts of consumers' decision process. While such formal theories require consumers to be economically rational, doing so would make them impervious to marketing techniques. In fact, the very existence of marketing as a viable genre of activity violates the predictions of current formal accounts of consumer behavior. What possible new information can the $43^{r d}$ viewing of an insurance company's ad give a consumer? Clearly, consumers receive a lot more information about products than just their 'utility' through such repeated interactions. Such associative influences have been difficult to document and incorporate into formal theorizing - hence have historically been ignored in marketing research - save as unspecified exogenous influences to be parametrized in econometric analyses." Now that online activity can be meticulously logged across content platforms, we argue that the sort of side information that was treated as noise in earlier generations of marketing theories can be incorporated to construct computational models that can make testable predictions about the efficacy of marketing interventions. This is the goal we pursue in this paper.

We do so by developing a psychological model of preference formation that can quantitatively relate manipulations of marketing variables to consumer demand. Our approach diverges from existing accounts of consumer/buyer behavior in several key aspects. First, unlike classic (Belk, 1975) and modern (Malhotra, 1988) integrated models of consumer behavior, our model can offer constrained quantitative predictions by virtue of relying on only observable variables (such as price distributions, exposure frequency, and transaction history), rather than relying on unobservable and immeasurable consumer valuations and beliefs. Second, unlike current quantitative models of consumer psychology behavior that consider choice mechanisms in very narrow settings
(e.g., reference price models; (Winer, 1986)), we attempt to provide a general account that can capture the effects of many marketing interventions. Finally, unlike classical approaches designed for brick-and-mortar retail that have relied on population-level market and consumption variables, our approach considers frequency distributions of individual observers' transactions, which are increasingly more measurable and relevant in internet commerce.

## Existing models of consumer behavior

In the absence of formal theory, existing quantitative models of marketing are primarily econometric - they regress multiple available variables against outcomes of interest, use focus groups or deductive arguments to suggest that such variables can be changed by particular marketing interventions, then extrapolate these changes to the consumer base to predict how much the underlying outcomes will change.

Econometric models of marketing interventions are fundamentally data analytic models that impose microeconomic constraints on estimated parameters. Thus while they are good at retrospectively estimating the effects of marketing interventions on demand curves, they can only make predictions about such effects by extrapolating parameters. Perhaps the most rigorous models of consumer behavior are in the domain of pricing. Price sensitivity has been shown to follow a Weber law, such that consumers are sensitive to proportional price changes (Monroe, 1973). Moreover, consumers seem to evaluate prices relative to a "reference"" price range that varies across products and categories (Kalyanaram \& Winer, 1995), appears to be learned from transaction history (Emery, 1969), and may be influenced by brand strength (Biswas, 1992). These models are typically used to explain and motivate narrow experimental manipulations, and while they hold promise for predicting changes in aggregate demand curves from transaction history, they have not been applied in this way; perhaps largely due to the fact that they do not integrate the effects of long-term marketing strategies. Although these models can capture the effects of long-term marketing strategies on demand curves via free parameters to account for changes in reference price with branding, advertising, etc., they do not offer a predictive account of how marketing actions will influence the reference price, and thus can only retrospectively describe their effects on demand curves.

In contrast, theories of consumer behavior that aim to explain the psychological mechanisms of a broad range of marketing interventions rely on qualitative, verbal accounts of psychological processes and invoke unobservable, and immeasurable, latent traits and beliefs of consumers (e.g., (Bettman, 1979)). While these theories offer pithy qual-
itative summaries of marketing researchers' intuitions about the psychology of consumers, they are neither designed to, nor capable of, offering quantitative predictions.

The account we present in this paper aims to capitalize on the strengths of these different approaches: First, by constructing a model at the level of individual choices, we capture intuitions about the psychology underlying consumer behavior. Second, by basing the individual choice on historically observed price distributions and transactions, we accommodate known relative price-range effects. Finally, by relying on only externally observable quantities as the inputs to the individual choice model, we make our theory empirically identifiable in the same manner as standard econometric models.

## A cognitive model of consumer psychology

Ultimately, population demand curves are created from aggregating individuals' buy/don't buy decisions, therefore any formal analysis of the efficacy of marketing techniques must model how they influence individual purchasing choices. Framed this way, the question such an analysis must ask is 'how do prices and other market signals influence purchase decision?'

The standard way of addressing this question is to treat choices as the outcomes of utility maximization. On this view, whatever choices an observer makes can be attributed to some underlying hedonic calculation which shows a higher evaluation for the chosen option. While this is a mathematically elegant way of describing the choice outcome, it is a very poor description of the process underpinning these choices. Prior research has demonstrated that consumers' price estimates of products tend to be drastically altered by presentation formats (Tversky \& Kahneman, 1981), the set of available options (Huber \& Puto, 1983), as well as a variety of seemingly irrelevant psychological primes (Ariely, Loewenstein, \& Prelec, 2006).

The success of various marketing strategies in increasing consumer preference for the same underlying product (Kirmani \& Rao, 2000) lends credence to a less optimistic view of consumer preferences: choices are based on dynamic, context-dependent comparisons between options, rather than reliable hedonic value judgments (Ariely et al., 2006). Consumers are likely to make any particular decision by drawing upon past experiences with choices among similar options (Gilboa \& Schmeidler, 1995). Given variability in experiences, variability in recall, and variability in the comparison process used to generate preferences, the resulting preferences will be considerably uncertain.Our theory is that marketing strategies capitalize on this uncertainty by manipulating the information available to observers at intermediate steps of the preference-construction process to influence preferences.

The principal contribution of our work is demonstrating how Bayes-optimal combination of prior choice-relevant observations yields an interpretable, simple, testable, and parsi-
monious account of marketing psychology. In particular this account predicts the efficacy of a number of interesting marketing strategies on several important consumer choice outcomes by virtue of their influence on a small, factored representation of consumer price history and knowledge.

## Consumer representation

What are the observable building blocks of a theory of marketing psychology? An intuitive simplification of a typical economic transaction is that a buyer decides that the price for a particular product is fair in a particular context. Thus the observable units of individual transactions are consumers, prices, products, choices, and auxiliary contextual information (e.g. physical location, web portal, company brand, etc). Of these units marketers cannot directly influence consumers' choices ( $b$ ), but they can affect prices ( $m$ ), products $(x)$, contexts $(c)$, and critically, the frequency and cooccurrence statistics with which consumers encounter each.

Although the full set of experiences of an observer can be described as a joint distribution of $p(b, c, x, m)$, there are several reasons to consider the agent's representation not as this complete joint distribution, but instead a factored set of several conditional distributions. First, it seems implausible for humans to keep track of the full joint distribution given the extreme sparsity of observations therein. Second, an argument from introspection suggests that not all conditional probabilities are equally easy to access as we would expect if they were all calculated form the same joint distribution: e.g., $p(m \mid x, c)$ (how much does yogurt cost at Safeway?) seems intuitive while $p(x \mid m, c)$ (what costs $\$ 5$ at Safeway?) seems to require an awkward explicit search. Third, by factoring the joint distribution, a consumer can learn about the distribution of goods and prices from observing the transactions of others independently of tracking her own choices. Finally, a fourth, practical, reason to factor the joint distribution in a consumer choice model is that it makes it usable for predicting consumption behavior; whereas a model based on the full joint distribution would be inestimable to marketers who do not have access to the full set of experiences of a particular consumer.

Thus, to retain psychological plausibility, and practical usability, we assume that individuals represent the important elements of only some conditional and marginal probabilities from the joint distribution of purchasing decisions, products, prices, and contexts. Specifically, we assume consumers learn the following distributions from observations of the world around them:

- $p(c)$ - what contexts populate a consumer's daily life?
- $p(x \mid c)$ - what products are available in this context?
- $p(m \mid x, c)$ - how much does this product cost in this context?

And from their own experience, they keep track of:

- $p(b \mid m, x, c)$ - how often do I purchase a particular good in a particular context, at a particular price?

## Consumer choices

These tracked conditional distributions can be combined via the rules of probability to estimate the joint distribution over consumption choices, products, prices and contexts; and thus any conditional distribution of interest. Of particular interest in our case are the conditional distributions that observers must use to make consumer decisions:

- $p(b \mid x)$ - do I want to buy product $x$ ? (preference)
- $p(m \mid b, x)$ - what price am I willing to pay to buy $x$ ? (valuation)
- $p(b \mid m, x)$ - how does willingness to buy change with price? (demand curve)
- $p(b \mid c)$ - will I make a purchase in a given context?
- $p(c \mid b, x)$ - if I am going to buy $x$, in which context will I do so? (brand/retailer selection)

Each of these distributions capturing key aspects of consumer behavior can be predicted by marginalizing and conditioning the joint distribution obtained via $p(b, m, x, c)=$ $p(b \mid m, x, c) p(m \mid x, c) p(x \mid c) p(c)$.

On our account, consumers determine their propensity for buying particular goods using accumulated evidence of previous purchases:

$$
\begin{equation*}
p(b \mid \hat{x})=\frac{\sum_{c, m} p(b \mid m, \hat{x}, c) p(m \mid \hat{x}, c) p(\hat{x} \mid c) p(c)}{\sum_{c, m} p(m \mid \hat{x}, c) p(\hat{x} \mid c) p(c)} \tag{1}
\end{equation*}
$$

What is more interesting to a firm, though, is finding the greatest price a consumer would be willing to pay to purchase a product. Prior research has suggested that people typically generate a range of prices that they would be willing to pay for a product (Mazumdar, Raj, \& Sinha, 2005). We formalize this intuition by casting this as a distribution over possible prices,

$$
\begin{equation*}
p(m \mid b=1, \hat{x})=\frac{\sum_{c} p(b=1 \mid m, \hat{x}, c) p(m \mid \hat{x}, c) p(\hat{x} \mid c) p(c)}{\sum_{c, m} p(b=1 \mid m, \hat{x}, c) p(m \mid \hat{x}, c) p(\hat{x} \mid c) p(c)} \tag{2}
\end{equation*}
$$

which directly gives us the distribution of prices at which consumers are willing to purchase a good.

With only a slight reformulation, this yields the relationship needed to obtain classical demand curves: purchase propensity as a function of price:
$p\left(b \mid m=m_{a}, \hat{x}\right)=\frac{\sum_{c} p\left(b \mid m=m_{a}, \hat{x}, c\right) p\left(m=m_{a} \mid \hat{x}, c\right) p(\hat{x} \mid c) p(c)}{\sum_{c} p\left(m=m_{a} \mid \hat{x}, c\right) p(\hat{x} \mid c) p(c)}$,
Of particular interest to a retailer, is the propensity of consumers to purchase while in their store,

$$
\begin{equation*}
p(b \mid \hat{c})=\frac{\sum_{x, m} p(b \mid m, x, \hat{c}) p(m \mid x, \hat{c}) p(x \mid \hat{c}) p(\hat{c})}{\sum_{x, m} p(m \mid x, \hat{c}) p(x \mid \hat{c}) p(\hat{c})} \tag{4}
\end{equation*}
$$

Finally, brands and retailers alike are interested in the likelihood that a consumer will choose their store or brand when making a purchase of a particular product:

$$
\begin{equation*}
p(c \mid b=1, \hat{x})=\frac{\sum_{m} p(b=1 \mid m, \hat{x}, c) p(m \mid \hat{x}, c) p(\hat{x} \mid c) p(c)}{\sum_{c, m} p(b=1 \mid m, \hat{x}, c) p(m \mid \hat{x}, c) p(\hat{x} \mid c) p(c)} \tag{5}
\end{equation*}
$$

Critically, each of these key facets of consumer choice and behavior will change in predictable ways under various marketing interventions designed to alter the conditional distributions that consumers keep track of. Thus, this formal setup, while sparse, allows us to test the influence of manipulating prices and context information on consumer demand curves.

## Model predictions

To substantiate our intuitions about marketing-based distortions of consumer preferences, we simulated a small test market, containing three purchase contexts, two goods, and five price labels where a consumer's purchases were generated via the following generative model. A purchase context was sampled from a random seed distribution $p(c)$, a product was sampled from a discrete random seed probability $p(x \mid c)$ for this context, a price label was sampled from a random seed probability $p(m \mid x, c)$ for the already sampled tuple $\{x, c\}$. Finally, this observation was flagged as a purchase decision with a small probability $(p=0.2)$, and within the samples thus flagged, purchase decisions were randomly generated while maintaining an inverse relationship with price.

Using this generative procedure, we sampled 10000 events to obtain baseline empirical estimates for each of the conditional distributions implicated in our account. The experimental results we report in succeeding sections were constructed by appending this baseline event history with manipulated event sequences corresponding to various marketing interventions.

## Rationalizing product-brand associations

The most obvious form of marketing is advertising by displaying the product and its associated brand. This form of advertising could be rationalized as providing information to potential consumers. It is harder to make a similar argument for event sponsorships and brand awareness campaigns, wherein companies advertise only brands, not products. What rational purpose is served by simply presenting the company's logo to a consumer, disconnected from product information? Also, why belabor people with redundant and uninformative visuals over and over again? Surely once or a couple of occasions would be enough to convey any information? Why are "tip of tongue" (Mowen \& Gaeth, 1992) and brand recognition metrics (Munoz \& Kumar, 2004) so popular, influential, and desirable? The answer, of course, is that firms aim to increase the rate at which consumers think of their brand. But why would increasing the ease with which consumers think about the brand change consumer purchasing decisions?

Figure 1: (Left) The effects of increasing the baserate of a particular brand context $(p(c))$ via advertising without aiming to associate the brand with particular products: Increasing the baserate of $c$ increases how often observers would choose brand $c$ when they are buying something $(p(c \mid b)$ ), but does not increase their propensity to purchase given exposure to the brand $(p(b \mid c))$. (Middle) In contrast, if increased brand exposure coincides with increasing the association of that brand with desirable goods $(p(x \mid c))$, consumers will also be more likely to purchase goods given that brand ( $p(b \mid c)$ increases). (Right) This increase in propensity to purchase goods by brand $c$ coincides with an increment in the marginal demand curve for brand $c: p(b \mid m, c)$ is elevated after such targeted promotions.

On our account, changing brand recall and recognition amounts to changing the context probability $p(c)$ for that brand (Figure 1 left). The immediate effect of increasing brand recognition and recall is an increase in $p(c \mid b, x)$ : given that a consumer has decided to buy a product, which brand will she choose? So long as the brand is associated strongly with products a particular product $x(p(x \mid c))$ an increase in $p(c)$ will yield an increase in $p(c \mid b, x)$; in other words consumers will be more likely to choose brand $c$ when asking themselves "I want to buy an $x$, which brand/retailer should I choose?".

However, our model also predicts that simply increasing $p(c)$ will have no effect on the consumers' eagerness to buy its specific products $p(b \mid x)$ or increase their eagerness to buy the brand $p(b \mid c)$. Our account suggests one immediate strategy for increasing consumers' eagerness to buy the brand: selectively increasing $p(x \mid c)$ for $x$ s with high $p(b \mid x)$ - in other words, strategically associating the brand with desirable goods. If the advertising that increases $p(c)$ also strategically increases $p(x \mid c)$ in this manner, then not only are consumers more likely to choose brand $c$ when making a purchase $(p(c \mid b))$, but they will overall be more likely to purchase the brand $(p(b \mid c))$. Moreover, this increase in propensity to buy the brand yields a uniform increase to the demand curve for the brand ( $p(b \mid m, c)$; Figure 1 right), showing just how effective a carefully selected increase in brand-product association can be.

Another interesting theoretical prediction from our model concerns the overuse of promotions presenting that brand without an associated product; this may be counterproductive as it might result in product-brand delinking. This could occur if, for instance, a company overemphasizes event sponsorships over product ads, such that the linking probability $p(x \mid c)$ is diluted by frequent observations of brand $c$ without
associated products $x$. Since such dilution will be accompanied by $p(c)$ gains, this will be a risk primarily for already familiar brands, for which $p(c)$ improvements are showing diminishing returns. In such situations consumers will show high brand awareness $p(c)$, but this will not translate into changes in consumption behavior $p(b \mid c)$.

This account also reaffirms other important elements of brand competition. In particular, it emphasizes product differentiation (Dickson \& Ginter, 1987), frequently cited as one of the major causes of ad campaign failures. If the product ( $x$ ) that a brand is associated with is considered to be a unique entity (e.g., "a Diet Coke") rather than a generic category (e.g., "a diet cola beverage"), then the gains of increased brand recognition will translate directly to increased demand for that brand's product. However, when a market is over-crowded, product differentiation becomes harder and costlier, thus gains in $p(c)$ will be lost because $p(x \mid c)$ does not adequately pick out the product of that particular brand, thereby reducing the potential gains from a higher $p(c)$. Furthermore, this account emphasizes the arms race nature of branding campaigns - the advantage is determined by relative frequency, rather than absolute frequency of brand exposure, which naturally imposes barriers to entry in existing competitive markets, as suggested previously by (Schmalensee, 1982) using empirical data.

## Rationalizing loss-leader strategies

Classically, the economic tension between the retailer and consumers' incentives maintains a price equilibrium. One potential advantage for the retailer is the relatively high costs of searching for low prices for every product, which motivates consumers to generalize about price (dis)advantages of retailers in aggregate, rather than for isolated products. Thus, insofar as consumers use aggregate price advantages to predict

Table 1：Predicted direction of effect of various marketing strategies on distributions stored by consumers．Direction of arrow shows whether effect is predicted to be positive $(\Uparrow)$ or negative $(\Downarrow)$ from the marketer＇s perspective．Citations given present evidence favoring the predicted direction．Arrows in both directions represent ambiguity about the effect of the intervention．

prices for new products，there is an opportunity to offer some carefully chosen products at a discount，and thus distort the aggregate inference：$p(m \mid c)=\sum_{x} p(m \mid x, c) p(x \mid c)$ ．

Specifically，by choosing to offer price reductions on salient products（high $p(x \mid c)$ ），promoters can skew the con－ sumers＇estimates of the overall priciness of brand $c$ ．Figure 2A－B shows this strategy in action．Reducing prices on highly observed items reduces observers＇estimates of how pricy a particular retail outlet might be $p(m \mid c)$ which informs their propensity to make purchases in such contexts $p(b \mid c)$ ．

Although exploiting salient products to distort consumers＇ estimates of overall price tendencies may seem exotic，it is not original to this paper．Amazon adopts this very policy by un－ dercutting competitors on their most popular products，while increasing prices on less salient goods（Del Rey，2015）．This strategy makes perfect sense under our account：with a keen enough understanding of $p(x \mid c)$（which we expect Amazon＇s Big Data provides）it may even be possible to increase overall prices while simultaneously decreasing consumers＇estimates of the prices offered by the brand．

## Rationalizing money－losing brand extensions

The principal way in which manufacturers can benefit from brand＇equity＇is by extending the repertoire of products as－ sociated with it．The problem lies in the possibility of dilution of the brand＇s association with individual products by virtue of exposure alongside multiple products．In the simple ac－ count of brand extensions，manufacturers bring new products to market to increase profits at the expense of brand equity． Our analysis，however，reveals the possibility of an inversion of this basic process－a manufacturer could potentially im－ prove brand equity by bringing a low－priced new product to market－trading off profits（or even losses）for brand equity．

In this situation，a company would manufacture a new product that sells for low prices at high volumes，and is in－ delibly associated with the company＇s brand．Such a sce－ nario would most likely play out for companies whose pri－ mary products are big－ticket，low volume items，e．g．cars， vacations etc，and that are looking to improve their visibility． Availabilty of the product at sufficiently low prices will raise
$p(b \mid x, m, c)$ ，which will in turn increase not just $p(b \mid x)$ for this low－price and likely low margin product，but also $p(b \mid c)$ and $p(c \mid b)$ ，thus increasing brand equity at fairly low cost．

To test this possibility，we added exposure to a new good specific to a particular context to the baseline event history in our simulation，available at the bottom two price labels in a＇cheap＇condition and at the top two price labels in a ＇pricey＇condition．We measured gain in brand equity as rel－ ative change in $p(r \mid c)$ from that measured in the baseline condition for this context．Figure 2C，which plots the rel－ ative gain in $p(r \mid c)$ for 100 model simulations from differ－ ent initializations，shows how brand equity improves through adding a loss－leader，and drops through adding a relatively expensive product to the product line．The latter is more prof－ itable，so this simulation demonstrates the existence of a com－ petitive tension between brand equity and capital－companies could potentially trade one off against the other sequentially， modulo diminishing returns from product－line overcrowding．

## Conclusion

Beginning with the intuition that marketing strategies influ－ ence consumers＇preference formation processes via associa－ tive influences within the preference construction process，we have created a theory of consumer preference formation that is grounded strongly in observable correlates for marketing variables．With a series of computational experiments，we have substantiated various predictions that this model makes about the impact of both existing and novel marketing strate－ gies，thus rationalizing several lines of consumer research findings via a simple inductive explanation of how consump－ tion preferences are formed．The model opens up a large space of possible experiments testing the effect of each of the variables we have defined on consumer behavior．Table 1 sug－ gests a number of directional hypotheses derived within our framework．We expect the strong observability of our model， in combination with its novel predictions，will benefit both theory and practice of marketing and consumer research，par－ ticularly in online retail settings，where the conditional distri－ butions implicated in our account are easy to access．

Figure 2: Predictions for advanced and speculative marketing strategies (Left) Flooding retail displays with cheap or discounted goods reduces observers' internal estimates of the price distribution $p(m \mid c)$, (middle) which promotes their propensity to make purchases in the retailer's chosen context. (Right) Similarly, the introduction of a cheap brand extension to the market can result in an increase in $p(b \mid c)$ - a measure of brand equity. All changes are measured from baselines estimated on the initial event history. Histograms show results for 100 simulations each.

# Spatial language promotes cross-domain associations in early childhood 

Ariel Starr (arielstarr@berkeley.edu) \& Mahesh Srinivasan (srinivasan@berkeley.edu)<br>Department of Psychology, University of California, Berkeley<br>Berkeley, CA 94720

#### Abstract

Spatial language is often used metaphorically to describe other domains, including time (a long sound) and pitch (a high sound). How does experience with these metaphors shape the associations we make across disparate domains? Here, we tested 3- to 6 -year-old English-speaking children and adults with a cross-domain matching task that assessed space-time and space-pitch mappings. We tested spatial relations that are expressed in English metaphors for time and pitch, as well as metaphors that are unfamiliar to English speakers, but expressed in other languages. Participants performed a perceptual matching task, in which they matched pictures and sounds, and a linguistic matching task, in which they matched pictures or sounds to verbal labels. Adults readily matched between space and time and between space and pitch, using relations expressed by both familiar and unfamiliar metaphors. Children showed an advantage for linguistic matching compared to perceptual matching, but their performance was similarly unaffected by metaphor familiarity. Together, these results suggest that spatial language promotes the development of cross-domain associations, and that experience with particular spatial metaphors is not required to produce this benefit.

Keywords: metaphor theory; linguistic relativity; crossmodal matching

## Introduction

Across languages and cultures, spatial language is frequently co-opted to describe other domains. In English, for example, we describe temporal duration as long or short, numbers as big or small, and auditory pitch as high or low. What can the prevalence of these spatial metaphors tell us about how we represent and reason about these other nonspatial domains? Previous work has demonstrated that spatial metaphors are not simply a communicative tool. Instead, they reflect our mental representations of nonspatial domains (Boroditsky, 2001; Casasanto \& Boroditsky, 2008; Dolscheid, Shayan, Majid, \& Casasanto, 2013). Here, we test how experience with spatial metaphors over development influences children's cross-domain associations.

Although spatial metaphors are common across languages, there is also variety in the exact spatial relations invoked. This cross-linguistic variation can be used to test hypotheses about the role of linguistic experience in the development of cross-domain associations. For example, in English, temporal durations are described in terms of twodimensional length, whereas languages including Greek and Spanish use three-dimensional spatial terms. Likewise, though English describes pitch in terms of height, languages including Turkish and Farsi use terms related to thickness (i.e., such that thicker sounds are lower in pitch).

Linguistic experience is not required to recognize crossdomain associations. Many studies have demonstrated that prelinguistic infants are already sensitive to many types of these correspondences (de Hevia \& Spelke, 2010; Lourenco \& Longo, 2010; Mondloch \& Maurer, 2004; Srinivasan \& Carey, 2010; Walker et al., 2010). Even neonates, for example, associate longer spatial lengths with longer temporal durations and larger numerical magnitudes (de Hevia, Izard, Coubart, Spelke, \& Streri, 2014). With regards to associations between pitch and space, infants appear to recognize both height-pitch and thickness-pitch mappings, even when only one of these associations is encoded in the language they are learning (Dolscheid, Hunnius, Casasanto, \& Majid, 2014; Walker et al., 2010; but see Lewkowicz \& Minar, 2014).

However, according to one recent study, young children may be less flexible than infants (Shayan, Ozturk, \& Bowerman, 2014). This study investigated thickness-pitch mappings in 2- to 5 -year-old children who spoke either German, Farsi, or Turkish, and found that while Turkish and Farsi speaking children (who speak languages that employ a thickness metaphor for pitch) can reliably map thickness to pitch, German-speaking children (who speak a language that does not employ a thickness-pitch metaphor) cannot. This finding suggests that maintenance of cross-domain associations between space and pitch may be dependent on the type of metaphorical mappings reinforced by language, at least during childhood.

In explicit matching tasks, adults appear to be more flexible than children. Adults can match pitch to both thickness and height, for example, and more generally can form mappings across innumerable domains, regardless of whether their language employs the relevant metaphors (Marks, 1978; Shayan et al., 2014) However, experience with linguistic metaphors does appear to influence the automaticity with which cross-domain associations are processed in adults. In one study, adult speakers of Dutch readily matched pitch to thickness in an explicit task, but their representations of pitch were only biased by irrelevant spatial height information and not by irrelevant thickness information (Dolscheid et al., 2013). This suggests that Dutch-speaking adults automatically process a height-pitch mapping but not a thickness-pitch mapping. The reverse pattern of results - a biasing effect of thickness but not height on pitch representations - occurs for Farsi speakers, consistent with the idea that experience with languagespecific spatial metaphors influences the automaticity with which cross-domain associations are accessed. A parallel pattern of results for the case of space-time mappings has been reported from English and Greek-speaking adults. In
this study, temporal duration judgments in English-speaking adults were biased by only irrelevant variation in spatial length (and not irrelevant volumetric information), and duration judgments in Greek-speaking adults were biased only by irrelevant volumetric information (and not irrelevant spatial length; Casasanto, 2008).

In sum, prior research suggests that experience with one's own language's spatial metaphors affects children's explicit cross-domain associations, as well as adults' implicit crossdomain associations. This suggests that experience with spatial metaphors may have a persistent influence on crossdomain associations throughout the lifespan. Here, we expand on previous studies of the development of crossdomain associations by testing both space-time and spacepitch associations, and by directly comparing the effects of familiar versus novel metaphors in the same population. In addition, we test a large number of children between the ages of three and six years to gain insight into the finegrained developmental trajectory of cross-domain associations. We test how children's experience with spatial metaphors influences their cross-domain associations by focusing on three critical factors.

First, we contrast cross-domain associations between space and time compared to associations between space and pitch. We focus on associations with time and pitch because while both time and pitch are frequently described using spatial language, they have different dimensional structures. Time, like spatial extent, is a prothetic dimension, meaning that it can be represented by an ordered continuum of increasing amount (Stevens, 1957). Differences in temporal duration and spatial extent are therefore quantitative. Pitch, on the other hand, is a metathetic dimension, meaning that differences in pitch are qualitative - pitches vary in frequency rather than amount. Therefore, it is possible that the shared ordinal structure of space and time may provide a specific advantage for cross-domain space-time mappings that does not extend to space-pitch mappings.

Second, we investigate the effect of experience with specific spatial metaphors by testing whether Englishspeaking children are better able to match domains in ways that reflect familiar spatial metaphors compared to unfamiliar metaphors. For time, we compared children's ability to map between sounds that varied in temporal durations and images that varied in either length (long vs. short; familiar relation) or in overall size (big vs. small; unfamiliar relation). For pitch, we compared children's ability to map between sounds that varied in auditory pitch and images that varied in either height (high vs. low; familiar relation) or thickness (thin vs. thick; unfamiliar relation). If experience with specific spatial metaphors constrains children's cross-domain associations, then matching performance should be higher for the familiar relations compared to the unfamiliar relations. In addition, the difference in performance between familiar and unfamiliar relations may increase with age, as children gain more experience with their language-specific spatial metaphors.

Finally, we probe whether children are better at matching across domains when the spatial metaphors are verbally labeled - even when the metaphors are unfamiliar compared to when the task is purely perceptual. Previous research suggests that verbal labels may help children organize their representations of perceptual domains by providing cues as to how to align the endpoints of disparate domains (Smith \& Sera, 1992). For example, if children understand that the word long in a spatial context refers to greater spatial extent, this may provide a cue for understanding that long in a temporal context refers to a greater temporal duration. Therefore, children's nonlinguistic ability to successfully map across domains (as measured by a perceptual matching task) may be enhanced by the presence of verbal spatial labels (as measured by a linguistic matching task).

## Methods

## Participants

80 children aged 3 to 6 years (mean age: 4.89 years, range: 3.13-6.98 years) and 16 adults (mean age: 21.25 years, range: 18.63-27.59 years) participated in this study. All participants were native English language speakers who were not regularly exposed to or fluent in a second language. Data from an additional 17 children and 6 adults were excluded from analyses due to proficiency with another language ( 9 children, 5 adults), failure to complete the experiment ( 5 children), inattention ( 3 children), or performance more than 3 standard deviations below the group mean (1 adult).

## Materials

Spatial stimuli consisted of pictures of cartoon aliens that varied in length (familiar space-time metaphor), overall size (unfamiliar space-time metaphor), vertical position (familiar space-pitch metaphor), or thickness (unfamiliar space-pitch metaphor). Temporal stimuli consisted of monotonic tones that varied in either duration or auditory pitch. Tones that varied in duration had a constant pitch of 384 Hz and were either 1 second or 3 seconds in length. Tones that varied in pitch had a constant duration of 2 seconds and a pitch of either 256 Hz or 512 Hz . All stimuli were presented using a laptop computer.

## Procedure

Participants' cross-domain matching ability was tested for both space-time and space-pitch pairings. Adult participants completed both the familiar (long/short for space-time and high/low for space-pitch) and unfamiliar (big/small for space-time and thin/thick for space-pitch) pairings. The order of the space-time and space-pitch blocks was counterbalanced across subjects, and the unfamiliar pairing always preceded the familiar pairing within each block. Child participants completed one block of space-time pairings and one block of space-pitch pairings, with the
order of the blocks and assignment to the familiar versus unfamiliar pairings counterbalanced across participants.

All experimental sessions began with the familiarization trials. At the beginning of each block, participants were first shown pictures of both relevant aliens and listened to both types of sounds. Within each block, the perceptual matching task always preceded the linguistic matching task so as to not bias participants' responses. Adults performed 8 trials of each task type, and children performed 4 trials of each task type.

## Familiarization Trials

The familiarization trials were designed to have the same structure as the test trials and involved matching pictures of animals to the appropriate sounds. In the first two trials, two animals were displayed on the screen. An animal sound was then played, and the participant was instructed to point to the animal that makes that sound. In the second two trials, one animal appeared centrally on the screen in front of two trees. The participant was told that the animal was looking for another animal just like it that was hiding in the jungle. The experimenter said that the animal was hiding behind one of the trees, and played a sound from each tree. The participant was instructed to point to the side where the animal sound that matched the visible animal was heard.

## Test Trials

Perceptual Matching Task In the perceptual matching task, participants matched pictures of aliens to the types of sounds they make. Critically, in these trials verbal labels were never used to describe the stimuli. There were two trial types: space as source (the referent is a spatial dimension and participants chose the sound that matched in pitch or duration) or space as target (the referent is a sound that varies in pitch or duration and participants chose the alien with a matching spatial attribute). For the space as source trials, a single alien was presented in front of two trees and the experimenter said that the alien was looking for another alien just like it. The experimenter said that the alien could be hiding behind either tree, and pointed to each tree as the sound of the alien hiding behind it was played. The participant was asked to point to the tree that had an alien behind it that was just like the visible alien. For the space as target trials, two aliens were presented on the screen and a single sound was played. The participant was instructed to choose which of the aliens is the one that makes that sound.

Linguistic Matching Task In the linguistic matching task, a verbal label was used to describe either the appearance of an alien or the type of sound made by an alien, and the participant matched this label to one of two exemplars in the opposite dimension. In the space as source trials, the spatial dimension was described and participants chose one of two auditory matches (e.g., the participant is told that a long alien is looking for another long alien just like it, and the long alien is hiding behind one of two trees; the two sounds are played and the participant chooses the sound that a long
alien makes). In the space as target trials, the type of sound was described and participants chose which of two visually presented aliens makes that type of sound (e.g., the experimenter asks the participant which of two aliens makes a long sound).

## Results

Accuracy for all matches was scored as correct if the match was in the direction reflected by spatial metaphors in language (e.g., matching the long or big alien to the long tone and the short or small alien to the short tone). Children's performance was analyzed using a repeated measures ANOVA with match type (perceptual or linguistic) and match direction (space as source or space as target) as within-subjects factors and dimension (space-time or space-pitch), familiarity (familiar or unfamiliar), and age as between-subjects factors. This model yielded a significant main effect of age $(F(3,144)=5.35, p<.005$; Figure 1A) and a significant main effect of match type ( $F(1$, $144)=17.14, p<.001$; Figure 1B). Interestingly, neither the main effect of dimension nor familiarity was significant, indicating that overall children were equally proficient at matching across space and time compared to space and pitch, and they performed just as well for spatial relations employed by English-language metaphors compared to unfamiliar space relations.

Figure 1: Children's cross-domain matching performance by age group (A) and by match type (B). Error bars indicate SEM.

Planned post-hoc comparisons revealed that 3-year-olds performed worse than the older age groups, all of whom performed at similar levels (3-year-olds: $\mathrm{M}=54.08$, $\mathrm{SEM}=$ 2.67; 4-year-olds: $\mathrm{M}=70.24$, $\mathrm{SEM}=2.68$; 5 -year-olds: $\mathrm{M}=$ $72.70, \mathrm{SEM}=3.16,6$-year-olds $=73.9, \mathrm{SEM}=3.42$; all $t \mathrm{~s}$ for 3-year-olds vs. older children $>3.9, p s<.001$; all $t$ s between 4-, 5-, and 6-year-olds < .7, ps > .5). In addition, performance was better for the linguistic matching trials compared to the perceptual matching trials (linguistic matching: 72.34, SEM: 2.09; perceptual matching: 61.56, SEM: 2.13, $t=3.12, p=.002$ ).

This analysis also revealed a significant interaction between match type and match direction $(F(1,144)=5.17$,

Figure 2: Children's matching performance on the linguistic and perceptual matching tasks, grouped by age and match direction. Error bars indicate SEM.

Figure 3. Children's matching performance for familiar and unfamiliar metaphors, grouped by age and match direction. Error bars indicate SEM.
$p<.05)$ and significant three-way interactions between age, match direction, and match type $(F(3,144)=3.62, p<.05)$, and between age, match direction, and familiarity $(F(3,144)$ $=3.12, p<.05)$. We analyzed the three-way interaction between age, match direction, and match type with separate ANOVAs for the linguistic and perceptual match trials (Figure 2). For the linguistic matching trials, the effects of both age and match direction were significant ( $F s>5.6, p$ s $<.05$ ). Overall, three-year-olds performed worse than older children, and performance was higher when space was the target dimension compared to the when space was the source dimension. For the perceptual matching trials, the main effect of age and the interaction between age and match direction were significant ( $F s>2.8, p s<.05$ ), indicating that older children outperformed younger children, and particularly so when space was the target dimension.

We analyzed the three-way interaction between age, match direction, and familiarity with separate ANOVAs for familiar versus unfamiliar metaphors (Figure 3). For familiar metaphors, there was a significant main effect of age and a significant interaction between age and match direction ( $F s>3.6, p s<.05$ ), indicating that older children
performed better than younger children, and the age effect was particularly pronounced when space was the source dimensions. For unfamiliar metaphor trials, there were no significant main effects, but the interaction between age and match direction was significant $(F(3,54)=3.11, p<.05)$, suggesting that the effect of age was more pronounced when space was the target dimension.

Adults' performance across all conditions was near ceiling (mean $=96.19$, $\mathrm{SEM}=.51$ ). Performance was analyzed using a repeated measures ANOVA with dimension (space-time or space-pitch), familiarity (familiar or unfamiliar), match type (perceptual or linguistic) and match direction (space as source or space as target) as within-subject factors. This analysis revealed no significant effects ( $F s<2.2, p s>.16$ ), nor any significant interactions ( $F s<3.1, p s>.1$ ). Therefore, adults performed equally well in all conditions.

## General Discussion

The present work explored cross-domain associations between space and time and between space and pitch, and the role that experience with spatial metaphors may play in shaping these representations. English-speaking children
and adults performed perceptual and linguistic cross-domain matching tasks for pairs of stimuli that varied in spatial extent and either temporal duration or auditory pitch. For both types of cross-domain pairings, we assessed matching performance for pairs that reflected familiar Englishlanguage spatial metaphors (length for time, height for pitch) or that reflected novel spatial metaphors not used in English (size for time, thickness for pitch). Consistent with previous work (e.g., Marks, 1978; Shayan et al., 2014), we found that adults readily matched time and pitch to both familiar and unfamiliar spatial attributes. Children's matching performance, however, revealed a nuanced developmental trajectory for these cross-domain associations, which we describe below.

Most notably, children's cross-domain matching performance was better for the linguistic matching task compared to the perceptual matching task. In the linguistic task, participants were provided with a verbal label that described a stimulus in terms of its spatial attributes, auditory pitch, or temporal duration, and needed to choose an exemplar from the other domain to match it. By comparison, in the perceptual matching task, participants matched the exemplars in the absence of a verbal label. This suggests that the presence of a verbal label conferred an advantage for cross-domain matching above and beyond matching the exemplars themselves.

Strikingly, we found that the verbal label provided an advantage even when it labeled a spatial relation not employed by English-language metaphors. In contrast to previous work (Shayan et al., 2014; but see Dolscheid, Hunnius, \& Majid, 2015), we found no significant effect of metaphor familiarity on children's matching performance. Children were equally proficient at matching spatial relations across domains that reflected both familiar and novel metaphors. Although English-speaking children presumably have little experience with thickness metaphors for pitch, they matched thickness onto pitch just as readily as they matched vertical height onto pitch. Likewise, they matched overall size onto duration just as readily as they matched spatial length onto duration. Given that previous findings have provided mixed results as to whether familiarity with specific spatial metaphors is required for children's success in space-pitch matching tasks, it is unclear whether these contrasting outcomes should be ascribed to differences in procedure or population. In addition, familiarity in the present experiment was defined based on the presence or absence of specific spatial metaphors in the English language. Therefore, it is possible that individual differences in children's experience with these metaphors may influence their matching performance. Regardless, the present results suggest that young children, like infants and adults, can flexibly map abstract domains onto multiple spatial reference frames. We also found no significant effect of dimension on children's mapping performance, which indicates that the shared ordinal structure between space and time did not confer an
advantage for mapping between these dimensions compared to mapping between space and pitch.

We found that verbal labels were most likely to improve performance for the youngest children when space was the target domain. On these trials, children were presented with two aliens and were asked to choose which one made a labeled sound (e.g., which alien makes a thick sound). Therefore, to match correctly, children could simply choose the alien whose visual appearance matched the label (e.g., a thick alien), without needing to represent the labeled sound (e.g., a thick sound). These were the trials on which three-year-olds performed the best, suggesting that understanding the spatial meaning of these words precedes understanding of the metaphorical meaning. Indeed, with regards to spatial metaphors for time, children typically produce the spatial meaning of the word earlier than the temporal meaning
(Clark, 1973). However, for older children the performance benefit for linguistic trials held both when space was the target domain and when space the source domain. Therefore, it was not solely the trials on which children could match a label to a spatial attribute that drive this effect because there was also improved performance when children mapped the label to a sound. Instead, it seems that the presence of labels themselves improves children's crossdomain matching performance.

The finding that children perform better on the linguistic matching task compared to the perceptual matching task is consistent with previous work suggesting that language is a facilitating factor in the development of cross-domain associations. This work suggests that children may initially form mappings between the labels for two domains, such that the association between the labels then drives the perceptual mapping. For example, when forming an association between size and auditory volume, children may initially map the word big onto the word loud and the word small onto the word quiet, and this linguistic association may lead children to think of loud as being more than quiet and lead to an association between the perceptions of size and volume (Smith \& Sera, 1992). This explanation can be logically extended to associations between space and time as well, with the common labels of long and short providing ordinal cues to children as to how to align and map these domains. However, it is less clear how this explanation applies to pitch, as the spatial metaphors used to describe pitch seemingly ascribe opposite ordinal anchors to the spectrum of pitch: both thick and low refer to low-frequency pitches, yet thick typically corresponds to more whereas low typically corresponds to less. Therefore, it seems that in the present task, labels must be providing an additional cue beyond an ordinal reference frame.

Another advantage that labels may provide is by clarifying what is otherwise an ambiguous task. When children are initially mapping between the pictures and the sounds, they may not spontaneously focus on the spatial attributes that are varying. However, labeling a particular dimension likely makes that dimension more salient, thus clarifying the goal of the task. For example, when shown a
thick alien and asked which of two sounds that type of alien would make, children may not immediately recognize that they could consider the width of the alien when making their choice. However, when asked which of two sounds a thick alien makes, children may perceive thickness as a relevant attribute. Therefore, the act of labeling itself may provide an additional cue for mapping that is not present in the perceptual matching task.

Although our results suggest that children's matching performance increases with age, the largest change in performance occurred between ages three and four. Overall, three-year-olds performed at chance, whereas four-, five-, and six-year-olds all performed at similar levels above chance. From the present data it is difficult to determine whether this jump in performance reflects improvements in cross-domain mapping ability, or whether the demands of our matching task may be too taxing for three-year-olds. Given that cross-domain associations have been demonstrated in infants using more implicit tasks, additional work is needed to trace the development of these associations between infancy and early childhood. Further, the present study involved making explicit matches between domains. Although adults can form explicit mappings across a multitude of domains (Stevens, 1957), there are constraints on the types of cross-domain associations that occur implicitly (e.g., Casasanto, 2008; Dolscheid et al., 2013; Srinivasan \& Carey, 2010). Therefore, it remains an open question whether children spontaneously associate space and time and space and pitch, and whether experience with particular spatial metaphors may influence the automaticity with which these associations are accessed. Reaction time measures may be useful for addressing this question, because implicit matching processes should proceed more rapidly than explicit matching processes.

Taken together, these findings suggest that spatial language promotes cross-domain associations in early childhood. Critically, this process appears to be equally accessible for spatial metaphors that are both familiar and novel, suggesting that experience with specific spatial metaphors is not necessary for forming these associations. Instead, spatial language may promote the perceptual organization of other domains by providing a reference frame for aligning these domains, as well as by highlighting relevant spatial attributes.

## Acknowledgments

We would like to thank Gillian Schwartz, Alagia Cirolia, and Leslie Wang for their assistance with data collection. This research is supported by NIH award F32HD085736 to AS and NSF award SBE-16302040 to MS.

# Preemption in Singular Causation Judgments: A Computational Model 

Simon Stephan (simon.stephan@psych.uni-goettingen.de) Michael R. Waldmann (michael.waldmann@bio.uni-goettingen.de)<br>Department of Psychology, University of Göttingen, Gosslerstr. 14, 37073 Göttingen, Germany

#### Abstract

Causal queries about singular cases are ubiquitous, yet the question of how we assess whether a particular outcome was actually caused by a specific potential cause turns out to be difficult to answer. Relying on the causal power approach, Cheng and Novick (2005) proposed a model of causal attribution intended to help answering this question. We challenge this model, both conceptually and empirically. The central problem of this model is that it treats the presence of sufficient causes as necessarily causal in singular causation, and thus neglects that causes can be preempted in their efficacy. Also, the model does not take into account that reasoners incorporate uncertainty about the underlying causal structure and strength of causes when making causal inferences. We propose a new measure of causal attribution and embed it into our structure induction model of singular causation (SISC). Two experiments support the model.

Keywords: singular causation; causal attribution; preemption; causal reasoning; Bayesian modeling; computational modeling

## Introduction

Most people hold the belief that smoking causes lung cancer. Now, imagine that you learn that Peter, a passionate smoker, has contracted lung cancer. How strongly would you be willing to say that it was Peter's smoking that was causally responsible for his disease?

This example illustrates a scenario in which we seek an answer to a causal query about a singular case. Queries about singular causation are prevalent in everyday life and professional contexts, such as the law or medicine. How do people derive causal judgments about singular cases? Of course, the mere fact that two factors $C$ and $E$ are generally causally connected (e.g., smoking often causing lung cancer) does not necessarily imply that a singular or token co-occurrence of these events (e.g., Peter's smoking and his lung cancer) manifests a causal relationship - a singular co-occurrence might be a mere coincidence. On the other hand, as causality is not directly observable in the world, to what else than our general causal knowledge could we turn to obtain answers?

We are going to present a theory that builds on the idea, first formalized by Cheng and Novick (2005), that the notion of unobservable causal powers (Cheng, 1997) plays an essential role in singular causation judgments. Yet, we will demonstrate that Cheng and Novick's (2005) power PC model of causal attribution ( CN model) makes assumptions that are not always plausible. Generally, the CN model is intended to provide a normative answer to the question how we can determine whether an observed outcome was actually caused by a potential cause factor. For example, for cases like the one above about Peter in which a potential cause $c$ and an effect $e$ have been observed, the CN model delivers the probability
$P(c \rightarrow e \mid c, e)$ with the arrow denoting a causal relation. We argue that the key problem of the model is that it treats target causes as singular causes whenever they are sufficient for the effect in a specific situation. This appears to be at first sight a reasonable assumption, yet it ignores that the exact points in time at which different causes exert their powers play an important role in singular causation judgments (see Danks, 2017): crucially, sufficient causal powers can be preempted by others, and in such cases they should not be held causally responsible for the occurrence of the outcome. We will argue that preemption of causes by background factors frequently occurs in singular causation scenarios, and therefore presents a problem for the CN model.

Another problem of the CN model is that it does not take into account uncertainty about both the underlying causal structure and the causal parameters (e.g., the size of the causal powers). To incorporate uncertainty about the causal parameters, Holyoak, Lee, and Lu (2010) have proposed a Bayesian version of the CN model that uses probability distributions over the parameters instead of point estimates. However, their model also neglects uncertainty about the underlying causal structure. Both sources of uncertainty have been demonstrated to influence causal learning and reasoning (Griffiths \& Tenenbaum, 2005; Meder, Mayrhofer, \& Waldmann, 2014). For this reason, Stephan and Waldmann (2016) proposed the structure induction model of singular causation (SISC) that incorporates both types of uncertainty. Although three experiments (Stephan \& Waldmann, 2016) showed that SISC better accounted for the results than the standard power PC model of causal attribution, one shortcoming of the initial version of SISC was that it used the CN conceptualization of causal attribution that we are going to criticize in the present paper.

We will start with a theoretical section in which we defend a new measure of causal attribution as a component of SISC that is sensitive to preemption. We then present the results of two experiments. Experiment 1a confirmed that singular causation judgments deviate systematically from the predictions of the CN model in line with our revised causal attribution equation. Experiment 1 b assessed participants' notion of preemption. In Experiment 2 we used a larger set of contingencies to compare the revised SISC with the CN and other models. The results of this experiment showed that both a revision of the causal attribution equation and the consideration of statistical uncertainty are crucial to explain the findings.

## The Power PC Model of Causal Attribution

According to Cheng's (1997) power PC theory, causal power (or causal strength) is a hypothetical, unobservable en-
tity that represents the strength of causes. Mathematically, causal power is (in the generative case) expressed as the probability with which a target cause brings about its effect in a hypothetical world in which all alternative observed and unobserved causes of the effect are absent. Because of the possibility of unobserved alternative causes, causal power cannot be assessed directly but must be inferred based on the observed covariation and background assumptions. For generative causes, the following equation can be used to estimate the causal power $w_{c}$ of a target cause $C$ :

$$
\begin{equation*}
w_{c}=\frac{P(e \mid c)-P(e \mid \neg c)}{1-P(e \mid \neg c)}=\frac{\Delta P}{1-w_{a}} \tag{1}
\end{equation*}
$$

In this equation, $w_{a}$ represents the aggregate causal power of all alternative causes $A$ of the effect, which are assumed to exert their influence independently of $C$.

Under the causal Bayes net framework, the causal power of $C, w_{c}$, corresponds to the probabilistic weight of the causal arrow that connects $C$ with its effect $E$ in a common effect structure in which the target cause $C$ and the alternative causes $A$ combine in a noisy- $O R$ gate (see $S_{1}$ in Figure 2). Likewise, $w_{a}$ corresponds to the weight of node $A$.

## The CN Measure of Causal Attribution

Cheng and Novick (2005) proposed several measures of causal attribution that apply to different cases. The measure of causal attribution for cases in which both $c$ and $e$ are present, as in the example above about Peter, utilizes the concept of causal power in the following way to deliver the conditional probability $P(c \rightarrow e \mid c, e)$ :

$$
\begin{equation*}
P(c \rightarrow e \mid c, e)=\frac{w_{c}}{P(e \mid c)}=\frac{w_{c}}{w_{c}+w_{a}-w_{c} \cdot w_{a}} \tag{2}
\end{equation*}
$$

Equation 2 shows that the CN model defines the probability with which $c$ is causally responsible for $e$ given that both have co-occurred by the fraction of the causal power of $C$ and the conditional probability of the effect in the presence of $C$. Since the power PC theory assumes that $C$ and $A$ exert their causal powers independently of each other, $P(e \mid c)$ can be rewritten as the sum of both causal powers minus their intersection (see second step of Equation 2). Hence, what the CN model delivers is an estimation of the relative frequency of cases among all co-occurrences of $C$ and $E$ in which $C$ 's causal power is sufficient for the production of the effect. Our key criticism is that this relative frequency, because it neglects the possibility of preemption, frequently overestimates the true proportion of cases in which we should actually causally attribute $E$ 's occurrence to $C$.

To illustrate the problem, let us consider the results of the fictitious experiment shown in Figure 1 in which the influence of a chemical substance on the expression of a gene was investigated. As it is the case that all mice in the test group ( $P[e \mid c]=1$ ) but only one half in the control group $(P[e \mid \neg c]=.5$, the base rate) exhibit the gene, the results provide strong evidence for the existence of a strong effect of the chemical. In fact, by applying Equation 1 one can see that

Figure 1: Illustration of a hypothetical study testing the effect of a chemical on the expression of a gene. The control group is shown on the left and the test group treated with the chemical substance on the right. Mice having the gene expressed are depicted in blue.
the causal power of the substance equals 1. Crucially, so does $P(c \rightarrow e \mid c, e)$. What the CN model therefore prescribes is that we should attribute causal responsibility to the chemical whenever the chemical and the gene are both present. But should we really be maximally confident that the expression of the gene in, for instance, Mouse \# 25 must be causally attributed to the causal power of the chemical? If you have doubts, you were probably led by a prior assumption about the point in space and time at which the causal background factors $A$ produced the observed base rate of fifty percent: in the given scenario it seems likely that these factors (e.g., transcription factors) already produced their effects prior to the introduction of the chemical. Under this assumption, however, it seems likely that not only fifty percent of the mice in the control condition but also in the test group already possessed the gene prior to the study. Consequently, in those fifty percent of the mice it cannot be the chemical that is causally responsible for the effect because its causal efficacy has been preempted by the background factors.

## A New Measure of Causal Attribution

In the example it seems appropriate to say that the expression of the gene is caused by the chemical in only about half of the observed cases in which $C$ and $E$ have co-occurred. This conclusion is based on the assumption that in roughly half of the cases the causal power of the chemical has been preempted by the causal power of the background factors $A$. We propose a new measure of causal attribution that captures this intuition by refining Equation 2 so that all cases among the joint occurrences of $C$ and $E$ for which the effect of $C$ is assumed to be preempted by $A$ are partialed out. This refined measure is given by:

$$
\begin{equation*}
P(c \xrightarrow{\text { singular }} e \mid c, e)=\frac{w_{c} \cdot\left(1-\alpha \cdot w_{a}\right)}{w_{c}+w_{a}-w_{c} \cdot w_{a}}, \tag{3}
\end{equation*}
$$

in which we introduce $\alpha$ as a discounting parameter that represents the assumed probability with which $A$ is a preemptive cause of the effect. For illustration, if we assume that $A$ has caused the observed base rate of 0.5 prior to the application of the chemical, and if we assume further that $A$ 's causal power has produced roughly equal proportions of the effect in both groups, $\alpha$ takes on a value of 1 . In this case, the point estimate for $P(c \xrightarrow{\text { sing. }} e \mid c, e)$ is about .5 instead of 1.0 that is predicted

Figure 2: The two causal structures considered by the structure induction model of singular causation as mutually exclusive explanations for observed patterns of covariation. $C$ is a general cause of $E$ under $S_{1}$ whereas all co-occurrences of $C$ and $E$ are coincidental under $S_{0}$. The parameters $w_{c}$ and $w_{a}$ denote the causal powers of the observed cause $C$ and the unobserved background causes $A$, respectively; $b_{c}$ denotes the base rate of $C$.
by Equation 2. The difference between the two measures is that under the CN model the presence of two sufficient causal powers ( $w_{c}$ and $w_{a}$ ) is invariably conceptualized as a case of "symmetric overdetermination", whereas the possibility that causes can preempt each other is neglected. Equation 3 takes into account the possibility of preemption and thus delivers an estimation of the relative frequency of singular cases in which the target cause has actually been successful in generating the effect. In our view, preemption of $C$ by a previously present background factor $A$ seems to be prevalent in the cover stories typically reported in the literature (see e.g., Griffiths \& Tenenbaum, 2005). However, the discounting parameter $\alpha$ can be set to capture other cases. For example, cases of overdetermination or cases in which $A$ is preempted by $C$ could be modeled by setting $\alpha$ to 0 . In these cases, our model and the CN model make identical predictions because Equation 3 reduces to Equation 2.

## SISC: The Structure Induction Model of Singular Causation

Apart from the fact that the CN model does not take into account the possibility that preempted causes should not be classified as singular causes, a further problem of the CN model is that it is insensitive to statistical uncertainty about both the underlying causal structure and the size of the causal parameters. SISC (Stephan \& Waldmann, 2016) is sensitive to both types of uncertainty.

SISC was developed in the framework of causal Bayesian inference models; it takes observed data as evidence to update prior probabilities of mutually exclusive hypotheses. Under SISC, these competing hypotheses represent two causal structures that can account for a particular observed pattern of covariation. The two causal structures, $S_{0}$ and $S_{1}$, are depicted graphically in Figure 2. While there exists a causal arrow from $C$ to $E$ in $S_{1}$, which indicates that $C$ is a general cause of $E$, there is no causal arrow between $C$ and $E$ in $S_{0}$. Both models assume a background cause $A$.

The core principle of SISC can be illustrated with Figure 1. Assume someone suggests that $S_{0}$ is the causal structure that underlies the results. Under this hypothesis all observed cooccurrences of $C$ and $E$ would be mere coincidences. Yet, since the observed distribution of the events appears very unlikely to be coincidental, $S_{0}$ is weakened as an explanation while the alternative hypothesis, $S_{1}$, is proportionally strengthened. In fact, the probability computed by SISC for
$S_{1}$ for the data shown in Figure 1 (i.e., the posterior probability of $S_{1}$ ) is almost 1 . Now, imagine the same study had been conducted with a sample of merely eight mice but that $P(e \mid c)$ and $P(e \mid \neg c)$ remain the same. In this case, it seems less certain that $S_{1}$ underlies these results. Smaller samples not only increase uncertainty about the underlying causal structure, they also impede the reliable estimation of the size of parameters. SISC is sensitive to both types of uncertainty when estimating $P(c \xrightarrow{\text { sing. }} e \mid c, e)$.

SISC implements different steps. First, it derives the posterior probabilities for each causal structure illustrated in Figure 2. Applying Bayes' rule, the posterior probability for a causal structure is proportional to the likelihood of the data given the causal structure, weighted by the structure's prior probability:

$$
\begin{equation*}
P\left(S_{i} \mid D\right) \propto P\left(D \mid S_{i}\right) \cdot P\left(S_{i}\right) \tag{4}
\end{equation*}
$$
